Preface

The *Handbook on the Toxicology of Metals* is a comprehensive review dealing with the effects of metallic elements and their compounds on biological systems. Special emphasis has been laid on the toxic effects in humans, although toxic effects in animals and biological systems *in vitro* are also discussed whenever relevant. As a basis for a better understanding of the potential for adverse effects on human health, information is also given on sources, transport, and transformation of metals in the environment and on certain aspects of the ecological effects of metals.

The first edition of the handbook appeared in 1979, and was followed by a second edition in 1986. The work rapidly fulfilled the aims of the editors and became a standard reference work for physicians, toxicologists, and engineers in the fields of environmental and occupational health. There has been a long interval between the 2nd edition and the present one, but the aims of this third edition are basically the same as those of the previous editions, i. e., to provide easy access to basic toxicological data and also give more in-depth treatment of some information, including a general introduction to the toxicology and risk assessment of metals and their compounds.

As with the previous editions, writing the 3rd edition of this book has been a part of the activities within the Scientific Committee on the Toxicology of Metals under the International Commission on Occupational Health, and the editors are happy that the work to make a third edition has been given a high priority among members. In some cases, we have been honored to include authors from outside of this committee. The chapter authors have, as far as possible, been the same as those who wrote the second edition, but in many cases, we were happy to introduce new colleagues.

Since the publication of the 2nd edition, a wealth of data has appeared, and several of the chapters dealing with specific metals have been completely rewritten; others have undergone a comprehensive updating. In order to not expand the present book and make it much larger than the second edition, which was published in two volumes, some of the general chapters have been merged and shortened, and the present book is published in one volume in a larger format. For the interested reader who searches more detailed information on specific topics, each chapter contains a large number of relevant references also to recent reviews whenever these are available.

The development of modern devices in society demand new chapters which reflect the present concerns of the use of new materials, such as semiconductors in electronic devices, metallic nanotechnology devices, and platinum- and palladium-based catalytic converters.

The increasing use of biomarkers in occupational and environmental health has made it necessary to add a new chapter on biological monitoring and biomarkers. Immunotoxicology is an expanding field, and considerable achievements have been made in recent years. A chapter on "immunotoxicology of metals" has therefore been included. Immunological and genetic findings provide, in some cases, good explanations for the differences in susceptibility to development of disease from exposure to metals. Principles for prevention of the toxic effects of metals and risk assessment are important chapters, somewhat expanded, and a new chapter on a related topic "Essential Metals: Assessing Risks from Deficiency and Toxicity" brings up-to-date knowledge into this 3rd edition.

Before the manuscript of this 3rd edition could be finalized, our co-editor and friend Professor Lars Friberg died. He was the main editor of the two first editions of this handbook, and his ideas constituted the basis for the present edition. His stringent analytical views were invaluable, and his expertise and knowledge are greatly missed. We will also remember him as a loyal, generous, and warm friend, and hope that this book will be a lasting tribute to his memory.

The editors acknowledge each contributor to this book for their devotion and enthusiasm and for having prioritized the work to make the 3rd edition of *Handbook on Toxicology of Metals* available to the reader.

Gunnar F. Nordberg
Bruce A. Fowler
Monica Nordberg

Foreword: Outlook

Metals – a new old environmental problem

"Toxic metals" are one of the oldest environmental problems. Today, there are new dimensions of the problem, such as the production of metals in developing countries, leading to occupational exposure and exposure to the general public through the ambient air, drinking water, food, and consumer products. High technology development has also resulted in new products that need more metals in, for example, electronics, fuel cells and car exhaust technology. E-waste, together with drug waste, are new waste problems. The use of metals like gallium, indium, and germanium, which are used in semiconductors has increased steadily over the last 25 years. The e-Waste problem is further augmented by the export of electronic waste from developed to developing countries. Nanotechnology can also lead to unforeseen problems caused by consumer products and combustion of material based on nanoparticles.

Arsenic is a common toxic element which produces clinical disease in India and Southeast Asia from drinking water. This region is also experiencing growing use in semiconductor production. High concentrations of arsenic in drinking water also occur in South America and the U.S. Arsenic is a good example showing how old knowledge is forgotten or ignored, creating new problems. In a number of developing countries, this problem is further exacerbated by expanding human populations and the overexploitation of ground water.

Environmental health problems—and successes stories from the toxicology of metals—have been highlighted in the EEA report on Environment and Health 2005. Some of the key conclusions concerning toxic metals are:

- A number of chemicals are potentially carcinogenic. Approximately 500 metals are classified as carcinogens and are not legally allowed to reach the consumer. They may, however, reach the environment via diffuse sources, for example, in accidental cases. Arsenic in drinking water and cadmium from diffuse sources are environmental contaminants of special concern, because of increasing environmental exposure and their established carcinogenicity.
- Radon exposure is the best documented environmentally related cause of cancer, but is localized in geographical areas where radon precursors (uranium) occur naturally in the ground. Uranium can also contaminate drinking water, leading to kidney injuries.
- Mercury at concentrations that are sometimes observed in the environment is well known to have neurodevelopmental effects, for example, attention problems, reduced learning ability, and slightly reduced IQ in children. Measures are now being taken in Europe to reduce, *inter alia*, prenatal mercury exposure in order to ensure that tolerable daily intakes for pregnant women are not exceeded.
- Lead is an established neurodevelopmental toxicant to humans. Mild mental retardation of children 0-4 years of age in the WHO-Europe region resulting from lead exposure accounts for 4.4% of DALYs (disability adjusted life years). Recent studies on the effects of lead in humans suggest that a "safe" exposure level currently cannot be established. More data on lead exposure of European citizens are necessary and are currently being collected. A ban on leaded petrol has been very successful in lowering blood lead levels in children, which clearly indicates a reduced exposure.
- The global distribution of "new" metals used in automobile catalytic converters to reduce hydrocarbon pollution is clearly shown in the Arctic. Concentrations of platinum, palladium, and rhodium in ice and snow in Greenland have increased rapidly since the 1970; the same trend has been observed in Germany.
- The cadmium contamination of agricultural land has increased during the 20th Century in Europe, leading to exposure from vegetables. Suspicions of kidney and skeleton injuries exist in Europe.

- The effects of combined, long-term and cumulative exposures to *Mixtures of Metals* from diffuse sources might be under-estimated (sometimes called the "*cocktail effect*"). Research in this area needs to develop methods and models to analyze exposures and pathways to disease from *Combinations of Toxic Metals*.

21st Century approaches for 21st Century problems

The shift in focus from legislation for stationary sources to diffuse sources is clearly demonstrated in European Union (EU) legislation, exemplified with directives on integrated pollution prevention and control, Eco-Management and Audit Scheme, European Eco-label, and Integrated Product Policy looking at all phases of a products' life-cycle and taking action where it is most effective. The precautionary principle is also an important starting point.

However, the problems of the 21st century need tools developed in the 21st century. The issue of environment and health is characterized by multicausality with different strengths of association. This means that the links between exposures and their health consequences depend on the environmental pollutants and diseases being considered, but are also influenced by factors such as genetic constitution, age, nutrition and lifestyle, and socio-economic factors, such as poverty and level of education. Important elements of exposure and risk assessment are the estimation of the body burden of chemicals, combined exposures from multiple sources (food, air and water) and the timing of exposures. Preventive measures require the development of proactive risk assessment and management replies that can contribute to the formulation of adequate responses, not at least consider the costs of action and non-action.

Given the complexities and uncertainties relating to environmental health issues, a new participatory framework for risk assessment and risk management is developing, involving a broader framing of scientific assessment of risks, uncertainties, and ignorance, and options for action, communication, monitoring, and evaluation of the effectiveness of actions. Approaches, systems, and services are required to support many different types of actors and other afflicted individuals, not just the policymakers. At a symposium organized by the Scientific Committee on the Toxicology of Metals, International Commission on Occupational Health, a number of these approaches for toxic metals and metalloids were discussed, along with the ongoing need for international collaboration. This "Symposium on Risk Assessment of Metals," hosted by the European Environment Agency in Copenhagen, Denmark, June 13-14, 2005 was sponsored by FORMAS, (Sweden) and co-sponsored by the Agency for Toxic Substances and Disease Registry (USA). This conference brought together a number of international experts on the toxicology of metals to review, discuss, and critique chapters for the *Handbook on the Toxicology of Metals* so that the most relevant and up-to-date information will be available for the production of this important reference work.

Research, knowledge, assessments, and monitoring

Environmental research is a prerequisite for evidence-based policymaking, assessing new knowledge and early warnings. The production of the handbook is one assessment example. The project has also highlighted biomarkers and biological monitoring as an important tool to identify and quantify the exposure, predict health effects, sensitive populations, and perhaps also diagnose a disease. Bio-monitoring is also an effective mean to evaluate the target setting and other policy interventions. However, it raises ethical questions that must be addressed.

CHAPTER

1

Introduction—General Considerations and International Perspectives

GUNNAR F. NORDBERG, BRUCE A. FOWLER, MONICA NORDBERG, AND LARS T. FRIBERG

ABSTRACT

This introductory chapter is composed of two parts. The first section is a brief history of the science of the toxicology of metals by the late Dr. Lars Friberg. He delineates the early realization of the need for international cooperation and consensus that have guided seminal studies related to environmental and occupational toxicology. In this spirit, he initiated work on the first edition of the *Handbook of Toxicology of Metals* that included contributors from around the world.

The second section takes up some current concerns related to the toxicology of metals. It highlights such concerns in relation to the current status of the scientific understanding to date of the metals included and discussed fully in the chapters of the Handbook. Furthermore, it draws attention to future directions in generating new knowledge to fill gaps in the continued quest to assemble the knowledge base necessary for the protection of human health from adverse consequences related to exposure to metals.

1 METALS AND HEALTH—AN INTERNATIONAL PERSPECTIVE*

Lars Friberg

In the years after the Second World War, lists of MAC concentrations (maximum allowable concentrations) for chemicals were constructed for use primarily in industry. There were often substantial differences between the values in different lists (e.g., from the United States and Russia) for the same substance. Reliable background information on methods used was also often lacking or for other reasons difficult to interpret.

At an International symposium on MAC values in 1963, it was recommended to have expert groups convene to establish international MAC concentrations of a number of the more important compounds. In 1966, the Subcommittee for MAC values (chairman, R. Truhaut) under the auspices of the Permanent Commission and International Association on Occupational Health met in Vienna, and responsibility was assigned for formation of groups to evaluate the scientific basis of MAC values for certain specific substances. As a consequence of decisions made at these meetings, an evaluation of MAC values for mercury and its compounds was made at a symposium at the Karolinska Institutet in Stockholm, 1968.

One of the recommendations from the Stockholm symposium was to form a group experienced in the toxicology of metals. The Scientific Committee on the Toxicology of Metals (SCTM) was established during the 16th congress of the International Commission on Occupational Health (ICOH) in Tokyo in 1969. Lars Friberg was elected chairman of the Committee and held this position until 1990. Gunnar Nordberg (1990) and later Bruce Fowler (1997) and Monica Nordberg (2003) took over the responsibility of leading the committee. At present, it has 60 members from

*Presentation at the International Symposium on Risk Assessment of Metals—with special reference to occupational exposures and human environmental exposures in contaminated areas, Copenhagen, June 13–14, 2005.

countries from all over the world. The first meeting was held in Stockholm in 1970.

The serious problems with the development of reliable MAC values were also acknowledged by international agencies like the World Health Organization (WHO), the United Nations Environment Programme (UNEP), and the International Labour Organization (ILO). In a joint venture, they initiated the International Programme on Chemical Safety (IPCS; see preamble to Environmental Health Criteria WHO/IPCS 2006).

The main objective of IPCS has been to carry out and disseminate evaluations of the effects of chemicals on human health and the quality of the environment. Supporting activities have included risk assessment methods that could produce internationally comparable results. The first Criteria Document was the one for mercury 1978. One reason why mercury had a high priority was probably the alarming situation worldwide due to the effects on humans from consumption of mercury in fish.

The Health Criteria Documents often constitute the best available information on the toxicology of chemicals. As a rule, they are very valuable, and it is hoped that the production of documents will continue as planned. There are, however, examples of intensive lobbying by states and industrial groups before, during, and after the preparation of the reports. Because practice has been to require consensus reports, some Criteria Documents were very difficult to finish. The Criteria Document for cadmium is an example in which such problems were formidable. The work on this Criteria Document took approximately 15 years to complete.

The Scientific Committee started a series of workshops and meetings dealing with basic aspects of factors related to metabolism, dose effects, dose response, and critical organs for metals. The first of these meetings was held in Slanchev Briag, Bulgaria, in 1971. It was followed by meetings in Buenos Aires, Argentina in 1972 (TGMA, 1973), Tokyo, Japan in 1974, and Stockholm, Sweden in 1977. Results of the consensus reached were published ("Effects and Dose Response Relationships of Toxic Metals" edited by G. F. Nordberg and published by Elsevier 1976 and the "Handbook on the Toxicology of Metals," 1st ed. 1979, 2nd ed. 1986). Several meetings dealt with more specific topics such as developmental and reproductive toxicity of metals (Clarkson *et al*., 1983) and the role of carcinogenesis. A workshop on neurotoxic metals was organized in Brescia in 2006. When there was a need for information on specific metals, we arranged meetings focusing on single metals, such as arsenic, mercury, cadmium, and lead.

As a result of ongoing research and the need for accurate information the interest in metal toxicology at the Karolinska Institutet increased. We prepared independent publications with an international perspective for evaluating the health risks of certain metals. At that time, we already had a close contact with the US Environmental Protection Agency, which wanted background information for mercury and cadmium for future Criteria Documents. This resulted in formal contracts, and the resulting reviews were submitted to the US Environmental Protection Agency and also published by CRC Press in a number of monographs: *Mercury in the Environment* (Friberg and Vostal, 1972), *Cadmium in the Environment*, and *Cadmium and Health* (Friberg *et al.*, 1985). It was also the start of the work for the *Handbook on the Toxicology of Metals*.

We had been aware for several years of the possible dangers from the use of methyl mercury. In 1958, Swedish researchers already demonstrated that seed-eating birds had high Hg levels in their feathers. Some years later, it was found that fish from several lakes and rivers had high levels of methyl mercury in their organs. One major source for the mercury exposure could be industrial discharge of mercury, but methyl mercury had also been used extensively over many years for the dressing of seed.

In Minamata and Niigata in Japan, there had been two outbreaks of severe poisoning with many fatal cases and prenatal poisonings. Reliable information on exposure and dose effect and dose response was lacking. It became obvious, however, that the source of the poisoning was fish and shellfish heavily contaminated by industrial discharge of mercury into the local waters.

We found increased concentrations of mercury in the blood of Swedish fishermen, who had extensively consumed fish. The mercury levels were alarmingly high, even if no signs of mercury poisoning were found. Some values later turned out to be as high as or even higher than the lowest that could be estimated to have caused symptoms in Japan. It points out that to get signs of intoxication when exposure is fairly low, you must belong to a sensitive part of the population. Based on an extensive research program with considerable international aspects, we were able to produce data that were of value for interpreting the serious effects in Japan. The report from a Swedish Expert Group ("Methyl Mercury in Fish," Berglund *et al.*, 1971) has been used to also evaluate health risks of methyl mercury in other countries.

In Iraq, several hundred farmers died after eating grain dressed with methyl mercury. The disaster has been studied in detail by a group from Rochester, New York. Their research program on mercury is still ongoing, and, in collaboration with Swedish

researchers, includes studies on the effect of exposure to MeHg through consumption of contaminated fish among inhabitants of the Seychelle islands. A Danish research group is carrying out a similar project at Färö Islands.

Inorganic arsenic occurs in high concentrations in bedrocks and groundwater in several parts of the world (e.g., in Taiwan, India, Bangladesh, Argentina, and Chile). Large populations have been exposed, and in some places mass outbreaks of severe poisonings have occurred. Skin cancer and cardiovascular disorders are common. I had the opportunity, as a WHO consultant, to observe the disastrous effect arsenic had had in some places in Taiwan.

In 1976, the Scientific Committee was one of the sponsors of an International Conference on Environmental Arsenic at Fort Lauderdale, Florida. In 1980, a WHO Task Group Meeting on Environmental Health Criteria for Arsenic was held in Stockholm, Sweden. It was pointed out that there was a risk for skin disease and certain forms of cancer from drinking water contaminated with arsenic.

The consequences apparently have not been taken seriously. Through the use of international foreign aid money, including Swedish, British, and the World Bank, a massive assistance program was launched in Bangladesh for several years with the aim to drill deep into the bedrock to get ground water. This was badly needed because contaminated surface water was the main source of water. No one was aware of the risk for arsenic poisoning. A detailed survey of the consequences of the Swedish assistance project, sponsored by SIDA (Swedish International Development Cooperation Agency), was recently published in a Swedish newspaper (DN April 19, 2005). Sweden was financing the drilling of approximately 12,000 wells between 1990 and 2000. In total, the drilling of approximately a million wells was sponsored by international organizations. Now the drilling has been stopped, and emphasis is on analytical and technical programs.

One meeting of particular importance for the Handbook and referred to previously (TGMT, 1979) concerned the concept of a critical concentration of a metal in a cell or in an organ. The metal concentration at which adverse functional changes occur in the cell was defined as the critical concentration for the cell. The critical organ concentration was defined as the mean concentration in an organ that would be necessary for a number of the most sensitive cells in the organ to be affected. The term "critical organ" was used to identify that particular organ that first attains the critical concentration of a metal under specified circumstances of exposure and for a given population. This definition differs from other ones used in radiation protection, in which the term "critical organ" refers to that organ of the body whose damage results in the greatest injury to the individual. The critical effect as defined by the Scientific Committee gives possibilities of preventing more serious effects. It is also important to recognize that the critical concentration varies between individuals and that it is, therefore, not possible to talk about one single value only.

With some modifications, which have been included in the glossary (Nordberg *et al.*, 2004a), we have, when drafting the different chapters in the new edition of the Handbook, tried to use the aforementioned concepts.

Another topic of great importance for evaluating exposure and risks relates to biological monitoring of metals in, for example, blood and urine. The quality of published data is often very poor, even if the situation has improved. The assessment of metals in trace concentrations in biological media is fraught with difficulties from the collection, handling, and storage of samples to chemical analyses.

A systematic approach to quality assurance aspects related to biological monitoring was taken in a 3-year global project by WHO/UNEP. Quality control exercises were carried out with 10 participating laboratories in different parts of the world. The Scientific Committee sponsored a meeting where the different aspects of biological monitoring were discussed in detail (Clarkson *et al.*, 1988).

Metals do not break down. As a consequence, a metal stays in the body until it is excreted. During this time, the metal may be transformed into another more toxic or less toxic species. Inhalation of mercury vapor may be used as an example. Metallic mercury vapor is released from both old and new amalgam fillings. It is taken up in the blood during inhalation and is oxidized within minutes to divalent mercury. Parts of the mercury vapor penetrate the blood–brain barrier and in pregnant women also the placental barrier. In the brain, it is oxidized into divalent inorganic mercury and is excreted only very slowly with a biological halftime of years. This explains why even minor inhalation of mercury vapor from amalgam fillings may create health problems.

Some reports indicate a potential danger of using dental amalgam, whereas others deny it. In some countries, the use of amalgam has been banned. The situation is to some extent similar to the banning of tetraethyl lead in gasoline. Even so there are problems. Old fillings will continue to release mercury for many years. The symptoms many patients complain about are nonspecific and are seen in many other diseases. It would be useful to collect as much information as possible on the health effects of amalgam in different countries (Chapter 33, Bellinger *et al.*, 2006).

Cadmium occurs naturally in the environment and some places, around, for example, mines may be heavily contaminated. Nowadays humans are exposed

primarily through contaminated food. Chronic occupational cadmium poisoning was observed in the late 1940s in Sweden in the production of alkaline batteries. It was shown that many of the symptoms were similar to what was seen in some areas of Japan and called Itai-Itai disease, where inhabitants were eating rice contaminated by cadmium from a river from a nearby mining industry. Japanese and Swedish researchers began long-term collaborative research projects. The research clearly showed that exposure to cadmium was a necessary factor for the development of Itai-Itai disease. Chronic cadmium poisoning has now been observed in several areas of the world, including Belgium, The Netherlands, and China. In many more countries, increased risks are seen as indicated by excessive concentrations in certain foodstuffs (e.g., rice).

Cadmium is a good example of the need and value of international collaboration. Questions relating to cadmium poisoning have been on the agenda at several meetings arranged by national and international bodies. IPCS published a Health Criteria Document in 1992 (WHO/IPCS, 1992) based on several earlier drafts during the entire 1980s. The Scientific Committee held a meeting in Bethesda, Maryland, in 1978 and one in Shanghai, China, in 2003. The last meeting focused on health impacts of cadmium in China and its prevention (Nordberg *et al.,* 2004b).

I hope this has given some information on the need to have international perspectives when evaluating and preventing health effects of metals. The responsibility for this is partly up to governments and international and national organizations. The Scientific Committee has an important role as an organization with high competence and with no formal strings to governments, communities, or industries. It is important that in the future IPCS also gives a high priority to metal toxicity.

It is important to disseminate information on metals and their occurrence and toxicity not only to active scientists and administrators but also to local doctors and engineers. Here the concept of a Handbook is extremely important. The earlier editions of the *Handbook on the Toxicology of Metals* have served this purpose. We expect that the third edition will continue to have such a tutorial task. A Handbook also gives the easiest access to the entire spectrum of metal toxicology.

2 CURRENT CONCERNS RELATED TO THE TOXICOLOGY OF METALS

In addition to the considerations in the first part of this chapter, including the need for international joint action to control identified risks from exposures to metals in humans, the following considerations are of importance with regard to current and future areas of research. This section of the chapter will summarize a number of cross-cutting research areas for metals that are discussed in much greater detail in subsequent individual chapters.

2.1 Expanding Current Industrial New Technological Uses of Metals

The toxicology of metals is concerned with some 80 elements and related species, ranging from comparatively simple ionic salts to complicated structures, such as complexes consisting of a metal atom and a set of ligands and organometallic compounds. Pollution of the environment and human exposure to metallic elements may occur naturally, for example, by erosion of surface deposits of metal minerals, as well as from human activities, such as mining, smelting, fossil fuel combustion, and industrial application of metals. The modern chemical industry is based largely on catalysts, many of which are metals or metal compounds. Production of plastics, such as polyvinyl chloride, involves the use of metal compounds, particularly as heat stabilizers. Plating and the manufacture of lubricants are still other examples of industrial uses of metals. The industrial and commercial uses of metals are continuously increasing. In the development of advanced technology materials, new applications have been found for the most familiar and for the somewhat less familiar metallic elements. Most notable are their uses in the development and production of semiconductors, superconductors, metallic glasses, magnetic alloys, high-strength, low-alloy steel, and most recently in nanotechnology (IARC, 2006).

Some of the new uses like nanotechnology have the potential of causing direct exposure of humans. Many other uses, and also discharges from nonmetal-producing activities such as electricity production from coal combustion, may increase both the amount of and the distance over which metals are discharged into the human environment. The distance from source of emissions of metals to their sinks can sometimes be more than 1000 km for airborne transport. When metals are transported along aquatic and terrestrial routes, they often enter into the food chain. Furthermore, the use and disposition of the new technological equipment increase E-waste. If not recycled in appropriate waste-handling systems, metals/metalloids used in semiconductors will enter the ecological pathways.

2.2 Ecological and Natural Environmental Mobilization Processes

The acidification of soil and lakes by sulfur and nitrogen oxides has increased the possibility for adverse

effects of metals in the environment. The long-range transport of air pollutants not only contributes to the increasing metal load to ecosystems but also alters the mobility of metals. An increasing acidity of surface waters, including lakes, which is caused by acid precipitation, may increase the mobility of metallic compounds, thus increasing human exposures (Nordberg *et al.*, 1985). Natural events, like hurricanes and flooding, possibly amplified by global warming, will increase the mobility of metals, as seen, for example, for mercury in forestry in Sweden and of lead in flooding in New Orleans. Increased exposure may occur by means of increased concentrations of metallic compounds in drinking water and/or food. In addition, increased exposure to lead, cadmium, mercury, and aluminium is well recognized to be the result of long-range transport of air pollutants and the occurrence of acid rain (see Chapter 13).

The worldwide production of the two metals mercury and lead is several million tons per year. Their widespread use has added to natural cycles of these metals, and there is increasing epidemiological evidence that even background exposures may affect human health.

It has been known for a long time that anemia and effects on the brain in the form of cognitive deficits are common findings in children who eat lead paint (Lin-Fu, 1977). Exposure from lead paint in houses or soil near industrial stack gases has been a problem worldwide. In Texas, for example, of the young children living near a smelter and for whom paint was not an important source of exposure, 53% were found to have blood lead values of >400 μg/L—a level high enough to expect adverse effects (Landrigan *et al.*, 1975). Lead from automobile exhaust increases the body's burden of lead in areas where organolead is still used as an additive to gasoline and where there is heavy traffic. The important impact of this source of lead has been established in several countries by the fall in blood levels after the ban of lead in gasoline. Because of the possibility of adverse effects on the central nervous system, the US Centers for Disease Control and Prevention (CDC) guidelines identifies a blood level >0.48 μmol Pb/L (100 μg/L) to be of concern in children (see Chapters 12 and 31), and it was recently recommended by a group of scientists at a meeting in Brescia (see Chapter 16) that this level be lowered to 0.24 μmol Pb/L (50 μg/L). These are levels that sometimes occur as background levels in some countries.

Concern for metal exposure in developing countries was highlighted by WHO in South-East Asia (WHO, 2005). An example is the transference of the manufacture of lead products to developing countries, where child labor increases the exposure of children to lead.

Neurotoxic effects from exposure to lead, mercury, and manganese are well established, and increasing recognition of adverse health effects from Pb and Hg has initiated preventive action by banning or limiting certain uses of these metals. It is necessary to highlight that it is important to avoid using Mn and other neurotoxic metals in a way that causes widespread dispersion in ambient air. As stated in the declaration of Brescia, the avoidance of such new applications of the metals is of fundamental importance in protecting humans from potential adverse health effects (Landrigan *et al.*, 2006). It is also obvious that there is a need to find out more about the toxicology of other metals now suggested as replacements for the known toxic metals being phased out.

What is it that makes exposure to metals a specific problem? Metals are elements and have been an intrinsic component of the environment to which humans and animals have adapted. A "natural exposure" to any metal may thus be harmless to human beings and other species. However, geological factors and widespread contamination from industrialization, forming the general background exposure in some countries, give rise to adverse health effects among sensitive sections of the general human population. Some metals are required for human life (essential metals) because they have a biological function, for example, in many enzymes. In areas where food consumption is based on local produce, and where the levels of some minerals are low for geological reasons, deficiencies may occur. The impact of geological factors on human health is, considered by the science of "medical geology," recently attracting increasing attention (Selinus, 2005).

2.3 Routes of Exposure

Exposure to metals may take place by inhalation, ingestion, or skin penetration. For organometallic compounds, dermal uptake can cause substantial, sometimes lethal, doses (Nierenberg *et al.*, 1998). Inhalation is usually the most important occupational exposure route. Ambient air, except in the vicinity of an emission source, does not usually contribute significantly to the total exposure. Contaminated air may pollute soil and water secondarily, resulting in contaminated crops and vegetables. In countries where people eat food that originates from several or many different areas, the health significance of such contamination may be rather minor. In other countries, such as Japan and other rice-growing countries in Asia, as mentioned earlier, it has been the custom for farmers to depend, to a great extent, on locally grown products. Drinking water is sometimes a significant route of exposure. The extensive exposure to arsenic through ground water contaminated by geological occurrence of arsenic in Bangladesh and the West Bengal has already been mentioned. Other metals causing exposure through drinking water are aluminium,

iron, uranium, and sometimes manganese, cadmium, and lead. Whether local contamination exists, ingestion of metals via food and drinking water is ordinarily the main pathway of exposure for the general population.

A route of exposure that must not be forgotten is the inhalation of tobacco smoke, which contains a number of metals, including cadmium, nickel, arsenic, and lead. It has been shown in a number of studies that cadmium in cigarette smoke may have contributed a third of the total body burden found at age 50 (Friberg *et al.*, 1985; WHO, 1992). The relative contribution of cadmium made by tobacco smoke will, of course, be considerably less when the intake of cadmium via food or air is large. Some data clearly show that external metal contamination of cigarettes in industries where an exposure to metals through air already occurs may increase the workers' inhalation dose of metals several fold. In areas where tobacco is grown and soils are contaminated by cadmium, substantial exposure may occur through smoking (Cai *et al.*, 1995).

2.4 Essentiality of Metals

Metallic elements are found in all living organisms and play a variety of roles. They may be structural elements, stabilizers of biological structures, components of control mechanisms (e.g., in nerves and muscles), and, in particular, are activators or components of redox systems. Thus, some metals are essential elements, and their deficiency results in impairment of biological functions. Essential metals, when present in excess, may even be toxic (Chapter 9). Although this Handbook is concerned primarily with human health effects resulting from excessive exposure to metals and their compounds, it should be recognized that metals might also have deleterious effects on other animal species and plants. Such effects may lead to modification of an entire population or species assembly in an ecosystem. Such effects of metals may be of great significance to human life and should be considered in the total evaluation of environmental pollution by metals and their compounds (see Chapter 13).

It is difficult to rid the environment of a metal with which it has been contaminated. Two striking examples are mercury in the bottom sludge of lakes and cadmium in soil. In addition, several metals and metalloids may undergo methylation during their environmental and biological cycles (e.g., tin, palladium, platinum, gold, thallium, arsenic, selenium, and tellurium), but mercury is the only metal presently known to undergo biomagnification in food chains. The potential influence of acid precipitation on the methylation process for mercury has been considered as one possible explanation for the fact that concentrations of methyl mercury found in fish from acid lakes were higher than in lakes with waters with neutral pH (Wood, 1985; Chapter 13). It is obviously of great importance to understand the ecological cycles of metals to evaluate potential threats to human health from consumption of food and drinking water. There are still considerable gaps in our knowledge in this scientific field.

Essential metals may be toxic if exposure is excessive (e.g., molybdenum). Other metals are not known to have an essential function, and they may give rise to toxic manifestations even when intakes are only moderately in excess of the "natural" intake. Metal toxicity is explainable on the basis of the interference with cellular biochemical systems. Metals often interact at important sites such as the SH groups of enzyme systems. They may also compete with other essential metals as enzyme cofactors (Chapters 3, 5, 7, and 9). Thus the effects of a toxic metal may mimic the deficiency of an essential metal. For example, cadmium does not penetrate into the fetus to any considerable degree but causes an effect on the fetus most likely as a result of a secondary zinc deficiency. Cadmium has been found to be high in the placenta and most likely blocks the zinc uptake of the placenta. Several of the toxic metals have a long biological half-time and tend to accumulate in the body. For cadmium, the biological half-time in man is estimated to be 15–20 years or more. This long half-time may be related to the fact that cadmium is the most potent inducer of the synthesis of metallothionein, a high-affinity metal-binding protein (Kägi *et al.*, 1984; Nordberg, 1984; 1998; Nordberg and Kojima, 1979). With constant exposure, the long biological half-times imply that accumulation will sometimes take place over an entire lifetime.

2.5 Human Health Effects

Our information on metal toxicity, as far as humans are concerned, is derived from industrial health, large-scale, severe episodes of poisoning via contaminated drinking water and food (MethylHg, Cd, Pb) and recently from recognition of widespread occurrence of less obvious but adverse effects on large population groups. There are at least 20 metals or metal-like elements that can give rise to rather well-defined toxic effects in man. These are dealt with in the specific chapters of this Handbook. Arsenic, cadmium, lead, manganese, and mercury have been studied most thoroughly, but other metals are also of concern. Molybdenum brings about goutlike signs, and aluminum has been shown to have serious effects on the central nervous system (CNS) under certain circumstances. Antimony and cobalt may have effects on the cardiovascular system. Some organometallic tin compounds give rise to effects

in the CNS and may also affect the immune system. The latter type of effects are also known to be a result of exposure to platinum, palladium, and beryllium, in the latter case constituting the mechanism for development of chronic beryllium disease, a form of pneumoconiosis (Chapters 11 and 21). Effects on the lungs in the form of pneumoconiosis can also arise after exposure to aluminum, antimony, barium, cobalt, iron, tin, and tungsten or their compounds.

2.6 Metal Carcinogenesis and Reproductive Toxicology

Recognition of the carcinogenicity of metals is of ever-increasing public health importance. Conclusive evidence based on epidemiological, experimental, and mechanistic data has existed since the 1980s, with an increasing number of metals evaluated by International Agency for Research on Cancer (IARC). Chromium and nickel were the first metals classified as carcinogens by IARC. During the 1980s, animal studies with inorganic arsenic confirmed existing epidemiological evidence. On the basis of the convincing evidence for carcinogenicity of arsenic in humans and the fact that arsenic is released from gallium arsenide *in vivo* in animals, this compound has been classified as a human carcinogen. For beryllium the situation is the reverse: results of epidemiological studies have confirmed earlier experimental evidence. Cadmium can contribute to the development of lung cancer and possibly to cancer of the prostate. During the 1980s long-term studies on rats inhaling cadmium chloride showed remarkable dose-related incidence of lung cancer at low exposure levels. Cadmium and its compounds have been classified as carcinogenic to humans by IARC. Lead and its inorganic compounds have recently been evaluated by IARC and are classified as probable human carcinogens based on a combination of human and animal data. The experience with these metals emphasizes the importance of carefully evaluating the consequences in humans of exposures to metals proven to be carcinogenic in animals. Cobalt compounds and antimony trioxide are examples of a metal compounds considered to be possible human carcinogens mainly on the basis of animal data. A few metal and metalloid derivatives have shown chromosomal effects *in vitro* and *in vivo*, as well as point mutations in, for example, *Salmonella*, *Escherichia coli*, and *Drosophila*. However, for most of the carcinogenic metals and their compounds, epigenetic mechanisms are considered of importance in expressing their carcinogenicity. Carcinogenicity of metal compounds is further discussed in Chapters 5, 10, and 14.

Prenatal effects are known to take place in poisoning with lead, methyl mercury, and arsenic. Reproductive and developmental effects are not well documented in human exposures to other metals, but such effects have been observed in animals after exposure to large doses of cadmium, indium, lithium, nickel, selenium, and tellurium (Clarkson *et al.*, 1985; Chapter 12). The difficulties that have occurred in the past when performing epidemiological studies regarding these effects in humans are pointed out in Chapter 12. Further studies with improved methods, taking into consideration present knowledge about human reproductive endocrinology, developmental biology, and metal toxicology, are urgently needed.

2.7 Toxicokinetics and Metabolism

Once reliable data on critical organs, critical concentrations, and critical effects have been established, it may be possible to estimate the exposure required to give rise to such concentrations, provided enough information is available on the metabolism and kinetics of the metal. A toxicokinetic model may then be set up with data on the absorption, distribution, biotransformation, and excretion of a given metal. In only a few cases have adequate models been established, one example being methyl mercury (Berglund *et al.*, 1971; Chapter 23). Almost 100% of ingested methyl mercury is taken up. The accumulation may be described by a one-compartment model, indicating that the exchange between the different organs is considerably faster than the excretion of the metal. The biological half-time is on average approximately 70 days. This means that approximately 1% of the total body burden is excreted daily, primarily through the bile.

The metabolism of cadmium is more complicated, and an appropriate model is more difficult to establish. Some facts are well recognized, however. The absorption of cadmium from food will average around 5% in men and 10% in women, but under certain nutritional conditions, such as a low intake of calcium or iron, absorption levels as high as 20% may be reached (Flanagan *et al.*, 1978; Chapters 3 and 23). Absorption of cadmium after inhalation may vary between 10 and 50%, depending on particle size distribution. In long-term, low-level exposures, several series of autopsy data have shown that approximately one third of the total body burden could be in the kidneys and about one half in the kidneys and liver together. With higher exposure, proportionally more cadmium would be found in the liver. A physiologically based multicompartment model has been developed describing the behavior of cadmium. In long-term, low-level exposure, the biological half-time is in the order of one to two decades (Friberg *et al.*, 1985; Nordberg and Nordberg, 2002; Nordberg and Kjellstrom, 1979; WHO, 1992; Chapters 3 and 23). The usefulness and validity of this

model has been shown using NHANES data (Choudhury *et al.*, 2001). It has been possible to estimate the daily intake required to reach the critical concentration of cadmium in the kidney and of methyl mercury in the CNS, these being the two critical organs, respectively (Berglund *et al.*, 1971; Diamond *et al.*, 2003; Friberg et al., 1985; Kjellstrom and Nordberg, 1978; Nordberg and Strangert, 1985; Task Group on Metal Toxicity, 1976; WHO, 1990; 1991; 1992). These estimates are in fairly good agreement with directly observed associations between exposure, concentrations in organs, and effects. Toxicokinetic models have also been published for inorganic lead and for chromium compounds (see Chapter 3). There is a great need to set up appropriate toxicokinetic models for other metals, but in most cases no adequate data are available. Clarkson *et al.* (1988) (see also Chapter 3) advanced this issue and presented metabolic models for the metals seen as most important at that time. The concept is important and should be applicable for further improvement of existing models and for metals of interest in the future.

2.8 Biological Monitoring

Exposure biomonitoring using concentrations of metals in urine, blood, or hair has been increasingly used in recent years (see Chapter 4). When interpreting such data, an appropriate toxicokinetic model is of great value, because it will depict the relationships between concentrations in indicator media and concentrations in critical organs and in the body as a whole.

Blood levels, particularly red cell levels, of methyl mercury are valuable for assessing the concentration of methyl mercury in the CNS, as well as in the body as a whole. As a rule, urinary levels cannot be used, because the excretion of methyl mercury in urine is extremely small, the main excretion route being the bile (Chapter 33). For cadmium the situation is more complicated. In long-term, low-level exposures, urinary levels on a group basis give an indication of the concentration in the kidneys and the total body burden. In individual cases, caution has to be exercised because of wide individual variations.

When the critical level has been reached in the kidneys, cadmium excretion through urine increases simultaneously with the occurrence of tubular proteinuria. The cadmium concentration in urine under such conditions no longer reflects the total body burden. Blood levels may be useful for evaluating recent exposure, and in long-term, low-level blood exposures can also be used for estimating the body burden. The biological half-time of cadmium in blood is considerably shorter than that in the kidneys (Friberg *et al.*, 1985; Chapter 23).

2.9 Risk Assessment

It is obvious that exposure to metals in industrial and general environments may be related to health risks. The crucial questions are, of course, which safety margins are needed and which ones are available. These questions are not easy to answer because of a considerable lack of adequate data (Chapter 14). If we consider methyl mercury, we know that early developmental effects are caused by methyl mercury. Risks of such effects may result from regular consumption of fish like pike, tuna, shark, and swordfish by pregnant women. Risk assessments have resulted in restrictions of methyl mercury in food both in the United States and in the European Union. Some countries (e.g., Sweden) have high concentrations of methyl mercury in lake fish because of acid rain, and thus a government-directed program of information aimed at women of child-bearing age to avoid fish high in methyl mercury has been established. Grandjean and Landrigan (2006), on the basis of the slow development of knowledge about neurodevelopmental toxicity of lead and methyl mercury in humans, pointed out the lack of adequate data for a risk assessment of neurodevelopmental effects of a number of neurotoxic metal compounds like aluminum, bismuth, ethyl-mercury, inorganic mercury, tellurium, thallium, and tin compounds. Considerable efforts are thus required to fill the gaps in knowledge.

The process of establishing health criteria for exposure standards is a difficult, but important, task, as is being recognized increasingly on national and international levels. Discussions have been devoted to the question of whether it would be advisable to apply the philosophy of collective dose to some chemical substances, including metals. According to this concept, which is used in radiation protection, any emission, from a power plant, for example, is considered to involve a certain degree of risk even if the effects may be remote both geographically and time wise, and may occur only when a simultaneous exposure from a number of other sources takes place. These and other aspects on risk assessment are discussed further in Chapter 14.

Risk assessment in human health has been refined and improved by introducing new methods such as assessing benchmark dose, identifying new biomarkers, and differentiating assessments by speciation of metals (Chapter 14; WHO/IPCS, 2007).

2.10 Interactions Among Metals

Interactions among different metals and interactions among metals, other substances, and different host factors constitute a subject on which more and more

attention is being focused. This matter has been discussed at several international symposia (Fowler, 2005; Nordberg, 1978; Nordberg and Andersen, 1981; Nordberg and Pershagen, 1985). By means of recent methods for identification of genetic variation in populations, the role of genetic polymorphisms is presently being examined in relation to metal toxicology (Chapter 7). It is obvious that such interactions occur frequently and can both increase and decrease the toxicity of metals. For example, data support the conclusion that the risk of chronic beryllium disease developing is considerably increased among persons belonging to a specific HLA group. Another example is that selenium can decrease the toxicity of methylmercury. Age seems to be an interaction factor of particular importance. Several data indicate that the absorption of both cadmium and lead is substantially higher in young age groups than in other age groups. Children are more susceptible to development of neurotoxic effect of lead than adults (see Chapters 6, 7, and 31).

CHAPTER

2

General Chemistry, Sampling, Analytical Methods, and Speciation*

RITA CORNELIS AND MONICA NORDBERG

ABSTRACT

This chapter provides an introduction to the general chemistry of metals with particular emphasis on the biological and toxicological characteristics. This is followed by an elaborate description of analytical chemistry aspects relevant to trace element analysis. Because total element analysis is giving way to elemental speciation and fractionation, detailed information is given about useful strategies in sampling and sample preparation, followed by separation techniques and detection methods for the elemental species. In addition, the major issues of calibration, reference materials, and quality assurance are dealt with.

Of 111 identified elements—90 occurring naturally on earth—most (67) form metals, and all but one of these (Hg) are solid. Eleven elements make up atomic or molecular gases, and 12 more elements form solid or liquid nonmetals. The chemistry of metals represents a major part of inorganic chemistry. Understanding the toxicology of metal species has advanced substantially during the past decades, thanks to the considerable contributions of bioinorganic chemistry (e.g., the discovery that metal species undergo biomethylation and thus can form organometallic compounds). This discipline goes hand in hand with chemical speciation, which is instrumental in understanding metal toxicology and related adverse health effects.

The commonly used term "heavy metals" to describe metals or metalloids that can give rise to toxicity was brought to the attention of the participants of workshops held by the Scientific Committee on Toxicology of Metals (SCTM) under the International Commission on Occupational Health (ICOH) in the 1970s. It was concluded by the Task Groups that the term should not be used (Task Group on Metal Accumulation, 1973; Nordberg, 1976). Recently, the improper use of the term "heavy metals" to design a group of metals and semimetals (metalloids) associated with contamination and potential toxicity or ecotoxicity was brought to further attention, and the misuse of the term was critically commented upon (Duffus, 2002). Nevertheless, the term continues to be commonly (mis)used in toxicology and legislation to encompass the pure metal and all its chemical species. This meaningless terminology totally ignores the fact that pure metals and their compounds do not have the same physiochemical, biological, and toxicological properties. It is obvious that metal species need to be addressed in each case.

Considering the persistence of the misuse of the term "heavy metals," it is interesting to learn something more about the origin of the term. An excellent historic overview of the terminology "heavy metals" has been published by J. Duffus (2002), to which the reader is referred to find the historic references. A brief summary might be helpful to illustrate the confusion that surrounds the term and avoid its further

*Partly based on Chapter 2: General chemistry of metals by V. Vouk and Chapter 3: Sampling and analytical methods by T. J. Kneip and L. Friberg in Friberg *et al.* (1986).

use in matters concerning chemistry, policy, and regulations. Before 1936, the term was used with the meanings "guns or shot of large size" or "great ability." The oldest scientific use of the term to be found in the English literature is cited in Bjerrum's *Inorganic Chemistry* published in 1936. The Bjerrum definition is based on density of the elemental form of the metal, and he classifies heavy metals as those metals with elemental densities >7 g/cm^3. Over the years, this definition has been modified by various authors, and there is no consistency. There were various classifications according to the specific gravity either >4, a little >5, then 4.5, also 6, and even 3.5. It is evident that it is impossible to come up with a consensus on the basis of specific gravity, because it yields nothing but confusion. At some point in the history of the term, it has been realized that specific gravity is not of great significance in relation to the reactivity of the metal. Accordingly, definitions have been formulated in terms of atomic mass. The criterion was still unclear as some scientists opted for atomic mass greater than 23 (sodium), this means magnesium. Others take 40 as a criterion, thus starting with Sc. Another suggestion is the ability of the element to form soaps with fatty acids as a criterion of "heaviness." Still another group of definitions is based on atomic number, suggesting citing metals above sodium (11) as heavy. One more group of definitions is based on chemical properties, with little in common: density for radiation screening, density of crystals, and reaction with dithizone. With the preceding in mind, the rationale is that there is no basis for deciding which metals should be included in this "category" of "heavy metals." The term is hopelessly imprecise, leads to confusion, and is useless to describe toxic properties.

Detailed information about the chemistry of metals is given in a number of textbooks (Cotton *et al.*, 1999; Heslop and Jones, 1976; Parish, 1977), and the introductory text by Pauling (1970). A good source of information on the properties of ions in solution, an important field for understanding metal toxicology, is the introductory monograph by Pass (1973). The principles of bioinorganic chemistry were presented in the 1970s by Hughes (1972), Phipps (1976), Williams (1976), and Fiabane and Williams (1977). More advanced aspects about bioinorganic chemistry can be found in Dessy *et al.* (1971), Addison *et al.* (1977), Fraústo da Silva and Williams (1991), and Williams and Fraústo da Silva (1996). Theoretical and chemical aspects on the toxicology of metals can be read in Hill and Matrone (1970), Brakhnova (1975), and Goyer *et al.* (1995). Two handbooks on elemental speciation covering analytical techniques, methodology, and element-by-element review were recently published by Cornelis *et al.* (2003; 2005).

1 DEFINITION OF METALS

Metals are usually defined on the basis of their physical properties in the solid state. The physical properties of great technological significance are:

1. High reflectivity that is responsible for the characteristic metallic luster
2. High electrical conductivity, decreasing with increasing temperature
3. High thermal conductivity
4. Mechanical properties such as strength and ductility

Metals in the solid state are also characterized by their crystal structure, by the specific chemical bond in which electrons are delocalized and mobile, and by the magnetic properties. These physical properties have only limited value for understanding the systemic toxic effects, although some may be important in understanding the local effects of metal aerosols.

A more useful definition of metals to make it possible to explain the toxic effects is based on their properties in aqueous solutions. This definition is: "a metal is an element which under biological conditions may react by losing one or more electrons to form a cation." In the following text, the discussions will be based on the behavior of metals/metal ions in solution and, where applicable, in biological media.

The distinction in metal toxicology between metals and nonmetals, whether on the basis of their physical or on their chemical properties, is not sharp. In metal toxicology, some strictly defined metalloids are included because they produce adverse health effects in humans, either by themselves or by interaction. They exhibit certain properties that are typical of metals, whereas other properties make them similar to nonmetals. In general, in some groups of the periodic system, a gradual transition of properties occurs from nonmetals to metals when descending from the lighter to the heavier elements (e.g., C, Si, Ge, Sn, and Pb in group 14). Borderline elements such as As, Ge, Sb, Se, and Te are sometimes called metalloids.

2 THE PERIODIC TABLE

The periodic table consists of seven horizontal rows called periods and 18 vertical columns, as presented in Table 1 *(http://www.iupac.org/reports/periodic_table/index.html).* The element with the lowest number of protons is H with one proton. Increasing the number of protons increases the atomic number and yields a different element. With an equal number of protons, the number of neutrons for each element determines the

isotope. Elements can thus occur as several isotopes. Some have an unstable nucleus so that they also display radioactivity besides their chemical properties. The electron configuration of elements is described in orbitals assigned as s, p, d, and f shells or subshells, thus indicating the spatial configuration of the electrons. The s-orbital is spherically symmetrical around the nucleus of the atom of the element. The orbitals p, d, and f, are not spherically symmetrical. The chemical properties of an element depend on the specific electronic configuration of the atom, which varies in a systematic way according to the atomic number. This can be easily made clear from the very didactic display given on the website *http://www.webelements.com/index.html*.

3 COMPOUNDS OF METALLIC ELEMENTS

Metallic elements and metalloids form compounds in various oxidation states, yielding inorganic compounds such as salts and saltlike products, metal complexes (coordination compounds), and organometallic compounds. In metallic compounds, the atoms bind either in ionic or covalent bonds. Intermediate forms are also seen. Dissolved in water the metallic compounds dissociate into metal ions, mostly as cations. In some cases such as the permanganate ion (MnO_4^-), an oxoanion is formed. Metallic ions can form compounds with other metallic ions, forming alloys with two or more metals in varying proportions. Binary and multicomponent systems also exist in the crystalline phase (FeS is an example).

3.1 Covalent and Ionic Bonds

Two major types of chemical bonds exist (i.e., covalent and ionic). The covalent bond is defined as a region of relatively high electron density between nuclei that arises, at least partly, from the sharing of electrons and produces an attractive force and characteristic internuclear distance (McNaught and Wilkinson, 1997). Covalent bonds exist as homopolar and heterocovalent. When the two atoms of the diatomic molecule are the same (e.g., two hydrogen atoms), the electron density is distributed symmetrically between the two nuclei, and the covalent bond is homopolar. If the two atoms are not the same, the electron distribution will be asymmetrical, and the electron density will be displaced toward the atomic nucleus that is more electronegative (i.e., which has a higher capacity to attract electrons). This is a heteropolar covalent bond. The greater the difference in electronegativity of two atoms forming a bond, the more uneven the distribution of the electrons will be. In an extreme

case, a complete transfer of electrons from one atom to another occurs, thus forming an ionic bond. Metallic elements have low electronegativity. Chemical bonds are rarely entirely covalent or entirely ionic. Ionic bonds are predominantly formed in metal salts like chlorides (NaCl) or nitrates ($Ca(NO_3)_2$). Covalent bonds are predominantly, but not exclusively, formed between metals and carbon atoms as in organometallic compounds such as dimethylmercury (CH_3–Hg–CH_3).

3.2 Oxidation Number

Oxidation can be defined according to the following three criteria (McNaught and Wilkinson, 1997).

1. Oxidation is the complete removal of one or more electrons from a molecular entity (also called "de-electronation"), for example, the Zn^{2+} ion derives from the atom Zn of which 2 electrons have been removed.
2. This definition can be extended to chemical reactions in which a complete electron transfer does not occur and which, by custom and in current usage, are called oxidations. In this application, oxidation numbers are considered. Oxidation now is an increase in the oxidation number of any atom within a substrate, for example, $Fe^{2+} - e^- \leftrightarrow Fe^{3+}$. The oxidation number in an ion or a molecule is the charge the atom would have if the polyatomic ion or molecule was composed entirely of ions. Thus, for example, in MnO_4^-, manganese is considered to be in the oxidation state +7 (Mn^{VII}), and oxygen is assumed to exist as O^{2-} ion.
3. Oxidation is also the gain of oxygen and/or loss of hydrogen of an organic substrate. All oxidations meet criteria 1 and 2, and many meet criterion 3, but this is not always easy to demonstrate.

Alternately, an oxidation can be described as a transformation of an organic substrate that can be rationally dissected into steps or primitive changes. The latter consist in removal of one or several electrons from the substrate followed or preceded by gain or loss of water and/or hydrons or hydroxide ions, or by nucleophilic substitution by water or its reverse, and/or by an intramolecular molecular rearrangement.

This formal definition allows the original idea of oxidation (combination with oxygen), together with its extension to removal of hydrogen, as well as processes closely akin to this type of transformation, to be descriptively related to definition 1. For example, the oxidation of methane to chloromethane may be considered as follows:

$$CH_4 - 2e^- - H^+ + OH^- = CH_3OH \rightarrow \text{reversal of hydrolysis } CH_3Cl.$$

Oxidation number is used to define the state of oxidation of an element. Unbound atoms have a zero oxidation state. The oxidation number of a central atom in a coordination entity is the charge it would bear if all the ligands were removed along with the electron pairs that were shared with the central atom (McNaught and Wilkinson, 1997). It is represented by a roman numeral, for example, Cr^{III}, Cr^{VI}.

The oxidation state is a measure of the degree of oxidation of an atom in a substance. It is defined as the charge an atom might be imagined to have when electrons are counted according to an agreed-on set of rules: (l) the oxidation state of a free element (uncombined element) is zero; (2) for a simple (monoatomic) ion, the oxidation state is equal to the net charge on the ion; (3) hydrogen has an oxidation state of +1 and oxygen has an oxidation state of −2 when they are present in most compounds (exceptions to this are that hydrogen has an oxidation state of −1 in hydrides of active metals (e.g., LiH) and oxygen has an oxidation state of −1 in peroxides (e.g., H_2O_2); (4) the algebraic sum of oxidation states of all atoms in a neutral molecule must be zero. In ions, the algebraic sum of the oxidation states of the constituent atoms must be equal to the charge on the ion. For example, the oxidation states of sulfur in H_2S, S_8 (elementary sulfur), SO_2, SO_3, and H_2SO_4 are, respectively: −2, 0, +4, +6, and +6. The higher the oxidation state of a given atom, the greater is its degree of oxidation; the lower the oxidation state, the greater is its degree of reduction (McNaught and Wilkinson, 1997).

Another important reaction that metals undergo is the Fenton reaction, which is important in biological systems because most cells have some amounts of iron, copper, or other metals that can catalyze this reaction. Transition metals with redox potentials in a biologically accessible range, such as iron and copper, can accept and donate electrons in a catalytic fashion. The Fenton reactions results in generating oxidative species in the cell, as follows

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH + OH^-.$$

This is the iron-salt–dependent decomposition of dihydrogen peroxide, generating the highly reactive hydroxyl radical, possibly by means of an oxoiron(IV) intermediate. Addition of a reducing agent, such as ascorbate, leads to a cycle that increases damage to biological molecules (McNaught and Wilkinson, 1997).

3.3 Inorganic Compounds

Metallic elements form a great variety of inorganic compounds. They can be classified into binary and multielement compounds. The most important binary compounds, both from the technological and the

toxicological viewpoint, are oxides and sulfides. These are the chemical forms in which most metals appear in nature, the minerals and ores. The metal-containing aerosols produced in metallurgical processes often occur as metal oxides. However, in experimental toxicological studies, chlorides and acetates are the most commonly used metal compounds because of their high solubility in water and biological systems.

3.4 Metal Complexes

A metal complex or coordination compound is formed by the association of a metal atom or ion and another chemical species, called ligand, which may be either an anion or a polar molecule. The ligands such as BAL (2,3-dimercaptopropanol) and D-penicillamine ($(CH_3)_2C(SH)CH(NH_2)CO_2H$)) serve important biological functions, where –SH groups of the ligand easily bind to a metal. Because of this, they can be used as detoxifying agents in case of, for example, mercury exposure. Another example is EDTA (ethylenediaminetetraacetic acid) used in lead detoxification.

3.5 Organometallic Compounds

Organometallic compounds are classically compounds having bonds between one or more metal atoms and one or more carbon atoms of an organyl group. Organometallic compounds are classified by prefixing the metal with organo- (e.g., organopalladium compounds). In addition to the traditional metals and semimetals, elements such as boron, silicon, arsenic, and selenium are considered to form organometallic compounds. Examples are organomagnesium compounds MeMgI (iodo(methyl)magnesium); Et_2Mg (diethylmagnesium); an organolithium compound BuLi (butyllithium); an organozinc compound $ClZnCH_2C(= O)O$ Et) chloro(eth oxycarbonylmethyl)zinc; an organocuprate $Li^+(CuMe_2)^-$ (lithium dimethylcuprate); and an organoborane Et_3B (triethylborane). The status of compounds in which the canonical anion has a delocalized structure in which the negative charge is shared with an atom more electronegative than carbon, as in enolates, may vary with the nature of the anionic moiety, the metal ion, and, possibly, the medium. In the absence of direct structural evidence for a carbon-metal bond, such compounds are not considered to be organometallic (McNaught and Wilkinson, 1997).

4 SOLUBILITY

The solubility of metal compounds in water and lipids is of great toxicological importance, because it is one of the major factors influencing the availability and absorption of metals. The solubility of metal compounds in water depends on the presence of other chemical species, particularly H^+ or H_3O^+ ions (pH). Hence, it may vary widely, depending on whether the solvent is "pure" water or a biological fluid. In mammals, the biological fluids are slightly alkaline (pH 7.4), with the exception of the fluids in the gastrointestinal tract, which are acid (pH 2–6) in the stomach and almost neutral (pH 6.8) in the intestines. Biological fluids may also contain a variety of organic ligands that exert a further influence on the solubility. Experimental data on the solubility of metal species in biological fluids are limited. Some work has been published on aluminium (Dayde *et al.*, 2003; Desroches *et al.*, 2000; Harris, 1992; Salifoglou, 2002; Venturini-Soriano and Berthon, 2001), beryllium (Sutton and Burastero, 2003), and uranium complexes (Sutton and Burastero, 2004).

Although water is too simple a model for a biological medium, strategies used in solubility studies of elemental species in water may be copied to gain knowledge in complex systems. Some simple rules are governing the solubility of metal compounds/species in water, which may, indeed, be a useful indicator of solubility of these compounds in biological fluids. A simple rule used in chemistry divides various substances into "soluble or insoluble." "Soluble" substances have a solubility in water >1 g/100 ml^1 (10 g/L^1); "insoluble" substances have a solubility of <0.1 g/100 ml^1 (1 g/L^1). This distinction may not be meaningful if a substance is highly toxic. Within each group of the periodic table, the solubility of metal compounds/species generally decreases with increasing atomic numbers.

Usually nitrates, acetates, and all chlorides, bromides, and iodides of metals are soluble, except those of silver, mercury (I), and lead. All sulfates apart from those of barium, strontium, and lead are also soluble. All salts of sodium, potassium, and ammonium are soluble, except sodium antimonite, potassium hexachlorplatinate, and potassium cobaltinitrite.

Mainly insoluble are all hydroxides (except for those of alkali metals, ammonium, and barium), all normal carbonates and phosphates apart from those of alkali metals, ammonium, and the alkaline earth metals.

Solubility depends on factors such as pH, the presence of other ions, the oxidation state of the metal, and the rate of oxidation–reduction conversions (see section 5.2).

The solubility of sparingly soluble substances depends also on their particle size and aerodynamic diameter. Finely divided material is usually more soluble.

Generally, solubility of a substance is given as solubility in water, solvents, and acids. However, biological systems greatly influence the solubility. Thus, it is important to test the metal species of concern for solubility in the biological fluids, as mentioned previously.

5 PROPERTIES OF METAL IONS

5.1 Formation of Metal Ions

Metal ions are formed by the removal of one or more outer electrons from the neutral atom. The energy required for the ion formation depends on the environment in which this process takes place. The formation of ions in the gas phase requires a considerable amount of energy. Much less energy is required when the process takes place in water, because part of the ionization energy is provided by the energy of hydration (i.e., the energy that is gained when a positively charged metal ion binds dipolar water molecules). The number of water molecules that are bound directly to the metal ion (first hydration sphere) depends on the size and the charge of the metal ion and varies from 4 for Li^+ to approximately 10 for Ra^{2+}. Because further polarization of water molecules is contained in the first hydration sphere, additional water molecules will be attracted to form a second hydration sphere. This association can continue, but its extent decreases rapidly with distance from the ion. The size of the hydration sphere will depend on the polarizing power of the ion, which, in turn, depends on the charge/radius ratio. The hydrated ion is a dynamic system in which water molecules in the hydration sphere rapidly exchange with those in the bulk phase of the solution.

5.2 Redox Potential

Redox, or oxidation-reduction, processes involve the transfer of electrons from one reactant to another. The two processes, oxidation and reduction, are always coupled. This means that when one substance is oxidized (reducing agent), another must be reduced (oxidizing agent). Oxidizing or reducing power of an oxidation-reduction system is measured in terms of the standard electrode potential (i.e., the value of the standard emf of a cell in which molecular hydrogen under standard pressure is oxidized to solvated protons at the electrode). If the standard electrode potential, E^0 of a metal is large and negative, the metal is a powerful reducing agent, because it loses electrons easily. An example of a few standard electrode potentials of metals is given in Table 2. The actual electrode potentials, or redox potentials, depend on the concentration of metal ions, on the temperature, and on the presence of other ligands that can displace water from a hydrated ion. Oxidation-reduction reactions are of fundamental importance in biochemistry. Transition metals that can easily change their oxidation state play a very important role.

TABLE 2 Standard Electrode Potentials (Skoog *et al.*, 1994)

Reaction	E^0 at 25°C, V
$Ag^+ + e^- \leftrightarrow Ag$	+0.799
$Fe^{3+} + e^- \leftrightarrow Fe^{2+}$	+0.771
$Ni^{2+} + 2e^- \leftrightarrow Ni(s)$	−0.23
$Cd^{2+} + 2e^- \leftrightarrow Cd(s)$	−0.403
$Cr^{3+} + e^- \leftrightarrow Cr^{2+}$	− 0.41
$Zn^{2+} + 2e^- \leftrightarrow Zn(s)$	−0.763

5.3 Metal Ions as Lewis Acids

Lewis made a useful definition of acids and bases. An acid is an electron pair acceptor, and a base is an electron pair donor. This means that all positively charged metal ions can be classified as Lewis acids or electron acceptors. In the same way, the water molecule that is formally an electron donor can be classified as a Lewis base. The following equations illustrate this.

metal ion + water → hydrated metal ion

(Lewis acid + Lewis base → complex) hydrated ions + ligand → complex + water

The IUPAC compendium of chemical terminology (McNaught and Wilkinson, 1997) defines these terms as follows:

A Lewis acid is a *molecular entity* (and the corresponding *chemical species*) that is an electron-pair acceptor and therefore able to react with a *Lewis base* to form a *Lewis adduct*, by sharing the electron pair furnished by the Lewis base.

For example:

$$Me_3B + :NH_3 \leftrightarrow Me_3B\text{-}NH_3 + H_3$$

Lewis acid + Lewis base ↔ Lewis adduct
(Me, methyl; B, boron)

5.4 Hydrolysis

Hydrolysis is a reaction that can occur between the metal ion (M) and one or more water molecules in the coordination (solvation) sphere, in which a proton (hydrogen ion) is released and the solution becomes acidic.

$$(M(OH_2)_x)^{n+} \leftrightarrow (M(OH)(OH_2)_{x-1})^{(n-1)+} + H^+(aq)$$

Hydrolysis may proceed in several stages until the last coordinated water molecule is removed. The process of hydrolysis may be interrupted if at one stage an insoluble compound is produced. Hydrolysis occurs most readily with metal ions that strongly polarize the coordinated water molecules.

6 OTHER ASPECTS OF METAL CHEMISTRY OF BIOLOGICAL AND TOXICOLOGICAL INTEREST

6.1 Main Group and Transition Metals

According to the *IUPAC Nomenclature of Inorganic Chemistry* (Freiser and Nancollas, 1987), the main group metals are those belonging to the periodic system group 1 (alkali metals Na, K, Rb, Cs, Fr), group 2 (alkaline earths Be, Mg, Ca, Sr, Ba, Ra), group 13 (Al, Ga, In, Tl), group 14 (Ge, Sn, Pb), group 15 (Sb, Bi), and group 16 (Po). The transition metals are those belonging to group 3 (Sc, Y, La, Ac), group 4 (Ti, Zr, Hf), group 5 (V, Nb, Ta), group 6 (Cr, Mo, W), group 7 (Mn, Tc, Re), group 8 (Fe, Ru, Os), group 9 (Co, Rh, Ir), group 10 (Ni, Pd, Pt), group 11 (Cu, Ag, Au), and group 12 (Zn, Cd, Hg).

Elements with partly filled d- or f-orbitals are usually defined as transition elements. A broader definition would be elements in any oxidation state in which they form compounds with partly filled d- or f-orbitals. By this definition also Cu, Ag, and Au would be included. There are 56 transition elements of the d- and f-block. All have the same common properties:

a. They are all metals.
b. They exhibit variable oxidation states with a few exceptions.
c. Because of partly filled d- and f-orbitals, they form at least some paramagnetic compounds.
d. Their ions and compounds are colored in one or all oxidation states.

Properties b and c are of great biological importance because of their role in biological catalysis and by their electron transport function.

The transition elements are further subdivided into three main groups:

A. The main transition elements or d-block elements
B. The lanthanide elements
C. The actinide elements

The lanthanides and actinides are classified as elements of the f-series.

6.2 Metal-Containing Biological Molecules

Many metals play important roles for the biological activity of enzymes and vitamins when constituting either part of the structure or as a cofactor of these entities. Zinc, for example, plays an essential role in the zinc-dependent enzyme alcohol dehydrogenase, and cobalt is essential to vitamin B_{12}. Aspects on the biochemistry in this topic are given in Hughes' monograph (1972).

Metalloproteins (also called conjugated proteins) consist of a protein and a prosthetic group or cofactor that consists of a metal. Metalloenzymes are defined as holoenzymes and a prosthetic group or cofactor that consists of a metal.

Hemoglobin, hemerythrin, and myoglobin carry oxygen bound to iron. Examples of redox proteins are iron sulfur proteins like cytochromes *c* and *b5*. Redox enzymes are cyt-p450, catalase, and peroxidase.

A number of proteins are metal carriers, as in the case of the blood proteins shown in Table 3.

6.2.1 Metalloporphyrins

The metalloporphyrins include two important categories: the chlorophyll molecule and the molecules carrying the heme group. The ability of chlorophyll to absorb light is related to the conjugated polyene structure of the porphyrin ring. Magnesium ions that are coordinated to the nitrogen atoms of the four pyrrole rings have at least two functions. They provide the necessary structural rigidity, and they increase the rate of conversion of the singlet-excited state resulting from photon absorption into the triplet state that enables the transfer of the excitation energy into the redox chain.

The two main functions of iron-containing biological complexes are the transport of oxygen and the mediation in electron transfer chains. The heme group is in all cases associated with a protein molecule as in hemoglobin, myoglobin, cytochromes, and enzymes such as catalase and peroxidase. Cytochromes serve as electron carriers, and the heme-containing enzymes catalase and peroxidase catalyze the decomposition of hydrogen peroxide. Catalase is involved in the oxidation of mercury vapor.

TABLE 3 Examples of Metal-Carrying Proteins

Protein	Metal
Transferrin	Fe
Ceruloplasmin	Cu
Metallothionein	Zn, Cd, Hg, Cu
Albumin	Zn, Cd
Phosphoproteins	Ca

6.2.2 Non-Heme Iron Proteins

Non-heme iron proteins (e.g., rubredoxins, ferredoxins, hemerythrin, and high-potential iron proteins) contain strongly bound functional iron atoms attached to sulfur, but they do not contain porphyrins. All of them have a role in electron transfer.

Ferritin and hemosiderin are important iron-containing biological structures that both store iron in a protein structure. Transferrin binds ferric iron and transports it from ferritin to cells. In microorganisms, iron is transported by ferrichromes and ferrioxamines, structures containing cyclic or acyclic polypeptide chains.

6.2.3 Cobalt-Containing Biological Molecules

The best-known cobalt-containing biological molecules are vitamin B_{12} coenzymes (cobalamins). Cobalamins contain a cobalt atom, a macrocyclic ligand corrin, and a complex organic part constituting a phosphate group, a sugar, and an organic base also coordinated to the cobalt atom. Methylcobalamin is involved in the methane-producing bacteria and has been shown to transfer the methyl (CH_3) group to a number of metals and metalloids, including Hg(II), Te(III), Pt (II), Au(I) *in vitro*. It is considered the most likely methylator of mercury *in vivo*.

6.2.4 Metalloenzymes and Metal-Activated Enzymes

Some enzymes incorporate one or more metal atoms in their normal structure. They are called metalloenzymes, including many zinc metalloenzymes. The best known of these are carbonic anhydrase and carboxypeptidase. The zinc ion is bound in a distorted tetrahedral configuration, with two histidine nitrogen atoms, one glutamate carboxyl oxygen atom, and a water molecule as ligands.

Another group consists of the copper-containing metalloenzymes. Their structure is only known to a limited extent. Ascorbic acid oxidase and various tyrosinases are examples of this group. In lower animals (crabs, snails), the oxygen-carrying molecule is the copper-containing protein hemocyanin, which, however, does not contain any heme groups (Lloyd *et al.*, 2005; Pallares *et al.*, 2005).

Metalloenzymes containing molybdenum and iron (nitrogenases) play an important role in nitrogen fixation.

Metal ions can be bound to proteins in a reversible way. This is the case with metal-activated enzymes. Such systems are much less amenable to study than metalloenzymes, because they cannot be isolated with the metal in place. Most enzymes associated with phosphate group transfers or hydrolysis seem to be activated by Mg^{2+}.

6.2.5 Metallothioneins

Metallothionein (MT) is a low molecular mass protein of approximately 6500 Dalton with a high content of SH-groups from cysteine. Two distinct metal binding domains, the α- and β-clusters have been characterized in MT and are formed of the 61 amino acids in human MT. The genes coding for metallothioneins are present in most organisms, and their induction after exposure to metals plays an important role in the protection against metal toxicity. Both essential (zinc and copper) and nonessential (cadmium and mercury) metals can induce the synthesis of metallothioneins and also constitute part of the molecule. Thus, these proteins have a role in the metabolism of essential metals and protection against the toxicity of metals. The four major groups of metallothioneins consist of MT-1, -2, -3, and -4. Mammalian MT-1 and MT-2 are present and expressed in almost all tissues. Only MT-1 exists in many isoforms. MT-3 has seven additional amino acids for a total of 68, with differences in charge characteristics compared with MT-1 and MT-2. MT-3 was identified as a growth inhibitory factor (GIF) in brain. MT-4 consists of 62 amino acids and has one glutamate inserted. It is specific for squamous epithelium and expressed in keratinocytes. The 14 human MT genes are localized on chromosome 16q13-22. Of these, six are functional, two are not, and six have not been characterized. Metallothionein is important in the metabolism and kinetics of cadmium and copper, because these metals are transported by MT in the organism. Non-MT–bound cadmium is toxic and causes a toxic insult to the cell. MT also serves various important functions for zinc and mercury.

6.2.6 Lead-Containing Biological Molecules

Lead is interfering with the enzyme δ-aminolevulinic acid dehydratase (ALAD) by specific binding. Lead-binding proteins have been related to lead toxicity. For ALAD, genetic polymorphism is described. The polymorphism is important with regard to lead toxicity.

7 TOTAL ELEMENT ANALYSIS, ELEMENTAL SPECIATION, AND METALLOMICS

The adverse effects and toxicity of metals on a living organism depend on (1) the quantity and the chemical form *(species)* of the substance administered or absorbed, (2) the way it is administered *(inhalation,*

ingestion, topical application, injection) and is distributed in time *(single or repeated doses)*, (3) the type and severity of injury, (4) the time needed to produce the injury, (5) the nature of the affected organism(s), and (6) other relevant conditions (Duffus, 1993). A major share of the following paragraphs will cover the different aspects for identification and quantification of metal species as opposed to total element determinations in samples appropriate for toxicology. Addressing the chemical form of the element instead of the total trace element concentration renders the information gained through careful analysis much more valuable. The underlying reason for this is that the characteristics of just one species of an element may have such a radical impact on living systems (even at extremely low concentrations) that the total element concentration becomes of little value in determining the impact of the trace element. Good examples are mercury and tin. The inorganic forms of these elements are much less toxic (or even do not show toxic properties), but the alkylated forms are highly toxic.

This brings us to the definition of elemental speciation and fractionation.

The IUPAC has defined elemental speciation in chemistry as follows (Templeton *et al.*, 2000):

i. *Chemical species*. Chemical element: specific form of an element defined as to isotopic composition, electronic or oxidation state, and/or complex or molecular structure
ii. *Speciation analysis*. Analytical chemistry: analytical activities of identifying and or measuring the quantities of one or more individual chemical species in a sample
iii. *Speciation of an element; speciation*. Distribution of an element amongst defined chemical species in a system. When elemental speciation is not feasible, the term fractionation is in use, being defined as follows:
iv. *Fractionation*. Process of classification of an analyte or a group of analytes from a certain sample according to physical (*e.g.*, size, solubility) or chemical (*e.g.*, bonding, reactivity) properties.

As explained in the IUPAC paper (Templeton *et al.*, 2000), it is often not possible to determine the concentrations of the different chemical species that sum up to the total concentration of an element in a given matrix. Often, chemical species present in a given sample are not stable enough to be determined as such. During the procedure, the partitioning of the element among its species may be changed. The change can be caused by, for example, a change in pH necessitated by the analytical procedure or by intrinsic properties of measurement methods that affect the equilibrium between species.

New concepts are emerging in relation to the functional role metal species at trace and ultratrace levels play in biological processes such as signaling, gene expression, and catalysis. Therefore, the chemistry of a cell needs to be characterized not only by its genome in the nucleus and by its protein content, proteome, but also by the entirety of the metals and nonmetals among the different species in a biological system (metallome), examination of the metabolism of the elemental species and the speciation of the metallome (metabolomics), and examination of the metallomics underlying the mechanism that triggers biological/physiological/toxicological effects based on the metabolomics (Suzuki, 2005).

8 SAMPLING AND SAMPLE PREPARATION

8.1 General Considerations

The exposure of humans to toxic metals is estimated from measurements of the concentrations in environmental media (e.g., air, food, and water). Preliminary inventories of sources in both occupational and environmental settings are essential to the design of adequate sampling and analysis (Kneip and Friberg, 1986). Biological monitoring is done directly by measuring toxic substances in blood or urine or from tissues that are easily available (e.g., hair).

Sampling, subsampling, and sample handling must satisfy several conditions. The elemental composition should remain exactly the same as that of the original matrix to guarantee representativeness. The variance within the laboratory samples should be an unbiased estimate of the variance of the totality of the material. This implies that when the concentration of an elemental species has an estimated variance σ^2, the calculated variance on the result given by a laboratory should fall within the 95% confidence interval for the population σ^2.

The accuracy of all sampling operations together should be of the same order of magnitude as the accuracy of the subsequent analytical procedure (Sansoni and Iyengar, 1978). For example, it is, indeed, unthinkable to first contaminate your sample a 10-fold time with the elemental species you have to determine (e.g., contamination with lead ions) and then during all subsequent steps carefully determine the concentration of that species. The result is meaningless. The same when you first change the chemical species of the compound (lower pH so that metal-protein binding is disrupted) and then apply very carefully the full analytical procedure for analyzing that particular species.

Such are the first requirements for obtaining accurate and representative analytical data to be considered by physicians, epidemiologists, and toxicologists.

This chapter does not intend to give in-depth detail for every possible element in any feasible matrix. Such information is given in the specific chapters, metal by metal. Additional information can be found in publications in international journals and also in monographs and book chapters. Sample collection guidelines for trace elements in blood and urine have been published by IUPAC (Cornelis *et al.*, 1995). The article describes harmonized guidelines for collection, preparation, analysis, and quality control. The aim was to assist scientists worldwide to produce comparable data to be useful on a regional, national, and international scale. The guidelines cover the elements Al, As, Cd, Cr, Co, Cu, Pb, Li, Mn, Hg, Ni, Se, and Zn. Avoidance of contamination is a major issue when determining the trace elements in body fluids and tissues (Versieck, 1985). Informative chapters on sampling of clinical samples for trace element speciation purposes can be read in the *Handbook of Elemental Speciation* (De Cremer, 2003 and Muñoz Olivas and Cámara, 2003).

8.2 Air, Water, and Food

8.2.1 Air

Metals exist in ambient or workplace air in both vapor and particulate forms, depending on the specific metal and chemical species. In the case of particulate-borne metals, particle size distribution and chemical properties such as solubility are important in determining the site of deposition in the respiratory tract and the degree of absorption. These factors have been addressed in a number of studies (Baron, 2003).

Environmental surveys using stationary samplers did allow establishing the concentration of several metals in a number of cities and rural and remote locations (Van Dingenen *et al.*, 2004). More relevant estimates can be obtained by the use of personal samplers. The use of such devices for the determination of workplace exposures has become common practice (Schwela *et al.*, 2002; WHO, 1982). An interesting survey about sampling systems can be found in Dabek-Zlotorzynska and Keppel-Jones (2003). The choice of the filter substrate is very important. Filters should be mechanically and thermally stable and should not interact with the deposit, even when subject to a strong extraction solvent. The rule of thumb is that when no data are available from reliable studies by other research groups, the effect of sampling and storage conditions on the stability of the species in the matrix should be studied. Many species are thermodynamically unstable. The simple act of sampling and storing the species may alter them. The information is then irreversibly lost.

8.2.1.1 Ambient Air

Metal concentrations in ambient air are generally low, and intake through air is usually small in relation to intake of food. Exceptions may occur in the vicinity of plants emitting large amounts of metals (e.g., smelters) and in areas with heavy traffic. In the past, the intake of lead through inhalation exceeded that from food as a result of the use of leaded automobile fuels. Today, a new problem has occurred through the use of automobile exhaust catalysts containing Pt, Pd, and Rh (platinum group elements or PGE). Emission rates are estimated to be in the ng/km^1 range. The forms in which the PGEs are emitted are still unclear; however, a significant soluble fraction has been measured in automobile exhausts. Analysis of exhaust particles revealed the occurrence of metallic Pt(0) attached onto aluminium oxide together with a small amount of Pt(IV) (Rauch and Morrison, 2005).

8.2.1.2 Industrial Air

Occupational exposure takes place mainly by inhalation. Good sampling techniques and accurate analysis are thus essential for evaluating the exposure in workplaces. Concentrations in industrial air are usually much higher than in ambient air, which makes it easy to collect sufficiently large amounts for accurate measurements. Personal samplers are the preferred method. Special attention is needed concerning sampling techniques and storage of airborne metal species in the workplace (Dabek-Zlotorzynska and Keppel-Jones, 2003). The choice of the filter media plays a preponderant role. General criteria that must be considered in filter selection are: (1) representative sampling for particulates of $\geq 0.3\,\mu m$, (2) low hygroscopicity, because hygroscopicity exceeding 1 mg per piece leads to serious errors in weight concentration measurements and hence to the improper estimate of the environmental concentration, and (3) absence of impurities that might interfere with the analysis. As an example of the latter, glass fiber or Teflon filters were found to be unsuitable for the sampling of airborne dust with low platinum content (Alt *et al.*, 1993). Only polycarbonate and cellulose gave blank values as low as 5 pg Pt per total filter.

The absence of interaction between species and filter substrate is particularly relevant in the case of the analysis of Cr(III)/(VI) in air particulate matter. Spini *et al.* (1994) have reported the reduction of Cr(VI) to Cr(III) when cellulose filters were extracted with an alkaline solution containing a known amount of

Cr(VI). The same inconvenience was encountered by acid dissolution (H_2SO_4) of the filters, which can be explained by cellulose's well-documented reducing properties. Therefore, cellulose filters cannot be used for chromium speciation in airborne particulates. Polycarbonate membrane filters (Scancar and Milačič, 2002) and borosilicate microfiber glass disks (Christensen *et al.*, 1999) are suitable for this type of analysis.

Also crucial is the sample integrity during storage of particulate matter. Some changes can be anticipated (e.g., reduction of Cr(VI) because of interaction not only with the collection substrate but also with the air and with other compounds in the collected dust). Erroneous results may occur because of redox reactions. The enrichment of particles on the filter gives rise to enhanced contact of the Cr species with gaseous species (e.g., SO_2, NO_x, O_2, O_3) and/or with material collected on the filter (e.g, Fe^{II} [magnetite] and As^{III}-containing components) (Dabek-Zlotorzynska and Keppel-Jones, 2003). Storing the samples in closed polypropylene vessels under an inert atmosphere (nitrogen or argon) may minimize such changes (Christensen *et al.*, 1999, Dyg *et al.*, 1994). The shorter the time between collection and analysis, the better. The reverse, namely the oxidation of Cr(III) to Cr(VI), is most unlikely under the usual conditions of storage and sample treatment.

8.2.2 Water

In areas with tapwater, it might be interesting to determine the metals species in the cold as well in the hot water. Because water pipes may contain certain toxic metallic species, these can be released in larger amounts in warm water. The concentrations should be examined in the first portion of water after it was turned off for some time and compared with those in water that has been running for some time. Pb and Cd may accumulate in the tapwater when water is not used during longer periods. Very disconcerting are the organotin compounds, which are leached out of PVC tubing. Factors like hardness and pH should be determined, because they might be of importance for exposure evaluations.

It is evident that the sampling procedure must be contamination free and representative for the original sample (Emons, 2003). Whereas "contamination free" may be an overstatement, surely for naturally occurring species, whenever it may occur, the degree of contamination should be well documented and minimal compared with the expected concentration in the sample. When making exposure estimates, it should be kept in mind that water often comes from different suppliers during the day. The intake of drinking water may vary considerably, depending on individual and local habits and on climate. Sampling guidelines are available from WHO (1997).

8.2.3 Food

Food sampling strategies depend on the purpose of the study. This may be single food items that are analyzed for a given trace element, followed by an estimate of the amount of the element that could be ingested by people with different food consumption habits, using available food statistics. A second method is to collect certain classes of food (e.g., vegetables, dairy products, fish and meat products) in amounts similar to those that are actually consumed (as estimated for a nation, a region, or population group), analyze each class, and make estimates from that. Before analysis, each food should be treated as it would normally be (e.g., cooked, cured, fried). This approach is called the "market basket" method. Such surveys were done among others in the United States (Mahaffey *et al.*, 1975), Italy (Lombardi-Boccia *et al.*, 2003), Spain (Urieta *et al.*, 1996), and Japan (Maitani, 2004). A third method is called duplicate sampling. During a certain period, the people under study put meals identical to the ones they have eaten into a vessel. The trace elements can be determined in the deposited meals after homogenization and provide a total intake figure. For details on sampling and analysis of elements and their species in food, see Emons (2003) and Brereton *et al.* (2003).

Elemental speciation instead of total element determinations in nutrition has become very evident when evaluating human health risk assessment and has already substantially contributed to its improvement. Because this topic will be dealt with in great depth in the chapters dedicated to each element, only a few examples are cited here. Detailed knowledge is available about the different inorganic As^{III} and As^{V} species in food, as well as about the various organic As species (Gallagher *et al.*, 1999). The difference in toxicity between these compounds is large, going from the extremely toxic arsine to the totally inoffensive arsenobetaine, arsenocholine, and arsenosugars. A more detailed description can be found in the chapter on arsenic. Cadmium in food is originating for 70% from eating vegetables and meat such as liver and kidney. Relevant data should describe the Cd species in the edible parts. Cd is bound to high and low (<5000 Da) molecular mass compounds (Günther and Kastenholz, 2005). In meat, Cd is mainly bound to metallothionein. A third example concerns tin. Organotin compounds, such as tributyl tin, are known to be very toxic to marine organisms. They are originating from the use of antifouling paint

and are now monitored in crustaceans (oysters) and fish. Eventually, they could become harmful to man (Rosenberg, 2005).

8.3 Biological Monitoring

Biological monitoring consists of the continuous or repeated measurement of potentially toxic substances or their metabolites or their biochemical effects in tissues, secreta, excreta, expired air, or any combination of these to evaluate occupational or environmental exposure and health risk by comparison with appropriate reference values based on knowledge of the probable relationship between ambient exposure and resultant adverse health effects (Duffus, 1993). The purpose is to obtain an integrated estimate of the uptake of metal species through all pathways and media of exposure. The interpretation of the data requires knowledge of the absorption, metabolism, and excretion of the metal species in question. It becomes more and more evident that knowledge of total element concentrations in particular biological fluids and tissues is not sufficiently relevant. A typical example is arsenic, which is absorbed by humans as inorganic arsenic. It is methylated for the larger part first to monomethyl arsonic acid and next to dimethylarsinic acid. The inorganic and methylated species are the compounds to be specifically monitored in the urine of people exposed to inorganic arsenic from drinking water or through inhalation. This will allow discrimination against arsenic uptake from eating fish and seafood, where the element is mainly present as nontoxic arsenobetaine and arsenosugars (Buchet, 2005; Francesconi, 2002). Arsenobetaine progresses unaltered throughout the gastrointestinal tract and is excreted in the urine. Arsenosugars, however, are metabolized, and approximately 12 metabolites have been documented (Raml *et al.*, 2005). Before starting on speciation of the arsenic species, one should be aware that this element is easily subject to contamination from reagents, dust, and laboratory ware at the $\mu g/L^1$ level. If contamination occurs, it will most probably be in the form of inorganic arsenic and not organic arsenic. Another aspect to consider is the stability of the species. An extensive study by Feldmann *et al.* (1999) on the stability of common arsenic species such as arsenite (As^{III}), arsenate (As^{V}), monomethylarsonic acid (MMA), dimethylarsinic acid (DMA), and arsenobetaine in urine shows that low temperature conditions (4 and −20 °C) are suitable for the storage of samples for up to 2 months. For longer periods (4–8 months) the stability of the arsenic species was dependent on the urine matrix. Whereas the arsenic species in some urine samples were stable up to 8 months at both 4° and − 20 °C, other urine samples showed substantial changes in the concentrations of arsenite, arsenate, MMA, and DMA. The use of additives did not improve the stability of the arsenic species in urine. Moreover, the addition of 0.1 mol/L^1 HCl to urine samples produced relative changes in the inorganic arsenite and arsenate concentrations. Another research group (Jokai *et al.*, 1998) investigated the effect of storage on the stability of solutions of some organic and inorganic As species at room temperature and at 4 °C. The results indicated that organic arsenic species are stable during short-term storage, whereas solutions of inorganic species were only stable in refrigerated conditions.

Another example where speciation has become the rule is the monitoring of mercury. Exposure to the toxic alkylated species must be discerned from that of exposure to elemental mercury or its inorganic salts (Horvat and Gibičar, 2005). Methylmercury is bioaccumulating to mg/kg^1 levels in the top predators of the food chain, making up 90–100% of the total Hg concentration. Exposure to mercury vapor is highly toxic, because it is easily absorbed in the lungs into the bloodstream, from where a major share crosses the blood–brain barrier and even the placenta barrier (see Chapter 33).

One more element in which only the measurement of species is most relevant is tin. The widespread use of organotin compounds (OTCs) has led to their entrance into various ecosystems and in the food chain. Because of the high toxicity at even very low levels, tributyltin and triphenyltin have received great attention. These compounds (as well as the complete family of OTCs) are very persistent and represent a significant problem for the coming years. The analytical method to monitor the extremely low concentrations of these compounds in humans is possible, but, at present, the analyses require substantial preconcentration and sample cleanup. Therefore, they are time consuming and costly, not to say impossible, if too large a sample of blood or tissue is requested (Rosenberg, 2005).

9 SEPARATION TECHNIQUES

Species separation is mainly achieved by one of the following well-known techniques: liquid chromatography (LC), gas chromatography (GC), capillary electrophoresis (CE), and gel electrophoresis (GE). The choice will be determined by the chemical properties of the species, the available skills and infrastructure in the laboratory and, last, but not least, by the available resources.

9.1 Liquid Chromatography

The sample is introduced into a chromatographic column packed with a stationary phase while a liq-

uid mobile phase is continuously pumped through the column. The stationary phase is usually a chemically modified silica or polymer. The analytes interfere to a different extent with the stationary phase and the mobile phase. This determines the length of time each analyte resides in the column. Usually the LC system is coupled to a specific detector. Such a setup is perhaps the most common in elemental speciation analysis. High-performance liquid chromatography columns (HPLC) form a widely used subset of LC, with small diameter particles (3–5 µm) as the stationary phase, the mobile phase being pumped under increased pressure. A good overview of the role in elemental speciation can be found in Ackley and Caruso (2003). The most common types of LC are size exclusion chromatography (SEC), ion-exchange chromatography (IC), and affinity chromatography (AC). Today, it is also possible to couple an LC setup to a soft ionization system to obtain structural information. Examples of a soft ionization technique are electrospray mass spectrometry (ES-MS) (Chassaigne, 2003) and tunable plasma (Leach *et al.*, 2003). Figure 1 shows an example of the separation of Ni speciation analysis in the hyperaccumulating plant *Sebertia acuminata* (Schaumlöffel *et al.*, 2003). The authors first applied size exclusion chromatography on the plant extract and measured Ni with ICP-MS, followed by chromatography of the m/z fraction containing Ni on Superdex peptide HR (30 cm × 10 mm) column also coupled to ICP-MS. Next, electrospray ionization mass spectrometry (ESI-MS) was done of the fractions corresponding to the major peak. This allowed the identification of the compound as a complex of Ni with nicotinamide.

Multiple procedures are described in the literature for the separation of specific elemental species or groups of species. As an example, approximately 100 chromatographic conditions have been listed in the literature for the separation of organotin compounds (Harrington *et al.*, 1996), selenium species (Montes-Bayón *et al.*, 2000), arsenic species (Ali and Jain, 2004; B'Hymer and Caruso, 2004), mercury species (Harrington, 2000), elemental species bound to proteins (Templeton, 2005), elemental species bound to humic acids (Heumann, 2005), etc. Variations in the choice of the column and the elution conditions are legendary. Enrichment and derivatization of the species have been comprehensively outlined by Bouyssiere *et al.* (2003). Liquid chromatography will surely remain the major separation technique in the decades ahead. The electronic databanks prove to be very helpful in putting together a procedure that is ideally suited for the combination of matrix, analyte, and the available infrastructure of the laboratory.

9.2 Gas Chromatography

Only volatile and thermally stable species qualify for separation by gas chromatography. Very few compounds fulfill these requirements. Fortunately, the analyst can resort to chemical reactions that transform nonvolatile compounds into volatile, thermally stable ones. This process is referred to as "derivatization" (García Alonso and Encinar, 2003). Liu and Lee (1999) have written a comprehensive review on chemical modification or derivatization of analytes in speciation analysis.

Naturally occurring volatile species are dimethylmercury (Me_2Hg), dimethylselenium (Me_2Se), tetramethyltin (Me_4Sn), trimethylantimony (Me_3Sb), trimethylbismuth (Me_3Bi), methylated arsines, tetraalkylated lead compounds in sewage sludge, and many more gases from municipal waste disposal sites. This list is not exhaustive. Feldman (1997) has done interesting research on these compounds, describing innovative ways to convert nonvolatile into volatile species by derivatization techniques. Various separation schemes have been developed. Most common is the cryogenic trapping and sequential thermal desorption from the packed columns. This method is not very selective, but unstable compounds can be preserved for a long time before analysis. Next comes gas chromatography on packed columns, offering an improved separation of the analytes through interaction with the column, combined with separation on the basis of their volatility (Szpunar *et al.*, 1996). Gas chromatography with capillary columns offers a much-improved resolution. Their very small loading capacity forms the limiting factor for their exploitation.

The most common detector for this type of speciation is inductively coupled plasma mass spectrometry (ICP-MS), additionally inductively coupled plasma atomic emission spectrometry (ICP-AES). It is also possible to do isotope dilution measurements and isotopic ratio patterns when a high-resolution ICP-MS is available as the elemental detector.

9.3. Capillary Electrophoresis

The principle of separation by capillary electrophoresis (CE) is based on differences in the electrically driven mobility of charged analytes, similar to conventional electrophoresis. A high voltage electrical field (typically 20–30 kV) is applied along an open tube column with small internal diameter (Michalke, 2003).

This technique can be used as a primary or as a secondary separation technique (e.g., after HPLC) when it is referred to as a two-dimensional technique. Taking into account the very small loading capacity of CE, the

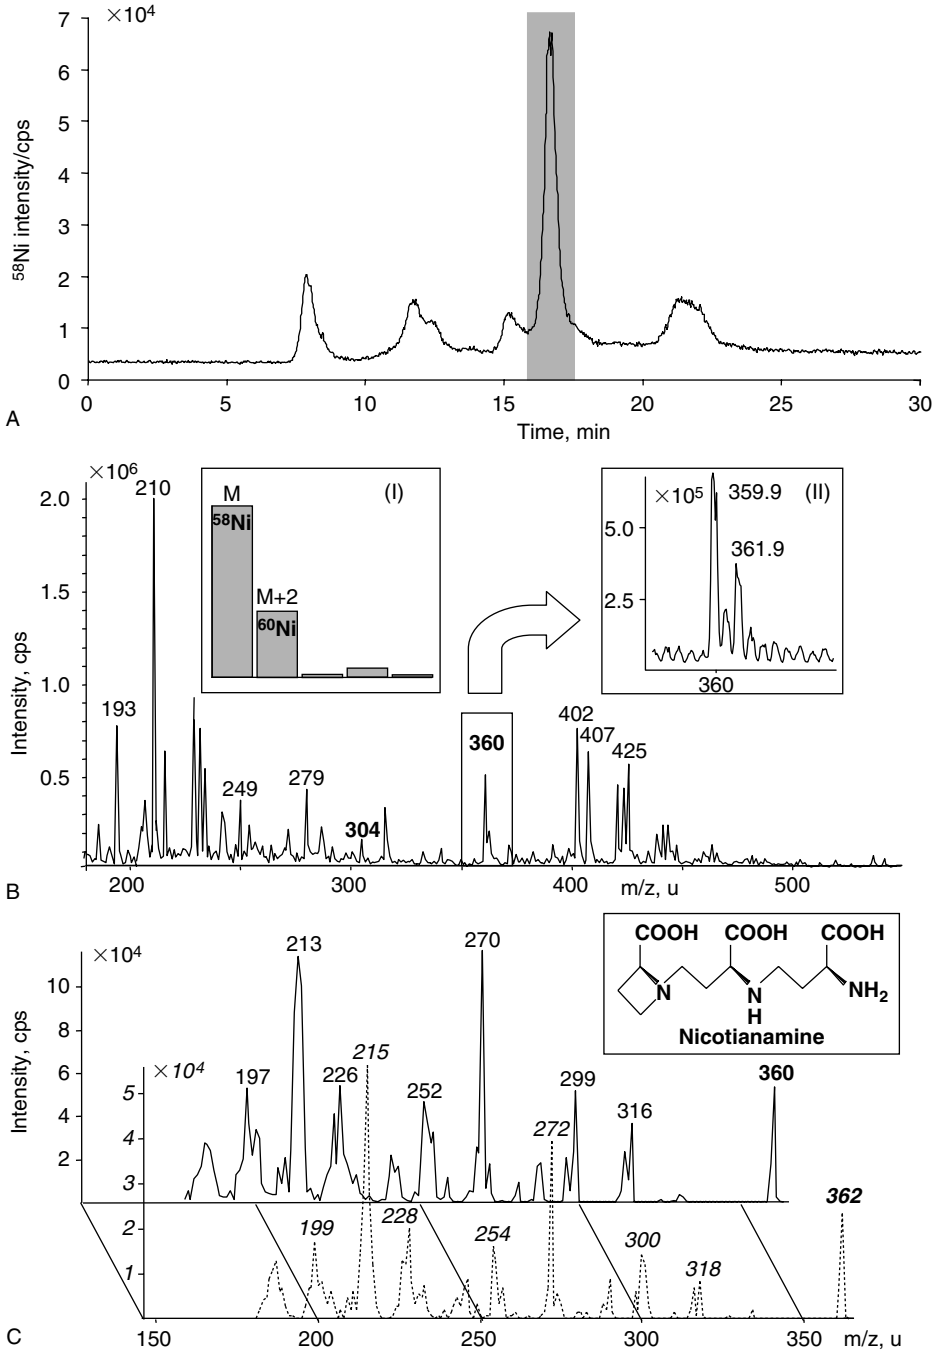

FIGURE 1 Ni speciation analysis in the hyperaccumulating plant *Sebertia acuminata*. (a) SEC HPLC - ICP MS chromatogram of the latex extract, elution with 5 m*M* ammonium acetate buffer (pH 6.8) from the Superdex peptide HR (30 cm × 10 mm) column; (b) ESI-MS spectrum of the fractions corresponding to the major peak (shaded area) in (a) inset (I): theoretical Ni isotopic pattern, inset (II): observed Ni isotopic pattern; (c) ESI MS/MS spectrum of the *m/z* 360 and 362 ions leads to the identification of a Ni-complex with nicotinamide, inset: structure of the ligand (Schaumlöffel *et al.*, 2003).

Reproduced by permission of The Royal Society of Chemistry.

two-dimensional approach will yield far more interesting results, bringing the high resolution of CE to its full potential. The system is often connected to ultraviolet (UV) detection for molecular information but also to ICP-MS or ES-MS (electrospray mass spectrometry) for either elemental or molecular information.

Different separation modes exist in CE: capillary zone electrophoresis (CZE) with separation on the

basis of the charge/mass ratio, capillary isoelectric focusing (CIEF) based on the isoelectric point, capillary isotachophoresis based on analyte conductivity, and micellar electrokinetic capillary chromatography (MECC) based on hydrophobicity.

CE analysis offers high resolution and high speed, and it is easily adaptable for automation and quantitative analysis. It has been successfully used for the speciation of many compounds (Alvarez-Llamas *et al.*, 2005), among others Cr(III)/Cr(VI) (Jung *et al.*, 1997), selenium and arsenic compounds (Sun *et al.*, 2004), Se in human milk (Michalke, 2000), and metallothionein of Cu, Cd, and Zn (Profrock *et al.*, 2003).

9.4 Gel Electrophoresis

The field covered by gel electrophoresis (GE) for elemental speciation consists of charged macromolecules to which a metal or metalloid is bound, covalently or not. These macromolecules can be proteins, humic acids, or other samples such as DNA or dyes. There are practical limitations because of the small amount of material that can be brought onto the gel and, consequently, the limit of detection of the species. For protein separation its resolution is unsurpassed (Chéry, 2003).

The first prerequisite during the separation procedure is again the preservation of the elemental species. This is not evident, considering the nature of the many reagents needed to operate gel electrophoresis. Not all publications hitherto included such a stability study, and neither did they address the contamination that may occur during the process. Very prominent is (e.g., the Pt) contamination of the samples because of the release of Pt ions from the Pt electrodes during electrophoresis. Substitution of Pt by Ag solved this problem when searching for Pt species (Lustig *et al.*, 1999). Other critical parameters are the choice of buffer and pH. More about the precautions to be taken during such separations can be found in section 9.5.

In case the metal is covalently bound, such as Cu in ceruloplasmin, denaturing conditions can be used during electrophoresis. The primary structure of the molecule will be preserved. This is not the case for noncovalently bound elements, for which nondenaturing conditions or native electrophoresis should be applied, to prevent the loss of the basic structure of the complex and stripping of the metal. Another factor that may even jeopardize the stability of covalently bound elements is oxidation of residues of proteins, as has been documented in the case of selenoproteins (Chéry *et al.*, 2001; 2005).

The method can be hyphenated with powerful detection methods such as MALDI-MS (matrix-assisted laser desorption ionization mass spectrometry) for molecular detection or with LA-DRC-ICP-MS (laser ablation dynamic reaction cell inductively coupled plasma mass spectrometry) for elemental detection (Chassaigne *et al.*, 2004). A more tedious way, but reliable for quantitative measurements, consists of cutting out zones of separated proteins in the gel and measuring the element offline with ICP-MS, by use of ETV (electrothermal vaporization) as the sample introduction system (Chéry *et al.*, 2002).

9.5 Precautionary Measures in Elemental Speciation

Whenever speciation analysis is called for, it is of paramount importance to conserve the species in the same form and ratio as in the original matrix (De Cremer, 2003). Before separating and analyzing the species, it is, therefore, necessary to define the conditions under which they remain stable. In practice, it turns out that these conditions are very close to those occurring in the sample. A well-documented example is the noncovalently bound vanadium (V)–transferrin complex, the principal vanadium species in serum with a log K value of 6.5 $mole^{-1}$. This is a relatively low-stability constant compared with those of Fe(III) and Al(III) with transferrin (log $K(Fe^{3+}) = 22.7\,mole^{-1}$ and $K(Al^{3+}) = 12.9\,mole^{-1}$). The V-transferrin complex was studied at varying pH, salt molarity, and acetonitrile concentrations (De Cremer *et al.*, 1999). All experiments were carried out by use of ultrafiltration. It turned out that only around the physiological pH is the percentage of vanadium bound to transferrin high, whereas in extreme acid and basic media, the binding is completely disrupted. This behavior can be explained by protonation and deprotonation of some amino acids at the protein-binding site. Out of this behavior it was concluded that the addition of an acid for preservation purposes (e.g., to urine) would lead to misleading results. Contrary to these findings, a study of the vanadate–albumin complex, showed that the addition of acid increased the binding capacity of vanadium to albumin at lower pH values. The addition of high amounts of salt caused a similar rupture of the transferrin–vanadate bond. Salts are added to the buffer during chromatographic techniques such as anion-exchange or hydrophobic interaction chromatography. The salts are added to generate a gradient, which governs the elution behavior of the analytes from the column. From these observations it was concluded that the use of hydrophobic interaction chromatography (high salt concentration at the starting point) is not recommended in the case of vanadium–transferrin complexes. In anion exchange chromatography, high salt concentrations are also used, but at the end of the chromatographic run. As such, limited use of this technique can be considered. There were,

however, also significant differences observed between the various kinds of salt. The addition of high amounts of acetonitrile in the buffer also disrupts the vanadium–transferrin bond, precluding the use of reversed-phase chromatography, because it usually requires high acetonitrile concentrations in the eluent.

Before embarking on a separation procedure, it is essential to investigate the stability of the trace elemental species in the different media. If not, the chromatograms will fail to give the original distribution of the metal species and, worse, they will only yield meaningless artifacts.

As mentioned in section 9.2, derivatization (chemical modification) of a compound is common practice before gas chromatography. When studying elemental species, care should be taken that the original moiety in which the trace element is sitting is not disrupted as a consequence of the derivatization. Liu and Lee (1999) warn about the problem that is sometimes encountered by using chemical modification for speciation analysis because of the loss of speciation information in the original sample. For example, when the fraction of free versus bound ions is of interest or when the species and its complexes originally existing in the sample are less stable than the complexes formed as a result of the added complexing agent (Olesik *et al.*, 1995), the use of that complexing agent will cause problems in identifying the original species. Therefore, attention must be paid to choosing modification methods and appropriate reagents and in controlling operational conditions governing the modification process.

When proteins are subjected to lysis, it is necessary to check whether the sidechains carrying the element remain unaltered. As mentioned in the previous section, it is fundamental to test the integrity of the elemental species when exposed to any reagent, and more so in the case of the harsh conditions encountered in gel electrophoresis. The procedures that can be used for this purpose are gel filtration and ultrafiltration (Chéry *et al.*, 2001).

In all these endeavors a main impediment is the lack of suitable standards for identifying and quantifying metal-binding biomolecules, which commonly appear during toxicological investigations.

10 DETECTION METHODS

10.1 General Aspects

During the past decade, substantial progress has been made in improving the sensitivity of the detection methods of the commercially available equipment.

There are two lines of use: total element and elemental speciation analysis. In routine work, most of the applications go for total element measurement. In case of liquid samples, a simple dilution of the sample may be sufficient to allow a direct measurement of the element(s) with calibration versus standard solutions. In case of difficult matrices (e.g., salts, organic compounds such as proteins), it may be necessary to apply the standard addition method. For solid samples, such as tissues, it is feasible to apply electrothermal vaporization (ETV) of the sample in a graphite oven and introduction of the fumes into the element detector ETV-AAS (atomic absorption spectrometry) and ETV-ICP-MS (inductively coupled plasma–mass spectrometry). Calibration is done versus a similar matrix calibrated for the element(s) of interest and undergoing the same procedure. This method has been developed (e.g., the measurement of Hg in solid samples by ETV-ICP-MS). In this particular case, the prerequisite for a similar matrix calibrated for the element can be circumvented by use of isotope dilution mass spectrometry. The direct determination of Hg in solid samples, such as hair and tissue, was done with a ^{200}Hg-enriched gaseous phase for calibration based on isotope dilution (Resano *et al.*, 2005). All matrix effects (suppression) observed during Hg vaporization were dealt with, allowing accurate values to be obtained in practically the same operating conditions for all sample types. The method presents interesting features such as a low sample consumption (a few milligrams), a high sample throughput (10 min/sample), a low limit of detection (6 ng/g^1), and a reduced risk of analyte losses or contamination.

In elemental speciation analysis, the trend is to go for online, also called hyphenated, systems. The most convenient methods for online coupling are inductively coupled plasma mass spectrometry (ICP-MS), hydride generation atomic absorption spectrometry (HG- AAS), and atomic fluorescence spectrometry (AFS). ICP-MS is the most versatile but also the most expensive "detector." It can be coupled to LC systems, gas chromatography, and capillary electrophoresis. This potentially multielement method is then only used for the detection of a single element. For economical reasons, it is, therefore, worthwhile to consider what other single element detection methods such as atomic absorption and fluorescence spectrometry have to offer.

10.2 Current Methods for the Detection of Metals

10.2.1 Atomic Absorption Spectrometry

Theory and practice of atomic absorption spectrometry (AAS) can be learned from the handbook by Welz and Sperling (1998), among others.

The basic principle underlying AAS is that atoms formed in the ground state in a gas will absorb radiation at characteristic ground-state energy levels. A light beam with the spectral composition of the ground state lines of the element will be specifically absorbed by the ground-state atoms of that element. For example, ground-state cadmium atoms thus absorb radiation at a characteristic wavelength of 228.8 nm, one of the ground-state cadmium lines, and lead atoms absorb at 283.3 nm. The light source is a high-intensity, ground-state line emitting hollow cathode lamp of the specific element. The decrease in intensity of the light beam compared with a blank is proportional to the amount of the element in the ground state in the plasma.

There are two main methods for atomization of a sample in AAS: the flame (F-AAS) and the graphite furnace method (GF-AAS). The flame method uses different gas mixtures for creating a high temperature atomization flame (e.g., air-acetylene). Different types of flames are required for different metals. The liquid sample is aspirated directly into the flame. Because of the relatively low atomization of the flame (approximately 500 °C), the method may not be sensitive enough to measure most elements in biological materials. In the graphite furnace, temperatures of approximately 2000 °C prevail, increasing by several orders of magnitude the number of atoms and hence the detection sensitivity. Typically, the detection limit for Cd by F-AAS is $1\,\mu g/L^{-1}$ and only 8 ng/L^{1} with GF-AAS. A small aliquot of the sample is injected into the oven. A matrix modifier may be added to assist the charring and atomization processes.

Nonspecific absorption may occur because of the presence of matrix atoms and molecules in the flame or the furnace. Salts such as sodium chloride and phosphates are especially apt to cause interference. This may be avoided by background correction, for which a deuterium lamp is generally used. A more sophisticated method uses the Zeeman effect that splits the lines with a magnetic field. In case the background correction fails, or when a concentration step is needed, it is necessary to mineralize the sample and to extract the element. A common chelating agent is APDC (ammonium pyrrolidine dithiocarbamate), which is extracted into MIBK (methylisobutyl ketone). This procedure has been used for several elements (e.g., cadmium, lead, and nickel).

For mercury with its high volatility at room temperature, the best detection method is cold vapor atomic absorption spectrometry.

Elements such as As, Se, Sb, and Hg that can easily be transformed into hydrides can be very advantageously measured by hydride generation (HG)-AAS. This method allows elimination of background interferences to a very large extent.

The difficulty, if not the impossibility, of making flame atomic absorption (F-AAS) and graphite furnace atomic absorption spectrometry (GF-AAS) an online method for measuring the elements in liquid chromatography fractions make them less popular for elemental speciation purposes. They have, however, earned their merits in the field. GF-AAS has been used for the offline measurement of elements in the elution fractions of LC, although insufficient detection limits proved to be a serious drawback in the case of many clinical applications in which the concentrations of the elemental species in the biological fluids and tissues are very low (Zhang and Zhang, 2003).

When species can be converted to hydrides, as is routinely done for Hg, Se, As, and Sb, hydride generation atomic absorption spectrometry is a very interesting and cheap online detection technique. It has been applied for the speciation of arsenic in persons with abnormally high arsenic concentrations in serum, such as dialysis patients (Zhang *et al.*, 1996; 1998). An online method was developed for the speciation of arsenic species in human serum, including monomethylarsonic acid (MMA), dimethylarsinic acid (DMA), arsenobetaine (AsB), and arsenocholine (AsC). The method is based on cation-exchange liquid chromatography (LC) separation, UV-photooxidation for sample digestion, and continuous hydride generation (HG) atomic absorption spectrometry (AAS) for the measurement of arsenic in the LC eluent. By developing the technique of argon segmented flow in the postcolumn eluent, a substantial improvement in chromatographic resolution for the separation of these four arsenic species was obtained. The LC separation, photooxidation, hydride generation, and AAS measurement can be completed online within 10 minutes. The detection limits for MMA, DMA, AsB, and AsC in serum were 1.0, 1.3, 1.5, and 1.4 $\mu g/L^{1}$ of arsenic, respectively. The concentration of the four species was determined in six serum samples of patients with chronic renal insufficiency. Only AsB and DMA were significantly detected by this method. The main part of arsenic in human serum is AsB. No MMA, AsC, or inorganic arsenic was detected.

Atomic absorption spectrometry with a quartz tube atomizer is a very sensitive, specific, rugged, and comparatively inexpensive detector for GC. Gas chromatography coupled with atomic absorption spectrometry has been described as a sensitive instrumentation for mercury speciation (Emteborg *et al.*, 1996). Online solid-phase extraction, coupled to graphite furnace AAS, has also been explored.

Cold vapor atomic absorption spectrometry (CV-AAS) is the most widely used technique for measuring Hg species. Direct coupling of solid-phase

microextraction and quartz tube-atomic absorption spectrometry has been used for the selective and sensitive determination of methylmercury in seafood (Fragueiro *et al.*, 2004).

It can be anticipated that these simple, rapid, and inexpensive procedures, based on AAS detection, will be readily accepted once routine laboratories get involved in speciation analysis.

10.2.2 Atomic Fluorescence Spectrometry

When species can be converted into hydrides, such as is routinely the case for Hg, Se, As, and Sb, atomic fluorescence spectrometry (AFS) becomes a very economical elemental detection technique. This method is based on measuring the intensity of the specific resonance fluorescence of the atom (Kirkbright and Sargent, 1974). It is, however, necessary to keep in mind that the conversion of the different species of an element into hydrides is not happening to the same extent and at the same rate. This has been documented (e.g., in the case of As). The conversion of methylated arsenic species into methylated hydrides gives a different response than the conversion of inorganic arsenite or arsenate to AsH_3 (Zhang *et al.*, 1996).

10.2.3 Atomic Emission Spectrometry

Inductively coupled plasma atomic emission spectrometry (ICP-AES) has become the most common emission spectrometric technique. It is sometimes referred to as ICP-optical emission spectrometry (OES). The argon-based plasma is compatible with aqueous aerosols and offers high energy for drying, dissociation, atomization, and ionization of the analytes. The temperature reached by an argon ICP is 5500–6500 K, high enough to destroy to a great extent the molecular bonds and to ionize many elements. The high degree of excitation results in a high atomization yield and thus high sensitivity. The standard configuration of an ICP includes a pneumatic nebulizer for the formation of the aerosols and a spray chamber acts as a filter selecting droplets with a maximum cutoff diameter. The light emitted by the atoms on their return from the excited to a lower energetic state is resolved into a line spectrum by either a polychromator or a monochromator, depending on the equipment. The wavelength is specific for the atom and the intensity for its concentration. The incidence of possible interferences caused by matrix constituents is very large and requires a careful study.

More information on ICP-AES can be found in specialized handbooks (Boumans, 1987; Dean, 2005)

ICP-AES is in principle multielemental, although in the case of elemental speciation, it will most often be used as a single element detector. It is easy to couple online with LC, because it can accept a continuous flow of eluent. The disadvantages are the overall inefficiency of the nebulizer and the plasma's sensitivity to organic solvents. The poor tolerance of the plasma source to common mobile phases, such as ion-pair reagents, limits the applicability of the technique. The fact that many ion exchange chromatography elutions are not isocratic (i.e., the elution is effected under variable, usually increasing, ionic strength) requires special protocols to circumvent the problem of varying analyte response during the elution (Zhang and Zhang, 2003).

10.2.4 Mass Spectrometry

10.2.4.1 Inductively Coupled Plasma-Mass Spectrometry (ICP-MS)

ICP-MS is a remarkably powerful technique for (ultra) trace element determinations. It is characterized by extremely low limits of detection and a wide linear dynamic range, multielement capability, and high sample throughput (Vanhaecke and Köllensperger, 2003). This method is based on measuring m/z ratios. The very low detection limits are due to the very high degree of atomization in the argon plasma at approximately 7000 K (Dean, 2004). This extreme temperature makes it far superior to the graphite furnace as an atomization source for atomic absorption spectrometry. When a quadrupole mass spectrometer is used, there are problems caused by spectral interference, because the resolution is limited to $\Delta m/m = 1$. For instance, when measuring ^{52}Cr (most abundant Cr isotope θ = 83.8%), mass 52 will experience interference from the isobars of $^{40}Ar^{12}C^+$, $^{35}Cl^{16}OH^+$, $^{36}S^{16}O^+$, occurring in samples having a high C, Cl, S,…content. ^{50}Cr and ^{54}Cr suffer from interferences from high background counts because of $^{36}Ar^{14}N^+$ and $^{38}Ar^{16}O^+$, respectively.

Today two major tools exist to reduce the spectral interferences so as to become negligible. The dynamic reaction cell allows chemical reactions in a collision cell so that the interfering isobars are neutralized or transform the analyte into another more heavy polyatomic. Another very reliable, but very expensive tool to ban isobaric interferences is the high-resolution ICP-MS with $\Delta m/m = 1/4000$ till $1/10000$ (Houk, 2003).

Besides spectral interferences, there may be numerous nonspectral interferences, which are matrix-induced signal suppression or enhancement. An additional hurdle is signal instability and/or drift. In case of total element determination, these, together with the nonspectral interferences, can often be corrected for by use of a carefully selected internal reference. To all blank, sample, and standard solutions an

equal amount of an internal reference element (internal standard) is added. It is assumed that this element undergoes the same suppression or enhancement as the analyte element(s). Usually an internal reference element with a mass number close to that of the analyte is chosen. It is, however, recommendable to consult the specialized literature, because much research has already been done for each specific element to describe optimal conditions.

ICP-MS is ideal to work online with HPLC (Ponce de Léon *et al.*, 2002). Similar difficulties caused by the influence of the eluent on the plasma can be anticipated and need careful consideration as mentioned in the section on ICP-AES.

An alternative way for sample introduction is solid-sampling electrothermal vaporization followed by ICP-MS detection. An interesting application is the direct determination of methylmercury and inorganic mercury in fish tissue with nonspecific isotope dilution (Gelaude *et al.*, 2002).

10.2.4.2 Plasma Source Time-of-Flight Mass Spectrometry

Plasma source time-of-flight mass spectrometry is a powerful tool for elemental speciation analysis through the use of a modulated or pulsed ionization source that provides both atomic and molecular fragmentation information (Leach *et al.*, 2003). Its use has been documented, among others, for the analysis of organotin compounds and the oxidation states of various elements.

10.2.4.3 Glow Discharge Plasmas as Tunable Sources for Elemental Speciation

Glow discharge plasmas offer a number of interesting possibilities as speciation detectors for gaseous and liquid sample analysis (Marcus, 2003). The plasma works at sufficiently low temperatures (kinetic temperatures in the range of 100–500°K) so as not to cause dissociation of the molecular species. The detector can be optical emission spectrometry or mass spectrometry. The technique has been successfully applied for the speciation of, for example, organotin compounds.

10.2.4.4 Electrospray Mass Spectrometry

This technique offers soft ionization of metal-containing species followed by tandem mass spectrometry for the precise determination of the molecular mass of the original species and of the individual fragments. This method is ideal to obtain structural molecular information about the species. There is a need for excessive sample cleanup to obtain high sensitivities (Chassaigne, 2003).

The method allows the coupling of HPLC online, on condition of using a suitable eluent. This method has been successfully applied for the speciation of organoarsenicals, selenium species, metallothioneins, etc.

10.2.5 Electrochemical Methods

Electrochemical methods are based on the measurement of electrical signals associated with molecular properties or interfacial processes of chemical species (Town *et al.*, 2003). Because of the direct transformation of the desired chemical information (concentration, activity) into an electrical signal (potential, current, resistance, capacity) by the methods themselves, they are easy and cheap. The two major difficulties in the application of electroanalytical techniques to complex real-world samples have been the lack of selectivity and the susceptibility of the electrode surface to fouling by surface-active materials in the sample. A variety of electroanalytical techniques that differ in the mode of excitation signal–response characteristics are currently being used: potentiometry, fixed potential methods, amperometry, various forms of voltammetry, and electrochemical detection in liquid chromatography and flow-injection analysis. These methods have been applied for the quantification of various oxidation states of several elements ((Fe(III)/Fe(II), Cr(VI)/Cr(III), Tl(III)/(I), Sn(IV)/(II), Mn(IV)/(II), Sb(V)/(III), As(V)/(III), and Se(VI)/(IV)). Electrochemical methods have also been used to investigate organometallic species or metal complexes in equilibrium with each other (e.g., butyltin species in harbor water measured by adsorptive stripping voltammetry with tropolone). The ideal is to perform *in situ* measurements with minimal sample perturbation. Despite many difficulties well known to specialists in the field, the sensitivity of electroanalytical methods makes them very powerful tools for many applications.

10.2.6 Spectrophotometry

Spectrophotometry usually involves the formation of a complex of the trace element with a selective reagent that absorbs light in the visible and UV region. Selective reagents have been used for measuring many trace elements and also to distinguish between oxidation states of certain elements. Most of them, however, suffer from interferences from either colored substances, from substances that also form complexes with the chosen reagent, or from oxidizing-reducing agents.

Spectrophotometry is still used for the measurement of Cr(VI) in welding dust. The selective determination is based on the formation of a complex between Cr(VI) and ammonium pyrrolidinedithiocarbamate (ADPC) (Andrle and Broeckaert, 1993). A major disadvantage of

the ADPC method is that interferences by other colored species such as Fe(III) or Cu(I), or species forming complexes with ADPC such as V, Mo, and Hg are possible.

10.2.7 Biosensors for Monitoring Metal Ions

Different types of biosensors exist: whole cell biosensors, enzyme- and apoenzyme-based biosensors, antibody- or protein-based sensors, and protein-based capacitive sensors (Bontidean *et al.*, 2003). They are a versatile tool for monitoring metal ions in the environment with high sensitivity and selectivity. Biosensors based on metal-binding proteins are an excellent tool to measure the bioavailable concentrations of metals.

10.2.8 Direct Measurement of Metals in Solid Samples (Particle Characterization)

The characterization of aerosol particles, their size distribution, and chemical composition is of great importance in occupational health monitoring to evaluate health hazards for workers exposed to dust from foundries, calcination ovens, powder handling, milling, etc (Ortner, 2003). The instrumentation necessary for these investigations is very specialized and quite expensive. The procedures routinely used are high-resolution scanning electron microscopy (HR-SEM) and electron probe microanalysis (EPMA). A series of explicit methods exist for particle speciation (Ortner (2003). In addition, there is the possibility of direct speciation of solids with X-ray absorption fine structure spectroscopy (XAFS), an element- and species-selective method (Welter, 2003). Only with the invention of synchrotron radiation as a source of very intense X-rays to XAFS spectroscopy in 1974 did it become possible to measure XAFS spectra within a reasonable time and in diluted samples. The region above the edge in the spectrum is normally divided into two subregions, the first 50–100 eV above the edge is called X-ray absorption near edge structure (XANES), the region above the XANES region is called extended X-ray absorption fine structure (EXAFS) (Welter, 2003). Between explicit methods for particle speciation, there exist valence band X-ray spectrometry by EPMA-WDX (electron probe microanalysis-wavelength-dispersive X-ray detector), TEM (transmission electron microscopy), and XPS (X-ray–induced photoelectron spectrometry (Ortner, 2003).

10.2.9 Neutron Activation Analysis

Neutron activation analysis (NAA) is a very sensitive and reliable multielement method (Ehmann and Vance, 1993). Today, it is only sparingly used as a consequence of the closure of a major share of the nuclear research reactors all over the world. NAA is based on the principle that when materials are irradiated in a nuclear reactor or in another neutron source, some of the atoms are converted into radioactive isotopes. The type and energy of their radiation and their decay rate are specific. A quantitative estimation can be made by comparing the element's radioactivity with suitable standards irradiated simultaneously. Gamma-spectrometry with high-resolution germanium detectors coupled to multichannel analyzers has become the method of choice for measurement of the induced radioactivity. The standardized k_o method offers unique possibilities, because it has modeled NAA into a very flexible procedure (Decorte *et al.*, 1994).

NAA has played a leading role in trace element analysis because the danger of contamination and loss of elements can be virtually eliminated.

This method is most interesting for the analysis of those elements that are converted into radioactive isotopes (i.e., they have an abundant isotope with a high cross-section for thermal neutrons, such as arsenic). Other elements, such as lead, have an extremely low sensitivity for NAA. In the latter case, it is necessary to resort to another technique such as F-AAS, GF-AAS, ICP-AES, ICP-MS.

NAA is divided into two broad categories: (1) instrumental neutron activation analysis (INAA) consisting of irradiation, measurement, and evaluation of the spectra; and (2) radiochemical activation analysis (RNAA), including irradiation of the samples, followed by radiochemical separation of the elements, measurement of the induced radioactivity, and evaluation of the spectra. In the case of INAA, advantage is taken of the decay properties of the isotopes so that the short-lived ones are measured first. As they progressively decay, the longer-lived isotopes can be measured. When analyzing biological material, a major matrix-induced radioactivity prohibits the measurement of the radioactivity attributable to the trace elements. Because of their overwhelming amount of gamma-rays and/or Bremmstrahlung, the ^{24}Na, ^{32}P, ^{38}Cl, and ^{82}Br isotopes (the list is not exhaustive) have to be removed from the isotopes of interest, such as ^{76}As, ^{64}Cu, ^{69m}Zn, ^{122}Sb, ^{51}Cr because these interferences are so outspoken when analyzing serum, packed cells, tissue, bone, and milk, RNAA is the only way out. INAA is feasible for long-living isotopes, such as ^{65}Zn, ^{75}Se, and ^{124}Sb; RNAA requires highly skilled technicians, is time consuming, and requires a heavy infrastructure. INAA may cover many months to allow the decay of the shorter living isotopes. INAA for very short-living isotopes (half-lives seconds or minutes) may be very fast but is generally not conceivable for the very low concentrations encountered in biological material because of the radioactivity induced into

major elements. For instance, ^{47}Ca ($t_{1/2}$ 4.5 d) and ^{32}P ($t_{1/2}$ 14.28 d) produce intense Bremsstrahlung radiation, which prevents the determination of several longer-lived but low-energy isotopes. Under such conditions, RNAA has to be done.

Interesting literature is available on the International Atomic Energy (IAEA) website (2004).

10.2.10 Spark Source Mass Spectrometry

Spark source mass spectrometry (SSMS) used to be the most sensitive widely used multielement technique until the 1960s. The basis for SSMS is the formation of ions when the sample is subjected to a high-energy discharge (Morrison, 1979). The apparatus uses a vacuum spark in which a high-voltage radio frequency discharge (20–100 kV) is produced between two closely spaced electrodes containing the material to be analyzed. This sparking results in vaporization and ionization of sample constituents. The repetition rate and duration of the radio frequency spark source is variable to meet the various analytical requirements. Nearly all masses are integrated simultaneously over a period of time to provide high sensitivity. For SSMS, the sample has to be electrically conductive. This is achieved for nonconducting biological material by blending them with high-purity graphite followed by briquetting to form electrodes that sustain the vacuum spark. Two major problems arise. First, the graphite used for making the electrodes also contains trace element impurities, and they may exceed the concentrations in the biological sample. The second problem lies with the interferences caused by the organic ions of differing complexity obtained from many possible combinations of C, H, O, N, S, P, etc. Therefore, to take full advantage of this multielement method, the samples are ashed before analysis. This will, however, cause the loss of volatile elements such as mercury and selenium, among others.

11 CALIBRATION

The calibration of the method forms a very critical point during the analysis. Calibration will be mostly done in the relative way (Heumann, 2003). The signal caused by the detection of the element in a sample will be compared with a set of calibration samples with known content. Because of the practical advantages of linear calibration graphs, they are always favored. Linear calibration graphs can be obtained by measuring only a few calibration standards and, in addition, are easily described by a simple mathematical function:

$$S = kc + b,$$

where S is the signal response of the detection method, k the calibration factor, c the concentration of the calibrant, and b the intersection with the y-axis. The k value reflects the sensitivity. The higher the k value for a given concentration range, the better the sensitivity.

External calibration modes, where the sample and the corresponding calibrant are separately measured, can only be used when there is no effect (either quenching or enhancement) by the sample matrix on the analyte signal. Internal calibration (i.e., standard addition method) becomes then compulsory to include possible influences of matrix composition on the signal intensity of the detection system (Skoog *et al.*, 1994). Two or more aliquots of the sample are transferred to volumetric flasks. One is diluted to volume, and the signal is measured. A known amount of analyte is added to the second, and its signal is measured after dilution to the same volume. Data for other additions may also be obtained. First, it should be checked that a linear relationship between the signal and concentration exists (and this should be established by several standard additions). If several additions are made, the signal can be plotted versus the added concentrations. The resulting straight line can be extrapolated to signal zero. The intercept with the concentration axis gives the concentration of the analyte in the sample. The addition method has the advantage that it often compensates for variations caused by physical and chemical interferences in the sample solution.

In the case of total element determinations using F-AAS, GF-AAS, HG-AAS, HG-AFS, ICP-AES, and ICP-MS, spectrophotometry, electrochemical methods, and biosensors for monitoring metal ions, it may be possible to calibrate versus the external mode. It is compulsory, however, to check the validity of this assumption by comparing the results of at least one series of samples versus those obtained by the more labor-intensive standard addition method.

In case of neutron activation analysis, external calibration is the rule. The one-point calibration curve is applicable, similarly as in isotope dilution mass spectrometry. ES-MS-MS is a stand-alone case as far as calibration is concerned, because this method is primarily used for obtaining structural information of the species. Calibration is, of course, evident when calibrants of the species are available.

Speciation analysis is usually the result of a separation of species followed by elemental detection. The standard addition method applied to the original sample, before the separation or enrichment of the species, is only justified when an equilibrium has been reached between the analyte in the sample and the standard. This also supposes that the calibrant is commercially available or can be synthesized by the laboratory.

Whereas most of the relevant inorganic elemental species are commercially available (e.g., selenite and selenate), there is often a lack of organoelemental species such as selenosugars. There is also a total lack of isotopically labeled elemental species needed for the species-specific isotope dilution technique, which contains the elemental species to be determined in a different isotopic composition from that of the sample. The synthesis of the corresponding spike must be carried out in the laboratory. The spiked calibrant is added to the sample before all analytical sample treatment steps. This method will allow coping with any loss of substance, because the isotopic ratio of the isotope diluted elemental species does not change. It also guarantees a similar response to that of the analyte from the sample. When no spiked calibrant is available, external calibration in ICP-IDMS is still very interesting with a species-unspecific standard added continuously just before the detection. Such a spike does not allow for any losses during the separation procedure, but it allows correction of any variation in response of the analyte in, for example, the eluent of the LC. Because the amount of spike is constant, any variation in response of the spike will be used to recalculate the response of the analyte from the sample. This assumes that detector systems working at high temperatures, such as those with inductively coupled plasma excitation, should not show significant differences in the detector response for various elemental species (Heumann *et al.*, 1998).

12 REFERENCE MATERIALS

The use of reference materials is the major monitoring tool for the performance of all analytical work. The ISO (International Organisation for Standardisation) Guide 30 gives the following definitions for reference materials (ISO, 1991).

Reference material (RM): a material or substance one or more of whose property values are sufficiently homogeneous and well established to be used for the calibration of an apparatus, the assessment of a measurement method, or for assigning values to materials.

Certified reference materials (CRM): a reference material, accompanied by a certificate, one or more property values are certified by a procedure which establishes traceability to an accurate realization of the unit in which the property value is accompanied, and for which each certified value is accompanied by an uncertainty at a stated level of confidence.

For determining total element and even some elemental species in matrices of toxicological importance, a relatively wide choice of CRMs is available. There are several serum, blood, urine, tissue, water, working place dust, and environmental matrices issued by internationally recognized bodies. The complete inventory of these products can be found on the web pages of these institutes: EVISA (European Virtual Institute for Speciation Analysis), IAEA (International Atomic Energy Agency), IRMM (Institute for Reference Materials and Measurement of the European Commission), NIST (National Institute for Standards and Technology of the USA), NRCC (National Research Council Canada), NIES (National Institute for Environmental Studies in Japan), and VIRM (Virtual Institute for Reference Materials).

When choosing a reference material, care should be taken to not only use a matrix that is the same or very similar to the matrix of the sample to be monitored but also that the concentration of the analyte in the RM is within the concentration range expected during the analysis of the actual sample. For example, a liver reference material with a concentration of an element in the mg/kg^{-1} range is not suitable as a reference material for analysis of blood or urine where the concentration of the analyte is in the $\mu g/L^{-1}$ range.

13 QUALITY ASSURANCE

Because the analyst provides scientific evidence for taking important decisions, he or she has to assure that all actions have been taken to ensure that any factor that has an influence on the final result has been considered and reported in a permanent record (Prichard, 1995). This should cover the several steps related to procedures before analysis (e.g., sampling, avoidance of contamination or losses during sampling, storage of the sampled material, that is, preanalytical quality assurance). Chemical changes of a substance after sampling may cause problems if the specific chemical form of a substance is to be monitored. Recording and treatment of data are to be included in both the preanalytical and analytical phase.

It must also be the policy to deliver analytical results that are fit for purpose. This implies a thorough discussion with the end user of the results before starting the analysis. It is vital to understand why the work is being done, what will happen to the results, and what decisions will be taken, depending on the reported numerical values. It goes without saying that the analyst should make the measurements to the best of his or her abilities. The highest level of precision is, however, not always required. The result should be precise and accurate enough for the intended purpose. Every result should carry an estimate of the uncertainty of the value.

13.1 Definitions

The terminology and symbols of practical statistical methodology required to process and interpret results assessed from a sample can be found in the ISO Standards Handbooks: *Terminology and Symbols, Acceptance Sampling* (1995a) and *Interpretation of Statistical Data and Process Control* (1995b). It is beyond the scope of this chapter to give a detailed account of the important actions to be taken. The comments about quality are therefore limited to some practical concepts:

- *Quality control (QC)*: The planned activities designed to verify the quality of the measurement.
- *Quality assurance (QA)*: The planned activities designed to ensure that the quality control activities are being properly implemented. These should fully reflect the need of the user.
- *Quality system*: A set of procedures and responsibilities that a company or organization puts into force to make sure that the analytical chemist has the facilities and resources to carry out the measurements that will satisfy the end user. The quality system should only be as comprehensive as is required to meet the needs of the users.
- *Accuracy (trueness and precision)*: The closeness of agreement between a test result and the accepted reference value. The term accuracy, when applied to a set of results, involves a combination of random components and a common systematic error or bias component.
- *Trueness*: The closeness of agreement between the average value obtained from a large series of test results and an accepted reference value.
- *Precision*: Closeness of agreement between independent test results obtained by applying the experimental procedure under stipulated conditions. The smaller the random part of the experimental errors that affect the results, the more precise the procedure. A measure of precision (or imprecision) is the standard deviation. Precision is often misused for accuracy. This problem will be avoided if one recognizes that precision only relates to dispersion, not to deviation from the conventional true value (McNaught and Wilkinson, 1997).
- *Method validation*: This applies to a defined protocol, for the determination of a specified analyte and range of concentrations in a particular type of test material, used for a specific purpose (Thompson *et al.*, 2002).

13.2 Sources of Error

Incorrect analytical results may be due to one or more of the following (Prichard, 1995): unsuitable methodology, contamination, interferences, calibration errors, sampling errors, losses and degradation, incompetence, or lack of care.

Avoidance of contamination is crucial in trace element analysis. Potential sources of contamination are the laboratory environment (including the analyst), the reagents, the utensils, and this as from the sampling until the detection of the analyte. Similarly, losses of the substance to be monitored can occur as a consequence of adsorption to sampling equipment, volatilization, decomposition of the species, or other problems.

There is no definite method that always gives accurate and precise results. Even so-called definitive methods such as IDMS and NAA may give inaccurate results if not properly performed. A definitive method is a method of exceptional scientific status that is sufficiently accurate to stand alone in the determination of a given property. Such a method must have a firm theoretical foundation so that systematic error is negligible relative to the intended use (McNaught and Wilkinson, 1997). Erroneous results may be obtained even with approved methods if they are wrongly executed, used outside the tested calibration range, or with matrices that were not included in the original validation process. For example, the presence of fat can cause problems if the digestion technique was not designed for a fatty matrix. Many analysts have a tendency to introduce subtle changes into the approved procedure: changes to sample mass, reagent ratios, times and temperatures, recommended purity of the reagents or columns, etc. The extent to which a method may be modified without change in performance is what is meant by its robustness.

It must also be stated that there is no measurement method that is exempt of interferences. These will be mainly due to one or more of the many other compounds of the sample or to the reagents, including the gases. Interferences possibly occurring during ICP-MS measurements are well documented. Fortunately, many problems, albeit not all, could be solved by the application of high-resolution ICP-MS (e.g., nonspectral interferences are not solved) or a dynamic reaction cell when using quadrupole ICP-MS (section 10.2.4.1). Inaccurate results may also be related to a lack of competence or concern among the analysts. Human factors are often very important and can introduce errors that may influence the entire chain of events.

13.3 Results of Interlaboratory Testing

The need for quality assurance/quality control procedures (QA/QC) has become very evident during interlaboratory testing, in which participants have been asked to analyze samples containing (for the participating laboratories) unknown concentrations.

Control of the actual concentration of the analyte in the samples for external quality control (EQC) should be established by reference laboratories, preferably

using different methods. It is recommendable that the reference laboratories also use methods other than those used for routine analysis to avoid systematic errors, which may be common in reference and routine laboratories. Duplicate analyses at reference laboratories are another way to check the analytical performance.

Interlaboratory testing schemes for routine measurements are now very well established in different countries and even on an international scale. New initiatives are under way for elemental speciation measurements (EVISA: www: speciation.net).

13.4 Elements of Quality Assurance

For each element/elemental species and in each particular matrix, a quality assurance plan should be worked out. This plan must specify in detail the different internal (IQC) and external quality control (EQC) procedures that will be used to guarantee an accurate performance. IQC is conducted by the laboratories themselves, whereas an outside laboratory or agency is involved in EQC procedures. Both IQC and EQC should include the analysis of a number of reference materials certified for the elements or species of interest. To test the quality of the laboratory, the control samples should be analyzed with the methods used for routine analysis, and the CRM samples should be treated in the same way as the other samples. If more care and control were given to these samples than to the others, the results will not reflect the quality of the routine analyses, often being more precise and accurate.

The IQC samples can be either certified reference material, such as those marketed by one of the organizations mentioned in section 12, or could be taken from specially prepared EQC samples.

QA procedures exist for sampling and sample handling. The sampling plan should never be allowed to be out of the control of the analyst. The method of sampling may be laid down in international and national standards or in a set of guidelines. Examples are the guidelines for sampling blood, urine, and tissues published by IUPAC (Cornelis *et al.*, 1995), the Codex Alimentarius Commission guidelines on the sampling of food (2004), and the guidelines about sampling of drinking water issued by WHO (1997). Whenever applicable, they should follow legal and statuary requirements, such as having been issued for the sampling of food.

It is further necessary that the measured sample has the same composition as the sample received. Holding time is defined as the maximum period of time that can pass from sampling to measurement before the sample has changed significantly. When degradation is a possibility, holding time is a very important element to be taken into account in the storage decision. Properties of the analyte such as volatility, sensitivity to light, thermal stability, and chemical reactivity all have to be considered in designing the sampling strategy.

13.5 Statistical Considerations

It has become common practice to report a result together with its uncertainty (i.e., an estimate that characterizes the range of values within which the true value is asserted to lie). This is described by the standard deviation or the standard error of the result. When analyzing a certified value in a reference material, the reported value should lie between the boundaries indicated by the standard error on the certified value.

13.6 Reporting of Quality Assurance Data

Today all published data have to be accompanied by quality assurance data. This may be helpful to explain large variations in levels obtained in different studies by methodological errors rather than by actual differences in concentrations. In cases in which extremely high (or low) values are reported without quality control, it is obvious that the data cannot be regarded as valid. Laboratories may well meet acceptance criteria on one occasion and for one metal, whereas 1 month later, or for another metal, results may be far from the true values. It is, therefore, important that quality assurance procedures form an integral part of any project in which trace metal analyses take place. It should be up to the individual investigators to prove that their data are reliable.

The data should be documented in a form that is easily understood by the layman. The customer requires information from the analyst to prove a point. The data need to be fully documented, although details such as a complicated chromatogram of which only one peak is of interest may be of little benefit.

It is also compulsory to report the method's detection limit for the analyte. Expressed as the *concentration*, c_L, or the quantity, q_L, it is derived from the smallest measure, x_L, that can be detected with reasonable certainty for a given analytical procedure. The value of x_L is given by the equation

$$x_L = \bar{x}_{bi} + k s_{bi}$$

where~$_{bi}$ is the mean of the *blank measures*, s_{bi}, is the standard deviation of the blank measures, and k is a numerical factor chosen according to the confidence level desired (McNaught and Wilkinson, 1997).

When the concentration of the analyte is well below the permitted level, pragmatism does not require a high

degree of accuracy. On the contrary, when the concentration of the analyte is close to the allowed maximum, accuracy is of paramount importance.

14 CONCLUSIONS

Today's available analytical techniques allow measuring accurately total element concentrations in most matrices, even at very low concentrations, and also a number of elemental species. Measurement of the right parameter with adequate accuracy is fundamental to assess the toxicity of metals. Standardized sampling procedures and good programmes for the quality control of analytical results of total element concentrations are well implemented in most laboratories. Speciation analysis is already well developed for many species of anthropogenic origin but needs to be further developed in the case of noncovalently bound compounds.

It is quintessential that the results are representative for the real exposure level. This is the only way to draw correct conclusions with regard to dose-response relationships and health hazards.

CHAPTER

3

Routes of Exposure, Dose, and Metabolism of Metals*

WILLIAM S. BECKETT, GUNNAR F. NORDBERG, AND THOMAS W. CLARKSON

ABSTRACT

The chapter first describes the main sources of exposure through air, food, and water but also points to unusual sources such as medical implants. Special attention is given to the processes of lung deposition and clearance of inhaled gases, vapors, and particulates, including ultrafine particles. In contrast to the extensive studies in the lung, absorption of metal in the gastrointestinal tract is less well understood. A diagrammatic example is given of the summation of all the absorption processes as they contribute to the total body burden. Since the publication of the first edition, new information has become available on the mechanisms of transport and distribution of metals in the body. In particular, it has been shown that several metals can cross cell membranes by specific carriers and ion channels intended for endogenous substrates. One well-documented example is the chromate oxyanion that is structurally similar to the sulfate anion and thereby gains entrance into the cell by the sulfate carrier. The fecal excretion of several metals occurs as the end result of extensive enterohepatic recirculation. In the case of certain organometallic species, the gut microflora may play a critical role converting the metal to the inorganic form, which is excreted in the feces. The renal accumulation and excretion of metals has also received considerable attention. The renal accumulation of cadmium in the form of its complex with the small molecular weight protein, metallothionein, still remains one of the best-documented mechanisms. Toxicokinetic models continue to be useful in providing a quantitative description of the overall body turnover of metals. They can be useful in establishing dose-response relationships where, for example, the range of half-times of elimination of a metal can contribute to the overall variance in the dose-response relationship. In addition to the observationally based models, pharmacokinetic models can be developed based *a priori* on physiological and mechanistic considerations. The chapter concludes with a consideration of indicator media that best reflect the dose to the critical organ.

1 INTRODUCTION

When evaluating the potential adverse effects of metal exposures, it is important to understand the mechanisms by which metals and their compounds are delivered from the source to the site of action in the human body. When such mechanisms constitute a result of events taking place in the ecosystem, they are dealt with mainly in Chapter 13. This chapter focuses on mechanisms and factors of importance for the uptake and distribution of metals when they come in contact with the human organism.

Airborne metals occur most frequently as aerosols, and metal particles inhaled into the respiratory tract frequently cause adverse health effects both to the lungs and other systems to which the metals are transported.

*This chapter is based on the chapter by Camner *et al.* with the same title in the 2nd edition of this Handbook.

Other absorption routes and factors governing distribution and excretion of metals are also dealt with.

Several new and exciting developments have taken place since the time of writing the previous version of this chapter. The disposition of ultrafine particles (including nanoparticles) in the lung is now an area of considerable interest and current research. Metal–protein complexes have long been a topic of interest. For example, nonspecific binding to serum albumin has been assumed to restrict metal movement from the blood compartment. However, an increasing number of publications indicate that many nonessential metals bind to proteins that normally bind essential metals. Such binding to these essential metal-binding proteins may affect the biological activity of nonessential metals in both intracellular and extracellular fluids. The mechanisms of transport of metals across cell membranes continue to be a subject of exciting research findings. Early in the history of metal toxicology, it was assumed that the free ionic species crossed into the cell through passive diffusion. Today, the picture is changing to one in which metals are the substrates of selective protein carriers. Some of these carriers are tailored to carry certain essential metals, but other carriers normally handle other endogenous substrates such as amino acids or inorganic anions. The terms "ionic mimicry" and "molecular mimicry" have been coined to describe these types of transport of the nonessential metals.

The metabolism and distribution of metals in the body continue to be a topic of interest but with fewer new developments. The term "metabolism of metals" is now usually restricted to those biochemical reactions that change the oxidation state of the metals or that form organometallic complexes, whereas this term was previously used to include the kinetics of metal disposition in the body. The previous usage is still acceptable and appears in some of the chapters of this handbook. An increasing number of metals have been found to undergo enterohepatic recirculation. This has proved to be a complex biochemical and physiological process involving the secretion into bile from the liver by specific transport processes, metabolic changes to the metal as it proceeds down the biliary and intestinal tract, followed by partial reabsorption in the gallbladder and intestine. This process not only plays a key role in the fecal excretion of metals but also affects the subsequent tissue disposition of the reabsorbed species.

An increasing emphasis on the use of biomarkers of exposure follows a long history of use of urine and blood, but the advent of molecular biology has opened up new vistas. For example, chromium–DNA complexes may serve as biomarkers of exposure. New analytical techniques and instrumentation open up an exciting field in the speciation of metals, whereby specific compounds of metals can be recognized in biological fluid and tissues. Speciation of metallic ions and complexes is important in the field of biomarkers of exposure, because only specific species of a metal can be transported into cells and across the blood–brain and placental barriers.

Some details on how the dose rate may influence mathematical models for dose-effect and dose-response relationships are discussed in Chapter 8. Sometimes, the influence of dose rate may be explained by the rates for absorption, transport, biotransformation, and excretion, which control the dose reaching their site of effects. These factors are dealt with in this chapter. As noted in another review (Goyer and Clarkson, 2001), there is a "need for quantitative information regarding dose and tissue levels as well as greater understanding of the metabolism of metals particularly at the tissue and cellular levels where specific effects might occur."

2 EXPOSURE

2.1 General Aspects

Air, food, and water are the major exposure media for humans. Air is especially important for occupational exposures, although the skin may also be exposed, and food and drink may be indirectly contaminated. All three exposure media can be important for the general population. In heavily industrialized regions and areas of high traffic density, air may well be the dominant route of exposure to certain metals. Water can be the dominant medium in geographical areas where metals such as arsenic or uranium are naturally present in soils and rock formations. Food can be the major exposure medium under a variety of circumstances, including accidental contamination and dietary habits. High natural background exposure may occur, such as to methylmercury in populations dependent on fish or marine mammals for their major source of protein. Infants and children may experience different degrees of exposure from air, water, or food compared with adults. Calculations of intake per kilogram of body weight for children compared with adults is twofold for air, threefold for water, and sixfold for food. The twofold difference for air is because the lung volume is lower in newborns but the alveolar surface area is larger per kilogram of body weight. In addition, the higher frequency of breathing in newborns gives them higher uptake of inhaled substances than adults. It is not clear how nose breathing, which is more frequent in early life, affects these factors.

Other routes of human exposure are through implanted medical devices such as hip and knee replacements made of Co/Cr/Mo alloys (cf Chapters

24 and 25) and dental amalgam fillings (cf Chapter 33). Other unusual routes of exposure such as hemodialysis and other medical therapeutic procedures will not be reviewed here (see Chapter 9).

2.2 Exposure by Inhalation

Metals as elements or metallic compounds constitute a certain part of the earth's crust. In air, metals may occur as aerosols and, in some instances, as vapor. Particles in ambient air from combustion sources are often composed of a mixture of carbon compounds and metals (USEPA, 2004). Particles coming from the earth's crust may contain Al, Mg, and Fe, whereas particles formed from burning fossil fuels contain transition metals and others, such as Cr, Co, Ni, Cu, Zn, As, Se, and Pb (USEPA, 2004). Metals have a vapor pressure, which is of very limited interest in regard to exposure, with the possible exception of mercury. However, the role of vapor pressure in environmental transport of metals may be considerable, particularly for mercury. It is known, for example, that mercury vapor is evaporated more efficiently from the continents than from the oceans (see Chapter 13).

Release of mercury vapor from dental amalgam restorations constitutes a special case. It has been shown that chewing and brushing of teeth gives rise to a release of small amounts of mercury, partly in the form of mercury vapor and partly as ionic mercury. This release can contribute significantly to the exposure of the general population to mercury vapor (Abraham *et al.*, 1984; Aronsson *et al.*, 1989; Brune and Evje, 1985; Hero *et al.*, 1983; WHO, 1991).

In certain industrial environments, human exposure to metals in vapor form may predominate (e.g., exposure to mercury vapor in chlor alkali plants or in mercury mines and to nickel carbonyl in some nickel refineries). Various natural and man-made sources contribute metal-containing aerosols to the atmosphere. A number of metals are thus found in the fly ash from coal-fired power plants. Depending on the source of the coal, the fly ash may contain different concentrations of Pb, Cd, Zn, As, etc. (Coffin and Stokinger, 1977). With oil-fired power stations, the dominating metals in the emitted aerosols are vanadium and nickel contained in oil (Ahlberg *et al.*, 1983), but they also may emit mercury (Boylan *et al.*, 2003).

Leaded gasoline (tetraethyl lead), which is still used as fuel in motor vehicles in some countries, gives rise to air pollution in the form of lead-containing aerosols, particularly in cities and along highways. In some countries where the addition of organolead compounds has been banned, organo manganese compounds are used for improvement of the octane of gasoline, and increased exposure to Mn aerosol is likely to occur. For smokers, inhalation exposure to the metal compounds that occur in tobacco smoke is of great importance. In this case, there is combined exposure to various metal compounds in aerosol form and a number of nonmetal gases and vapors.

In most industries, metal aerosols occur much more commonly than metal vapors. Examples of industrial exposure are lead or cadmium exposure in storage battery factories; exposure in metal smelters and refineries; exposure to all types of metals (Fe, Mn, Mo, Ni, Cr, etc.) that occur during the manufacture and use of steel; and exposure to solid particles of virtually all metals during grinding, finishing, and polishing of metal products.

Aerosols containing metals may be generated by various processes in the working and general environment. For an understanding of some of these processes, knowledge of the chemical and physical properties of metals is necessary. Formation of condensation and disintegration aerosols of metals is considered to depend, in part, on the electronic and crystal structure of the metals and their compounds (Brakhnova, 1975). For the formation of disintegration (pulverization) aerosols, the crystallochemical characteristic cleavage of a metal or its compound is of particular importance. Whereas, for example, graphite exhibits, under the action of mechanical forces, perfect cleavage along planes parallel to crystal faces, this is not the case for most of the metals, which display less perfect or indistinct degrees of cleavage. With decreasing particle size, the total surface of the particles increases. Thus, per 10 g of material, particles of 0.1-μm diameter have a surface 100 times greater than particles of 1-μm diameter. The increased surface area means that the number of disturbed metal–metal bonds increases and, as a consequence of this, there is an increase in the reactivity of the particles, their solubility in body fluids, and the possibility of a transition to an ionic state and interaction with the biological molecules (proteins, nucleic acids, etc.). In addition, these small particles have a greater ability to penetrate deeply into the respiratory tract (see Section 3.1.3), where they are less likely to be removed by mucociliary clearance and more likely to be absorbed into the blood.

Condensation aerosols, also known as metal fume, may be formed in various metallurgic processes. When metal vapors of high temperature react with atmospheric oxygen, metal oxides are formed. When a mixture of metals with different melting and boiling points is heated, compounds with lower melting or boiling points are released first (for example, manganese oxides), either as vapors or aerosols. A similar situation arises when tobacco is burned in a cigarette.

The metals in the tobacco will be released into the mainstream smoke as aerosols or may be retained in the remaining portion of the cigarette, depending largely on the melting point of the metal compounds in tobacco.

In various industrial processes, toxic and irritant gases are associated with metal oxide aerosols (fumes), including oxides of sulfur, oxides of nitrogen, hydrogen sulfide, and hydrogen selenide.

2.3 Exposure Through Food and Drinking Water

Human exposure to metal compounds in the general environment is usually greater through food and drink than through air. Even in occupational circumstances, exposure to metals by ingestion may be of importance, although absorption after inhalation is usually of primary importance in industry. Metals and their compounds occur naturally in food and drinking water, because they are intrinsic components of the earth's crust and of various biota. Depending on geological variation and agricultural and ecological processes, there are great geographical differences in metal intakes among populations living in various parts of the world. A striking modern example is the contamination of drinking water wells with arsenic in large areas of Bangladesh involving the exposure of millions of people (Wasserman *et al.*, 2004).

Industrial processes may, in some instances, add substantially to natural exposures, particularly in areas close to the sources of emission. A now classic example of local pollution contaminating the food supply is the outbreak of methylmercury poisoning that broke out in fishermen and their families eating fish caught from a large ocean bay in Minamata, Japan (for details, see Hunter, 1969). Mercury in various chemical forms had been discharged into the bay from a chemical plant manufacturing acetaldehyde. A mercury compound was used as a catalyst. Methylmercury either produced from other forms of mercury by a natural biomethylation process and perhaps released as such from the factory was bioaccumulated in the aquatic food chain to such an extent that consumption of fish from the bay resulted in cases of severe poisoning and even fatalities.

Attention has recently been directed to the increased metal content of crops from fields fertilized with metal-rich sewage sludge. The agricultural use of sewage sludge has, therefore, been regulated in some countries. In this context, it should also be noted that phosphate fertilizers, widely used in agriculture, might also contain some undesirable metals (e.g., cadmium). Furthermore, the acidification of soils by various processes including certain fertilizers as well as acid rain can increase the uptake of certain metals (e.g., cadmium) in crops (Nordberg *et al.*, 1985a). A metal discharged into the environment may be transformed into other chemical species by processes in the environment. The most well-known example is mercury as discussed previously and in Chapter 33.

Children may be exposed to metals in different ways than adults. The exposure of infants and children to lead is a well-documented example. Infants and toddlers crawling or playing close to floors can be exposed to lead dust and even larger particles released from indoor lead paint or entrained into the house from exterior paint and contaminated soils (for details, see Chapter 31). Liquid metallic mercury is occasionally spilled in the home as a result of breakage of mercury thermometers or through ethnic-religious practices with this metal. Mercury that evaporates from the liquid droplets forms the most concentrated layers of vapor near the floor where infants and toddlers can receive high exposures. Infants may be exposed indirectly from contaminants in the mother's tissues by ingestion of breast milk.

3 DEPOSITION AND ABSORPTION

This section will focus mainly on the two major routes of entry into the body, namely, inhalation and oral ingestion. Only limited new information has become available on absorption through the skin since the review by Wahlberg (1971). Although this route of exposure is usually less important than inhalation and ingestion, significant uptake through the skin has been reported, for example, of organic and inorganic thallium compounds (cf Chapter 41) and of cobalt in the hard metal industry (cf Chapter 25). Also, skin exposure may be important in sensitization of T lymphocytes to beryllium, with subsequent disease from inhalation exposure and immunological response. (Tinkle *et al.*, 2003). Fatal outcomes have been reported from skin absorption of organometallic compounds in rare instances (Nierenberg *et al.*, 1998).

After a metal has been taken into the lung by inhalation or into the gastrointestinal tract through food and drinking water, the metal will deposit on the walls of the airways or will be taken up in the mucosa of the gastrointestinal tract. The amount deposited will depend on physical characteristics of the aerosol or the chemical form of the metal in food and drinking water. After deposition has taken place, a certain fraction of the deposited amount will be transferred through the walls of the lung or gastrointestinal tract into the systemic circulation.

The physicochemical properties of metals in exposure media, such as air, food, and water, play an important role in determining the extent of absorption into the body. This has been investigated in great detail with respect to inhalation of metal aerosols. Less information is available in the physicochemical status of metals in other media, especially food.

3.1 Deposition and Absorption After Inhalation

In addition to chemical form, evaluation of the effects of airborne metal particles is complicated by the fact that these particles vary considerably in size, shape, and density. These physical characteristics, as well as the pattern of inhalation, determine the extent to which deposition and retention of the particles will occur.

The behavior of airborne particles greater than 0.5 μm is frequently described in terms of its equivalent aerodynamic diameter, which depends on the shape, size, and density of the particle. The aerodynamic diameter is equal to the diameter of a spherical particle of unit density (1 g/ml) with the same settling velocity in air as the particle in question. Under 0.5-μm aerodynamic diameter, particle deposition is governed more by diffusion, with particles striking molecules of gas and impacting airway walls as the result of Brownian motion. For such particles, size is usually defined by Stokes diameter, which for irregular particles is the diameter of a sphere with the same aerodynamic resistance. Unlike aerodynamic diameter, Stokes diameter is independent of mass (US EPA, 2004).

A given aerosol can be expected to contain particles of many different sizes and shapes. One method of categorizing the particles in an aerosol is by natural clustering into certain size distributions. Figure 1 shows an idealized frequency distribution of particles of different sizes that might be observed in traffic, with the particles falling into four peaks or modes of larger, intermediate, and smaller particles. Vapor may form small particles by the mechanisms of condensation or nucleation. Very small particles rapidly accumulate into larger particles by coagulation. The largest particles have a different source, usually generated

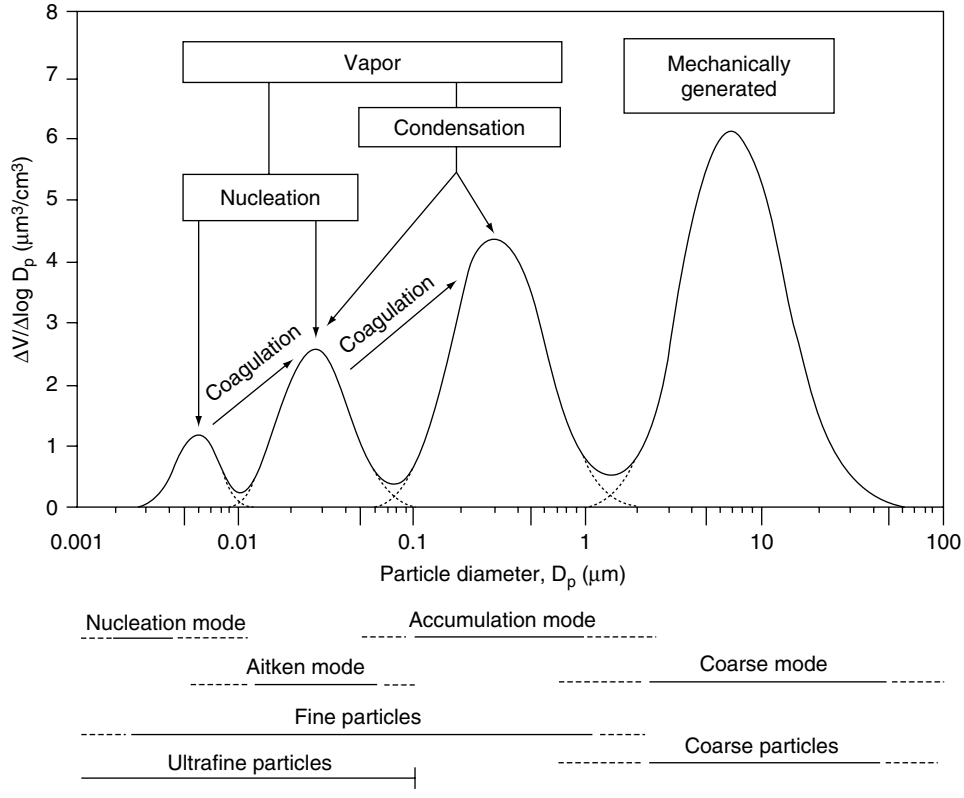

FIGURE 1 A volume or mass distribution of particles such as might be observed in traffic, according to particle diameter, showing four major modes of particle diameter. The largest particles are mechanically generated from geological dust and other sources, whereas the smaller particles originate from combustion and other sources and are formed from vapor by condensation or nucleation and then further coagulate into larger particles. The four modes, from smallest to largest, are the nucleation, Aitken, accumulation, and coarse modes. This is an idealized distribution. (USEPA 2004).

by mechanical forces on solid materials to break them down into particles.

The size distribution of larger or intermediate size particles in aerosols is often log-normal.

The mass median diameter is the diameter of a particle with the median mass, that is, half of the mass lies on either side of the median diameter. The mass median diameter is a measure of the mass distribution of the aerosol. The mass median aerodynamic diameter (MMAD) is important in determining pulmonary deposition of particles with penetration to the small airways and alveoli of particles less than 10-μm aerodynamic diameter. Particles greater than 10 μm aerodynamic diameter are efficiently filtered by the nasal passages, whereas particles smaller than this may penetrate to the alveoli, which are more sensitive to injury and may serve as a route for translocation to other parts of the body.

An alternate convention when describing the size of particles in ambient air pollution is to divide particles into categories of total suspended particulate (TSP) comprising all particles suspended in air; particulate matter less than 10-μm mean aerodynamic diameter (PM_{10}, which are likely to penetrate beyond the upper airway filtering mechanisms) and particulate matter less than 2.5-μm ($PM_{2.5}$), which are more likely to be deposited in the terminal bronchioles and alveoli (as shown in Table 1) and to have systemic effects.

In occupational health, particles are sometimes categorized into size categories according to the portions of the respiratory system they can reach when inhaled. Using this classification, "respirable particles" with a mass median aerodynamic diameter less than approximately 5-μm are considered more hazardous, because they can penetrate into and deposit in the alveolar or gas-exchange region. Thoracic particles are those that can penetrate the upper airways to the thoracic airways and beyond, whereas inhalable particles are all particles that can be deposited anywhere within the respiratory tract.

All particles, even very small particles, are efficiently filtered by the upper airways when breathed through the nose, but when the nasal passages are bypassed and particles are breathed through the mouth, there is a particularly high deposition for ultrafine particles, less than 100-nm diameter. In healthy subjects breathing through a mouthpiece at rest, the percentage of inhaled ultrafine carbon particles deposited (number deposition fraction) varied from 55% for particles 65 nm MMAD to 80% for the smallest particles 8 nm MMAD (Daigle *et al.*, 2003). This contrasts with a deposition fraction for fine particles under the same circumstances of well under 50% (Beckett *et al.*, 2005). The deposition fraction of particles further increases with exercise and is greater in subjects with mild asthma than in normal subjects (Chalupa *et al.*, 2004).

The biological fate and also the toxicological effects of deposited particles depend on the site of deposition in the airways and on particle characteristics, including size, solubility in airway lining fluid, and other physical characteristics (Oberdörster and Driscoll, 1997).

For a more detailed discussion of aerosol properties, generation, and measurement, see Mercer (1973), Stockham and Fochtman (1977), and USEPA (2004).

TABLE 1 Calculation of Total Absorption into the Body as a Function of Two Different Rates of Alveolar Absorption and Different Particle Sizes for a Specific Deposition and Clearance Model

Particle (MMAD) (μm)	Alveolar deposition (%)	Tracheobronchial - Total absorption Size (%) nasopharyngeal into body when alveolar absorption is:		
			100%	50%
0.1	50	9	50.4	26.7
0.5	30	16	30.8	16.6
2.0	20	43	22.2	12.6
5.0	10	68	13.4	8.6
10.0	5	83	9.2	6.8

From Task Group on Metal Accumulation, 1973.
MMAD, Mass median aerodynamic diameter.
Gastrointestinal absorption is assumed to be 5%.

3.1.1 Absorption of Gases and Vapors

The ability of vapors and gases to penetrate the airways depends on their solubility in water. The higher the solubility in water, the higher up in the tracheobronchial tract the gas will be absorbed. For example, sulfur dioxide is highly soluble in water, and more than 99% of concentrations found in typical air pollution episodes is absorbed in the nose (Speizer and Frank, 1966). Other less important factors determining the efficiency of uptake of vapors and gases include the rate of airflow (increased absorption with increased airflow) and the concentration of the gas (Fiserova-Bergerova, 1983). However, vapors and gases of metallic compounds are usually insoluble in water and will reach the alveoli, where they can penetrate the air–blood barrier.

3.1.2 Deposition of Particles

Most of the absorption of less soluble particles occurs in the lower part of the respiratory tract. However, it has been shown that some transfer of metals in the form of nanoparticles (ultrafine particles) and/or solutions may occur by a direct transfer from the olfactory

mucosa in the nose into the olfactory nerve in the brain, as shown in rats (e. g for cobalt) (Persson *et al.*, 2003).

Particle size is the primary determinant both for how many particles are deposited in the respiratory system and for the region of the respiratory systems in which they are deposited (Schulz *et al.*, 2000). The nose is an efficient filter not only for water-soluble gases but also for particles. It is a much more efficient filter than the mouth for particles of approximately 1 μm or larger (Heyder and Rudolf, 1977; Task Group on Lung Dynamics, 1966). During heavy physical work, breathing through the mouth is necessary (Proctor, 1977). Even during calm breathing, inhalation through the mouth occurs to some extent, and this affects the amount of particles deposited in the lungs (Camner, 1981; Camner and Bakke, 1980).

The main mechanisms for deposition of particles in the lung are impaction, sedimentation, and diffusion (Raabe, 1982). The effect of impaction increases with particle size and air velocity, and it is most important in the nose, throat, and the larger bronchi (i.e., where the velocity of the air is highest). The effect of sedimentation increases with particle size and decreases with air velocity. It is most important in the smaller airways and the alveoli. The effect of diffusion is of importance only for particles smaller than a few tenths of a micrometer, and the effect increases with decreasing particle size. Electrostatic effects may also be important for the deposition of particles, at least under some conditions. Melandri *et al.* (1977) have shown that unipolar electrostatic charges on particles increase the total deposition because of electrostatic attraction between the particle charge and the image charge on the airway wall.

Because the nose very effectively humidifies the air, the relative humidity is already 98–99% in the subglottic space (Ingelstedt, 1956). Particles that are hygroscopic can increase in size by increasing their water content and thus be deposited in the lungs quite differently from what could be expected from measurements at normal relative humidity. For example, particles of sodium chloride have been shown to increase seven times in diameter when they are inhaled (Dautrebande and Walkenhorst, 1964).

Several theoretical models for the deposition of particles in the lung have been proposed. The first was published in 1935 by Findeisen. The International Commission on Radiological Protection (ICRP) has used Findeisen's model with some smaller modifications (Task Group on Lung Dynamics, 1966). The model agrees fairly well with several experimental results (Raabe, 1982; Task Group on Lung Dynamics, 1966; Task Group on Metal Accumulation, 1973). A more recent model is also useful (National Institute for Public Health and the Environment, 2002). Particles greater than 100-μm aerodynamic diameter have a low probability of entering the human respiratory system, and particles less than 50-μm frequently enter. Under most circumstances, most inhaled particle mass is exhaled in the same breath, and the remainder is deposited in the respiratory system.

Particle size is the most important determinant of the location of deposition of inhaled particles (Schulz *et al.*, 2000). The upper airways—head airways and tracheobronchial region—serve as the site of deposition of much of the inhaled particle mass and serve to protect the more vulnerable alveolar region from exposure to inhaled particles. Particles greater than 10-μm aerodynamic diameter are mainly deposited in the head airways, also known as the extrathoracic region. Particles less than 10-μm diameter may be deposited in the tracheobronchial airways or the alveolar region. Particles deposited in the larger bronchi are more likely to be cleared to the pharynx by the mucociliary ladder and swallowed into the gastrointestinal tract, whereas particles deposited in small terminal and alveoli are less efficiently cleared.

Some examples of numerical values of deposition in tracheobronchial and peripheral lung structures (alveolar) for particles with varying mass median aerodynamic diameter are given in Table 1. Theoretical models predict the deposition in different parts of the respiratory tract as a function of particle size. In real situations there are always large variations in the particle size. However, theoretical calculations with the ICRP model show that estimates obtained using the aerodynamic mass median diameter give a rather good approximation of the deposition of an aerosol even when large size variations occur.

More sophisticated theories of particle deposition have been developed (e.g., the model by Yu and Taulbee, 1977). This model agrees very well with theoretical estimates of the total deposition by Heyder *et al.* (1975). The particle-size range of 0.3–3 μm was used during several breathing patterns. Compared with the ICRP model, the model by Yu and Taulbee gives lower values for deposition.

One difficulty with the theoretical models is that even if they give a good average estimate of deposition, they do not take into account the large individual differences that are known to exist. The part of the total deposition in the lung that is deposited in alveoli has, for example, been shown to vary at least by a factor of two, even among relatively young healthy male nonsmokers (Albert *et al.*, 1967; Camner and Philipson, 1978; Lippmann *et al.*, 1971). The penetration of particles (6 μm) to the alveoli has been found to correlate with lung function parameters as forced expiratory volume in 1 second (FEV_1) and airway resistance (Svartengren *et al.*, 1984; 1986).

3.1.3 Clearance of Particles from the Respiratory System

Mechanisms for clearance or translocation of particles depend on the regions of deposition. Sneezing, nose wiping or blowing, mucociliary transport, dissolution and absorption into the blood or lymph, or endocytosis by macrophages or epithelial cells may remove particles deposited in the extrathoracic or tracheobronchial regions. Particles deposited in the alveolar region may be removed by dissolution and absorption into the blood or lymph, endocytosis by macrophages or epithelial cells, or translocation into the systemic circulation (Schlesinger, 1995).

3.1.3.1 Tracheobronchial Clearance

3.1.3.1.1 Mucociliary Clearance The upper airways, the nasal passages, the paranasal sinuses, the auditory tube, and the upper part of the pharynx are provided with ciliated epithelium as are the lower airways from the lower parts of the larynx down to and including the terminal bronchioli. The upper airways cilia drive mucus backward and downward to the pharynx, and the lower airways cilia drive mucus upward to the pharynx whereafter it is swallowed. Lucas and Douglas (1934) proposed a two-layer model for mucociliary transport. The lower layer, in which the cilia beat, was proposed to consist of a low viscous secretion (the sol layer) and the upper layer of a highly viscous secretion (mucus or gel layer). Most particles deposited on the ciliated epithelium of the large airways are rapidly cleared (within hours to days) by this mechanism.

The importance attached to mucociliary transport in the airways has been motivated by theoretical considerations. If mucociliary transport is impaired, the concentration of particles per unit surface area should increase, and the particles should remain for a longer time on the area. People with congenitally immotile cilia have been identified and studied by Eliasson *et al.* (1977), Levison *et al.* (1983), Mossberg *et al.* (1983) and Pedersen and Stafanger (1983). Studies on these persons provide a unique opportunity to evaluate the importance of mucociliary transport. Such patients often have chronic infections in the upper and lower airways since childhood and commonly have bronchiectasis and obstructed airways.

In healthy humans, the tracheal mucus transport rate has been estimated to be in the range of about 4–20 mm/min (Santa Cruz *et al.*, 1974; Yeates *et al.*, 1975). The velocity is lower in the more peripheral airways. The particles deposited in the most peripheral ciliated airways are eliminated from the lung usually within 24 hours (Albert *et al.*, 1967; Camner and Philipson, 1978).

Mucociliary clearance of inhaled particles depends on genetic factors (Bohning *et al.*, 1975; Camner *et al.*, 1972). Clearance can also be affected by many different agents (e.g., tobacco smoke and other air pollutants, drugs, and infectious agents). The effect of tobacco smoke on mucociliary transport has been the subject of numerous investigations. In many *in vitro* and *in vivo* studies in animals, an immediate impairment of the transport rate was seen after exposure to cigarette smoke (see e.g., Asmundsson and Kilburn, 1973). In man, however, the average short-term effect of smoking cigarettes is an increased mucociliary transport (Albert *et al.*, 1976; Camner *et al.*, 1971). The average effect of long-term cigarette smoking is impaired mucociliary transport (Camner and Philipson, 1972; Lourenco *et al.*, 1971). However, some individuals who have smoked for 20–30 years do not have impaired clearance develop. The impaired clearance after long-term smoking is at least partially reversible (Camner *et al.*, 1973d).

Inhalation of agents other than tobacco smoke, carbon dust, sulfur dioxide, or sulfuric acid can immediately give rise to an increased mucociliary transport (Camner *et al.*, 1973a; Newhouse *et al.*, 1978; Wolff *et al.*, 1975). It is well known that inhalation of all three of these pollutants can give increased airway resistance mediated by the vagus. Because the administration of cholinergic compounds increases mucociliary transport, it seems probable that the vagus has a role in mediation of the effect of pollutants (Camner and Philipson, 1974; Camner *et al.*, 1974). High concentrations of sulfuric acid mist (980 $\mu g/m^3$) produce a transient slowing of clearance (Leikauf *et al.*, 1981).

Because more than 99% of SO_2 at common ambient concentrations is absorbed in the nose, its effect on mucociliary transport should also be most pronounced in this organ. Andersen *et al.* (1974) found a reduced transport after exposure to approximately 15 mg SO_2/m^3 for 3 hours. A tendency toward reduced mucociliary transport in the nose was seen even after exposure to 3 mg/m^3 over a period of 6 hours. In experiments on animals for longer exposure times, SO_2 reduced mucociliary transport in rats after exposure to about 3 mg/m^3 for 770 hours (Ferin and Leach, 1973), and in dogs after exposure to approximately 3 mg/m^3 for 12 months (Hirsch *et al.*, 1975). NO_2 has also been reported to impair mucociliary transport in animals after long-term exposure. In rats, exposure to approximately 12 mg $N0_2/m^3$ for 6 weeks caused decreased transport (Giordano and Morrow, 1972).

Not only administration of cholinergic compounds but also of adrenergic compounds has been shown to increase the mucociliary transport rate in man to a high degree (Camner *et al.*, 1976; Foster *et al.*, 1976;

Konietzko *et al.*, 1975; Yeates *et al.*, 1975). A marked effect of adrenergic compounds is interesting, because it may suggest that levels of catecholamines in the blood affect the mucociliary transport velocity. Wolff *et al.* (1977) showed that physical exercise increased bronchial clearance in healthy men. This could have been caused by an increase in catecholamine during exercise.

Both acute and chronic diseases of the lung have been shown to be associated with impairment of mucociliary transport. During acute infections with influenza A virus or mycoplasma pneumoniae, patients had markedly reduced mucociliary transport (Camner *et al.*, 1973b; Jarstrand *et al.*, 1974). Approximately 1 month after the onset of the infection, a definite improvement of clearance was seen in both groups of patients. Observations of cases with mycoplasma infection suggest that some impairment persists even 5–15 months after the onset of the disease and that persons with slow clearance more easily contract the disease than those with fast clearance (Camner *et al.*, 1978). Patients with chronic bronchitis usually have a clearly impaired clearance (Camner *et al.*, 1973c; Santa Cruz *et al.*, 1974; Togio *et al.*, 1963) and impaired mucociliary transport. In these patients, coughing is an effective elimination mechanism that seems to compensate for the reduced mucociliary transport (Camner *et al.*, 1973c), but only partly, because patients with immotile cilia syndrome do not have healthy lungs. An increase in tracheobronchial secretion is necessary for coughing to be effective (Camner *et al.*, 1979).

3.1.3.2 Peripheral Lung Clearance

Particles deposited distal to the ciliated epithelium, as well as some particles deposited on this epithelium, are cleared much more slowly from the airways. This may occur through the interaction of several mechanisms, which include dissolving of particles in epithelial lining fluid, interstitial fluid, or phagocytic cells; transport by phagocytic cells (alveolar macrophages, polymorphonuclear leukocytes) to ciliated epithelium, lymphatics, or alveolar spaces; and translocation out of the lung of dissolved material through epithelial lining fluid, interstitial fluid, lymphatic fluid, or blood. Phagocytosis of particles is most effective for particles between 0.5 and 2 μm (Bair *et al.*, 1994; Kreyling and Scheuch, 2000).

The most distal lymph vessels do not reach the level of the air–blood barrier or of the interalveolar septa (Lauweryns and Baert, 1974). However, some elimination of particles takes place through the lymphatics.

Inhaled ultrafine carbon particles (less than 100-nm diameter) are deposited in the alveoli in high proportion, but it is still unclear how rapidly and to what degree they can pass into the blood of the systemic circulation (Mills *et al.*, 2006; Nemmar *et al.*, 2001).

3.2 Absorption After Ingestion

Metals in the gastrointestinal lumen may originate from food and drink or may be transferred to the gastrointestinal tract by mucociliary clearance (Figure 2). The metal may also enter the gastrointestinal tract by secretion through intestinal mucosa and in bile and pancreatic fluids. The subsequent reabsorption of metals secreted in bile amounts to an enterohepatic cycle that will be discussed later. The metal may be absorbed and sequestered inside intestinal mucosal cells only to be returned to the intestinal tract when the cells exfoliate. Because intestinal cells turn over at a high rate, this process can prove to be an important limitation of the degree of absorption into the bloodstream. Not illustrated in Figure 2 is the role of intestinal microflora that are capable of methylation and demethylation and

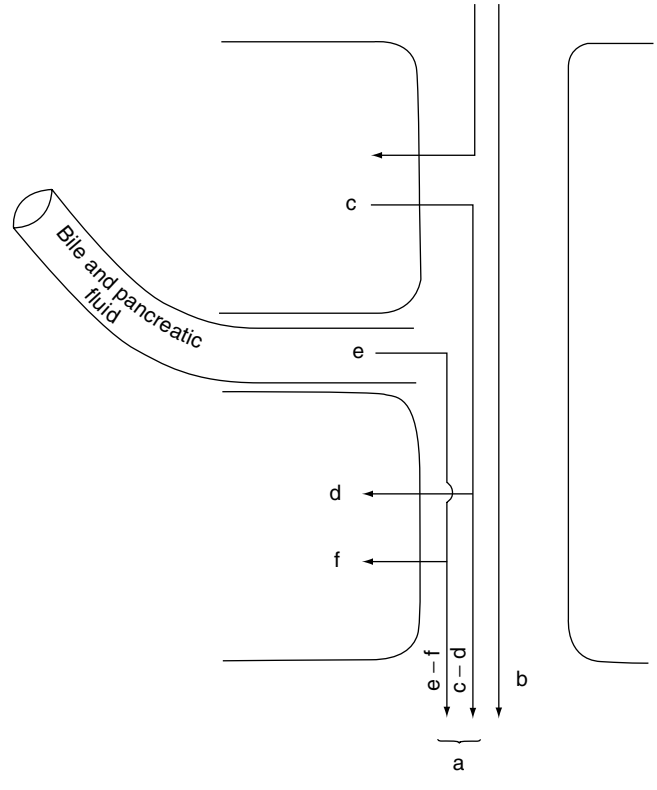

FIGURE 2 Routes for ingested metals. (a) Metal ingested and absorbed; (b) metal ingested but passing unabsorbed through gastrointestinal tract; (c) excretion of metal through intestinal mucosa; (d) reabsorption of metal excreted through intestinal mucosa; (c–d) Excretion minus reabsorption through intestinal mucosa; (e) Excretion of metal through bile and pancreatic fluid; (f) reabsorption of metal from bile and pancreatic fluid (enterohepatic circulation). g = (e – f) + (c – d) = net gastrointestinal excretion. g + b = fecal content of metal.

changing the oxidation state of metal. The metabolic interaction between metals and intestinal microflora may affect the degree of intestinal absorption and fecal excretion of the metal.

Depending on the source, metals may be presented to the fluids of the gastrointestinal tract in elemental form or as inorganic or organometallic compounds. The chemical form in which the metal occurs is of great importance, because absorption can be entirely different for different compounds of the same metal. This is particularly so when inorganic and organometallic compounds of the same metal are compared. Methylmercury, for example, is almost completely absorbed (approximately 90–100% absorption), whereas inorganic Hg (II) salts are absorbed to an extent of 10% or less.

Another consideration with regard to exposure to metals through the gastrointestinal route is the physical form of the metal. In food, metal or metal compounds may sometimes occur as particles of various sizes mixed with other components of food. Whereas the particle size is not as important as it is in the case of the lung, it may sometimes be of great importance for solubility and subsequent absorption. In addition, nonmetal compounds present in food may influence the uptake of metals from food. Such interacting substances should also be examined when evaluating metal exposures through food.

Knowledge about the chemical compounds of metals in foodstuffs is, therefore, of great importance. Established analytical methods can achieve some degree of speciation of metals, for example, distinguishing between the methylated and inorganic forms. However, identification of specific metal compounds and complexes remains a task for the future. A promising start has been made in the case of methylmercury, where a sophisticated instrumental method was used to identify methylmercury bound to cysteine residues in protein in fish meat (Harris *et al.*, 2003). Cadmium in the form of cadmium metallothionein has been studied in human and animal tissues (Lu *et al.*, 2005; Nordberg and Nordberg, 2000).

A chemical is absorbed from the gastrointestinal lumen by passive diffusion or by specialized (metabolic-dependent) transport systems and, in addition, ultrafiltration may contribute to transport into the lumen. With respect to absorption by passive diffusion, the lipid solubility of the molecule and its ionization are important (see reviews by Rozman and Klaassen, 1996 and WHO, 1978). The pH in the unstirred surface mucus layer adherent to the intestinal epithelium reflects the presence and activity of acid/base transporters in the apical membrane of the enterocytes. It determines the degree of ionization and thus the rate of absorption of weak acids and bases and is slightly alkaline or neutral in the duodenum, slightly acidic in the jejunum, and neutral in the ileum and the large intestine (Allen and Flemström 2005). Furthermore, diseases affecting intestinal electrolyte transport and mucosal paracellular permeability to ions, like celiac disease, may increase or decrease surface pH.

Inorganic salts of metals are usually not lipid soluble and are thus poorly absorbed by passive diffusion. For absorption of metals to occur, it is, in most instances, necessary that the metals are dissolved in the luminal fluids of the gastrointestinal tract, and subsequently they may be bound to molecules that facilitate their absorption. Absorption mechanisms for some essential metal ions sometimes serve to transfer nonessential metals into the body. Examples of such mechanisms have been shown for thallium salts (Leopold *et al.*, 1969) and for cadmium ions, the latter metal ion being transported by the DMT-1 transporter, also transporting iron and other divalent essential metals (Tallkvist *et al.*, 2001; see also Chapters 30 and 47).

The large differences in gastrointestinal absorption of inorganic salts of metals from less than 10% for ionized cadmium, indium, tin, and uranium to almost complete absorption (90–100%) for water-soluble inorganic salts of arsenic, germanium, and thallium may be related to the presence or absence of suitable transport systems. The importance of solubility in the fluids of the gastrointestinal tract has already been alluded to, and, for obvious reasons, this has been most easily demonstrated for metals whose soluble salts are readily absorbable.

The proportion of an oral dose of a metal salt that is absorbed is often influenced by dose level. For many essential metals (e.g., Cu, Fe), small doses are absorbed to a greater extent than larger doses. This is because homeostatic mechanisms—absorption and excretion—serve to keep concentrations of these metals at physiological levels. For nonessential metals (e.g., Cd), there is some evidence indicating the opposite (i.e., small doses are absorbed to a lesser degree than moderate [nontoxic] ones) (Engstrom and Nordberg, 1979a). For both essential and nonessential metals (e.g., Fe, Cd), excessive doses affect the integrity of the gastrointestinal mucosa with subsequent increase in uptake.

For several metals (Pb, Cd, Fe, Co, Hg), it has been shown that gastrointestinal absorption is greater in newborn or young animals than in adults (Engstrom and Nordberg, 1979b; Ezekiel, 1967; Kello and Kostial, 1977; Kostial, 1983; Kostial *et al.*, 1971). This may be related to the high pinocytotic activity of the immature intestinal mucosa or a greater (paracellular) leakiness of the young epithelium. One of the important factors in childhood susceptibility to lead exposure in the home is the high rate of intestinal absorption.

The composition of the diet is of concern, because components like phytate, ascorbic acid, other metals may have great influence on absorption (see Chapter 7). The transfer of metals from the intestinal lumen into the mucosal cells is not always associated with further transport into the organism (systemic uptake). The binding of metals by the low molecular weight protein, metallothionein, in the mucosa and subsequent loss by mucosal shed has been suggested as an important mechanism in homeostatic regulation of the systemic uptake of an essential metal-like zinc (Nordberg and Kojima, 1979; Richards and Cousins, 1976). High oral doses of zinc induce metallothionein synthesis in the mucosal cells and block the uptake of copper by the intestinal mucosa. This is used clinically to avoid tissue accumulation of copper in patients with Wilson's disease (see Chapter 26). A homeostatic mechanism for iron implies that iron is stored in intestinal cells bound to ferritin (see Chapter 30).

3.3 Total Absorption

Figure 3 describes the pathways of metals after inhalation or gastrointestinal intake and includes retention in the lung or intestinal compartment. Corresponding mathematical expressions for total absorption or uptake (I), and concentration (amount) of metal in lung (E), or intestine (E2) are also given.

As mentioned in the previous sections, aerosols deposited on the mucociliary escalator will be transferred to the gastrointestinal tract, and the uptake there will be governed by the factors discussed in Section 3.2. It is important to remember that for the effects of metals that occur as a result of systemic uptake, both the part of metal that is absorbed directly through the lung and the part that is absorbed after gastrointestinal translocation of inhaled particles will have to be taken into account, as well as those amounts of metal that are absorbed from the gastrointestinal tract from exposure through food and drink.

4 TRANSPORT, BIOTRANSFORMATION, AND DISTRIBUTION

The transport and distribution of metals will, to a large extent, depend on the form in which the metal occurs in the blood, which is the main transporting

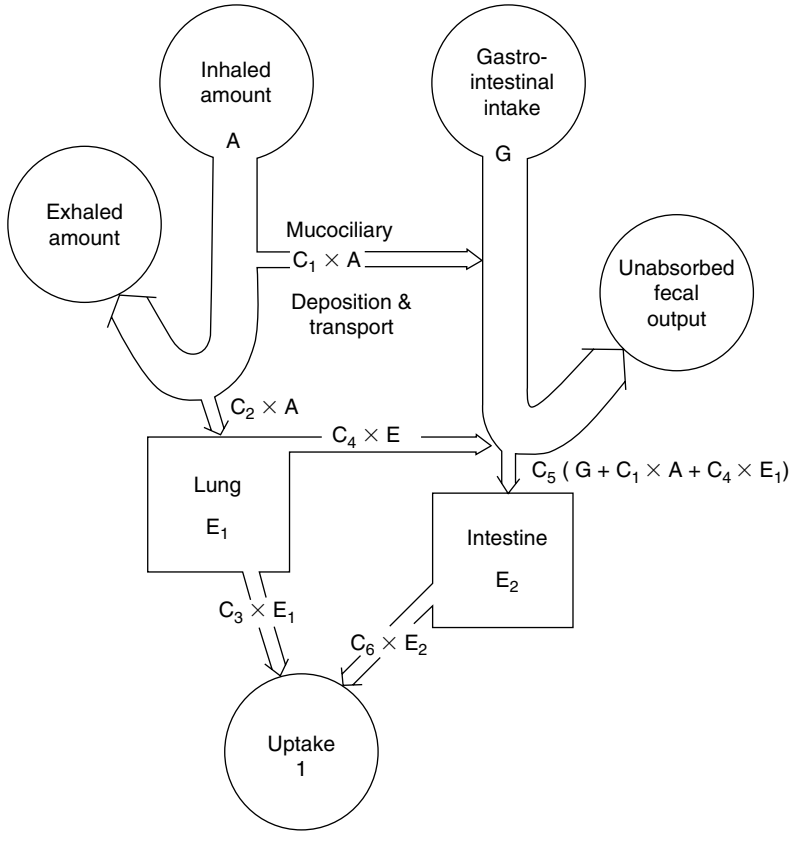

FIGURE 3 The pathways of metals after inhalation or gastrointestinal intake including retention in the lung or intestinal compartment. Corresponding mathematic expression for total absorption or uptake (1) and concentration (amount) of metal in lung (E_1) or intestine (E_2) are also given.

medium in the body. The lymph may also, in certain instances, constitute an important route for transport of metals, for example, from the lung into the blood circulation. Among metals, there are very large differences between the fraction of an absorbed dose that is transported to various organs and the fraction that is excreted. The following basic factors are of importance for distribution as presented diagrammatically in Figure 4: the protein bound and "diffusible fraction" in plasma, interstitial, and intracellular fluid; the rate of organ vascular perfusion; the rate of biotransformation; the permeability of cell membranes to the metal as it occurs in plasma; and the availability and turnover rate of intracellular ligands for the metal.

Protein binding of metal ions in plasma and body organs varies greatly among metals. Germanium is thought not to bind to plasma protein, but cadmium and mercury are protein-bound to at least 99%. Beryllium may be transported in the form of a colloidal phosphate, adsorbed to plasma α-globulin. Metals may also bind to proteins that normally handle essential metals, and, in some instances, protein-binding metal may serve a transport function for the metal (see review by Nordberg, 1982). For example, transferrin normally binds and transports Fe^{+3}, but transferrin also binds In^{3+}, Mn^{3+}, Ga^{3+}, Bi^{3+}, and Al^{3+}. A slow release of cadmium bound to metallothionein (mol. Wt., 6500) is thought to be of importance for the selective uptake of filtrated cadmium in the proximal tubule of the kidney by tubular reabsorption (Foulkes, 1978; Nordberg and Nordberg, 2000; Nordberg *et al.*, 1975; 1985b).

The diffusible fraction in plasma is of special importance to renal accumulation and excretion. As discussed previously, the Cd–metallothionein complex is filtered at the glomerulus as the initial step in renal uptake. Another example is the renal accumulation of uranium present in plasma as a bicarbonate complex. Its renal accumulation and excretion will be discussed in the following section.

The term "diffusible fraction" does not necessarily imply that metals move from one body compartment to another by passive diffusion. Instead, the term stands for the small molecular weight or ultrafiltrable fraction that oftentimes includes small molecular weight compounds of the metal that may be transported on specific protein carriers. For example Figure 5 illustrates the structure of the arsenate and chromate oxyanions. Such structures mimic those of the endogenous anions phosphate and sulfate, respectively, and are transported across cell membranes by the protein carriers for the endogenous anions. This type of "ionic mimicry" also accounts for transport of monovalent cations such as Tl^+ on K^+ and Li^+ on Na^+ carriers.

Methylmercury-cysteine is carried into the endothelial cells of the blood–brain barrier on the large neutral amino acid carrier. The process is inhibited by large neutral amino acids such as methionine and is so selective that only the complex of methylmercury with the L optical isomers is transported (Figure 7).

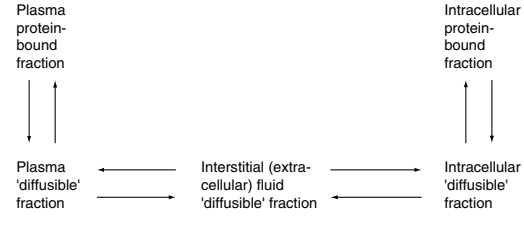

FIGURE 4 Model for the exchange of metal between blood and other tissues. (From Task Group on Metal Accumulation, 1973).

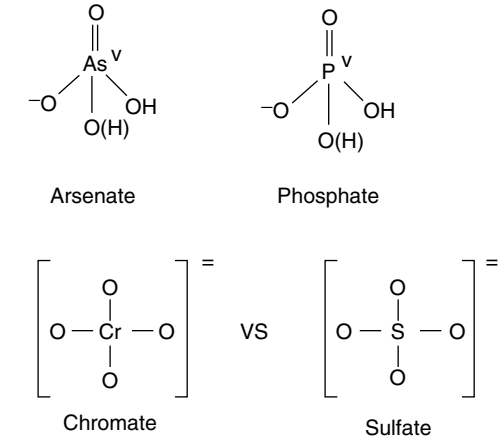

FIGURE 5 A diagrammatic comparison of the structures of the oxyanions of arsenate and chromate with those of the endogenous oxyanions of phosphate and sulfate, respectively.

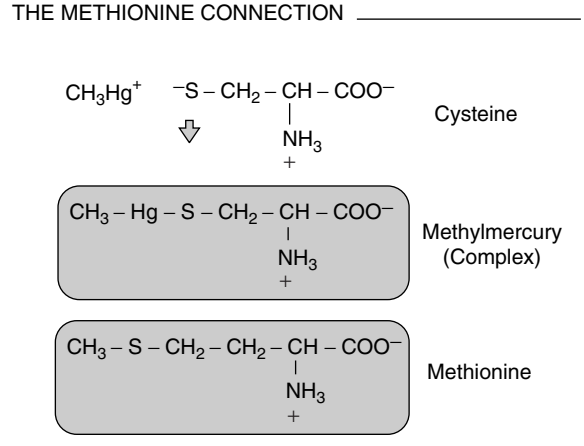

FIGURE 6 The structure of the methyl mercury–cysteine complex structurally mimics that of the large neutral amino acid, methionine.

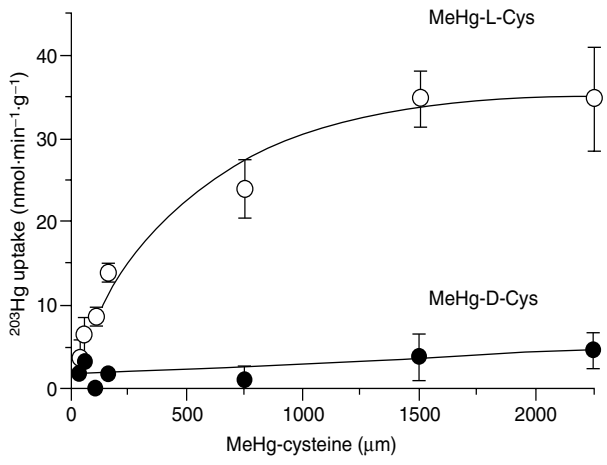

FIGURE 7 The uptake from plasma to brain in rats of the L and D optical isomers of the mercury–cysteine complex. (From Kerper *et al.*, 1992).

Studies on methylmercury secretion into bile indicate that methylmercury is extruded from cells as a complex with glutathione on the reduced glutathione carrier (Ballatori and Clarkson, 1982; 1983; Refsvik and Norseth, 1975). Thus, transport across the endothelial cell of the blood–brain barrier probably involves a stepwise process: transport into the cell on the large neutral amino acid carrier, the exchange of methylmercury from a cysteine thiol to one on glutathione because the latter is present inside the cell at much higher concentrations than cysteine, and finally transport out of the cell on the glutathione carrier.

Some aspects illustrating the importance of biotransformation (formation or breakdown of metal–carbon bonds [e.g., breakdown of organomercurials to inorganic mercury] or change of oxidation state of a metal in the biological system) are given in Chapter 33. The importance of the oxidation of mercury vapor to mercuric ion for the toxic effects on the CNS is described in Chapter 33 in some detail. Exposure to mercury vapor also exemplifies the importance of a rapid vascular perfusion for distribution. The rapid perfusion of the brain makes it possible that physically dissolved mercury vapor is transported from the lung to the brain before Hg^0 is oxidized to Hg^{++} in the blood. The vapor can penetrate the blood–brain barrier and will thereafter be oxidized to Hg^{++}, which will be "trapped" in the cells of the CNS and exert its toxic effect. Hexavalent chromium is an example of transport into the cells followed by metabolic reduction to trivalent chromium that is assumed to induce mutations and ultimately carcinogenesis by a direct reaction with DNA (Figure 8).

The methylation and/or demethylation of metallic compounds is of great importance for toxicity. Whereas methylation processes are of importance as a detoxifying process for arsenic in most animals and man (Buchet *et al.*, 1981; Vahter and Norin, 1980), demethylation serves as an important step in the detoxification and elimination of mercury from animals and man after exposure to methylmercury, as will be discussed in more detail in the next section. The breakage of one carbon–metal bond in tetraethyl tin, on the other hand, yields a highly toxic metabolite (triethyl tin) believed to be responsible for the toxic effects (Cremer, 1959).

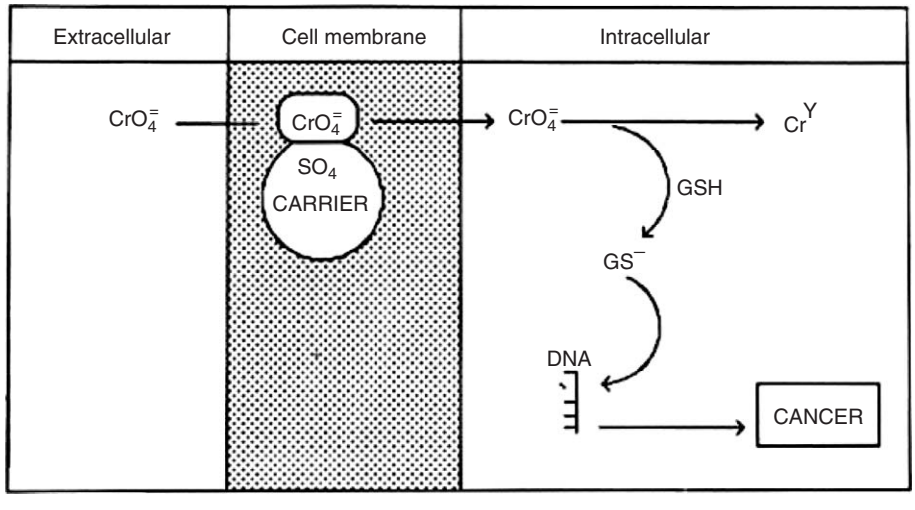

FIGURE 8 Diagrammatic representation of the entry of the chromate oxyanion into the cell of the sulfate carrier and its subsequent reduction to trivalent chromium. The latter forms complexes with DNA to produce mutations that may ultimately lead to cancer.

The metabolism of tetra to triethyl lead is a similar example (Cremer, 1958), because triethyl lead is considered to be the toxic metabolite of tetraethyl lead (Grandjean and Grandjean, 1984). The metabolism of these organometallic compounds is mediated through microsomal enzymes.

5 PATHWAYS AND MECHANISMS OF EXCRETION

Various routes exist by which a metal may be excreted from the body. The most important excretory pathways are the gastrointestinal and renal ones. Other processes of excretion such as salivary secretion, perspiration, exhalation, lactation, exfoliation of skin, loss of hair and nails, and bleeding may be of interest in special cases, both as a significant means of elimination and as an index of exposure and body burden. However, these will not be considered here.

5.1 Gastrointestinal Excretion

Routes by which metals may be excreted through the gastrointestinal tract are shown in Figure 2. Excretion through the intestinal mucosa may occur as an active or passive process by which metals are transported by the cells of the mucosa into the lumen of the gastrointestinal tract. Both inorganic mercury and cadmium seem to be excreted by this route as indicated by autoradiographic studies (Berlin and Ullberg, 1963a,b). Cells of the intestinal mucosa turn over rapidly, and passive loss of metal bound to cells that are shed and excreted in feces is another route of excretion that may be of considerable importance in certain cases.

The other main route of gastrointestinal excretion is through bile (and pancreatic secretions). Biliary excretion has been demonstrated for both inorganic and organometallic compounds of many elements (e.g., Al, As, Cd, Co, Hg, Pb, and Te). Many factors influence the extent to which metals are excreted in bile. An obvious example is the difference depending on valence state that has been shown for arsenic. Whereas arsenate—As(V)—was excreted to an extent of approximately 1% in 2 hours, approximately 10 times more of an injected dose of arsenite—As(III)—was excreted through the bile of rats (Cikrt and Bencko, 1974). Because the concentration of As in bile was several hundred times greater than the one in plasma, the biliary excretion is likely to involve an active transport system (Klaassen, 1974).

A variety of chemicals and drugs influence biliary excretion of metals. Compounds capable of inducing liver enzymes stimulate secretion of methylmercury into the bile (Klaassen, 1975; Magos and Clarkson, 1973; Magos *et al.*, 1974,). Low molecular-weight thiol compounds such as cysteine, reduced glutathione (GSH), and penicillamine also stimulate biliary excretion of methylmercury (Norseth, 1973). Ballatori and Clarkson (1983) have produced further evidence that methylmercury secretion into bile is intimately linked with the secretion of reduced GSH in bile; inhibitors of GSH secretion, such as bromosulfophthalein and its conjugates, also inhibit methylmercury secretion; sex differences in GSH secretion are mirrored by similar differences in methylmercury secretion, and developmental changes in GSH secretion during and just after the suckling period (Ballatori and Clarkson, 1982) seem to explain changes in methylmercury secretion. A similar relationship between inorganic mercury secretion and GSH in bile also seems to exist (Ballatori and Clarkson, 1984a, b). The preceding observations suggest that the liver plays an active role in the formation and secretion of methylmercury complexes and that factors affecting liver metabolism will influence biliary excretion. The role of the liver enzymes with regard to secretion of other metals remains to be investigated.

Metals secreted in bile may be reabsorbed further down the gastrointestinal tract and, consequently, become available for re-excretion in the bile. This process of biliary secretion followed by subsequent reabsorption in the biliary tree and intestinal tract is usually referred to as enterohepatic circulation. As discussed previously, it is known that many metals are secreted in bile. Some degree of subsequent intestinal absorption is likely to occur. Thus, to varying degrees, enterohepatic recirculation must occur with many metals. Enterohepatic circulation is known to occur for As^{3+}, CH_3Hg^+, Hg^{++}, Mn^{++}, and Pb^{++}.

The process can be quite complex. Methylmercury is a well-documented example. It is secreted into bile as a complex with reduced glutathione. Animal data indicate that this first step is dramatically age dependent—it being completely absent during the suckling period. The glutathione complex is hydrolyzed to its constituent amino acids by the enzyme glutathione transpeptidase as it passes down the biliary tree. Methylmercury is released as a complex with cysteine. As discussed in a prior section, this complex of methylmercury is readily transported across cell membranes on the large neutral amino acid carrier. Some absorption back into the bloodstream takes place in the gallbladder, and the remainder enters the intestinal tract. At this juncture, further reabsorption takes place across the mucosal cells. However, methylmercury also comes into contact with intestinal microflora present in the ileum and the large intestine. Rowland *et al.* (1983) have demonstrated that methylmercury is degraded to inorganic mercury by microflora in the gut and that

such demethylation is a key step in the fecal excretion process. Changes in diet or doses of antibiotic that affect the composition of gut flora also affect the fecal excretion rate of methylmercury in rodents. Inorganic mercury is poorly absorbed and passes directly into the feces. The process of biliary secretion followed by demethylation accounts for approximately 90% of the total elimination from the body.

The process of enterohepatic recirculation preserves the body pool of bile acids. For drugs, the recirculation has been most extensively studied in the area of clinical pharmacology. It can result in the appearance of at least two concentration peaks in the blood compartment; first, because of the initial dose of the drug and the next, because of the enterohepatic circulation. The process is subject to genetic control, as well as to physiological changes with age and disease. The cycle can be broken, and fecal excretion increased by oral doses of a nonabsorbable binding agent. Resins binding methylmercury in the gut have been used in this way and successfully tested in cases of human poisoning. Much remains to be learned of the role of the enterohepatic cycle with respect to metals.

Most studies on biliary excretion of metals have been performed on rats. It should be remembered, however, that there might be considerable quantitative differences in the proportion of biliary excretion in relation to other excretion routes among various animal species and between such species and man.

5.2 Renal Excretion

It is also important to understand detailed mechanisms of renal excretion of metals: the renal pathway is a major route of excretion for many metals, and the urinary concentration of metals is frequently used as an index of body burden. An understanding of this excretory route may also make it possible to influence such excretion and thereby speed up the elimination of metals, thus providing a means for treatment of poisoning.

Classical renal physiology has related renal excretion mainly to the "ultrafiltrable fraction" in plasma. The complex physicochemical state of metals in blood, involving in some instances colloidal solutions and protein binding of various types, has to be considered to understand the renal excretory mechanisms. The glomerular ultrafiltrate contains various ions and compounds from plasma, ranging in size up to plasma albumin. Only a small proportion of plasma albumin appears in the glomerular filtrate, and proteins with larger molecules are retained in blood. Macromolecules with relatively low molecular weight, such as inulin (mol. wt., 5000) and metallothionein (mol. wt., 6500), pass the glomerular membrane. Metals bound to such low-molecular-weight proteins may thus be cleared from plasma into the tubular fluid. The filterable fraction of metal in plasma may be influenced by some factors (e.g., changes in the concentration of some ions and other substances that occur normally in plasma).

The renal clearance and the ultrafiltrable fraction in plasma have been determined for several metals (Cr, Cu, Ni, Ra, Tl, U, and Zn). Renal clearance was found to be lower than the calculated glomerular filtration, which may be explained by tubular reabsorption of part of the metal present in tubular fluid (see review by Nordberg, 1982). Cadmium bound to metallothionein is very efficiently reabsorbed in the renal tubule, and only a small fraction is excreted in urine. Urinary excretion of beryllium is considered to take place through tubular secretion. The role of tubular secretion or other forms of transtubular transport may be important for the renal accumulation and urinary excretion of mercury and lead.

Changes in the urinary pH give rise to changes in the urinary excretion of metals such as uranium and lead. Uranium is the first and still the most dramatic example of the influence of acid–base balance on renal accumulation and excretion of this metal (Voegtlin and Hodge, 1960). Uranium was shown to be present in plasma as the uranyl cation, UO_2^{++}, partly protein bound and in part complexed with bicarbonate anions (Figure 9).

The bicarbonate complex is readily filtered through the glomerulus to enter the proximal tubular fluid. Here, dependent on the pH, it dissociates to release the uranyl cation that can then bind to the proximal tubular cells. In this way, when present at sufficient concentration, damage occurs to the resorptive mechanisms as evidence by the appearance of aminoaciduria (Clarkson and Kench, 1956). The undissociated bicarbonate complex is not absorbed and passes directly into urine. Pretreatment with sodium bicarbonate maintains a high pH in the tubular fluid such that little dissociation takes place and virtually all the uranium passes into the urine. Acidification of the animal by pretreatment with ammonium chloride resulted in a low tubular pH, almost complete dissociation of the complex, a large renal uptake, and a small excretion of uranium (Figure 10). The urinary excretion of lead is also affected by pH. The concentration of some amino acids such as cysteine and histidine may increase the filterable fraction of some metals (mercury, copper, or nickel).

Magos and Clarkson (1977) have reviewed interrelationships between renal injury and urinary excretion of metals. The increased excretion of heavy metals because of exfoliation of tubular cells has been

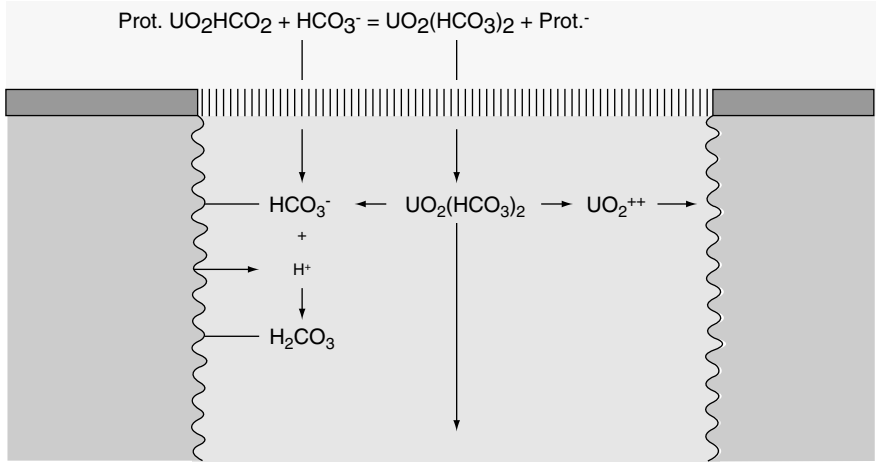

FIGURE 9 A diagrammatic representation of the renal uptake and urinary excretion of uranium present in plasma as the uranyl cation complexed with bicarbonate anions.

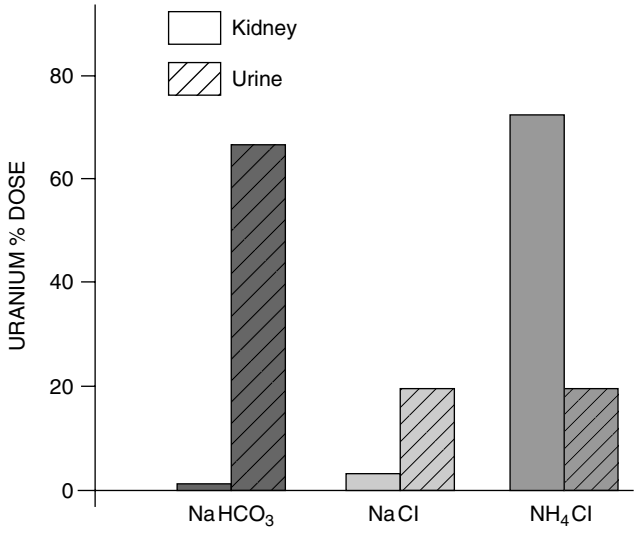

FIGURE 10 The effect of alkalosis and acidosis on the kidney level and urinary excretion of uranium.

extensively studied. Thus, any agent that elicits exfoliation of cells will increase urinary excretion of a metal. In contrast, acute renal failure will dramatically reduce urinary excretion of metals.

5.3 Excretion Rate—Biological Half-Time

The rate of excretion or clearance of a metal compound from an organ or from the body as a whole depends on a number of specific processes. When the course of an elimination process is governed only by the concentration gradient, the process can be represented with reasonable accuracy by a single exponential function.

According to the Task Group on Metal Accumulation (1973), the concentration in the organ under consideration may be expressed as

$$c_1=(c_0 \times \exp(-bt), \qquad (1)$$

where c_1 = concentration in the organ at time t; c_0 = concentration in the organ at time 0; b = elimination constant; and t = time. The biological half-time (i.e., the time it takes for the concentration to be reduced to half of its initial value) is then

$$T_{1/2}=\ln 2/b, \qquad (2)$$

where $T_{1/2}$ = biological half time; and $1n\ 2$ = natural logarithm of 2 = 0.693. The concept of biological half-time has been much used in evaluations of metal toxicity, and this is illustrated further in the following section of this chapter, as well as in the chapters on the various metals, where available data on the biological half-times are given.

The biological half-time varies greatly among metals. When discussing half-time, it is customary to lump together various parts of the body that have the same elimination rate into one "compartment," and one may speak of, for example, the "soft-tissue compartment" or of a compartment with a half-time of, for example, 5 days. Data on the half-time of a compartment may be obtained by actual measurements of elimination from that compartment after the termination of exposure, and in such a case, the anatomical structures comprising the compartment will be known. Such measurements may even be possible in humans through external scanning techniques after ingestion or inhalation of substances labeled with radioisotopes. When chemical analysis is used, it is usually necessary to limit the investigation to studies on blood, urine, and feces.

As discussed later, knowledge of the population variance in excretion rates (biological half-times) is essential for a quantitative estimate of risk. This information is lacking for most metals. Methylmercury is the best-studied example, where it has been shown that many factors influence the magnitude of biological half-time. Species differences range more than two orders of magnitude—from approximately 7 days in the mouse to more than 700 days in certain marine mammals (for a review see Clarkson, 1972). Half-times in humans (average value of approximately 70 days) are bimodally distributed and cover approximately a fivefold range—approximately 33–189 days (WHO, 1991). Lactating women—average half-time 42 days—have significantly shorter half-times than non-lactating adult women—average 76 days (Greenwood *et al.*, 1978). Biological half-times in suckling infants are not known, but experiments on mice (Doherty *et al.*, 1977) indicate that no elimination of methylmercury takes place during the suckling period. Other experiments on mice indicate that dietary changes can alter biological half-times (Rowland *et al.*, 1983).

6 TOXICOKINETIC MODELS AND THEIR USE FOR ESTABLISHMENT OF DOSE-RESPONSE AND DOSE-EFFECT RELATIONSHIPS

A toxicokinetic (or pharmacokinetic) model describes the processes of absorption, distribution, biotransformation, and excretion quantitatively as a function of time. Such a model is sometimes named "metabolic model." Such models may help us in a general manner to understand the occurrence of adverse effects of chemical compounds. They may also be used together with toxicodynamic knowledge, particularly when critical concentrations in the critical organ can be estimated, to define exposures that are associated with a certain risk of adverse effects. In instances where this is possible, the toxicokinetic model constitutes a very important part of a total model for risk estimation. Such models may be of great value, because they provide a means of calculating expected dose-response relationships and may be helpful as a basis for setting exposure limits in industry and in the general environment (see Chapter 14).

Toxicokinetic models may also serve a useful purpose by enabling conversions of information about concentration in biomarker media (e.g., blood, urine) to intakes and vice versa. However, the most important use of such models is to calculate the concentration in the critical organ under various conditions of exposure. The following sections deal with models of different complexity and with different types of exposure.

6.1 One-Compartment Model

6.1.1 Description

The one-compartment model can be described by the same mathematical expression as used in the foregoing section (5.3), where biological half-time is defined. Equation 1 describes the course of the elimination process from a compartment when there is no further influx (e.g., after a single dose). In this equation, *c* stands for the concentration of metal in the compartment. The same mathematical expressions are also valid when the amount of metal in the compartment is studied. When additional doses are given at time intervals that are several half-times long, the doses will not appreciably influence each other, and the concentration curve in the organ will take a course that is a repetition of the one after a single dose (Figure 11). When the interval between doses is shorter, there will be an accumulation of metal in the organ (Figure 12a). This will also be the case if there is continuous exposure (Figure 12b). The situation with continuous exposure is the one that represents the greatest accumulation hazard and, therefore, deserves special attention. The accumulated amount (A) of metal in a compartment can be expressed mathematically as

$$A = a/b[1 - \exp(-bt)], \qquad (3)$$

where A = accumulated amount; a = fraction of daily intake taken up by the organ; b = elimination constant; and t = time of exposure. At steady state

$$(t = 8)$$

$$A = a/b \qquad (4)$$

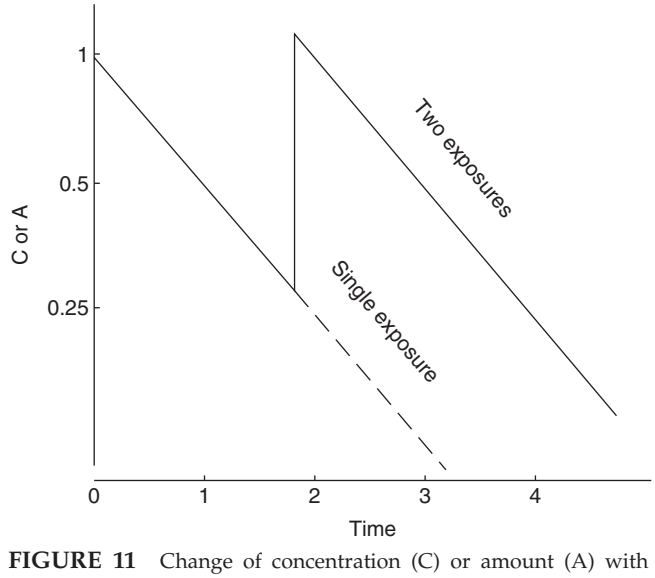

FIGURE 11 Change of concentration (C) or amount (A) with time in a compartment after single exposure or after two consecutive exposures with a relatively long time interval in relation to the biological half-time.

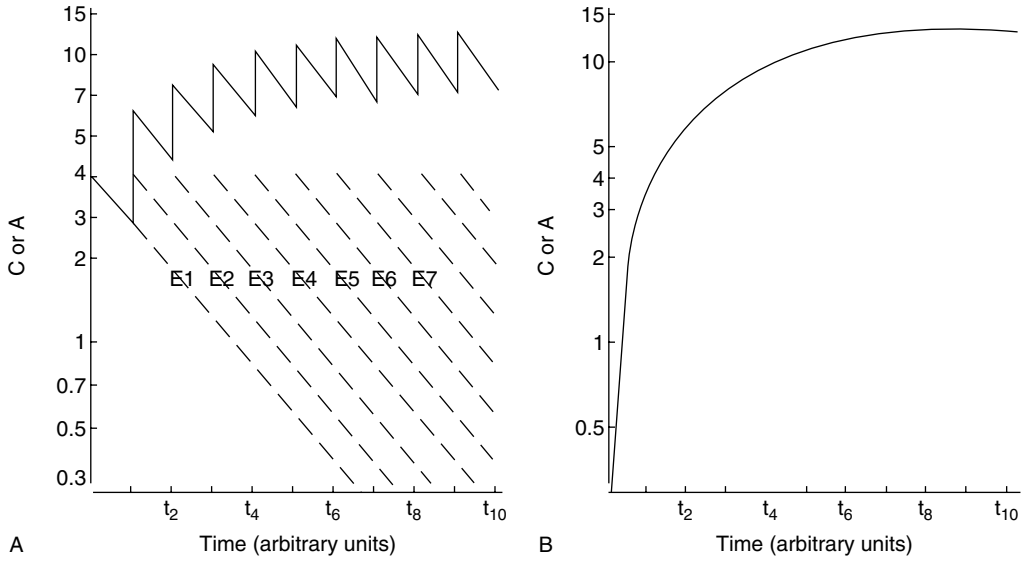

FIGURE 12 (a) Simulation of the cumulative plasma concentration of a chemical (C) or amount in the body (A) after repeated administration or exposure (from WHO, 1978). (b) Plasma or organ concentration in relation to time during continuous exposure.

When t is sufficiently long (i.e., corresponding to five times the biological half-time or more), the steady state can be regarded as reached from a practical point of view.

These mathematical expressions are based on the assumption that intake and absorption are constant. If either intake or absorption changes systematically with age, type of exposure, period in time, etc., the equation must be modified. Some examples of this will be given.

6.1.2 Use of One-Compartment Model for Toxicokinetic (TK)–Toxicodynamic (TD) Modeling of Dose-Response or Dose-Effect Relationships

The one-compartment model—as well as more complex models—has been used extensively for description of distribution and elimination of drugs and various organic chemicals (Teorell, 1937; WHO, 1978). In radiation protection, the one-compartment model has been successfully applied in estimating radiation doses to body tissues that are used to recommend maximum permissible exposure (ICRP, 1968; 1971; 1979; 1982). Radiation protection calculations were based on "standard man" and thus did not provide for individual variations. The "standard man" and "reference man" were specified by the International Commission on Radiological Protection (1959; 1975).

As mentioned previously, interindividual variation in intake, absorption, distribution, and excretion may greatly influence the accumulation in critical organs and should be taken into account to obtain correct predictions (Nordberg and Strangert, 1985). Systematic changes in organ weights and daily intake should be considered when estimating accumulation. Such factors have been considered in calculations regarding cadmium accumulation in the kidney (Kjellstrom and Nordberg, 1978, 1985) and have also been taken into account by the Task Group on Reference Man (IRCP, 1975) and by Choudhury *et al.* (2001). Age-dependent changes in organ composition and organ function should also be taken into account when they are of importance for the modeling process. Renal changes have, for example, been identified as important in modeling the kinetics of cadmium (Kjellstrom and Nordberg, 1978; Travis and Haddock, 1980). For dose-effect evaluations regarding neurological effects of methylmercury, the one-compartment model has been successfully used for calculations of accumulation in the CNS (Berglund *et al.*, 1971). The use of this model and the information concerning interindividual differences in biological half-time (Shahristani and Shihab, 1974; as shown in Figure 13), and information concerning interindividual differences in threshold body burden for elicitation of clinical symptoms and signs of poisoning (see Figure 14; from Bakir *et al.*, 1973), Nordberg and Strangert (1976) calculated the risk of poisoning in relation to long-term daily intakes of methylmercury (see Figure 15). Nordberg and Strangert (1978; 1985) have further discussed principles for risk estimations by use of interindividual variation of metabolic and organ sensitivity parameters.

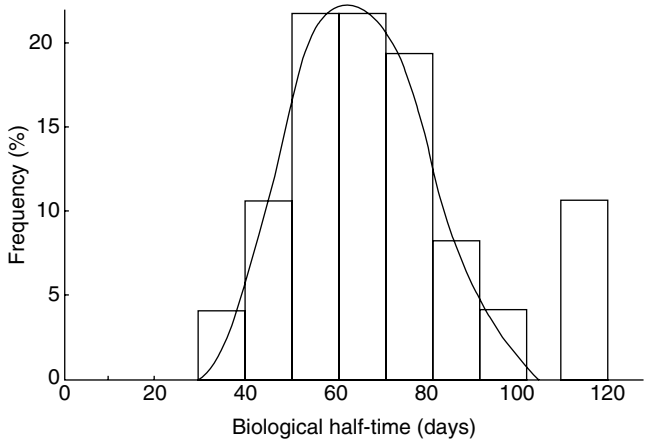

FIGURE 13 Population distribution curve of biological half-time of methylmercury obtained by measurement of hair concentrations. (From Shahristani and Shihab, 1974).

6.2 Multicompartment Models and Physiologically Based Models

Atkins (1974) and the WHO (1978) have discussed the use of multicompartment models for interpretation of experimental data on essential trace elements and drugs. It has been recognized that for an adequate and useful quantitative description of the toxicokinetics of many metals—including inorganic lead, cadmium and mercury—multicompartment models are required (Task Group on Metal Accumulation 1973; Task Group on Metal Toxicity, 1976). It has also been recognized that multicompartment models for these toxicologically important metals would be useful as a basis for interpretation of data from environmental and biological monitoring programs and for calculation of dose-response relationships (i.e., for toxicokinetic/toxicodynamic TK/TD modeling).

For animal data, Cember (1969) and Nordberg and Skerfving (1972) developed a model for retention and accumulation of inorganic mercury in the kidney. Matsubara-Khan (1974), Matsubara-Khan and Machida (1975), Shank *et al.* (1977), and Marcus (1982) developed models for accumulation of cadmium in various organs of experimental animals. Several mathematical models have been advanced for the description of the retention of alkaline earth metals (Sr, Ba, Ra) in the body and particularly in bone (Harrison, 1981; Marshall and Onckelinx, 1968). Because lead is also a bone-seeking element, similar models have also been considered for this metal. Piotrowski (1971) discussed a model for the kinetics of lead. A power function was required to fit the accumulation of lead in tissues. A multicompartment model with spatial diffusion of lead in bone was developed by Marcus (1983) and adapted to lead disposition in dogs. For humans both physiologically based (O'Flaherty

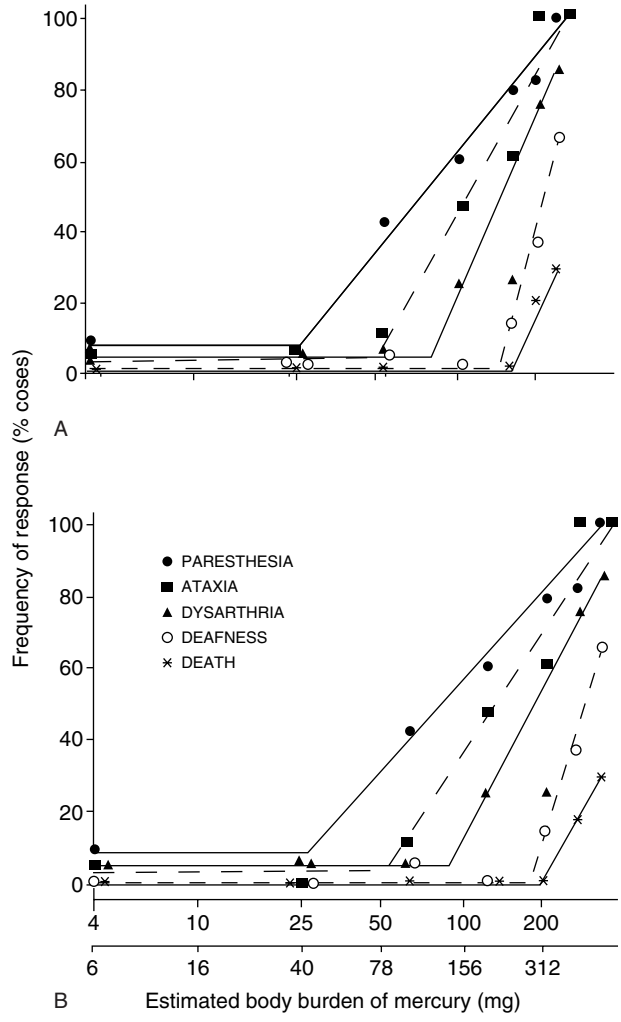

FIGURE 14 The relationship between frequency of signs and symptoms and the estimated body burden of mercury (A) at the time of onset of symptoms and (B) at the time of cession of ingestion of methylmercury in bread. Both scales on the abscissa are for body burden of methylmercury and were calculated in different ways as described by Bakir *et al.* (1973). For the top scale, use was made of the observed relationship between mercury concentration in blood and the ingested dose. The bottom scale was estimated from the relationship between the mercury concentration in blood and the ingested dose as reported by Miettinen (1972).

1993) and compartment models have been developed and used in assessments of human uptake of lead from environmental sources (US EPA 1994; 2002; see also Chapter 31). Several parts of human lead toxicokinetics have alternative mathematical descriptions. This is true for the relationship between exposure levels and blood lead levels and the relationship between bone lead and blood lead (cf further discussion in Chapter 31).

The concept of "physiologically based" models has been advanced since the early 1990s in metal toxicology. These models use information about physiological

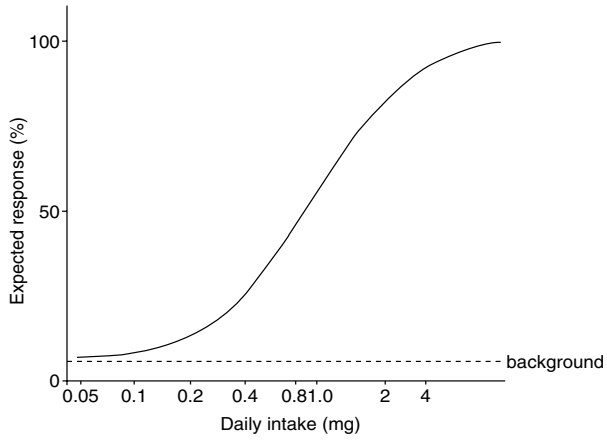

FIGURE 15 Relationship between intake of methylmercury and risk of poisoning in adult persons.

processes (e.g., bone formation and incorporation of bone-seeking elements into bone and oxidation-reduction processes changing the oxidation state of metallic compounds in human body fluids). All physiological processes that have an important impact on the toxicokinetic model for the element under consideration are included in such models. When such models are developed for pharmacologically active substances, they are named physiologically based pharmacokinetic models, PBPK models. Such modeling has been developed for the toxicokinetics of lead in humans (O'Flaherty 1993; 1995) and for chromium toxicokinetics in humans after ingestion (O'Flaherty *et al.*, 2001). These models, like multicompartment models based on knowledge of metal binding in plasma and tissues (see later), both try to use as much as possible of actual data and understanding of the metabolic and toxicokinetics behavior of metallic compounds in human tissues and body fluids.

A multicompartment model for cadmium has been developed and applied to the interpretation of data on human cadmium exposure. This model for cadmium has been used for a long time with some modifications (cf Section 6.2.1) and will, therefore, be used as an example of such a model. This model (Choudhury *et al.*, 2001; Kjellstrom and Nordberg, 1978; 1985; Nordberg and Kjellstrom, 1979) is briefly described in the following section.

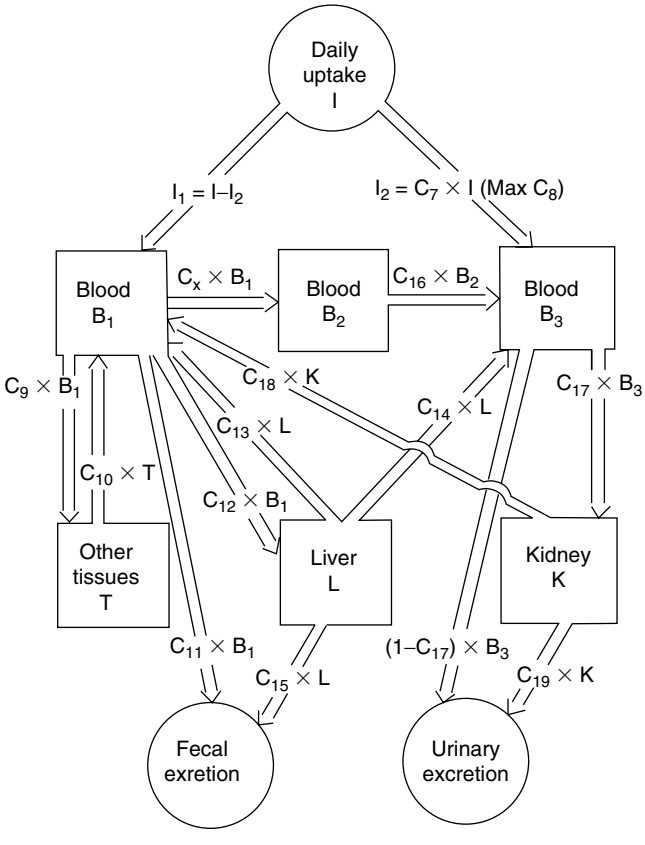

FIGURE 16 Flow scheme describing the movement of cadmium among various compartments. (From Nordberg and Kjellstrom, 1979).

6.2.1 Description of a Multicompartment Model for Cadmium

The flow scheme describing the model is shown in Figures 3 and 16. The first part of the model is identical with the general pathways for absorption described in Section 3.3 and in Figure 3.

The amount transferred daily to the systemic circulation (daily uptake I) will be distributed among three blood compartments: B_1, representing cadmium bound to albumin and other proteins (except metallothionein); B_2, representing cadmium in erythrocytes; and B_3, cadmium bound to metallothionein in plasma. The amount of cadmium that can be bound to metallothionein directly in plasma (I_2) is limited, because the amount of circulating metallothionein is extremely small. Other binding sites in plasma are abundant, however, and it is assumed that cadmium not bound to metallothionein in plasma will instead be bound to these other binding sites ($I_1 = I–I_2$). The amount of cadmium reaching B_1 will be further transferred to the various tissues in the body, and only a small proportion of the cadmium from these compartments will return to B_1, because tissue binding is much stronger than binding to ligands in B_1. Part of the cadmium in B_1 will be excreted in feces through the intestinal mucosa ($C_{11} \times B_1$). Part of the liver cadmium ($C_{14} \times L$) will be released in the form of metallothionein to the blood (B_3), and a very small proportion will be excreted in the bile ($C_{15} \times L$). The kidney derives its cadmium content

from the metallothionein fraction in plasma. A very minor part of B_3 (approximately 5%) is transferred to the urine. Because renal tubular reabsorptive capacity diminishes with age, C_{17} is partly age dependent.

The flow of cadmium among the compartments in the model described by Kjellstrom and Nordberg was derived by a series of equations. An improved mathematical approach that uses the same model for Cd flow in the human body (Figure 17), has been described by Choudhury *et al.* (2001). The equations describing intercompartmental transfers of Cd were implemented as differential equations in Advanced Continuous Simulation Language (ASCL v 11), and improved growth algorithms and other adjustments were used. A Monte Carlo simulation was used to propagate variability in daily intake through the model. On the basis of data concerning intake of Cd in the US population, levels of Cd in urine in the US population were computed by this model. When comparing their results with those measured in NHANES II, they found good agreement in men as shown in Figure 17, whereas the urine Cd values in women generated by the model were lower than those observed in NHANES II. Data demonstrating a higher gastrointestinal absorption in women than men have been published since the Kjellstrom-Nordberg model was developed in the 1970s. This information was used and gastrointestinal uptake in women was adjusted to 10% (instead of 5% in both men and women originally used by Kjellstrom and Nordberg). With this modification, Choudhury *et al.* (2001), found reasonably good agreement between observed and model generated values in females also.

6.2.2 Use of Multicompartment and Physiologically Based Models for TK/TD Modeling

Toxicokinetic (TK)—toxicodynamic (TD) modeling describe quantitative estimations of expected dose-response relationships by the use of TK/TD data. Early contributions to this field that used data on cadmium were those published by Nordberg and Strangert (1985), described and discussed in more detail in Chapter 23. More recently, multicompartment (IEUBK model) and physiologically based models (e.g., O'Flaherty, 1993) have been used to assist in risk assessment of metal exposures in humans, but published estimates of expected dose-response relationships are not available.

7 USE OF INDICATOR MEDIA FOR ESTIMATION OF EXPOSURE OR CRITICAL ORGAN CONCENTRATION

To estimate the risk of poisoning for an individual or a group of individuals, it would be desirable to measure the dose at the site of effect (i.e., the concentration in

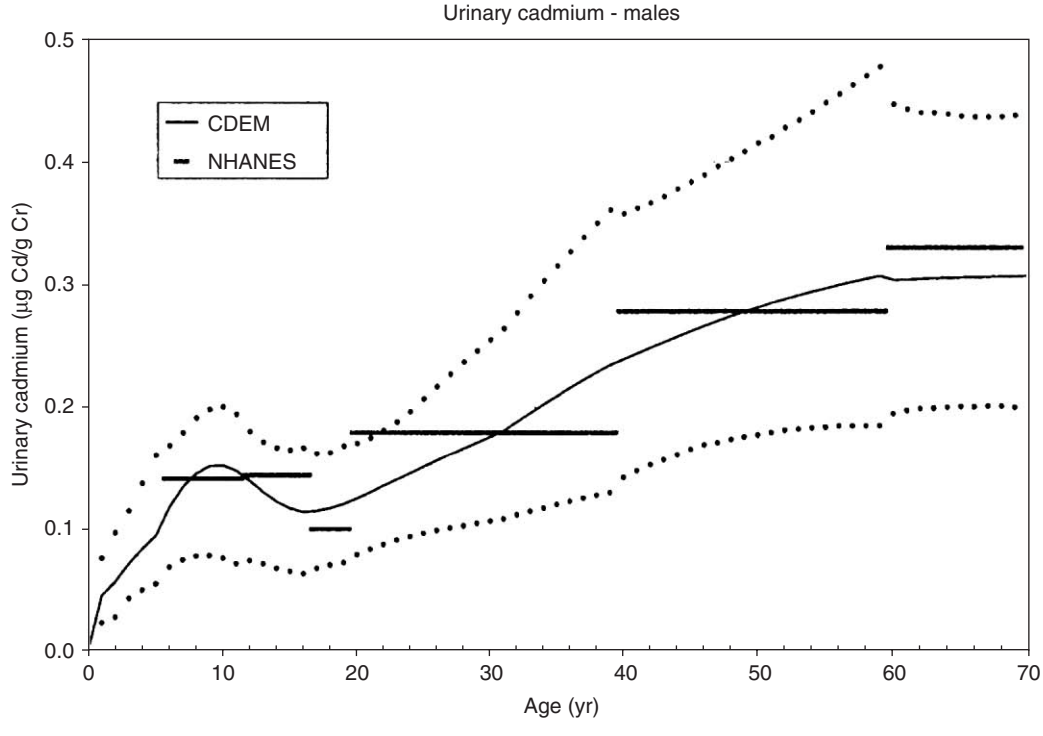

FIGURE 17 Urine levels of Cd in relation to age in the US population and a comparison with values calculated by Choudhury *et al.* (2001).

the critical organ). In living individuals, this is seldom possible. However, because metal concentrations are also found in other biological media such as blood, urine, or hair, these are often used as indicators of the concentration of the metal in the critical organ and, thus, provide an indication of risk of adverse effects (review by Clarkson *et al.*, 1983). When useful biological indicator media can be found (i.e., when metal concentrations in such media correlate accurately with the appearance of effects), biological monitoring provides a more accurate means for evaluating the risk than does measurement of exposure. Often, such measurements are also more easily and conveniently performed than measurements of exposure. Measurement of the concentration of lead in the blood of a worker, for example, is less time-consuming and gives more accurate information about the risk to this person than does measurement of lead in air, even when a personal air-sampling device is used over an entire working shift. The reason for this is that the blood determination reflects an integrated exposure over a longer period and the soft tissue and critical organ concentration of lead, and thus is more directly related to the appearance of adverse effects. It also integrates uptake by various routes such as inhalation, dermal uptake, and gastrointestinal absorption.

Biological monitoring programs can be designed on various scales and have different objectives. The example with lead, just mentioned, refers to the use of blood sampling for lead analysis in the control of occupational lead exposure in industry. A worldwide pilot project to monitor the present exposures and body burdens of a number of metals and some organochlorine pesticides by analysis of human biological samples has been performed under the auspices of the World Health Organization and the United Nations Environment Programme (Friberg, 1983; WHO, 1977).

When biological monitoring is used, it is important to consider the results obtained in the light of knowledge of the toxicokinetics for the particular metallic compound under study. In some instances, monitoring of an unsuitable biological medium may give a false impression of safety. Although the determination of mercury concentration in urine is a useful tool to estimate risks for groups of workers exposed to elemental mercury in vapor form or inorganic mercury salts, such determination gives no information of value for individuals exposed to alkylmercurials.

Head hair is a useful indicator medium in the case of certain metals. The usefulness of head hair is best illustrated in the case of methylmercury (Clarkson

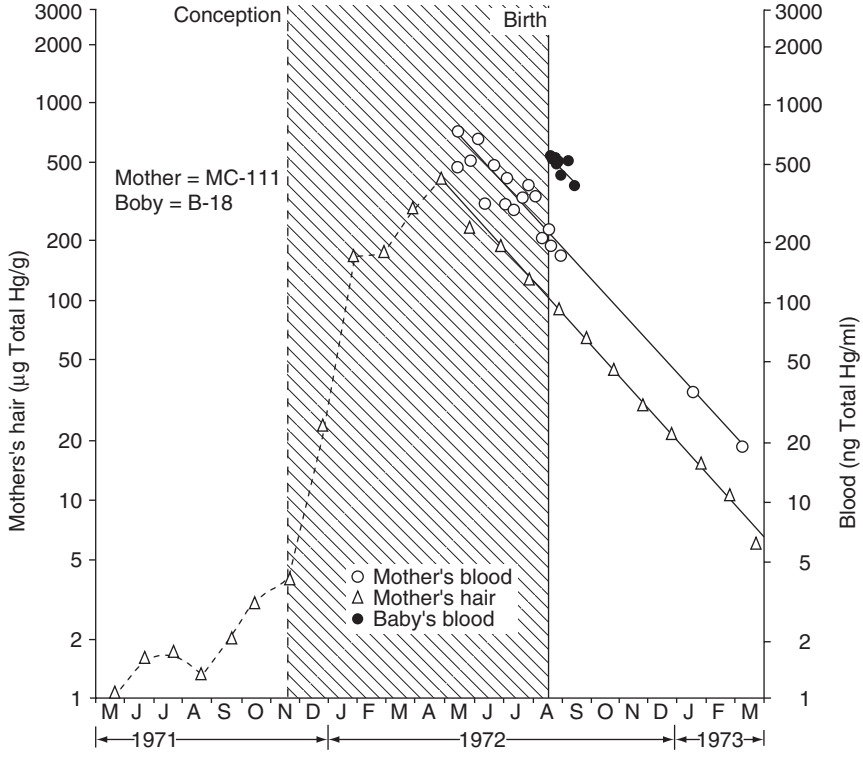

FIGURE 18 Concentration of total mercury in 1-cm segments of sample of mother's hair, whole blood, and baby's blood—prenatal exposure reproduced from Amin Zaki. (from Amin-Zaki *et al.*, 1976).

et al., 1976; Marsh *et al.*, 1981; Shahristani *et al.*, 1976). Methylmercury is incorporated into the newly forming hair in such a way that the concentration in hair is directly proportional to the simultaneous concentration in blood. Once incorporated into the hair strand, the concentration of mercury does not change. Thus, the concentration profile along the strands of hair represents a recapitulation of previous blood concentrations. The hair growth rate is approximately 1 cm/month so that the distance from the scalp in centimeters corresponds to the number of months of exposure before the time of collection of the sample. In the example given in Figure 18, it was possible to recapitulate, from the analysis of one hair sample, the past exposure over a period of almost 2 years, including the entire period of pregnancy. The close parallel between maternal hair and blood concentrations is obvious. It has been possible to use the approach of analyzing segments of hair to obtain an estimate of interindividual variability in biological half-times of a great number of individuals (Figure 13).

Caution must be observed when applying this approach. Hair samples are liable to external contamination, and satisfactory washing procedures have not been established. Furthermore, each metal should be tested to see whether hair concentration is proportional to blood concentration. Thus, it is difficult to find an indicator medium that is useful for estimation of exposure or concentration in critical organs for a wide range of metals. Blood is probably the single biological medium that has greatest general applicability. In some instances, blood values are not easily interpretable without detailed information on previous exposure history, etc. An example of this is cadmium, for which metal there is no direct relationship between blood concentration and the concentration in critical organs. Blood cadmium may thus be used to estimate exposure but does not necessarily reveal anything about risk of adverse effects if exposure has been highly variable over a period of years.

Because some biological samples (e.g., urine samples) are readily available, measurements performed on such samples may also be useful as a tool in the control of exposure (i.e., if analytical results obtained reflect recent exposure) but not concentration in critical organs. Considerations of biological monitoring for a number of metals and their compounds have been presented by Clarkson *et al.* (1988) and in Chapter 4.

When embarking on a program of biological monitoring, it is advisable to acquaint oneself with the toxicokinetic model and patterns of toxicity for the particular metal compound to be analyzed (see the specific chapters on individual metals). This is necessary to make the best possible choice.

Difficulties in the chemical analysis should also be given due consideration, because faulty chemical analysis can make an entire monitoring program entirely useless (WHO, 1979; see also Chapters 2 and 4).

CHAPTER

4

Biological Monitoring and Biomarkers

ANTERO AITIO, ALFRED BERNARD, BRUCE A. FOWLER, AND GUNNAR F. NORDBERG

ABSTRACT

Biomonitoring was developed for the assessment of the health risks from exposure to metals at work, and the approaches and concepts of biomonitoring are derived from such exposures. At present, biomonitoring is increasingly used to assess exposure from the environment. Biomonitoring and assessment of external exposure are complementing activities, where the exposure assessments are much more widely applied, especially when the number of chemicals concerned is considered; environmental analysis also offers the distinct advantage of speciation analysis, which is very poorly developed for biomonitoring. Biomonitoring, on the other hand, provides information on exposure from all sources, and via all absorption routes, and also considers accumulation of the chemical in the body. Biomonitoring using exposure biomarkers thus considers interindividual differences in the absorption, whereas use of effect biomarkers also considers interindividual differences in sensitivity. Few effect biomarkers, however, have been validated. Biomarkers of susceptibility have so far not been adapted for use in metal toxicology. The major challenges of biomonitoring are the development of monitoring methods, which are inexpensive enough to be applied at a frequency that makes possible meaningful biomonitoring of metals with a short half-time; development of exposure biomarker guidance values specific to individual species of different metals; expansion of the repertoire of validated effect biomarkers; and validation and application to effect monitoring of the "omic" technologies.

1 INTRODUCTION

We approach the 80th anniversary of biological monitoring: in 1927, the first paper was published on the use of the concentration of lead in urine in exposed workers as means of diagnosing lead-induced industrial disease (Badham and Taylor, 1927). Throughout these 80 years, concepts and practices in biomonitoring have been developed mainly in relation to metals, and still today exposure to metals is the main area of application of biomonitoring.

Detailed description of the state of art of biomarkers for individual metals will be given in the respective chapters. This chapter will describe and discuss general principles and in some cases illustrate the principles by a few examples. In risk assessment of metal exposures, indicators of effects and indicators of exposure have been considered in several consensus documents published since the 1970s by the Scientific Committee on the Toxicology of Metals of the International Commission of Occupational Health (ICOH) (Belman and Nordberg, 1983; Clarkson *et al.*, 1988; Nordberg, 1976; Nordberg and Skerfving, 1993). Authoritative reviews on different aspects of biological monitoring, including analytical methods, reference values, and guidance values, have been published by IPCS, WHO, and others (Aitio, 1999; Albertini *et al.*, 2000; DFG, 1985–2003; 2006; IPCS, 1993; 2001; 2006; WHO, 1996 a,b). The term "biological monitoring" (synonym, biomonitoring) has been used for a long time and more widely during the past two decades (Berlin *et al.*, 1984; Clarkson *et al.*, 1988) to describe exposure and internal dose of metals by measurements in biological samples such as blood and urine and other human tissues and fluids.

The term has more recently been extended to also include other biomarkers, as will be described. The term "biomarker" was introduced during the past 20 years into the field of metal toxicology, environmental, and occupational health (IPCS 1993, 2001, IUPAC 2004; US NRC, 1989).

A *biomarker* is an indicator signaling an event or condition in a biological system or sample, giving a measure of exposure, effect, or susceptibility (IUPAC, 2004).

A *biomarker of exposure* relates exposure to a xenobiotic (i.e., a metal or metal compound) to the levels of this substance, or its metabolite, or of the product of an interaction between the substance and some target molecule or cell that can be measured in a compartment within an organism (after IUPAC, 2004, IPCS, 1993).

As seen from this definition, biomarkers of exposure include indicators of exposure, internal dose, and dose/concentration in critical organs, as in the classical concept of biological monitoring. It also encompasses measurements of interaction between the substance and macromolecules (e.g., DNA and protein adducts and enzyme complexes) as will be discussed in later sections of this chapter. The concept "biomarker of exposure" thus includes all aspects of exposure and internal dose from the contact with the external environment through internal dose to the dose at cellular level and at the molecular target site. The ultimate measurement of dose (i.e., interaction with target molecules) is also included.

Biomarkers of exposure are indirectly related to the occurrence of disease via information about the relationships between the exposure biomarker (the dose at the target) and the development of disease. Although relationships between exposure biomarkers and effects are indirect, biomarkers of effects or susceptibility have a direct relationship to the occurrence of disease or other adverse health effects. Definitions of the latter concepts are as follows:

A *biomarker of effect* is a biomarker that, depending on its magnitude, can be recognized as associated with an established or possible health impairment or disease (IUPAC, 2003; WHO, 1993).

A *biomarker of susceptibility* is a biomarker of an inherent or acquired ability of an organism to respond to exposure to a specific substance (IPCS, 1993; IUPAC, 2003).

In Figure 1, relationships have been outlined between exposure and dose, environmental monitoring,

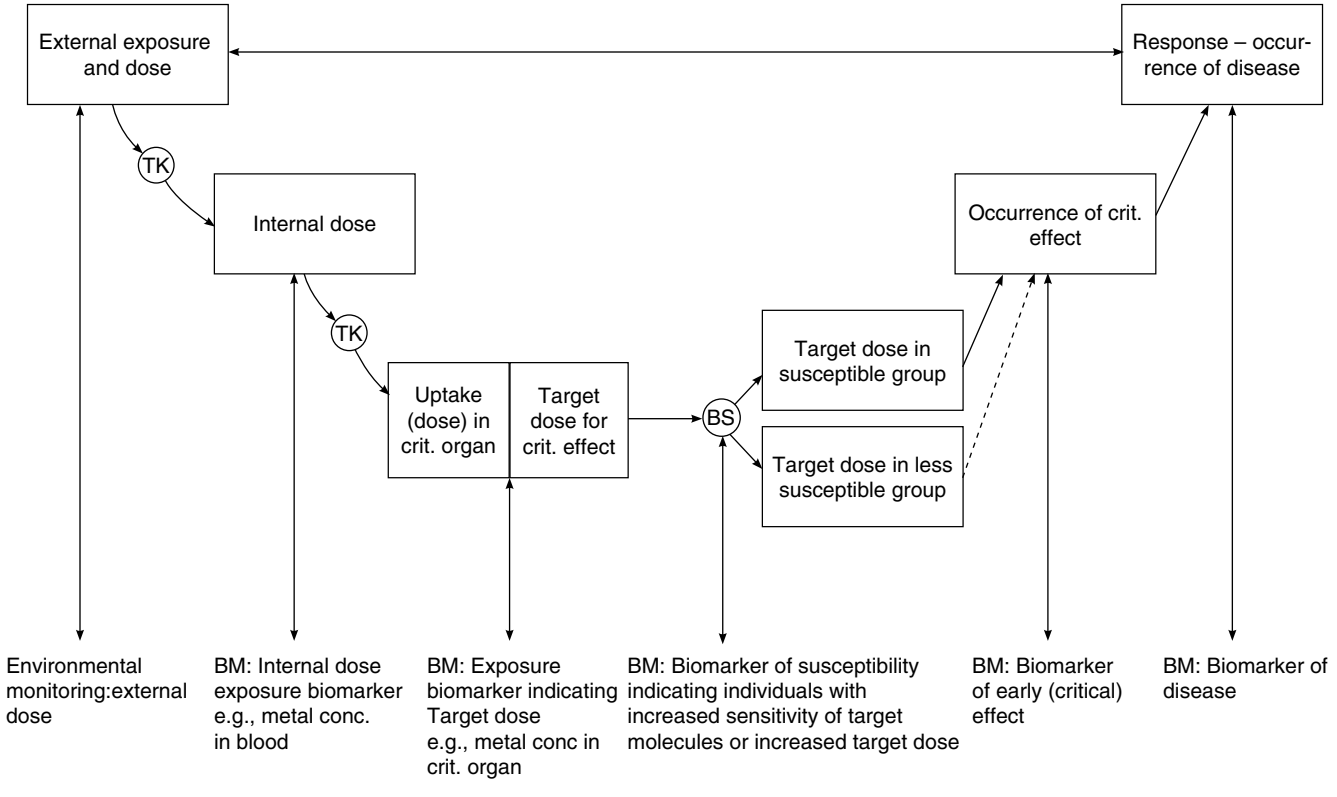

FIGURE 1 Relationships between external exposure and dose, environmental monitoring, biological monitoring (BM), and response. The importance of toxicokinetics a (TK) and susceptibility to adverse (critical) effects (as shown by biomarkers of susceptibility–BS) is indicated.

biological monitoring (BM), and response. External exposure can be measured by environmental monitoring as the concentration of a metal compound in air or food. The dose or intake per day can be estimated from the measured concentrations and estimated daily ventilation volume (inhaled dose) or amount of food consumed (oral dose or oral intake). A proportion of an oral or inhaled dose is taken up in the body, initially to blood. Metal concentration in blood, if monitored, is an *exposure biomarker of internal dose*. The proportion of the external dose absorbed into the body can be derived, and such information is an important aspect of the toxicokinetic or metabolic model of the metal compound in question and impacts on the adverse effects induced. Another important component of the toxicokinetic model describes the relationship between levels in indicator media (biomarkers), such as blood and urine, and accumulation (dose) of the metal in critical organs. The latter is closely related to the target dose. Accumulation of metals in critical organs can sometimes be monitored by external measurements such as Cd in kidney by *in vivo* neutron activation, thus providing *an exposure biomarker, indicating concentration in critical organ*. For effects occurring in internal organs, direct measurements of the interaction between the metal and target molecules are seldom possible. However, in some instances, there is a close relationship between effects in blood and in critical organs. An example is the interaction between lead and enzymes in the bone marrow, which can be monitored by measurements in blood, and they can, thus, be a useful biomarker of target dose. In some instances, it may be possible to use DNA adducts in blood cells as a biomarker of target dose causing carcinogenic effects in body organs. However, documentation of such relationships for metallic compounds is limited at present and may only be applicable for a few metal compounds, as pointed out in the Chapter 5.

In some instances, it may be possible to define population subgroups with particular sensitivity by studying polymorphism in enzymes and membrane molecules as *biomarkers of susceptibility*. However, actual examples of successful application of biomarkers of susceptibility in risk assessment of metal exposure so far are limited. Variation in binding of metals to sequestering proteins before interaction with target molecules may also form a basis for classifying subpopulations into susceptible and less susceptible groups. The observations of such a relationship using metallothionein gene expression in peripheral blood lymphocytes as a biomarker of renal susceptibility to damage caused by cadmium (Lu *et al.*, 2001) are interesting but need to be confirmed, refined, and developed.

Some examples of useful *biomarkers of early (critical) effects follow:* The detection of early damage to the kidney tubules by cadmium using urinary levels of low molecular weight proteins such as $beta_2$-microglobulin, protein HC, and the enzyme *N*-acetylglucosaminidase. *Biomarkers of disease* are monitoring markers used clinically in the diagnosis of disease. In the case of cadmium, damage to the kidney, excessive excretion of $beta_2$-microglobulin (>1 mg/g Crea), or decreased tubular reabsorption of phosphate are such markers for tubular damage.

In biological monitoring of toxic metals, knowledge about the toxicokinetics of the compound is of crucial importance. Because many metals display differentiated and specific patterns of disposition among tissues in the human body, and for several metals adequate knowledge is available on toxicokinetics and metabolic models, this situation can be seen as a special aspect of metal biomonitoring. Other aspects are that it has been possible for a long time to perform relatively precise determinations of metals in biological indicator media at a reasonable cost. The database and experience of biological monitoring of metals thus is considerable. However, the data are focused on a limited number of metals, whereas data on other metals are still incomplete or even lacking.

For cadmium and lead, biomarkers of effect have been available for a long time, and they are reasonably well validated. This effect of cadmium, renal tubular damage, is considered a critical effect.[1] However, in the case of lead, adverse effects on the central nervous system, notably in children, are considered to be the critical effect, and it is not known how closely the hematological effects of lead are related to the neurotoxicological effects. At present, available biomarkers of nonthreshold effect or target dose have not been validated and cannot be widely used or recommended for routine assessments. Considerable efforts are needed in validating recently developed effect and susceptibility biomarkers (Albertini *et al.*, 2000; IPCS, 2001).

2 SOURCES OF PREANALYTICAL AND ANALYTICAL ERROR

A number of errors may occur before the chemical analysis of the substance of interest, and analytical errors may also occur in the chemical analysis. When using exposure biomarkers in the classical sense of biological monitoring (i.e., analyses of metals in blood,

[1]For a discussion of critical effects in occupational and environmental health see Nordberg (1976), and Chapter 14.

urine, and other biological materials), such errors have been identified, and methods for their control have been developed. The errors include errors in design and sampling, such as poorly defined criteria, and biased selection of individuals for sampling. A number of errors can be grouped as physiological and kinetic, such as timing of specimen collection (in relation to the exposure), diurnal, meal- and exercise-induced variation, other variations in distribution (e.g., those induced by changes in body posture and by application of tourniquet). A further fundamental aspect important in the exposure biomonitoring of metals is contamination (and sometimes losses) during blood and urine specimen collection, storage, pretreatment, and analysis (Aitio, 1981; Aitio and Järvisalo, 1984; WHO, 1996). The importance of contamination depends on the level of interest so, for example, contamination is a much more important problem for the determination of plasma lead, where only a small fraction of whole blood lead is found, than with determination of lead in blood cells or whole blood. Vials used for collection and storage of samples should not contribute any significant amounts of the metal being analyzed. For example, glass tubes should not be used for aluminum analyses, Cd-softened plastic tubes should not be used for Cd analyses, etc. For metals constituting components of steel (e.g., Cr, Mo, Ni, Mn, V), considerable contamination can occur from steel needles during blood sampling, and special precautions are necessary to obtain meaningful results (see Chapter 2, Section 8). Smoking chemists performing the analyses can sometimes contaminate samples from metals present on their skin (e.g., cadmium). Improper calibration and standardization of instruments used for analyses can introduce analytical errors. Errors have been considerable in the past, as seen, for example, in the development of what is considered to be the reference values for several trace elements in blood or urine. Appropriate sampling, quality control, and descriptions fulfilling the recommendations by IUPAC (Cornelis *et al.*, 1995) have been provided in some articles, and such information has allowed the definition of reference values for some metals (Nordberg, 1996), but a continuous need exists for critical evaluation and continuous emphasis on quality control aspects for biomonitoring programs to generate good and useful information.

For biomarkers of target dose (e.g., metal–enzyme complexes, DNA and protein adducts) similar quality control aspects are warranted, but such biomarkers are still mainly a research tool at present, and very few, if any, have been validated, and quality control conditions have usually not been specified in detail.

Some biomarkers of effects have been validated according to principles developed in clinical chemistry. Further validation activities are warranted (Albertini *et al.*, 2000; IPCS, 2001).

3 QUALITY ASSURANCE; REFERENCE MATERIALS

The International Standardization Organization Guide ISO 17025 (ISO, 2000) general requirements for the competence of analytical laboratories and instructs on the main components of quality management, that is, quality system, audit, and review. Quality management has been proposed as a prerequisite for laboratory accreditation. An integral part of quality management is continuous assessment and control of quality; this can be divided into internal quality control and external quality assessment. A guideline has been published for the internal quality control for clinical chemistry laboratories (Büttner *et al.*, 1983). The IUPAC guideline for external quality assessment (proficiency testing) (Thompson and Wood, 1993) is being updated, with special emphasis on analyses for which the number of laboratories is small, which is the case for most biomonitoring analyses.

Internal quality control comprises the set of procedures undertaken by the laboratory for the continuous monitoring of operations and results to decide whether the results are reliable enough to be released. Internal quality control mostly depends on repetitive analysis of the same, homogeneous control specimens (reference materials). Together with replicate analyses of all samples, an estimate of the imprecision and changes in the systemic error, bias, may be obtained. By use of certified reference materials, accuracy may be ascertained (see Chapter 2, Section 12). Although the availability of reference materials, and notably of certified reference materials, has improved recently, for many elements certified reference materials (i.e., blood and urine) and concentration ranges relevant for biomonitoring are not available in matrices. At present, reference materials with specified concentrations of metals are presently available from the Institute for Reference Materials and Measurements, Reference materials unit, Geel, Belgium, web page: *www.irmm.jrc.be*; International Atomic Energy Agency, Vienna, Austria, web page: *www.iaea.org*; or National Institute of Standards and Technology, Gaithersburg, MD, USA web page: *www.nist.gov*

External quality assurance: The other main procedure to assist in achieving good quality in metals analyses are programs providing comparison among results from different laboratories. Such comparisons can be organized ad hoc by interested laboratories or more efficiently by joining an available external quality

assessment scheme. Guidance on the organization and running of such proficiency testing has been published and summarized (WHO, 1996). Examples of such schemes are those available from German Society for Occupational and Environmental Medicine, Erlangen, Germany *http://www.g-equas.de/*; United Kingdom National External Quality Assessment Service, *http://www.ukneqas.org.uk/*; Robens Institute of Industrial and Environmental Health, Guildford, UK *http://www.su rey.ac.uk/SBMS/eqas/index.html*; and Toxicology Centre, Québec, Canada *http://www.inspq.qc.ca/ctq/page/*

4 SPECIMENS IN USE; URINE SAMPLE STANDARDIZATION

It was mentioned previously that samples from a number of human tissues and fluids could constitute adequate materials for biological monitoring. However, the samples most often used are blood samples and urine samples.

4.1 Urine

The kidneys continuously produce urine. Blood is flowing through the renal glomeruli where fluid from blood plasma is filtered into the renal tubules. Such filtrate (i.e., primary urine) contains substantial amounts of glucose, salts, amino acids, and small proteins that are reabsorbed in the renal tubules together with most of the water. Determinations of metals in urine often can be used as an exposure biomarker, indicating internal dose of the metal, because a relationship often exists between levels in blood and other tissues and levels in urine. In steady-state conditions, excretion and absorption are balancing each other, and such conditions will make it possible to derive the absorbed dose from excretion. However, in practice, it is difficult to know whether steady-state conditions are at hand or not. Regardless of whether strict calculations are possible or not, knowledge about the toxicokinetic model of the metal under study is helpful when interpreting the results of BM. For metals that are accumulating in renal tubules (e.g., Cd, Hg), a relationship may also exist between renal and/or body burden and urinary excretion of the metal. This may be particularly useful for BM, because urinary excretion of the metal (e.g., Cd) may be a useful biomarker of dose in the kidney, which may be the critical organ, and the resulting damage constituting a critical effect.

Determinations of metal concentrations in urine for biological monitoring purposes and various means for their adjustment have been discussed (Aitio, *et al.*, 1994; Araki, 1980; Araki and Aono, 1989; Araki *et al.*, 1990; Diamond, 1988; Nieboer *et al.*, 1992). Analysis of metal concentration in urine in combination with measurement of the volume of urine excreted during a specified, not too short, time gives a measurement of *timed urinary excretion* of the metal, and this may be a useful exposure biomarker and also a biomarker of dose in the critical organ. The collection of such timed urine samples is usually preferred, not only for exposure biomarkers but also for effect biomarkers determined in urine (e.g., enzymes or other proteins). However, the total excretion, even during a longer interval of several hours, even 24 hours, may vary, depending on urine flow (Araki *et al.*, 1990), and correction for urine flow is necessary even for timed urine samples. The classical timed urine sample is the one obtained during 24 hours. Such a long time is advantageous, because it will include diurnal physiological variations. However, for routine biological monitoring, it is, in practice, not possible to collect all urine voided during such a long time, and shorter intervals may be used. Then imprecision in collection may be a problem, because it may be difficult to know whether a person has completely emptied the bladder or not. By hydrating the person, urine volume will be kept high, and the influence of this problem decreases. Collection of timed urine samples requires very detailed instructions and sometimes training programs and supervision.

In routine biomonitoring, the only available alternative is to use *spot samples.* When this is done, an adjustment for dilution can be done by various methods, the two most common ones are by creatinine and by relative density.

Creatinine (*CR*) is excreted in urine in relation to muscle mass. In persons with normal glomerular function, the amount excreted every day is relatively constant in the same person if the physical activity is constant and the same diet is consumed every day. However, creatinine clearance increases with increasing urine flow, and thus correction with creatinine is not an accurate correction for differences in the hydration state. Because of the dependence on muscular mass, creatinine correction gives a different estimate of the dose in men and women and in children. There is also a variation in the creatinine excretion in population groups on a variable diet. With variable physical activity, a considerable variation in CR excretion may occur even in the same individual. According to Alessio *et al.* (1985), the intraindividual coefficient of variation ranged from 10–50% of the mean. Adjustment by CR is done by analyzing the concentration of this substance in the same urine sample as the metal is analyzed. The concentration of metal is then expressed in relation to

CR (e.g., milligrams of metal per gram of CR or, preferably, micromoles of metal per moles CR).

The *relative density* of urine is the other commonly used measurement for adjustment of spot samples. In contrast to creatinine correction, relative density correction only concerns differences in urine density (i.e., changes in urine flow). The adjustment is usually by specific gravity increment in relation to a reference, most commonly a density of 1.018 or 1.024 using the formula:

$$C_s = C_o \times RD_s/(RD_o - 1.000), \text{ where:}$$

C_s = corrected concentration; C_o = observed concentration, RD_s = reference relative density increment (usually 1.024 or 1.018 − 1.000 = 0.024 or 0.018), and RD_o = observed relative density. It, thus, makes a big difference what the reference relative density is: using the value 1.024 results in corrected concentrations 33% higher than those when 1.018 is applied; the reference RD must be known when different studies are compared.

Araki (1980) has made extensive comparisons of the different corrections for metal excretion in urine and has derived a generic equation for the correction of concentrations in urine depending on the rate of urine flow:

$$C_s = C_o \times F^b$$

where C_s = concentration corrected to urine flow of 1 ml/min; C_o = observed concentration, F = observed urine flow ml/min; b = chemical-specific constant.

It can be seen from the equation (Aitio *et al.*, 1994) that when the chemical-specific constant approaches zero, no correction is needed (i.e., the urinary concentration is constant and independent of urine flow). This, however, does not seem to be true for any chemical. When b approaches 1, the corrected concentration is proportional to urine flow rate, and correction to relative density is accurate. This is the case for mercury (Araki *et al.*, 1990) and nickel in some circumstances (Nieboer *et al.*, 1992). At the value of b of 0.67, which is the constant for creatinine (Araki *et al.*, 1990), correction to creatinine excretion would seem most appropriate. Manganese and cadmium are candidates for this approach, whereas chromium and copper are intermediate and correction to relative density and creatinine are equally good (Aitio *et al.*, 1994). However, for several chemicals, interindividual variation of the constant b is very large (e.g., cadmium, manganese), and consequently, no general correction method will give accurate results. Also, the constant b may not be truly a constant but may depend on the concentration.

When the urine is very dilute or very concentrated, it is unlikely that any correction will give accurate results. Thus, when the relative density falls outside the range 1.010–1.030, a new specimen should be analyzed rather than a highly unreliable result reported. For creatinine, concentrations 3 and 30 mmol/L can be used as such limits.

4.2 Blood

Blood is composed of cells and plasma. Serum is obtained after clotting. All these blood components may be used for BM.

According to general concepts in toxicokinetics, the area under the plasma metal concentration curve (AUC) can be used to calculate absorbed dose after short-term exposure. However, for some metal species, this measurement is difficult and may not be possible in practice. It is, for example, very difficult to measure the relevant concentration of mercury vapor in blood plasma, because concentrations are low, and there is a rapid uptake in membranes of blood cells and subsequently by brain tissue (see further discussion in Chapter 33). However, plasma (total) mercury concentrations can be quite useful in BM of mixed methylmercury and inorganic mercury exposures, because they reflect predominantly inorganic Hg. Blood cell Hg, on the other hand, reflects mainly methylmercury exposure (but also partly inorganic Hg) as discussed in detail in Chapter 33. Because for several metals (e.g., Pb, Cd, MethylHg), plasma or serum levels are considerably lower than whole blood or blood cell levels, detection limits of chemical analyses have been a limiting factor. Serum or plasma values also are more prone to problems of contamination as mentioned previously. Even a limited degree of hemolysis will seriously influence (e.g., Pb) serum values because of the concentration gradient between blood cells and plasma for Pb. Whole blood metal determinations are widely used in BM. With the ongoing improvements of analytical methods and their detection limits, this may change in the future, but until then, a lot of the available databases are for whole blood values. In long-term exposures, like those prevailing in occupational and environmental situations, short-term fluctuations in plasma levels related to variations in hourly uptake may be of limited interest, because it is the uptake of the metal in the critical organ that is of interest, and this uptake and accumulation may be more closely related to the level in blood cells or urine. However, it is obvious that an understanding of the toxicokinetics of the metal compound in question (cf. Chapter 3 and the chapters on individual metals) is of fundamental importance for interpretation of levels of metals in various blood components.

Blood has a more constant composition than urine, and results of metal analyses are expressed as concentration values (i.e., mg/L, µg/L [or preferably, mmol/L, µmol/L], etc. Some metals (e.g., Pb, Cd) are bound mainly to blood cells, and it may be useful to adjust obtained values by hemoglobin concentration or hematocrit value (cf. Hense, 2003). Despite the obvious advantage of such adjustment, it is seldom practiced.

Another aspect when using metal analyses in blood for BM is the impact of hemolysis. Although some metal exposures may themselves induce hemolysis (e.g., mild hemolysis in occupational lead exposure and severe hemolysis in arsine poisoning), of more practical importance are other conditions giving rise to hemolysis such as glucose-6-phosphate dehydrogenase deficiency and hemolytic anemias.

5 REFERENCE VALUES

Although for many organic chemicals, the sole exposure may be at work, and thus any detected concentration in biomonitoring means that occupational exposure has taken place, this approach for the identification of the exposed people does not work for most metals: There is always an exposure from the environment (mostly from the diet). Thus, the identification of the exposed individuals in biomonitoring is on the basis of a comparison to reference values. IUPAC has given guidance on the development of reference values, reference intervals, and reference limits, and recommended the terminology to be used (IUPAC, 1993). For the biomonitoring of an occupationally exposed population, the reference limits are the highest (usually 95th percentile) concentrations of the element (reference values) observed in an occupationally nonexposed population that is similar in terms of ethnicity, sex, age, environmental exposure, and also smoking and other social habits to the occupationally exposed population studied (reference population). It is of fundamental importance that reference values are not influenced by contamination and other errors encountered in trace metal analyses (cf. foregoing sections). Reference values for a number of metals have been published from various countries. There is considerable variation among countries, depending on a combination of geological factors, dietary habits, and anthropogenic exposures that may affect an entire country (Iversen *et al.*, 2003). Examples are mercury levels in blood and hair that are much dependent on the fish consumption in the population studied (McDowell *et al.*, 2004; JECFA, 2004). Cadmium levels are higher in Japan than in other countries, probably because of a low-level contamination of rice that originates from a combination of geological factors and mobilization of Cd into the environment by human activities (Herber *et al.*, 1997). Substantial increases in the serum selenium concentration was observed in Finland, when selenium-enriched fertilizers were taken to wide use to counteract the low selenium intake caused by the low selenium content, high pH, and high iron content of the soil (Aro *et al.*, 1995).

6 ETHICAL CONSIDERATIONS

Biomonitoring produces data on an individual and, thus, information that is confidential. The results must not be used against the worker, thus, for example, compliance with legally binding blood lead values must not be achieved by sacking those who have high values. A worker's biomonitoring history must not be used to discriminate against him or her (e.g., at hiring—employers might wish to decide not to hire anyone for a job with exposure to lead with a previously elevated blood level or anyone with a documented previous nonexposure to lead). All BM activities require an informed consent from the persons monitored, and the samples may only be used for the stated purpose, thus, for example, ethanol, drugs or HIV, must not be analyzed). Results should be dealt with in the same way as other clinical chemistry data (i.e., they would not be disclosed on an individual basis to anybody except the person monitored and his or her doctor). It may, however, be necessary in some instances to make exceptions to this rule when there is legislation requiring biological monitoring of workers and it is required that results are communicated to the employer also. It is then important that the physician obtains informed consent before employment for such jobs. For further aspects, *cf.* Aitio (1999).

It is generally considered that ambient monitoring ensuring that no harmful exposures occur is preferred over BM, which can be seen as using the worker as a sample-collecting device. The problem is especially acute when the worker is exposed to genotoxic carcinogens, for which no exposure is considered to be safe.

7 BIOMARKERS OF EXPOSURE

7.1 Analytical Approaches

In-depth discussion of analytical methods for elements in different matrices, including those used in biomonitoring, is given in Chapter 2. The detection methods most widely used when analyzing metals in biological specimens are graphite furnace atomic absorption spectrometry and inductively coupled plasma mass spectrometry. For elements that can be converted to hydrides,

hydride generation atomic absorption spectrometry and atomic fluorescence spectrometry may be alternatives with good sensitivity. Atomic emission spectrometry is also a sensitive metal analysis method and offers the possibility of multielement analysis; however, in biomonitoring, this special feature is seldom very useful. For routine analysis, electrochemical methods are not very well suited for biomonitoring purposes.

7.2 Speciation in Biomonitoring

With few exceptions, routine biomonitoring depends on the analysis of the total content of an element as the biomarker rather than a speciation analysis. For some elements, this simplistic approach is sufficient; this is notably the case when the key effect of the element on the health is systemic and the relationship between the total element concentration and the effect is known. Thus, most of the time in occupational exposure, a reliable prediction of long-term health effects may be made from (total) lead in blood, (total) mercury in blood or urine, and total cadmium in blood or urine. However, in exposure to tetraethyl lead, or in exposure to methylmercury from diet, these analyses may be very misleading. This error may be even more marked when there is concomitant exposure to different species of the same metal. As is evident from element-specific chapters in this volume, the toxicity, including mutagenicity and carcinogenicity, of several metals very much depends on the identity of the elemental species or, for example, the oxidation state (see chromium, nickel, arsenic, mercury), inorganic versus organic compounds of the same element (see mercury, arsenic, tin). To overcome these problems, speciation analysis is an important aspect in biomonitoring now and will continue to be in the future. Speciation in biomonitoring may be approached by three different strategies: analysis of specific element species (as of now, practically limited to arsenic), fractionation by chemical analytical means to organic versus inorganic species (mercury, lead in blood mainly), or application to the analysis of information on the differences in the distribution of different species of an element (mercury in plasma, blood cells, urine; chromium in erythrocytes/plasma) (IPCS, 2007).

Even when the total concentration of an element is measured, exposure indices of the individual species to which the population is exposed should be developed and used when appropriate (IPCS, 2007).

7.3 Kinetics and Sampling: Timing and Frequency

The kinetics, especially kinetics of the disappearance, is a key element in the interpretation of the results from biomonitoring, and it also determines the timing and frequency of the sample collection.

When the half-time of the metal in the body fluid in which it is measured is long, the concentration reaches an equilibrium in continuous (or repetitive, e.g., daily) exposure and reflects long-term intake. The concentration thus forms a reliable basis for the assessment of long-term health effects, and the timing of sample collection during the working day or even working week is not important.

When the half-time is shorter, from a few hours to a day, there is a remarkable variation in the concentration over a working week and working day, and thus the concentration measured also reflects exposure over a short time and may not be representative of the average exposure over several days (the exposure also being variable, often with a shorter half-time than that of the concentration in blood/urine). A meaningful picture of the average exposure thus may only be obtained from several samples.

If the half-time is shorter than 6 hours, it may be impossible to do any quantitative biomonitoring. Concentration in the urine is related to the time-weighted average concentration in blood (or actually to the free concentration in plasma). Thus, for elements with a short half-time in the blood, it may be kinetically advantageous to analyze the urine rather than blood.

For many, if not all, metals, the disappearance from the blood exhibits several consecutive half-times, and thus by an appropriate sampling strategy, an idea of exposure over different time periods may be obtained (e.g., concentration of chromium in the urine of manual metal arc welders on Friday afternoon reflects mainly exposure over that day, that in a Monday morning urine specimen, exposure over the preceding week) (Aitio, 1988).

7.4 Interpretation of Results

Biomarkers of exposure may be used to identify exposed individuals or groups, quantify the exposure, assess the health risks, or assist in diagnosis of (environmental or) occupational disease. For the identification of the exposed, the analytical results are compared with the reference interval for the element in the matrix studied (see Section 5). Reference intervals are derived from reference values observed in a reference population, usually as the 95th percentile, meaning that 1 of 20 nonexposed will give a result outside the reference range. Because the reference values are different in different geographical locations (mainly because of variation in exposure to the element in question in the diet), reliable identification of exposure crucially depends on reference values determined in the area of analysis

and is up-to-date. For example, reference values for blood lead have changed drastically in many countries in recent years. A biomarker level above the reference limit does not tell anything of a possible health hazard; it simply means that the individual has been exposed to a greater extent than the reference population.

Reference values are intended to identify exposed individuals; if biomarker concentrations are available for several members of a group, a more appropriate assessment of the exposure situation of the group is obtained from a statistical comparison of the exposed group and the reference population.

Quantification of exposure relies on knowledge of the relationship between the exposure, usually measured as the time-weighted average concentration of the chemical in the air, and the concentration at a specified time of the biomarker in the blood or urine or, in rare cases, other biological media.

Assessment of health risk from biomonitoring may be achieved if the relationship between the effects and the biomarker concentrations is known. This is the case for lead in blood, cadmium in blood and urine, mercury in blood and urine, and, to a more limited extent, for arsenic in urine (see Chapter 19). For these elements, epidemiological studies area available, which have studied the relationship between the biomarker level and long-term health effects. Such studies are difficult to carry out, and often the study results are not very consistent.

For some chemicals (styrene, carbon disulfide), an assessment of health risks may also be obtained indirectly from the relationship between health effects and external exposure (concentrations in the air) and that between the biomarker concentration and the concentration in the inhaled air. For metals, however, this approach so far has not been used successfully for inhalation exposures. For oral exposures, however, a good correlation has been reported between cumulative intake of cadmium through food and health effects.

The interpretation of results obtained from biomarker studies, particularly molecular or "omic"-based biomarkers, requires correlative validation with other health outcome parameters such as more standard clinical chemistry markers and ultrastructural/histopathological evaluations for preclinical disease and ultimately overt clinical manifestations of disease (Fowler, 1980). These data are essential for interpreting and defining the predictive power of a given biomarker endpoint. Usually, such studies are conducted in experimental animal model systems, where it is possible to conduct all the necessary correlative studies and then extrapolate these findings to exposed human populations. Such extrapolations are usually possible because many biomarker systems (e.g., the heme pathway) are highly conserved across species.

Factors that may complicate interpretation of biomarker endpoints include species differences in metabolism of chemical agents, genetic susceptibility factors, nutritional status, and the presence of other compensatory molecular systems such as metallothionein induction, stress proteins, and glutathione synthesis. These protective systems, which are finite, may alter the expected shape of the dose-response curve for metals/metalloids with regard to biomarker responses as long as they are able to compensate for exposure to a given toxic element.

In addition, interpretation of results of biomarker studies for metals will also be influenced, particularly at low dose levels, by concomitant exposure to combinations of toxic elements (Fowler *et al.*, 2004; 2005; Mahaffey *et al.*, 1981). Interactions between toxic elements that are frequently additive and may also produce unexpected alterations in predictive responses to a given toxic element on an individual basis. Because humans are frequently exposed to mixtures of toxic elements (e.g., Superfund sites), it is critical to take such combined exposures into account for risk assessment purposes.

Chemically induced adverse health effects or diseases usually are not different from the same disease induced by other causes, and thus the causal diagnosis or etiognosis depends on the diagnosis proper plus a history of exposure considered sufficient to cause the disease. In the assessment of the history of exposure, biomonitoring is probably the best means, because it provides direct information of the exposure of the individual.

7.5 Biomarkers of Exposure as a Complement to Industrial Hygiene Measurements

Biomonitoring of metals is most widely applied in occupational health and thus has a similar objective as industrial hygiene measurements (i.e., mostly measurement of the concentration in the air). Although it is clear that for most chemicals, industrial hygiene measurements are the best and often the only way of assessing exposure, the two approaches complement each other because their scope and performance are not identical.

Air is a homogeneous and relatively simple matrix, and therefore, sample preparation is often simple and straightforward, and analytical methods relatively easy. When the metal compound is present in the air at low concentrations, the amount of air collected on the filter may be increased, and thus the sensitivity of the analysis is improved. Because air measurements also have a long tradition, established methods exist for practically every metallic element. For several

elements, fractionation and speciation analysis methods are available (see Chapter 2), and thus important qualitative information on the exposure may be gained from such analyses.

On the other hand, concentrations of chemicals in workplace air are seldom stable but fluctuate with time and are different in different locations. The amount of a chemical that reaches the alveolar region of the respiratory tract is directly related to the volume of respiration and thus to the workload. Exposure peaks often coincide with increased workloads caused by, for example, the malfunctioning of a closed process. Several chemicals, including some metal compounds, are absorbed also via the dermal route, and absorption through the skin is generally not related to the concentration in the air. Even when the exposure takes place mainly by inhalation, the bulk of the actual absorption may be through the gastrointestinal tract (notably aerosols with particle sizes too large to lead to deposition in the alveolar region). Personal working habits vary, and individuals may absorb different amounts of chemicals in apparently similar conditions. Protection afforded by masks varies, depending on the individual who wears it and on the condition of the mask. Furthermore, biomarker, in contrast to industrial hygiene measurements, reflects the accumulation of the chemical in the body. Biomarkers of exposure, which reflect all this variation in exposure and, at the same time, exposure from all sources, are thus closer than industrial hygiene measurement to the toxicologically important concentration of the chemical at the target site (Aitio, 1999).

Biomarkers of exposure do not consider interindividual or intraindividual differences in the toxicodynamics of the chemical, which are covered in an ideal case of effect biomarkers (see Section 8). Biomarkers do not differentiate between sources of exposure and to decrease the risk from the chemical, it may be necessary to consider (and analyze) separately, from where the exposure is derived, from work or from for example hobbies, or environment.

Biomarkers of exposure reflect the amount of the chemical in the systemic circulation, and models have been developed to predict concentrations in other compartments in the body. However, a major obstacle in the interpretation of biomonitoring data involves concentration and effects at the site of entry, such as the lungs after exposure to particulates containing metals; concentrations in the urine or even blood of nickel tell little of the concentrations or the health risks in the lungs after exposure to soluble or insoluble nickel. Similarly, irritation, a mainly concentration-derived effect, is not easily assessed from exposure biomonitoring data.

8 BIOMARKERS OF EFFECTS

Biomarkers of effects are molecular tools that can serve to identify changes or effects occurring in the organism as a result of exposure to any given toxicant. In the case of exposure to toxic metals, tests relying on effect biomarkers are usually only used when excessive metal levels are found in exposed populations or their environment. The combined use of biomarkers of effects and biomarkers of exposure is also important for a correct interpretation of the data, because a diagnosis of metal intoxication relying on biomarkers can be made only if the observed effects are, indeed, associated with an excessive exposure or body burden of the metal. To be applicable to the diagnosis of intoxication or to the monitoring of populations at risk, biomarkers must meet several criteria. First, they must be sensitive enough to detect effects at a stage when these are still reversible or at least not yet predictive of further organ degradation. They must also be specific of the target organ, and if this is not the case, sufficient information must be available on the possible confounding factors. Finally, biomarkers of effects must be measurable in the least invasive way possible by use of easily accessible biological media such as urine, blood, sputum, exhaled air, or exhaled breath condensate. Because of their noninvasiveness, some biomarkers can be used repeatedly without any major restriction related to exposure conditions, age, or health status of the examined subjects. These tests are particularly useful for monitoring susceptible populations such as children. Biomarkers meeting all these criteria and applicable to detect metal toxicity are relatively few, and among them the number of biomarkers that have undergone a complete validation are even less numerous.

8.1 Renal Toxicity Biomarkers

Metals, notably cadmium, lead, and mercury, have been known for a long time to be nephrotoxic, with numerous reports of tubulointerstitial nephritis possibly leading to renal failure, in most cases linked to high occupational or environmental exposures. Early signs of renal dysfunction have also been found at low environmental exposure levels, consisting for instance of an increased urinary loss of tubular enzymes and proteins. These effects have mainly been described in adults, but certain reports have also shown them to occur in children (de Burbure *et al.*, 2003; 2006). The early recognition of the nephrotoxicity of metals has led, since the 1960s, to intense research aimed at developing sensitive screening tests and deriving thresholds of toxicity. These studies have shown that the acute or chronic nephrotoxicity of most metals can be detected

by measuring a panel of a few specific urinary proteins or enzymes reflecting the integrity of the glomerulus or of the proximal tubule. Table 1 lists the biomarkers that have been the most validated in humans and animals for assessing the nephrotoxicity of heavy metals such as cadmium, lead, and mercury. These biomarkers are now routinely used in the health surveillance of industrial workers and also for screening metal-induced kidney damage in environmentally polluted areas (e.g., in Japan). To be reliable, these tests require the use of sensitive immunological methods with a detection limit lower than 1 mg/L for albumin and alpha$_1$-microglobulin and lower than 0.01 mg/L for retinol-binding protein and beta$_2$-microglobulin. Test packs based on radioimmunoassay, enzyme immunoassay, or fluoroimmunoassay are now commercially available. When applying these tests, it is advisable to avoid first morning samples and also extreme variations in urinary flow. Samples with urinary creatinine <3 mmol/L or >30 mmol/L (0.3/3 g/L) should be used with caution, because results obtained on these samples are no longer related to the diuresis (Bernard *et al.*, 1997).

In most cases, metal-induced nephrotoxicity develops in a dose-dependent manner after a prolonged exposure. This means that renal effects are likely to occur only above a certain accumulated dose. Depending on the susceptibility of the exposed population and the sensitivity of the renal biomarker, the threshold of urinary cadmium associated with the development of tubular proteinuria (e.g., increased urinary excretion of low molecular weight proteins) ranges from approximately 1–10 μg/g creatinine (Åkesson *et al.*, 2005; Bernard, 2004; Fowler and Norberg, 1996; Järup *et al.*, 2000; Uno *et al.*, 2005). Above these thresholds, the risk of tubular proteinuria increases almost linearly with the accumulated dose of the metal as reflected by the urinary cadmium level. In cadmium exposure, clearly increased excretion of low-molecular-weight proteins is predictive of clinical renal disease (Mueller *et al.*, 1998; Mutti, 2001). Renal effects of inorganic mercury resulting in an increased excretion of tubular enzymes or albumin are also likely to occur only from a threshold of urinary mercury that has been estimated to vary between 30 and 50 μg/g creatinine in occupationally exposed subjects.

8.2 Neurotoxicity Biomarkers

Neurotoxic effects of heavy metals are also well documented, especially for mercury or lead, with numerous reports of neurobehavioral changes after occupational exposure and of developmental effects in children with prenatal or early postnatal exposure. Much effort has been devoted during the past years to identify potential biomarkers of neurotoxicity. Serum prolactin and urinary homovanillic acid have been the most studied in experimental animals and in humans. These two markers that reflect the integrity of the dopaminergic system have been proposed for monitoring exposure to some metals such as lead, mercury, manganese, and aluminum. However, their sensitivity seems limited, because significant changes in these biomarkers have only been described at relatively high exposure levels such as those found in industry. At environmental exposure levels, these biomarkers show no or only weak associations with heavy metal exposure even in particularly sensitive populations such as children (de Burbure *et al.*, 2006).

8.3 Lung Toxicity Biomarkers

Current research in the field of biomarkers is opening new perspectives in the assessment of lung toxicity with the development of noninvasive molecular tools measuring the extent of lung inflammation or damage.

TABLE 1 Urinary Markers of Metal Nephrotoxicity

	Normal value	Significance	Precautions/confounders
Albumin (microalbuminuria)	<20 mg/g Cr	Glomerular damage	Very stable in urine Increases in orthostatic proteinuria, heavy exercise, pregnancy
β_2-Microglobulin (β_2-m)	<300 μg/g Cr	Proximal tubule damage/dysfunction	Unstable at urinary pH <5.6 Increases in some autoimmune or infectious diseases Increases in renal insufficiency (overflow proteinuria)
α_1-Microglobulin (protein HC)	<10 mg/g Cr	Proximal tubule damage/dysfunction	Very stable in urine Increases in renal insufficiency (overflow proteinuria)
Retinol-binding protein (RBP)	<300 μg/g Cr	Proximal tubule damage/dysfunction	Very stable in urine Increases in renal insufficiency (overflow proteinuria)
N-Acetyl-β_2-*D*-glucosaminidase	<5 UI/g Cr	Proximal tubule damage/dysfunction	Very stable in urine but sensitive to repeated freezing/thawing cycles Possibility to measure isoenzymes

Most promising current biomarkers of lung toxicity are those measurable in serum, sputum, exhaled air, and exhaled breath condensate. In exhaled air, one of the most useful biomarkers seems to be nitric oxide (NO), a marker of acute or chronic lung inflammation. Although few studies have applied the exhaled NO test to subjects exposed to heavy metals (Lund *et al.*, 2000), it is very likely that these tests could contribute to a better assessment or understanding of the effects of metals on the lung. Exhaled breath condensate (EBC), a fluid obtained by cooling exhaled air, also seems to be a promising tool for the assessment of the accumulated dose or the effects of inhaled chemicals, including toxic metals. EBC contains so little protein that it is unlikely that this material could serve for the dosage of lung-derived proteins. By contrast, it is possible to measure a variety of small molecules, including metals that could effectively reflect lung inflammation or oxidative stress and the metal doses retained or stored in the lung. Such a biomarker is, for instance, malondialdehyde, which has recently been found to be increased in workers exposed to a mixture of both transition and hard metals (Goldoni *et al.*, 2004). The assay of lung-specific proteins in serum ("pneumoproteins") represents another interesting approach in the detection of the effects of air pollutants, including their effect on the lung–epithelium barrier (Hermans and Bernard, 1999). One of the most studied lung-specific measurable proteins, called the Clara cell protein, is an indicator of the number of Clara cells lining the terminal airways. Surfactant-associated proteins A and B can also be used to assess the permeability of the alveolar–capillary barrier. However, tobacco smoking is a major confounder of these biomarkers, and experience with other lung toxicants suggests these biomarkers are mainly useful research tools for the refinement of risk assessment and the derivation of toxicity thresholds. These lung-specific proteins can also be measured in normal circumstances in serum at very low concentrations, which can only be determined with very sensitive immunoassays.

8.4 Biomarkers for Other Target Organs

Biomarkers of toxicity or disease exist for a variety of potential target organs of metals such as bone (urinary cross-linked N-telopeptide and C-telopeptide of type II collagen, bone-specific alkaline phosphatase, procollagen type 1-C peptide, osteocalcin, urinary calcium) or the male reproductive system (sperm count, morphology, and motility). Biomarkers of sperm quality seem quite sensitive to some metals (Telisman *et al.*, 2000), but difficulties in collecting the samples limit their application in practice. As to biomarkers of metal effects on the bone, very few studies, except those concerning cadmium effects on bone, have looked to the use of biomarkers for the assessment of the impact of metals on this target (Aoshima *et al.*, 2003). Effects of cadmium on the prostate have also been recently investigated by use of biomarkers (Zeng *et al.*, 2004).

8.5 Genotoxicity Biomarkers

Most potent carcinogens are genotoxic and can produce gene mutations. The search for alterations with appropriate biomarkers can, therefore, be used to assess the potential risk of cancer associated with exposure to organic chemicals but also some metals (Albertini *et al.*, 2000). Most biomarkers of genotoxicity require the collection of nucleated cells and are usually applied to blood lymphocytes. There are three types of genotoxicity assays that are most commonly used in the context of exposure to metals: the measurement of sister chromatid exchange (SCE) and in particular of cells with a high frequency of SCEs (HFCs); the measurement of micronuclei, which are fragments of DNA; and the analysis of chromosomal aberrations. However, as of now, these analyses are mainly used for research purposes. The available validation studies suggest that chromosomal aberrations are more closely related to individual susceptibility than to exposure to genotoxic chemicals; whereas sister chromatid exchanges are not related to cancer risk (Bonassi *et al.*, 2000; 2004; Hagmar *et al.*, 1998, 2004). DNA or protein adducts, or mutagenicity in urine, have not been successfully applied in the biomonitoring of metals.

9 FUTURE TRENDS

There is an ever-increasing capacity for speed, sensitivity, and understanding the importance of chemical species for both analytical techniques for metals/metalloids and biotechnology innovations for applying molecular or "omic" technologies for biomarkers. In particular, the incorporation of automated or robotic analytical systems has greatly improved the speed with which analyses for metals may be conducted. Linkages between complementary analytical systems (e.g., GC mass spectrometry or HPLC mass spectrometry) have also increased the ability of the analyst to rapidly conduct chemical speciation studies that provide valuable information on the chemical species that are present.

The advent of the "omic" molecular technologies (genomic, proteomic and metabolomic/metabonomic) has also greatly increased the speed and precision of biomarker endpoint measurements. These technologies are also being automated and developed with

computerized interfaces. As noted elsewhere (Fowler, 2005a), there are a number of challenges facing the validation of "omic" technologies, but there is also great promise if the nature of these early molecular responses can be understood in relation to other toxicological endpoints. A recently published symposium on "Molecular Biomarkers" (Fowler, 2005b) provides a useful review of studies from a number of countries with a particular emphasis on toxic metal/metalloid exposures.

CHAPTER

5

Selected Molecular Mechanisms of Metal Toxicity and Carcinogenicity

TODD DAVIDSON, QINGDONG KE, AND MAX COSTA

ABSTRACT

This chapter will summarize some of the molecular responses exhibited by cells that come into contact with toxic metals. We will consider the transport of toxic metals into cells and how this interferes with the transport of essential metals. Toxic metals also interfere with the intracellular action of essential metals and may cause toxicity and cancer by this mechanism. Some metals have very specialized effects on enzymes, and there are proteins that can bind toxic metals such as metallothionein, which will also be discussed. Some metals are also slightly mutagenic and genotoxic, and these effects will be discussed. Because most metals that are carcinogenic, such as nickel (Ni), arsenic (As), beryllium (Be), and cadmium (Cd), with the exception of chromium (Cr), do not interact with DNA and are not mutagenic, we discuss other mechanisms such as epigenetic effects to account for their carcinogenic activity, as well as how they affect the expression of genes. Metals also interfere with cell signaling, and, in particular, we will discuss the hypoxic signaling pathway as well as those involving PI3K, AKT, ROS, MAPK, NFκB, NFAT, and AP1. Finally, the basis of the interaction of toxic metals with all cellular constituents involves their coordination with biological ligands, which will be addressed throughout the chapter.

1 TRANSPORT OF TOXIC METALS BY MOLECULAR/IONIC MIMICRY OF ESSENTIAL COMPOUNDS

1.1 Introduction

Metals are found throughout the environment, and although certain metals are highly toxic, others are essential to living systems. Essential metals are needed in the diet to maintain proper human health, because they cannot be synthesized by the body and are required for enzyme reactions or other physiological processes. The cellular uptake and export of these essential metals is tightly regulated by various homeostatic transport mechanisms, because an excess of, or lack of, an essential metal, can also be toxic. Some of these processes are very specific, whereas others are more promiscuous and are able to transport a multitude of metals that are potentially toxic. Transport proteins may recognize nonessential metals because they resemble essential metals or other compounds, effectively acting as molecular mimics. Unregulated transport of nonessential metals or deregulation of essential metal transport is a major factor in determining the potential toxicity or carcinogenicity of metallic compounds. In fact, various diseases are caused by alterations in metal transport and metabolism. The transport of a number of metals is discussed here, but more detailed reviews are available (Ballatori, 2002; Clarkson, 1993; Goyer, 1997).

1.2 Iron

Iron (Fe) is an essential metal whose regulation is controlled by both uptake and export proteins. Both iron deficiency and excess iron can be potentially toxic to cells, so its transport is stringently controlled. One of the major proteins involved in the cellular uptake of iron is transferrin. Transferrin is capable of binding two molecules of ferric iron. In addition to binding ferric iron, transferrin is also able to bind nickel, vanadium, and other metals (Boffi *et al.*, 2003; Harris, 1986; Sun *et al.*, 1999). One may speculate that other metals may interfere with iron transport by occupying sites on transferrin molecules. Diferric transferrin gets internalized into an acidic endosome via transferrin receptor–mediated endocytosis. Iron is subsequently released from the transferrin receptor, reduced, and transported out of the endosome into the cell via the divalent metal transporter-1 (DMT1/DCT1/NRAMP2). DMT1 is also involved in the transferrin receptor's independent transport of iron. Interestingly, DMT1 is able to transport a multitude of other metals including nickel (Ni), manganese (Mn), cobalt (Co), copper (Cu), and zinc (Zn) (Chen *et al.*, 2005; Garrick *et al.*, 2003). The transport of metals into the cell by DMT1 is one example of how nonspecific transport of toxic metals like Ni may interfere with the transport of essential metals. Indeed, it has been shown that Ni and other toxic metals can compete with iron for entry into the cell at DMT1 (Chen *et al.*, 2005; Garrick *et al.*, 2003).

1.3 Zinc

Zinc is an essential component of many metalloenzymes and transcription factors that are involved in various cellular processes such as gene expression, signal transduction, transcription, and replication (Berg and Shi, 1996). The movement of zinc across cellular membranes in humans involves various zinc transporters, including the ZnT family of proteins and the Zip proteins, both members of the transporter super family known as the ZIP (ZRT1, IRT1-like protein) family. The ZnT family of transporters is involved in the sequestration and release of zinc, whereas DMT1 and Zip proteins are believed to be responsible for importing Zn into the cells (Harris, 2002). Similarly to DMT1, the ZIP proteins are not specific for Zn transport and can also likely transport other transition metals into the cell. It has been shown that Mn, Cd, and Cu can compete with Zn for uptake by hZIP2, a human zinc transporter, suggesting that these metals are also substrates for the transporter (Gaither and Eide, 2000).

1.4 Phosphate and Sulfate Mimics

Phosphate and sulfate are carried across the cell membrane by various transport proteins (Clarkson, 1993). Some metal oxyanions resemble these compounds and compete for transport with phosphate and sulfate through their respective carriers. For example, selenate, molybdate, and chromate resemble sulfate and can be transported by sulfate transporters. The transport of sulfate has been shown to be inhibited by these mimics (Cardin and Mason, 1975; Mason and Cardin, 1977; Shennan, 1988). Likewise, vanadate and arsenate are structurally similar to phosphate, and, as a result, they are substrates for phophate carriers. Arsenate has been shown to compete with phosphate transport in a number of cell lines and tissue systems (Clarkson, 1993). Vanadate has also been shown to inhibit the uptake of phosphate at the NaPi-3 cotransporter (Timmer and Gunn, 1998). In addition, phosphate can be mimicked in nontransport-related reactions like the synthesis of ATP (arsenate) or inhibition of ATPase (vanadate) (DeMaster and Mitchell, 1973; Karlish *et al.*, 1979).

1.5 Organic Complexes

Toxic metals are often transported into cells complexed to organic solutes. Methionine is an amino acid that can be transported into the cell via the L-type neural amino acid carrier (Ballatori, 2002). Unfortunately, the toxic metal methylmercury can bind to the amino acid cysteine, forming a complex that resembles the amino acid methionine, which can then be transported into the cell by this amino acid carrier (Aschner and Clarkson, 1988; Kerper *et al.*, 1992). In addition, glutathione carriers can transport methylmercury complexed with glutathione (Ballatori and Clarkson, 1984a; 1984b; Dutczak and Ballatori, 1994). Other metals (Cu, Zn, Cd, Cr, and Pb) have been reported to form complexes that mimic glutathione and are transported by glutathione transporters (Aaseth *et al.*, 1982; Alexander *et al.*, 1981; Ballatori and Clarkson, 1985; Cherian and Vostal, 1977; Gyurasics *et al.*, 1991; Norseth *et al.*, 1982). In addition, uptake of zinc–histidine and copper–histidine complexes by amino acid transporters has been reported (Aiken *et al.*, 1992; Horn *et al.*, 1995; Horn and Thomas, 1996; Oakley *et al.*, 2004). Arsenite can be transported by glucose transporters and by the water transporter, aquaglyceroporin (Liu *et al.*, 2002). The ability to directly bear a resemblance to organic compounds or form complexes that mimic endogenous compounds is an important mechanism by which toxic metals can be transported by cells.

1.6 Metal–Anion Complexes

Metal–anion complexes are also capable of mimicking endogenous anions. For example, it has been suggested that various metals may be transported on the HCO_3^-/Cl^- anion exchange carrier as a carbonate complex by mimicking the monovalent anions that are usually transported. Zinc has been shown to be taken up by the anion exchanger as the anionic complex ($[Zn(HCO_3)_2\ Cl]^-$) (Torrubia and Garay, 1989). Cadmium and lead have also been shown to be transported into red blood cells through the anion exchanger (Lou *et al.*, 1991; Simons, 1986b; 1986c).

1.7 Calcium Channels

Voltage-dependent calcium channels are other sites where toxic metals may gain access to the cell. It is well known that lead can mimic calcium in many cellular processes. Indeed, it has been shown that lead is able to enter voltage-activated L-type calcium channels in place of calcium. Further research has shown that these channels will actually be blocked by and may transport a wide variety of divalent and trivalent metal cations, including cadmium, nickel, and other toxic metals (Schafer, 2000).

1.8 Summary

Various mechanisms exist for the transport of toxic metals into the cell. Most of them involve molecular mimicry, in which the toxic metal either directly or as a complex resembles an endogenous compound. The transport of toxic metals is then carried out, because the transporters for the endogenous compounds have low substrate selectivity, allowing them to transport toxic metals into the cell.

2 INTERFERENCE WITH THE FUNCTIONS OF ESSENTIAL METALS BY TOXIC METALS

2.1 Introduction

Essential metals have numerous functions inside the cell. Perhaps one of the most important, although not the only, role is to act as a cofactor/component in enzymes and various molecules. There are hundreds of enzymes that contain essential metals, and it would be nearly impossible to discuss all of them and their possible interactions with toxic metals, but a few representative examples are discussed. It is important to realize that even though many enzymes contain the metal iron, for example, not all of the enzymes have iron bound in the same manner or even the same form. The manner by which the metal is bound and the form of the essential metal in a given enzyme, likely play a major role in its susceptibility to interference by toxic metals.

2.2 Calcium

Proper calcium metabolism is crucial at both an intracellular and an extracellular level. Toxic metals are able to interfere at both levels by an assortment of mechanisms. The toxic metal cadmium interferes with calcium metabolism in both the kidney and in bones. Hypercalciuria is observed in the kidneys of people exposed to cadmium, indicating an interference with calcium regulation (Buchet *et al.*, 1990; Lauwerys *et al.*, 1990; Scott *et al.*, 1978). This may be one of the causes of Itai-Itai disease. In addition, cadmium can be deposited in the bone and may interfere with calcification, decalcification, and bone remodeling (Berglund *et al.*, 2000; Tsuritani and Honda, 2004). Aluminum has also been shown to replace calcium in the soft tissue part of the bone and affect bone structure, although this may be related to cellular toxicity (Severson *et al.*, 1992). Lead, another toxic metal, also interferes with calcium metabolism in a variety of ways. Evidence has shown that a diet low in calcium can result in higher levels of lead in tissues, demonstrating an important metabolic link between the two (Barton *et al.*, 1978; Fullmer, 1992; Mahaffey *et al.*, 1973). Lead also affects calcium at the cellular and molecular levels. In the nervous system, lead is able to disturb proper neurotransmitter kinetics, block the uptake of calcium by nerve terminals, and compete with calcium for uptake by calcium channels (Barton *et al.*, 1978; Fullmer, 1992; Mahaffey *et al.*, 1973; Minnema *et al.*, 1988; Simons, 1986a; Simons and Pocock, 1987). In addition, lead can replace calcium in calcium/sodium ATP pumps, compete with calcium for binding sites on calcium-binding proteins, compete for uptake into mitochondria, and bind to or interfere with secondary messenger calcium receptors such as calmodulin or protein kinase C (Fullmer, 1992; Goldstein, 1977, 1990; Habermann *et al.*, 1983; Simons, 1986a). It has also been reported that nickel, another potentially toxic metal, results in an elevation of free intracellular calcium (Salnikow *et al.*, 1999).

2.3 Zinc

Cadmium, lead, and As have all been shown to affect the proper regulation of zinc, an essential metal found in more than 300 enzymes and numerous transcription factors. Cadmium can occupy the same sites as zinc on metallothionein (MT), and whereas MT-bound cadmium is nontoxic in the liver and kidney, it is toxic to the renal tubules when it is excreted in the

urine (Chan and Cherian, 1993; Nordberg *et al.*, 1971a; 1971b). Lead has wide-ranging effects on processes that use zinc. Lead is known to increase zinc excretion in rats (Victery *et al.*, 1987). The activity of zinc-containing heme enzymes like δ-aminolevulinic acid dehydratase can be decreased by lead, suggesting that lead may substitute for zinc in some zinc-containing heme enzymes (Meredith *et al.*, 1977; Tomokuni *et al.*, 1991). In addition, lead, arsenite, and selenium may disrupt zinc finger proteins. By disturbing zinc finger proteins (approximately 3% of identified genes in the human genome code for proteins with zinc finger domains), these metals may have widespread effects on transcription factors, DNA damage signaling, and DNA repair proteins (Hartwig *et al.*, 2003; Maret, 2004).

2.4 Magnesium

Magnesium can be found attached to phosphate on the backbone of DNA. One model suggests that nickel can replace magnesium, leading to increased chromatin condensation and subsequent DNA methylation (Lee *et al.*, 1995). This model provides an interesting link between the interaction of toxic metals with essential metals and epigenetics.

2.5 Iron

Iron (Fe) is an important essential metal used in many enzymes and cellular redox reactions. Low cellular iron levels can be detrimental to a healthy cell, whereas excess free iron can lead to the production of reactive oxygen species (ROS) via the Fenton reaction. Cellular iron levels are tightly regulated by homeostatic mechanisms to maintain the appropriate amount of iron in the cell. Disruption of iron homeostasis by toxic metals is a newly emerging area, with many aspects currently under investigation. We previously mentioned that nickel and other divalent metals could compete with iron for entry into the cell at DMT1. One reason why nickel may be able to compete for iron-binding sites is because they have similar ionic radii. Metals can interfere with many other iron-dependent processes as well. Iron homeostasis is maintained by the iron regulatory protein-1 (IRP1)/iron response element (IRE) system. When iron levels are low, the 4Fe–4S cluster protein aconitase loses its cluster and is converted into IRP1. IRP1 can alter the regulation of mRNAs that have IREs in their sequence. These IREs can be found in the 3′ or 5′ untranslated region of mRNAs that encodes for proteins involved in iron uptake, storage, and use (For a complete review of eukaryotic iron regulation systems, see Aisen *et al.* (2001). Nickel has been shown to increase the binding of IRP1 to IRE by lowering cellular iron levels (Chen *et al.*, 2005). Aluminum has been reported to increase the stability of IRP2, another iron regulatory protein (Ward *et al.*, 2001).

Toxic metals also affect iron-dependent enzymes. The 4Fe–4S enzyme aconitase loses its enzymatic activity when cells are exposed to nickel or cobalt. It has also been shown that toxic metals can affect various iron-dependent enzymes involved in the hypoxic response. The hypoxia inducible factor (HIF)-1α is controlled by two enzyme groups that are members of the iron and 2-oxoglutarate–dependent dioxygenase family of enzymes, the HIF-prolyl hydroxylases and an asparagine hydroxylase. It has been reported that the activity of both of these enzymes can be inhibited by toxic transition metals such as cobalt and nickel (Ivan *et al.*, 2001; Hewitson *et al.*, 2002; Hewitson *et al.*, 2003; Jaakkola *et al.*, 2001; Schofield and Ratcliffe, 2004; Ward *et al.*, 2001).

2.6 Copper

Copper (Cu) is an essential metal for living systems and is found in an assortment of enzymes, including superoxide dismutase (SOD), ferroxidases, and cytochrome oxidase. Its transport is highly regulated, and various metals, including zinc, cadmium, and molybdenum, have been reported to interfere with its transport or availability in biological systems. It has also been shown in rodents that lead can alter copper metabolism, leading to decreases in plasma copper levels (Klauder and Petering, 1979; Skoczynska *et al.*, 1994).

3 TOXIC METAL–BINDING MOLECULES

3.1 Introduction

Because metals are generally indestructible, the accessibility of metals in biological solutions plays a crucial role in determining their potential toxicity. Metals can bind to many types of macromolecules in the cell, although this discussion will be limited to molecules involved in the transport and/or storage of toxic metals. Frequently, the binding of metals to proteins is a defense to reduce toxicity by preventing availability of the metals, although there are instances when a metal bound to a protein can be more toxic than the metal alone. The ability of low-molecular-weight thiols and protein sulfhydryl groups to bind metals plays a major part in determining which proteins/peptides will bind and transport toxic metals. We have limited consideration to two important metal-binding molecules, MT and glutathione.

3.2 Metallothioneins (MTs)

MTs, which were originally isolated from equine kidney, are low-molecular-weight, cysteine-rich, intracellular proteins that have the capability to bind toxic metals (Margoshes and Valee, 1957). MTs are rich in cysteine, and therefore, thiol groups, which gives them avid metal-binding characteristics (Waalkes and Perez-Olle, 2000). They can bind essential metals such as Cu and Zn, as well as toxic metals such as Cd, Pb, and Hg (Nordberg and Nordberg, 2000). MT can integrate as many as 7 divalent metal atoms (e.g., Zn^{2+}) or 12 monovalent atoms (e.g., Cu^{+}) (Binz and Kagi, 1999). The metal content of MTs can vary, depending on the stability constants of different metals, and does not have to contain only one type of metal. Thus, MTs can exist as mixed metal proteins, carrying multiple metal species. It has been reported that up to 18 different metals can associate with MTs, although the stability constant of the different metals varies (Kagi and Kojima, 1987; Nath *et al.*, 1988). For example, the toxic metals Cd, Pb, and Hg can displace the essential metal Zn. In addition to binding toxic metals, MTs can also donate metal ions to ligands that have higher affinity constants. It is believed that MTs play an integral role in the detoxification of toxic metals, although they also play a major role in essential metal metabolism.

With respect to toxic metal detoxification, MTs are regulated in an interesting manner. *In vivo*, MTs are mainly bound to Zn. Based on the affinity constants for MT, a number of toxic metals, including Hg^{2+}, Ag^{+}, Cu^{+}, Cd^{2+}, Pb^{2+}, and Bi^{2+}, would be able to displace Zn^{2+} from MT (Kagi and Kojima, 1987; Nath *et al.*, 1988). The free zinc is able to bind the metal transcription factor (MTF-1) and induce the synthesis of MT by binding to metal response elements in the promoter region. The newly synthesized MT molecules would be available to bind free toxic metal ions. In addition to Zn^{2+}, other metals such as Cd^{2+}, Hg^{2+}, Cu^{+}, Bi^{2+}, Pb^{2+}, Ni^{2+}, and Mn^{2+} have been shown to induce MT synthesis by diverse mechanisms, indicating the general nature of MTs in responding to toxic metal stress with a detoxification response (Waalkes and Goering, 1990; Waalkes and Klaassen, 1985).

One of the most extensively studied properties of MTs relates to the hypothesis that they protect the cell against cadmium toxicity (Nordberg *et al.*, 1994). Studies in which the primary isoforms of MT (MT-1 and MT-II) are knocked out in mice have shown that these mice were more susceptible to cadmium toxicity than control mice (Masters *et al.*, 1994; Michalska and Choo, 1993; Zheng *et al.*, 1996). In addition, when MT-1 was overexpressed in transgenic mice, cadmium was less lethal and produced less nephrotoxicity at levels of exposure to cadmium that injured control mice expressing normal amounts of MT-1 (Liu *et al.*, 1995). Other studies have cautioned that MTs are not the sole factor in determining Cd toxicity, because only a subset of the adverse effects of Cd can be prevented by MT. Testicular necrosis in mice exposed to Cd could not be blocked by the overexpression of MT-1 (Dalton *et al.*, 1996), but this may be because Cd was injected, and there was not enough time to induce MT as there would be if exposure occurred by ingestion. In addition, progesterone-induced synthesis of MT actually increased cadmium cytotoxicity in rat liver cells (Shimada *et al.*, 1997). MT can also increase the residence times of toxic metals in the body, which may lead to chronic effects when protective mechanisms are overwhelmed (Satoh *et al.*, 1997).

Protection against metal toxicity was probably not the intended purpose for MTs, because many of the toxic metals that they bind have only in recent times been concentrated in the biosphere through anthropogenic releases. The more likely explanation is that the ability of MTs to detoxify toxic metals is an accidental occurrence related to the ability of toxic metals to mimic physiological metals such as zinc that MTs are known to bind and perhaps regulate its homeostasis in cells (Richards and Cousins, 1975; 1976). MT affects Zn absorption and excretion by the intestine, as well as the supply of Zn to cellular transport proteins like ZnT-1 and DMT1, and the supply of Zn to Zn-containing enzymes and zinc finger proteins (Gunshin *et al.*, 1997; Palmiter and Findley, 1995; Palmiter *et al.*, 1996a; 1996b; Richards and Cousins, 1975; 1976). Although it seems MT can play a role in sequestering various metals, the precise physiological role is still unknown and the subject of current investigations.

3.3 Glutathione

Glutathione (GSH) is responsible for carrying out a variety of physiological and metabolic functions, including, but not limited to, the detoxification of electrophilic compounds, free radicals, and metals. It is the most abundant nonprotein thiol in many species and contains six possible metal binding sites (Wang and Ballatori, 1998). As summarized by Ballatori, GSH can affect the transport, disposition, and overt toxicity of metals in four ways: (1) it functions in the mobilization and delivery of metals between ligands; (2) it functions to transport metals across cellular membranes; (3) it serves as a source of cysteine, and (4) it serves as a cofactor for redox reactions (Ballatori, 1994). Although GSH is able to bind a large number of endogenous compounds, here we will be concerned only with its ability

to bind toxic metals. GSH is able to bind, transport, and store several metals affecting metal homeostasis in biological systems. In addition, glutathione-bound metals are more easily eliminated from the cell and the entire organism (Wang and Ballatori, 1998). Metals that can reportedly bind to glutathione are copper, selenium, zinc, chromium, mercury, cadmium, arsenic, silver, and lead (Aaseth *et al.*, 1982; Alexander *et al.*, 1981; Ballatori, 1994; Ballatori and Clarkson, 1985; Cherian and Vostal, 1977; Gyurasics *et al.*, 1991; Norseth *et al.*, 1982; Wang and Ballatori, 1998). The metal–sulfhydryl complexes are kinetically labile, and GSH-bound metals can exchange with other ligands leading to a rapid redistribution of metals in biological systems.

When GSH binds to a metal, two main outcomes are possible. The metal can be stabilized in a nonreactive form, or metal compounds with different speciation can be formed by redox reactions. Under the right conditions (when thiol groups dissociate to their thiolate anion), the latter can actually result in the formation of reactive oxygen species (ROS), although this event is usually quenched by other amino acid groups on GSH (Pompella *et al.*, 2003). More often, GSH can bind to metals and prevent the toxic effects of those metals. It has been reported that 0.5 m*M* GSH could prevent the inhibition of ethoxyresorufin O-deethylase activity by Hg^{2+}, Cu^{2+}, and Zn^{2+} but not Cr(VI) or Fe^{2+} (Oliveira *et al.*, 2004). The toxic effects of copper have been inversely associated with GSH concentration (Freedman *et al.*, 1989). The addition of GSH has been shown to protect against Hg^{2+}-mediated toxicity in *in vitro* preparations of renal tissue, isolated proximal tubule fragments from rabbits, and proximal tubular cells from rats (Burton *et al.*, 1995; Lash and Zalups, 1996; Zalups and Barfuss, 1993). Other beneficial effects of GSH–metal complexes are that they can serve as sources of metals during the synthesis of metalloproteins. GSH has been reported to deliver copper to apometallothionein, aposuperoxide dismutase, and apohemocyanin (Wang and Ballatori, 1998). Not all metal binding to GSH is beneficial. GSH can affect the transport of metals across cellular membranes (see Section 2). Metals like Hg^{2+} bound to GSH can accumulate in target organs, leading to increased toxicity. It has been shown that excess GSH can increase the toxicity of Hg^{2+} (Zalups and Barfuss, 1993). Thus, the precise role of GSH in metal toxicity remains unclear, and there may be species-, organ-, metal- and cell-specific effects.

Overall, GSH is an important mediator of metal toxicity because of the relatively high affinity of metals for thiol groups. It can affect metal transport, deposition, and overall exchangeability. Although GSH can chelate metals and reduce their overall availability, thus decreasing toxicity, it can also facilitate their transport across biological membranes and intensify toxicity in target organs.

3.4 Summary

MT and GSH are not the only metal-binding proteins in biological systems. In fact, many more exist and play a role in overall metal metabolism. Other thiol-containing proteins, such as bovine serum albumin (BSA), are important in binding toxic metals. In addition, proteins like transferrin and ferritin ensure that the redox-active metal Fe does not create oxidative stress. In plants, phytochelatins are important metal-binding proteins (Cobbett, 2000). The ability to sequester potentially toxic metals in an unreactive form is an essential trait in all organisms.

4 MUTAGENIC AND GENOTOXIC EFFECTS OF METALS

4.1 Introduction

Most of the toxic metals have very poor direct interactions with DNA and in general are weakly mutagenic. Even chromate, which can yield trivalent Cr DNA adducts is not highly mutagenic in many systems (Landolph, 1989; Patierno and Landolph, 1989). However, it is of interest that carcinogenic metals can interact with other environmental carcinogens. For example, metals can inhibit the repair of benzo[a]pyrene (BaP) or UV-induced DNA adducts and potentiate the mutagenicity of BaP or UV (Hartwig, 1998; Hu *et al.*, 2004a; 2004b). It is also of interest to note that there are poor animal models for metal-induced tumors, and many of the cancers that arise in humans occupationally exposed to carcinogenic metals, such as Ni compounds and chromate, are associated with exposure to other environmental carcinogens such as cigarette smoking (Gibb *et al.*, 2000; Grimsrud *et al.*, 2002; 2003). Recent success in inducing cancers with arsenite and chromate in mice was associated with the use of hairless mice exposed to both UV and these carcinogenic metals through their drinking water (Davidson *et al.*, 2004; Rossman *et al.*, 2001; 2004). Thus, in general, carcinogenic metals have strong interactions with carcinogens, such as PAH, UV, and the many carcinogens that are present in cigarette smoke. Some carcinogenic metals such as Ni compounds are able to induce cancers in animals exposed to these metals alone, although Ni also has a strong interaction with other organic carcinogens such as BaP and UV (Schwerdtle *et al.*, 2002; Waalkes *et al.*, 2004; Wozniak and Blasiak, 2004).

4.2 Mutagenicity and Genotoxicity of Nickel Compounds

Ni compounds have been deemed human carcinogens by the International Agency for Research on Cancer (IARC) (International Agency for Research on Cancer, 1990). Interestingly, these compounds are not very mutagenic in most of the tested assay systems (Coogan *et al.*, 1989; Costa, 1991b; Costa *et al.*, 2002). Although, Ni compounds are not mutagenic in cultured murine or human fibroblasts, they do induce strong cell transformation, particularly in murine systems (Biedermann and Landolph, 1987; Miura *et al.*, 1989). Other studies have shown that Ni compounds induce oxidative stress, genomic instability, and chromosome damage (Biggart and Costa, 1986; Conway and Costa, 1989; Costa *et al.*, 2002; Kargacin *et al.*, 1993; Kasprzak *et al.*, 2003; Lin *et al.*, 1991; Sen and Costa, 1985). Ni compounds have also been shown to cause cell transformation accompanied by global deregulation of gene expression (Landolph *et al.*, 2002; Verma *et al.*, 2004). Perhaps one of the most important effects of Ni in terms of affecting DNA is its ability to silence genes through DNA methylation and other epigenetic effects (Klein and Costa, 1997; Klein *et al.*, 1991). The epigenetic effects of nickel compounds are more potent with the water-insoluble forms of Ni compounds such as Ni_3S_2, but this effect is also evident when cells are exposed to soluble Ni compounds for long periods of time (Costa, 1995; Lee *et al.*, 1995; Oller *et al.*, 1997). Ni compounds can also induce oxidative stress *in vivo* (Coogan *et al.*, 1989; Doreswamy *et al.*, 2004; Kasprzak, 1995).

4.3 Mutagenicity and Genotoxicity of Chromium Compounds

IARC (1990) concluded that hexavalent Cr compounds are likely human carcinogens based on the available data. Water-soluble chromate compounds were tested for cell transformation, mutagenicity, and chromosomal damage and were found to be very active (Bianchi *et al.*, 1983; Biederman and Landolph, 1987; 1990; Patierno *et al.*, 1988). Analysis of the nature of mutations in a 104-base pair segment of the HPGRT gene exon 3 showed a selectivity in substitutions for GC base pairs (Chen and Thilly, 1994). Treatment of a shuttle plasmid *in vitro* with a Cr (VI) reduction system with glutathione or cells containing the shuttle plasmid yielded mutations predominantly at GC sites (Liu *et al.*, 1999). Cr is known to have a preference for binding to the phosphate backbone of DNA and with positively charged N7 of guanine (Voitkun *et al.*, 1998; Zhitkovich, 2005; Zhitkovich *et al.*, 1995). Chromate is also synergistic with other organic carcinogens, such as those present in cigarette smoke. One possible mechanism for these effects involves the inhibition of the repair of BaP DNA adducts (Feng *et al.*, 2003; Hu *et al.*, 2004a). Chromate exposure has been shown to induce oxidative stress in cells, and these effects are greater with some insoluble Cr compounds (Leonard *et al.*, 2004b; Martin *et al.*, 1998; Shi and Dalal, 1994). Oxidative stress, the reduction of Cr (VI) to Cr (III), and the binding of Cr (III) to DNA are thought to be involved in its mutagenesis and genotoxicity. The binding of Cr (III) to the DNA can yield a wide variety of DNA lesions, including ternary complexes of Cr (III) with its reducer (ascorbic acid or GSH), as well as DNA–DNA crosslinks, DNA–protein crosslinks, single-strand breaks, and formation of alkaline labile sites (Cantoni and Costa, 1984; Coogan *et al.*, 1991; Costa, 1990; 1991a; Miller and Costa, 1989a; 1989b; Miller *et al.*, 1991; Sugiyama *et al.*, 1986; 1987; Zhitkovich, 2005; Zhitkovich *et al.*, 1995).

4.4 Mutagenicity and Genotoxicity of Arsenic

IARC has determined that As and As compounds are carcinogenic to humans. In general, As compounds show poor genotoxicity and mutagenicity. Some studies have found evidence of DNA damage by arsenite such as micronuclei formation (Liu and Huang, 1997; Schaumloffel and Gebel, 1998) and DNA protein crosslinks (Gebel, 1998); however, others did not find DNA protein crosslink formation by arsenite (Costa *et al.*, 1997). As has not been found to be mutagenic in bacteria and cultured mammalian cells (Rossman *et al.*, 1980). However, a very consistent effect of As compounds is being a comutagen, possibly by inhibiting the repair of DNA lesions produced by genotoxic agents such as UV (Rossman, 1981a; 1981b; Rossman *et al.*, 1977; 1986). Additional studies that support the comutagenic effects of As are those studies showing that it is also a cocarcinogen (Rossman *et al.*, 2001; 2004). In addition, As has been shown to inhibit the ligation step of DNA repair and, thus, can interact with many genotoxic insults (Hu *et al.*, 1998).

4.5 Mutagenicity and Genotoxicity of Cd

IARC has determined that there is sufficient scientific evidence to classify cadmium and cadmium compounds carcinogenic in humans. In general, Cd compounds are weakly mutagenic in most assay systems (Filipic and Hei, 2004), but have been shown to be genotoxic to Leydig cells of the testes (Yang *et al.*, 2003). The mechanism by which Cd may be genotoxic is by indirectly inducing oxidative stress in cells as a result of its inhibition of antioxidant enzymes and depletion of antioxidant molecules such as GSH (Stohs *et al.*, 2000). Cd has been reported to be very active in

inducing apoptosis in a wide variety of cells, because of its induction of oxidative stress (Aydin *et al.*, 2003; Bagchi *et al.*, 2000; Jimi *et al.*, 2004; Poliandri *et al.*, 2003; Shin *et al.*, 2004; Tzirogiannis *et al.*, 2003; Watjen *et al.*, 2002). Cd has also been shown to inhibit DNA repair (Buchko *et al.*, 2000; Hartwig *et al.*, 2002a; 2002b; Waisberg *et al.*, 2003; Zharkov and Rosenquist, 2002).

5 EPIGENETIC EFFECTS OF METAL COMPOUNDS

5.1 Introduction

Epigenetics involves a heritable change in gene expression that does not result in a change of DNA sequence (Riddihough and Pennisi, 2001). Recent research has established that epigenetic changes play an important role in tumorigenesis (Feinberg, 2004). The major epigenetic changes taking place during the development of cancer include aberrant DNA methylation and histone modifications (Momparler, 2003). These epigenetic events can act in concert to silence the expression of genes that suppress tumorigenesis or activate oncogenes (Feinberg, 2004). Metal compounds, such as As, Cd, and Ni, have been shown to affect levels of DNA methylation and/or histone modifications at both global and gene-specific levels. In the first part of this section, DNA methylation and specific histone modifications will be introduced. The effects of metal compounds, mainly, As, Cd, and Ni, on these epigenetic parameters will be reviewed, and at the end of this section, we will include a summary table of epigenetic events affected by metals for easy future reference (Table 1). Because this is an emerging field of study, we have spent considerable time on this part of the chapter.

5.2 Epigenetic Events in the Development of Cancer

5.2.1 DNA Methylation

DNA methylation occurs at the cytosine residue of CpG dinucleotides of DNA, in which a methyl group is transferred from S-adenosyl-methionine (SAM) and covalently attached to the C-5 position of cytosine by a family of DNA-methyltransferases (DNMTs). DNA methylation plays an important role in the regulation of gene expression and the silencing of repeat elements in the genome (Feinberg, 2004). The deregulation of DNA methylation mainly includes hypomethylation, which leads to oncogene activation and chromosomal instability, and hypermethylation, which leads to the silencing of tumor suppressor genes (Jones and Laird, 1999).

TABLE 1 Summary of the Epigenetic Events Affected by Metals

Epigenetic events	Classification	Metal inducers
DNA methylation	Hypomethylation	As, Cd, Ni
	Hypermethylation	As, Cd, Ni
Histone modifications	Acetylation	As, Ni
	Methylation	Ni
	Phosphorylation	As

5.2.2 Histone Modifications

Histone modifications occur at the N-terminal and the C-terminal of histone tails, and include, but are not limited to, acetylation, methylation, phosphorylation, ubiquitination, sumoylation, and ADP-ribosylation. These modifications play a pivotal role in regulating gene transcription and other chromatin-associated processes (Jenuwein and Allis, 2001).

5.2.2.1 Histone Acetylation

All four-core histones can be reversibly acetylated at defined lysine residues on their N-terminal tails by histone acetyltransferases (HATs) and deacetylated by histone deacetylases (HDACs) (Klochendler-Yeivin and Yaniv, 2001). In general, hyperacetylation contributes to the formation of an "open" chromatin state and permits access of transcription factors to DNA. In contrast, hypoacetylation contributes to a "closed" chromatin and transcription repression (Turner, 2000). Lysine acetylation is believed to neutralize part of the positively charged histone tails, which may weaken the interactions between histone–DNA (Grant *et al.*, 1998), histone–histone (Fletcher and Hansen, 1996), nucleosome–nucleosome (Lutter *et al.*, 1992; Norton *et al.*, 1989; 1990), or the interaction between nucleosomes and other nonhistone chromosomal proteins (Hecht *et al.*, 1995). As a result, it may destabilize higher order chromatin organization and facilitate the access of transcription factors to nucleosomal DNA, resulting in enhanced DNA transcription. In addition, proteins with histone acetyltransferase (HAT) activity have been shown to be coactivators of transcription, whereas those with histone deacetyltransferase (HDAC) activity are corepressors of transcription (Lehrmann *et al.*, 2002). The balance between acetylation and deacetylation of histones plays an important regulatory role in gene transcription. Deregulation of this balance has been linked to the progression of cancers and diverse human disorders (Lehrmann *et al.*, 2002; Timmermann *et al.*, 2001).

5.2.2.2 Histone Methylation

Histone methylation occurs predominantly on histones H3 and H4. There are two types of histone

methylation, targeting either arginine (R) or lysine (K) residues. Generally, arginine methylation is involved in gene activation, and histone methyltransferases (HMTs) are recruited to promoters as coactivators. By comparison, methylation of the lysine residue can have multiple effects on chromatin function, depending on the specific lysine and the level of modification (mono-, di-, or trimethylation of a single lysine). For instance, H3-K9 dimethylation and H3-K27 trimethylation are both largely associated with gene silencing and heterochromatin formation, whereas methylation of H3-K4, H3-K36, or H3-K79 is associated with active chromatin (Maison and Almouzni, 2004; Peterson and Laniel, 2004).

5.2.2.3 Histone Phosphorylation

The correlation between mitotic chromosome condensation and phosphorylation of histones H1 and H3 is well established, although the specific function of this modification in chromosomes remains to be determined. Physical studies have shown that phosphorylation disrupted histone–DNA interactions and destabilized chromatin structure (Chadee *et al.*, 1995; Hendzel *et al.*, 1997). Phosphorylation of a histone H2A variant, H2A.X at serine (S) 139, increases during the early stages of DNA fragmentation in apoptosis and correlates with double-stranded DNA breaks (Gurley *et al.*, 1973). Recently, it has been reported that phosphorylation of histone H2B at S14 correlates with cells undergoing apoptosis in vertebrates, which may serve as a marker for apoptosis (Cheung *et al.*, 2003).

5.2.2.4 Histone Ubiquitination

The most prevalent ubiquitinated histones are monoubiquitinated-H2A and H2B (Nickel and Davie, 1989). Approximately 10% of total H2A and to a lesser extent, 1–1.5% of H2B is ubiquitinated in eukaryotic cells, although ubiquitinated H2A (uH2A) has not been reported in the budding yeast *Saccharomyces cerevisiae* (Goldknopf *et al.*, 1977). In higher eukaryotic organisms, the ubiquitin molecule is linked to K119 of H2A and K120 of H2B (K123 in yeast). Physiological observations suggest that ubiquitinated histones may have multiple functions and structural effects rather than playing a role in the degradation by the 26S proteasome (Nickel and Davie, 1989). Reports on the roles of histone ubiquitination in chromatin fractions are controversial and, in many cases, contradictory. Nevertheless, the current view favors that the ubiquitination of H2B is associated with gene transcription (Davie and Murphy, 1990; Krogan *et al.*, 2003). It is also required for methylation of H3 K4 and K79 in yeast (Dover *et al.*, 2002). In contrast, the ubiquitination of H2A has been linked to polycomb gene silencing (Wang *et al.*, 2004a). It has been shown that the levels of uH2A were higher in transformed human fibroblasts and keratinocytes than in their normal counterparts (Vassilev *et al.*, 1995).

5.3 Impacts of Metal Compounds on Epigenetics

5.3.1 As

Arsenite (As) has been shown to reduce global levels of DNA methylation, as well as cause both DNA hypomethylation and hypermethylation of specific genes or DNA fragments. The status of histone acetylation and phosphorylation is also changed on As exposure and has been associated with the activation of genes.

It has been shown that chronic exposure of TRL 1215 (a rat liver epithelial cell line) to As (0.125–0.500 μ*M* for more than 18 weeks) resulted in the depletion of S-adenosyl-methionine (SAM), global DNA hypomethylation, and malignant transformation. As-induced DNA hypomethylation was a function of dose and exposure duration and remained constant even after withdrawal of As (Zhao *et al.*, 1997). Overexpression of several oncogenes and genes regulating cell proliferation were detected in the As-transformed cells, including the protooncogene *c-myc* (Chen *et al.*, 2001). Although the DNA methylation status on the promoter of the *c-myc* gene was not examined, the transcription of *c-myc* gene was increased by As in a dose- and time-dependent manner and strongly correlated with levels of global genomic DNA hypomethylation. Because As is detoxified by methylation using a methyltransferase and SAM as the methyl donor, it is conceivable that As metabolism may deplete intracellular methyl group storage and thereby lead to DNA hypomethylation. This, in turn, may facilitate aberrant gene expression and play a role in As carcinogenesis (Chen *et al.*, 2001). However, the data concerning DNA methylation alterations after As exposure are ambiguous. By using quantitative PCR/*Hpa*II restriction site analysis to examine DNA methylation status, it has been shown that exposure of human lung adenocarcinoma A549 cells to sodium arsenite (As III) (0.08–2 μ*M*) or sodium arsenate (As VI) (30–300 μ*M*) for 2 weeks produced significant dose-dependent DNA hypermethylation within the promoter region of p53 (Mass and Wang, 1997). In addition, by use of methylation-sensitive arbitrarily primed PCR, both hypomethylation and hypermethylation of genomic DNA fragments (300–500 bp) were detected with As treatment in both human kidney cells (UOK) and in A549 cells. Although the affected genes have not yet been identified, this result suggested that

the As-induced imbalance of DNA methylation could disrupt normal gene expression and may have a potential role in the As-induced cellular dysfunctions and cancer development (Zhong and Mass, 2001).

As-induced gene expression changes have been associated with alterations in histone modifications and signaling pathways. As has been shown to activate the stress-inducible gene Hsp70 through the p38 MAPK pathway (Thomson *et al.*, 2004). The activation of this gene was accompanied by histone H4 acetylation and H3 phosphorylation, whereas histone H3 remained markedly hypoacetylated at Hsp70 chromatin (Thomson *et al.*, 2004). As could also upregulate protooncogenes *c-jun* and *c-fos*, which would require the action of ERK. Chromatin immunoprecipitation (ChIP) assays revealed that As treatment dramatically induced the phosphorylation and acetylation of H3 associated with the *c-fos* and *c-jun* genes through an ERK-dependent pathway (Li *et al.*, 2003). In addition, it has been shown that As induced phosphorylation of histone H3 at serine 10 in a time- and dose-dependent manner in JB6 Cl 41 cells (He *et al.*, 2003). As also dramatically increased phosphorylation-acetylation of histone H3 at a global level, which preceded the induction of mRNA levels of MAPK phosphatase 1 (MKP-1). ChIP revealed that As-induced phosphorylation-acetylation of histone H3 associated with the MKP-1 gene and enhanced the binding of RNA polymerase II to MKP-1 chromatin (Li *et al.*, 2001). MKP-1 has been shown to play a critical role in mediating the feedback control of MAPK cascades in a variety of cellular processes, including proliferation and stress responsiveness. Therefore, it has been suggested that As contributes to the carcinogenic process by triggering alterations in global chromatin structure, as well as perturbing the transcription of specific genes, including *c-jun*, *c-fos*, and MKP-1 (Li *et al.*, 2001; 2003).

5.3.2 Cd

Cadmium (Cd) exposure can result in DNA hypomethylation initially, but prolonged exposure can lead to DNA hypermethylation (Takiguchi *et al.*, 2003). In TRL1215 rat liver cells, after 1 week of exposure to cadmium (<2.5 μ*M*), DNMT activity and genomic DNA methylation were reduced. However, significant increases in DNMT activity and DNA methylation were detected after 10 weeks of Cd exposure. These cells exhibited properties of a transformed phenotype, including hyperproliferation, increased invasiveness, and decreased serum dependence (Takiguchi *et al.*, 2003).

5.3.3 Ni

Nickel (Ni) can cause global hypermethylation and gene specific hypermethylation, both of which have been linked to gene silencing. Ni exposure can also lead to global and gene-specific decreases of histone acetylation.

It has been shown that Ni inhibits the activity of DNMTs both *in vivo* and *in vitro* (Lee *et al.*, 1998). In cells, Ni reduced DNMTs activity and the levels of genomic DNA methylation; however, this inhibition was transient. After a recovery period after Ni treatment, DNMT activity rebounded slightly and genomic DNA methylation levels increased to above basal levels (Lee *et al.*, 1998). In Chinese hamster ovary (CHO) cells, Ni bound selectively to heterochromatin and caused chromosomal damage in heterochromatic regions (Klein and Costa, 1997; Klein *et al.*, 1994a; 1994b). The binding of Ni to heterochromatin may play a key role in Ni-induced cell transformation and loss of senescence. Senescence in Ni-transformed cells was restored after treatment with the DNA methylation inhibitor 5-azacytidine (5-AzaC), suggesting that DNA hypermethylation played an important role in the silencing of the senescence gene(s) during Ni-induced cell transformation (Klein *et al.*, 1991). Further studies in transgenic CHO cell lines provided additional evidence linking Ni with DNA hypermethylation and inactivation of genes positioned near heterochromatin. Ni was found to silence a transgene that was stably transfected adjacent to a heterochromatic region in CHO cells without causing mutations or deletions of the transgene (Lee *et al.*, 1993). Instead, increased DNA methylation and chromatin condensation were observed at the Ni-silenced transgene locus. The demethylating agent 5-AzaC reversed this silencing, indicating that DNA hypermethylation was involved in the Ni-induced transgene inactivation (Lee *et al.*, 1995).

In addition to affecting DNA methylation, Ni has been shown to decrease histone acetylation globally in yeast, as well as a variety of mammalian cells (Broday *et al.*, 2000; Kang *et al.*, 2003). ROS generation has been shown to play a role in the inhibition of histone acetylation by Ni (Kang *et al.*, 2003). Ni was also found to inhibit the acetylation of histones *in vitro* using purified recombinant histone acetyltransferase (Broday *et al.*, 2000; Kang *et al.*, 2003). The decrease of histone H4 acetylation in chromatin associated with the Bcl-2 promoter region was verified by ChIP assays, indicating the involvement of histone hypoacetylation in Ni-induced Bcl-2 downregulation. This suggested that histone hypoacetylation might play a role in Ni-induced cell apoptosis, where Bcl-2 is one of the targets (Kang *et al.*, 2004). Hypoacetylation of H4 induced by Ni was observed at lysine's 12 and 16 in the N-terminal tail of histone H4 (Broday *et al.*, 2000). Because a histidine residue is present at

position 18 on histone H4, it has been suggested that this may be an anchoring site for Ni coordination. It was proposed that Ni might inhibit the acetylation of histone H4 through binding with its N-terminal histidine-18, rendering the neighboring lysine residues less accessible to histone acetyltransferases (Zoroddu *et al.*, 2000; 2002). Besides histidine 18 of histone H4, Ni-binding sites in H3, H2A, and H2B have also been identified *in vitro* (Kasprzak *et al.*, 2003). By using ^{63}Ni autoradiography of proteins on nitrocellulose membranes, Ni was found to bind to histone H1 and core histones (Huang *et al.*, 1995). In cells, such as CHO, NRK-52 (rat renal tubular epithelium), and HPL1D (human lung epithelium) cells, cleavage of C-terminal tail H2A by Ni was also found. Although the mechanisms and the consequences of this event remain unknown, Ni-induced truncation of H2A is likely to alter the chromatin structure and affect gene expression (Kasprzak *et al.*, 2003).

Histone modifications also participated in the Ni-induced transgene silencing and cell transformation. In yeast, changes in histone acetylation patterns, but not DNA methylation, are important regulators of gene transcription. Ni silenced a URA3 marker gene when it was located near (1.7 kb) a heterochromatic telomeric silencing element but not when it was placed 2.0 kb from this same element. Pretreatment of yeast cells with the histone deacetylase inhibitor trichostatin A (TSA) resulted in reduced levels of URA3 gene silencing after Ni exposure, indicating that histone acetylation was involved in this silencing (Broday *et al.*, 1999). Similarly, in mammalian cells, TSA pretreatment prevented Ni-induced transformation of PW or HOS cells. In addition, the exposure of Ni-transformed cells to TSA reversed the transformed phenotype as indicated by their inability to grow in soft agar (Zhang *et al.*, 2003). Results from ChIP assays revealed a loss of acetylation at histone H3 and H4, as well as increased methylation of H3 K9 at the Ni-silenced transgene locus in the transgenic Chinese hamster cells (Yan *et al.*, 2003). In a similar manner, treatment of the transgenic Chinese hamster cells with TSA during or after Ni exposure reduced Ni-induced inactivation of the transgene. Moreover, although exposure of Ni-silenced cell clones to 5-AzaC or TSA alone could partially reactivate the transgene expression, combining 5-AzaC with TSA was more efficacious in reactivating the transgene. These data suggested that in mammalian cells, both DNA hypermethylation and histone deacetylation participated in Ni-induced transgene silencing (Sutherland *et al.*, 2001). Table 1 summarizes the epigenetic events caused by metal compounds discussed previously.

6 EFFECTS OF METALS ON CELL SIGNALING PATHWAYS AND GENE EXPRESSION

6.1 Introduction

Epidemiological studies have shown that occupational and environmental exposure to metals and metalloid species, such as arsenic (As), cadmium (Cd), cobalt (Co), chromium (Cr), copper (Cu), iron (Fe), nickel (Ni), and vanadium (V), was associated with increased risk of various cancers and adverse health effects. Although the underlying mechanisms through which metals cause cancers remains unclear, recent studies have shown that activation of a variety of signaling pathways caused by metal exposure can affect the expression of numerous genes that play important roles in carcinogenesis. The metal-induced cellular signal transduction pathways mainly include ROS, the mitogen-activated protein kinases (MAPKs), the phosphoinositide 3-phosphate kinase (PI3K), hypoxia-inducible factor 1 (HIF-1), nuclear transcription factor κB (NF-κB), nuclear factor of activated T cells (NFAT), and activator protein 1 (AP-1). In the first part of this section, each pathway will be introduced briefly, and the impact of individual metals on these pathways will then be reviewed, with particular attention given to changes in gene expression. At the end of this section, we will summarize these effects in Table 2. It should be noted that the effects of metals on other pathways or transcription factors have been previously reviewed elsewhere (Chen and Shi, 2002; Leonard *et al.*, 2004a; Salnikow *et al.*, 2000).

TABLE 2 Summary of Signaling Pathways and Transcription Factors Affected by Metals

Factor	Description	Major components	Metal inducers
ROS	Reactive oxygen species	$^{-}$OH, H_2O_2, O^{-}	As, Cd, Cr, Co, Ni
MAPKs	The mitogen-activated protein kinases	ERK, JNK, p38	As, Cd, Cr, Co, Ni
PI3K	The phosphatidylinositol-3 kinase	p85, p110	As, Ni, Cu
HIF-1	Hypoxia-inducible factor 1	HIF-1alpha, HIF-1beta	As, Cr, Co, Ni, V
NF-κB	The nuclear transcription factor kappa B	p50, p65	As, Cd, Cr, Co, Ni
NFAT	The nuclear factor of activated T cells	NFATC1-C4	Ni, V, Fe
AP-1	Activator protein 1	c-fos, c-jun	As, Cd, Cr, Ni, Fe, V

6.2 Signal Transduction Pathways Affected by Metal Compounds

6.2.1 ROS

Reactive oxygen species (ROS) are highly reactive molecules with unpaired electrons formed during oxidative metabolism. They include the superoxide anion (O_2^-), the hydroxyl radical (OH), and hydrogen peroxide (H_2O_2) (Halliwell, 1981; Halliwell and Gutteridge, 1984). They are continuously generated and eliminated in biological systems and play important roles in the regulation of cell proliferation, apoptosis, transformation, and senescence. Cells are able to defend against ROS stress with antioxidant scavengers (i.e., ascorbate, glutathione, and thioredoxin), and antioxidant enzymes (i.e., superoxide dismutase [SOD], catalase, glutathione peroxidase, and thioredoxin reductase). With their antioxidant defense systems, cells can adapt to low physiological concentration of ROS (Storey, 1996). However, ROS can cause oxidative damage to cellular macromolecules, including DNA, proteins, and lipids, when generation of these potentially harmful species exceeds cellular antioxidant defenses. ROS play important roles in the initiation of cellular injury that can lead to the development of cancer (Toyokuni, 1998; Toyokuni *et al.*, 1995). One of the most important ways that ROS may cause cancer is by acting as signal transduction messengers to activate signaling pathways, such as MAPK, PI3K, NF-κB, and NFAT (Leonard *et al.*, 2004a). Therefore, we have included ROS in the discussion of the effects of metal compounds on signaling pathways. Studies have shown that exposure of cells to As, Cd, Co, Cr, Cu, Ni, as well as many other metal compounds, can generate excessive ROS in cells by Fenton-type reaction, Haber–Weiss reaction, or by reacting directly with cellular molecules.

6.2.2 MAPK

The mitogen-activated protein kinase (MAPK) signaling pathway plays an important role in controlling gene expression programs in response to extracellular signals in eukaryotic cells. There are four major groups of MAPK family in mammalian cells, and they are serine/threonine kinases: extracellular signal regulated kinase (ERK), c-jun N terminal kinase (JNK), p38, and extracellular signal regulated kinase-5 (ERK5)/big MAPK-1 (BMK1) (Lewis *et al.*, 1998). Each group also contains a number of isoforms. MAPK signaling pathways feature a series of phosphorylation cascades. On receiving extracellular signals such as growth factors, hormones, and stress stimuli, the MAPKs are activated by phosphorylation on threonine and tyrosine by the MAPK kinases (MAPKK), which are activated by serine/threonine phosphorylation by MAPK kinase kinases (MAPKKK). Additional protein kinases and members of the Ras and Rho families of small GTPases may also participate upstream of the MAPKKKs. Once activated, MAPKs can alter the activity of target transcription factors and transcriptional coregulators by phosphorylation, resulting in changes in the expression of genes that mediate cell growth, proliferation, differentiation, apoptosis, and transformation (Schaeffer and Weber, 1999). Studies have shown that metals, such as As, Cd, Co, Cr, and Ni, can activate MAPK pathways.

6.2.3 PI3K/Akt

The phosphatidylinositol-3 kinase (PI3K) pathways are involved in regulating cell growth, differentiation, and apoptosis (Fresno Vara *et al.*, 2004). PI3Ks constitute a lipid kinase family characterized by their abilities to phosphorylate phosphoinositides (PIPs) at the 3′-OH of the inositol ring in the cell membrane (Toker and Cantley, 1997). The best-known class of PI3Ks is a heterodimer composed of a regulatory subunit, p85, and a catalytic subunit, p110. On activation by growth factor receptor protein tyrosine kinases, PI3K is recruited to the cell membrane, where it phosphorylates PIPs to generate the second messenger phosphatidylinositol-3,4,5-triphosphate (PIP3). PIP3 then recruits a subset of signaling proteins to the membrane, including protein serine/threonine kinase 3′-phosphoinositide–dependent kinase 1 (PDK1) and Akt/PKB. Akt is also a serine/threonine kinase and is activated by phosphorylation by PDK1 (Fresno Vara *et al.*, 2004). Activation of the PI3K/Akt pathway induces cell growth and inhibits apoptosis. As, Cd, Co, Ni, and V have been shown to be able to activate the PI3K/Akt pathway.

6.2.4 HIF-1

The transcription factor hypoxia-inducible factor 1 (HIF-1) plays an essential role in cellular oxygen homeostasis (Wang and Semenza, 1993). It is a heterodimer composed of α- and β-subunits (Wang *et al.*, 1995). The β subunit, HIF-1β/ARNT, is constitutively expressed; whereas the α subunit (HIF-1α) is highly oxygen sensitive. It is rarely detectable under normal oxygen tension but is dramatically induced in response to hypoxia. Under reduced oxygen tension, HIF-1α is stabilized and translocates to the nucleus, where it dimerizes with HIF-1β and HIF-1 becomes activated (Wang *et al.*, 1995). As a result, the activated HIF-1 stimulates the transcription of various cancer-related genes involved in angiogenesis, cell survival, glucose transport, and metabolism (Semenza, 2003). For example, HIF-1 upregulates the vascular endothelial growth

factor (VEGF), which plays a key role in tumorigenesis and angiogenesis. HIF-1α is regulated by a reduced oxygen level largely by its posttranslational modifications, resulting in stabilization, nuclear translocation, DNA binding activity, and transcriptional activity of the protein (Ferrara and Davis-Smyth, 1997). The posttranslational modifications of HIF-1α include prolyl hydroxylation at proline 402 and 564 within the oxygen-dependent degradation (ODD) domain by HIF-prolyl hydroxylases (HPHs) (Epstein *et al.*, 2001), asparaginyl hydroxylation at asparagine 803 in the C-terminal activation domain (C-TAD) by factor inhibiting HIF-1 (FIH-1) (Lando *et al.*, 2002), acetylation of lysine 532 in the ODD domain by an acetyltransferase (ARD-1) (Jeong *et al.*, 2002), phosphorylation induced by ERK activity (Richard *et al.*, 1999), as well as ubiquitination by the Von Hippel–Lindau (pVHL) complex (Maxwell *et al.*, 1999; Salceda and Caro, 1997). Co and Ni are well-known agents that mimic hypoxia and, in turn, activate HIF-1. Some other metals such as As, Cd, Cr, and V have also been reported to activate the HIF-1 pathway.

6.2.5 NF-κB

Initially discovered as a factor in the nucleus of B cells that binds to the enhancer of the kappa light chain of immunoglobulin, the nuclear transcription factor kappa B (NF-κB) was later found to be present in all cell types. In resting cells, NF-κB is inactive in the cytoplasm and composed of a heterodimer of p50 and p65 bound to the inhibitor of NF-κB (IκB). In response to inflammatory stimuli, tumor promoters, carcinogens, viral proteins, or mitogens, IκB is phosphorylated and ubiquitinated, leading to its degradation. Degradation of IκB releases NF-κB to translocate into the nucleus, where it regulates the transcription of specific genes that mediate various cellular functions, such as inflammation, transformation, proliferation, invasion, angiogenesis, metastasis, and apoptosis (Shishodia and Aggarwal, 2004). Although NF-κB is required for the normal function of the immune system, its deregulation has been implicated in a variety of cancers in which NF-κB is overexpressed. Metals such as As, Cd, Co, Cr, and Ni have been found to affect NF-κB.

6.2.6 NFAT

The nuclear factor of activated T cell (NFAT) proteins are a family of transcription factors whose activation is controlled by Ca and the Ca/calmodulin-dependent serine phosphatase calcineurin. Like NF-κB, originally identified in T cells as an inducer of cytokine gene expression, NFAT was later found to play various roles in cells outside of the immune system, including differentiation, angiogenesis, chondrogenesis, and adipogenesis. The best-characterized transcription factors of NFAT family are NFATC1-C4 (Rao *et al.*, 1997). In resting cells, NFAT proteins are phosphorylated and reside in the cytoplasm; on stimulation, during a sustained elevation of calcium, they are dephosphorylated by calcineurin and translocated to the nucleus. Once in the nucleus, NFAT proteins become transcriptionally active and bind to consensus DNA sites, therein controlling the transcription of target genes. On cessation of Ca signaling, NFAT proteins are rephosphorylated and translocated back to the cytoplasm, resulting in the termination of their activities. NFAT can interact with NF-κB and AP-1 (Macian *et al.*, 2000; 2001). Their activities are further modulated by diverse signal transduction pathways, which affect NFAT kinases and nuclear partner proteins. Ni, V, and Fe have been shown to activate NFAT.

6.2.7 AP-1

The transcription factor activator protein 1 (AP-1) is a dimeric complex that is composed of members of the JUN, FOS, ATF (activating transcription factor), and MAF (musculoaponeurotic fibrosarcoma) families (Eferl and Wagner, 2003). The predominant form of AP-1 in most cells is Fos/Jun heterodimer, which has a high affinity for binding to the TPA-responsive element (TRE) (also called AP-1 site). C-jun and c-fos are mostly considered to be oncogenic and associated with carcinogenesis (Angel and Karin, 1991). Extracellular stimuli such as cytokines, UV radiation, growth factors, oxidative stress, and carcinogens can induce AP-1 and promote AP-1 binding to the TRE of its target genes that are involved in cell growth, inflammatory responses, and repair processes. As, Cd, Cr, Co, Ni, and V have been shown to activate AP-1.

6.3 Impacts of Metal Compounds on Signal Transduction Pathways and Gene Expression

6.3.1 As

Arsenite (As III) has been shown to generate ROS, activate MAPK, PI3K/Akt, HIF-1, and AP-1. It can also activate or inhibit NF-κB depending on the doses, cell types, and/or exposure time.

As can induce ROS formation by activating radical-producing systems in cells. As (>1 μ*M*) activated NADH oxidase to produce superoxide, which then caused oxidative DNA damage during a 4-hour treatment in human vascular smooth muscle cells (Lynn *et al.*, 2000). Similarly, As (5 μ*M*) stimulated a twofold increase in the activity of plasma membrane NADH oxidase by 1 hour and generated excessive superoxide

in PAEC porcine aortic endothelial cells (Smith *et al.*, 2001). As also induced a dose-dependent increase of up to threefold in intracellular oxygen radical production in A (L) human–hamster hybrid cells within 5 minutes. This As-induced ROS, particularly hydroxyl radicals, played an important causal role in its genotoxicity (Liu *et al.*, 2001b).

It has been shown that both As (III) (arsenite) and As (VI) (arsenate) activated the MAPK kinases, ERK, JNK, and p38 in NHEK normal human epidermal keratinocytes (Tanaka-Kagawa *et al.*, 2003). As (III) also activated ERK, JNK, and p38 in BEAS human bronchial epithelial cells (Samet *et al.*, 1998), resulting in the activation of c-jun (a major phosphorylation target of JNK) and transcription factor 2 (ATF-2) (a substrate for p38 and JNK), as well as, increased interleukin-8 (IL-8) protein levels. In addition, activation of JNK by As was involved in As-induced p21Cip1/Waf1 upregulation and endothelial apoptosis in human umbilical vein endothelial cells (HUVEC) (Nuntharatanapong *et al.*, 2005). In JB6 Cl 41 mouse epidermal cells, activation of JNK was required for As-induced p53-independent apoptosis (Huang *et al.*, 2001b), whereas activation of ERK, but not JNK, was required for As-induced cell transformation (Huang *et al.*, 1999). Moreover, in LMH chicken hepatoma cells, As induced heme oxygenase 1(HO-1), which is overexpressed in various cancers, in an ERK- and p38-dependent manner (Elbirt *et al.*, 1998). The ability of As to activate different MAPKs and cellular signals depends on its concentration. In rat lung epithelial cells, a low level of As (2 μ*M*) stimulated the ERK signaling pathway and enhanced cell proliferation. In comparison, a high level of As (40 μ*M*) stimulated JNK signaling pathway and induced cell apoptosis. This result indicated that a high concentration of arsenic exposure caused apoptosis, whereas a low concentration of arsenic exposure was carcinogenic and might result in accumulation of aberrant cells (Lau *et al.*, 2004).

Studies have indicated that As activated Akt and its downstream effector eNOS via PI3K and p38 pathways in HaCat human keratinocytes (Souza *et al.*, 2001). In human Jurkat cells (a T cell leukemia cell line), As induced the activation of Akt and its downstream glycogen synthase 3β (GSK3β) via PI3K, and this activation promoted the As-triggered caspase activation (Hossain *et al.*, 2003).

It has been shown that As induced HIF-1α protein levels and increased the expression of VEGF through HIF-1 in DU145 human prostate carcinoma cells. As-activated PI3K/Akt pathway and As-generated H_2O_2, but not MAPK pathway, were required for this induction (Gao *et al.*, 2004). Upregulation of VEGF by As has also been shown to be independent of HIF-1, but dependent on p38, in OVCAR-3, human ovarian cancer cells (Duyndam *et al.*, 2003).

As could be an inducer or inhibitor of NF-κB, depending on the cell type, the concentration of As, and the duration of treatment. In human foreskin keratinocytes, arsenic induced keratinocyte proliferation and enhanced both NF-κB and AP-1 activity at lower concentrations (≤1 μ*M*), whereas at higher concentrations (≥5 μ*M*), it induced keratinocyte apoptosis by the Fas/Fas ligand (Fas/FasL) pathway, in which NF-κB activity was not enhanced while AP-1 was activated. These results indicated that upregulation of NF-κB at lower As concentrations was correlated with keratinocyte proliferation. In contrast, higher concentrations of As enhanced AP-1 and induced Fas/FasL-associated apoptosis (Liao *et al.*, 2004). At low concentrations, As activated NF-κB and NF-κB–dependent transcription in PAEC cells, although it was insufficient to activate MAPKs with these concentrations. However, the MAPKs, ERK and p38, were activated in response to levels of As that caused cell death (Barchowsky *et al.*, 1996; 1999). As induced transactivation of NF-βB in a dose- and time-dependent manner in C141 mouse skin epidermal cells through ERK- and JNK-pathways (Huang *et al.*, 2001b). At high concentrations, As has been shown to activate NF-κB, resulting in p53-independent apoptosis in JB6 mouse epidermal cells. Conversely, high levels of As (500 μ*M*) have also been shown to inhibit NF-κB–mediated gene transcription by blocking IκB kinase activity and IκBa phosphorylation and degradation in BEAS/2B and HEK293 human embryonic kidney cells (Roussel and Barchowsky, 2000). In human GM847 fibroblasts, As increased the DNA binding of NF-κB after 24 hours of treatment, whereas it decreased this inflammatory mediator with longer treatment (10–20 weeks) of As (Hu *et al.*, 2002).

As is an efficient inducer of *c-fos* and *c-jun* gene expression and a potent stimulator of AP-1 transcriptional activity. Induction of c-jun and c-fos transcription by As correlated with activation of JNK and p38 in human keratinocytes. Phosphorylated JNK and p38 transcription factors in turn activated the *c-jun* and *c-fos* genes (Cavigelli *et al.*, 1996).

6.3.2 Cd

Cadmium (Cd II) exposure of cells can generate ROS, activate MAPKs, NF-κB, and AP-1 but is known to suppress HIF-1 levels.

Cd caused a significant increase of ROS production, especially H_2O_2, in MRC-5 human fetal lung fibroblasts (Yang *et al.*, 1997). A concentration-dependent increase in ROS and loss of activities of antioxidant enzymes such as superoxide dismutase (SOD), catalase, glutathione

reductase, and glutathione peroxidase, were observed when CRL-1439 normal liver cells were exposed to Cd (100–300 μ*M*) (Ikediobi *et al.*, 2004). In mouse neuronal cells, Cd induced ROS, which in turn, activated JNK and p38, as well as their substrates, such as activating transcription factor 2 (ATF-2), CRE-binding protein (CREB), and c-Jun. This response was accompanied by the induction of HO-1, poly (ADP-ribose) polymerase cleavage, and a caspase-independent cell death (Rockwell *et al.*, 2004).

MAPKs (i.e., ERK, JNK, and p38) are activated with differing sensitivity to Cd exposure. In CL3 human non-small cell lung carcinoma cells, the kinase activity of JNK was induced dose dependently by Cd (30–160 μ*M*) treatment. High doses of Cd (130–160 μ*M*) markedly activated p38, but low Cd doses did not. Conversely, the activity of ERK was decreased by doses of Cd (≤80 μ*M*) and moderately activated by high Cd doses. Low doses of Cd transiently activated JNK and simultaneously reduced ERK activity, whereas high doses of Cd persistently activated JNK and p38. JNK and p38 cooperatively participated in apoptosis induced by Cd. In addition, the decreased amount of ERK signaling induced by low Cd doses contributed to growth inhibition or apoptosis (Chuang *et al.*, 2000). In CCRF-CEM cells, a human T cell line, ERK and p38 were phosphorylated by 1 μ*M* of Cd, whereas levels greater than 20 μ*M* of Cd were required for the phosphorylation of JNK. In the time-course study, ERK and p38 were phosphorylated earlier than JNK after Cd exposure (Iryo *et al.*, 2000). It has also been shown that exposure of human breast cancer cells (MCF-7) to 10 μ*M* Cd stimulated phosphorylation of ERK, JNK, and p38, and activation of p38 pathway was required for Cd-induced HO-1 gene expression (Alam *et al.*, 2000). Pulse treatment of U-937 monocytic cells with Cd (2 hours at 200 μ*M*) induced a rapid phosphorylation of p38, as well as a late phosphorylation of ERK. P38 activation was an early and specific regulatory event for the Cd-induced apoptosis (Galan *et al.*, 2000). Cd persistently activated the JNK pathway in LLC-PK1, a renal epithelial cell line, and an elevation of intracellular Ca was required for this activation (Matsuoka and Igisu, 1998). P38 and ERK can be simultaneously or independently activated, depending on the concentrations of Cd ranging from 40–100 μ*M*. These signaling pathways have been shown to participate in the induction of heat shock proteins (HSPs) by Cd in 9L rat brain tumor cells (Hung *et al.*, 1998).

Cd has been shown to increase p53 protein level and induce phosphorylation of p53 at Ser 15 in MCF-7 cells, and this effect depends on PI3K related kinases, but not on MAPKs (Igisu, 2001).

Cd reduced the amount of HIF-1α protein in hypoxia and inhibited HIF-1α accumulation induced by Co and desferrioxamine (DFO), although it did not affect the levels of HIF-1α mRNA in Hep3B human hepatoma cells. Antioxidants and a proteasome inhibitor prevented the HIF-1α degradation caused by Cd, indicating that Cd triggered a redox/proteasome-dependent degradation of HIF-1α protein, reducing HIF-1 activity, and in turn, suppressing the induction of hypoxia-inducible genes (Chun *et al.*, 2000).

Cd induced significant activation of AP-1 and all three members of the MAPK family in mouse epidermal JB6 cells, and activated ERK was involved in Cd-induced AP-1 activity (Huang *et al.*, 2001c). Exposure of mesangial cells to Cd caused an increase of protooncogene *c-fos* mRNA level. Activation of ERK and JNK acted in concert during the Cd-induced *c-fos* increase (Ding and Templeton, 2000a; 2000b; Wang and Templeton, 1998). JNK activity and c-jun mRNA levels, as well as AP-1 DNA binding activity, were significantly enhanced by Cd in primary rat hepatocytes (Hsiao and Stapleton, 2004).

In mouse brain microvessel endothelial cells (bEnd.3), Cd induced the translocation of NF-κB and increased its DNA binding activity. This activation was required for Cd-induced intercellular adhesion molecule-1 (ICAM-1) expression (Jeong *et al.*, 2004).

6.3.3 Cr

Chromium (Cr (VI)) can generate ROS, activate MAPKs, NF-κB, and HIF-1 in cells. Cr mediates free radical generation by Fenton-type reaction, Haber–Weiss reaction, or by reacting directly with cellular molecules (Leonard *et al.*, 2004b). It has been shown that Cr (VI) was able to enter A549 cells at low concentrations (<10 μ*M*), resulting in an elevation of ROS in cells (Liu *et al.*, 2001a). In the same cell line, Cr-induced ROS generation was shown to be responsible for the early stage of Cr-induced apoptosis, whereas Cr-activated p53, mostly by ROS-mediated free radical reactions, contributed to a late stage induction of apoptosis (Wang and Shi, 2001; Ye *et al.*, 1999). Cr (VI)-induced ROS production, as well as oxidative damage to tissue and to DNA, was also observed in a number of cell lines, such as human peripheral blood mononuclear cells, chronic myelogenous leukemic K562 cells, and J774A.1 murine macrophage cells. Moreover, p53 has been shown to play a major role in Cr (VI)-induced oxidative stress and toxicity (Bagchi *et al.*, 2001). ROS acted as a second messenger mediating Cr (III)-induced apoptosis in lymphocytes. It activated the Src-family tyrosine kinases, which, in turn, led to the activation of caspase-3 in Cr-induced apoptotic cell death (Balamurugan *et al.*, 2002; 2004).

Exposure of CL3 human non-small cell lung carcinoma cells to Cr (VI) markedly activated JNK and p38 and moderately activated ERK in a dose- (10–80 μ*M*) and time- (1–12 hours) dependent manner. Activation of ERK, JNK, and p38 by Cr (VI) were through diverse redox mechanisms. When Cr (VI) was removed from the medium, the activated p38 decreased rapidly, whereas the activated JNK decreased gradually (Chuang *et al.*, 2000). In A549 human lung epithelial cells, Cr (VI) (10 μ*M*) increased ROS and selectively activated JNK, relative to ERK or p38 MAPK (O'Hara *et al.*, 2003). Moreover, it has been shown that ERK acted as the upstream kinase for the phosphorylation of the p53 at Ser15 in response to Cr (VI) in the same cell line (Wang and Shi, 2001).

Cr (VI) has been shown to activate HIF-1 activity by inducing HIF-1α but not HIF-1β and increased the level of VEGF expression in DU145 human prostate carcinoma cells. P38, but not PI3K nor ERK, was required for Cr-induced HIF-1α expression (Gao *et al.*, 2002).

Exposure of cultured Jurkat cells to Cr (VI) (2 μ*M*) resulted in activation of DNA binding activity of NF-κB via Cr (VI)-mediated free radical reactions (Ye *et al.*, 1995). Cr (<10 μ*M*) also activated NF-κB in A549 cells (Liu *et al.*, 2001a). By use of two cell lines that were developed from BEAS-2B human bronchial epithelial cells, IKK cells, in which a IκBα expression vector with normal NF-κB activity was stably transfected; and KM cells, in which a mutated IκBα kinase expression vector exhibiting very little NF-κB activity was stably transfected, it has been shown that with Cr (VI) stimulation, KM cells, but not IKK cells, exhibited pronounced cell death. This result indicated that NF-κB activation was required to prevent cells from undergoing Cr (VI)-induced apoptosis (Wang *et al.*, 2004b). Cr (VI) activated NF-κB and AP-1 in a dose-dependent manner, but both activations were substantially inhibited by antioxidants. Furthermore, Cr-induced AP-1 was mediated by p38, and Cr-induced NF-κB involved the IKK pathway (Chen *et al.*, 2000).

6.3.4 Co

Cobalt (Co II) can produce ROS, activate MAPKs, NF-κB, and HIF-1 in cells.

Co can generate ROS by Fenton-type or Haber–Weiss reactions. It has been shown that exposure of a variety of cell lines to soluble salts of Co, such as pulmonary artery smooth muscle cells (PASMC), A549, neuronal PC12 cells, human hepatoma cells Hep3B and HepG2, resulted in increased ROS production (BelAiba *et al.*, 2004; Chandel *et al.*, 1998; Porwol *et al.*, 1998; Salnikow *et al.*, 2000). Co-mediated ROS production in neuronal PC12 cells was believed to mediate Co-induced apoptosis (Zou *et al.*, 2002). Co (400 μ*M*, IC50) has been shown to activate ERK in C6 glioma cells, as well as in HeLa human cervical cancer cells, and this pathway is believed to mediate Co-induced apoptosis (Kim *et al.*, 2003; Yang *et al.*, 2004).

Co has been known to mimic hypoxia by inducing HIF-1 and hypoxic-regulated genes, such as erythropoietin (EPO) and VEGF in various cell lines (Semenza *et al.*, 1994; Wang and Semenza, 1993). Co also induced Cap43, a hypoxia-regulated gene in a HIF-dependent manner in A549 cells (Salnikow *et al.*, 2000). Activation of HIF-1α by Co involved the PI3K pathway and production of ROS in airway smooth muscle (ASM) cells (Chachami *et al.*, 2004). However, it has also been shown that the formation of ROS was not involved in Co-induced HIF-1 activation or upregulation of hypoxia-dependent genes in A549 cells (Salnikow *et al.*, 2000). The ability of Co to mimic hypoxia occurs because Co can affect a variety of genes/enzymes that are responsible for the posttranslational modification of HIF-1α. Co has been shown to inhibit prolyl hydroxylase activity, alter the levels of factor inhibiting HIF (FIH1) and ARD1, and occupy the VHL-binding domain of HIF-1α. These changes prevent HIF-1α degradation, lead to increased stability of HIF-1α, and increase the transcription of HIF-1–dependent genes.

Co induced the DNA-binding activity of NF-κB in HUVEC, which could induce the transcription of adhesion molecules ICAM-1, VCAM-1, and E-selectin in endothelial cells (Goebeler *et al.*, 1995; Sultana *et al.*, 1999).

6.3.5 Ni

Nickel (Ni II) can generate ROS, activate MAPKs, PI3K, HIF-1, and NF-κB, although its impact on AP-1 is equivocal.

Ni compounds, such as NiS, Ni3S2, NiO (black and green), and NiCl2, have been shown to be active inducers of ROS in CHO cells (Huang *et al.*, 1993; 1994a; 1994b). Intracellular glutathione was also depleted by Ni exposure (Andrew *et al.*, 2001b). The Ni-induced ROS played a role in oxidative base damage, measured by the formation of 7,8-dihydro-8-oxo-2′-deoxyguanosine (8-oxo-dG) (Huang *et al.*, 1995). An involvement of ROS has also been shown to participate in the inhibition of DNA repair by Ni^{+2} (Lynn *et al.*, 1997). Increase of ROS generation by Ni exposure was suggested to increase Ca-dependent activation of NFAT, possibly contributing to cell transformation (Huang *et al.*, 2002b). However, it has been shown that the formation of ROS was not involved in the activation of other transcription factors and their downstream genes. For example, activation of HIF-1 and HIF-1–dependent

genes by Ni seemed to be independent of ROS generation (Salnikow *et al.*, 2000).

Ni induced the phosphorylation of ERK, JNK, and p38 in human monocyte–derived dendritic cells. These MAPKs were involved in Ni-induced CD83 and the interleukin-12 p40 production (Aiba *et al.*, 2003). It has also been shown that ERK, JNK, and p38 participated in the expression of CD83, CD86, and CCR7, therefore regulating maturation induced by Ni in human CD34(+)-derived DC dendritic cells (Boisleve *et al.*, 2005).

Exposure of Cl 41 mouse epidermal cells to Ni^{+2} resulted in activation of PI3K, Akt, and p70 S6 kinase (p70(S6k)). PI-3K/Akt pathway, but not p70(S6k), was required for Ni-induced HIF-1 transactivation and Cap43 induction (Li *et al.*, 2004).

It is well documented that Ni is able to mimic the hypoxic response. Ni can stabilize HIF-1α protein, and activate HIF-1, which in turn upregulates a battery of hypoxia-inducible genes (Semenza *et al.*, 1994; Wang and Semenza, 1993). By using the Affymetrix gene chip combined with Northern blots, a variety of genes have been shown to be upregulated or downregulated in an HIF-dependent manner when cells were exposed to Ni compounds (Salnikow *et al.*, 2002; 2003a; 2003b). For example, it has been shown that 1,4-alpha-glucan branching enzyme 1 (GBE1) was one of the most upregulated genes by Ni (Zhao *et al.*, 2004a). This gene was also upregulated by Co, hypoxia, the iron chelator (deferoxamine, or DFO), and the prolyl hydroxylase (PH) inhibitor (dimethyloxalylglycine, DMOG). Moreover, it was upregulated by these treatments only in HIF-$1\alpha^{+/+}$, but not HIF-$1\alpha^{-/-}$ mouse cells, suggesting that this gene was induced through a HIF-dependent hypoxic signaling pathway (Zhao *et al.*, 2004a). Similarly, Bcl-2-binding protein Nip3 (BNIP3) was upregulated by Ni^{+2} in a HIF-dependent manner (Salnikow *et al.*, 2003b). Serpina3g, a member of the mouse serpin family, was downregulated by Ni treatment through the HIF-1 pathway (Zhao *et al.*, 2004b). Although the mechanism of HIF-1 activation by Ni is not clear yet, several hypotheses have been proposed. For instance, it has been reported that the ability of Ni to stabilize HIF-1α protein is likely by inhibiting the posttranslational modifications of HIF-1α. The enzymatic activity of prolyl hydroxylases requires Fe as the activating metal, 2-oxoglutarate as a cosubstrate, and ascorbic acid as a cofactor. Ni may impair the activity of prolyl hydroxylases by depleting cellular Fe through its competition of Fe entry into cells through the DMT-1 transporter and/or by substituting for Fe in the HIF-prolyl hydroxylase (Bunn *et al.*, 1998; Chen *et al.*, 2005; Huang *et al.*, 1997). Ni also down regulated the transcription of the asparaginyl hydroxylase FIH-1 and acetyltransferase ARD-1 in A549 cells (Ke *et al.*, In Press).

Ni^{+2} activated NF-κB DNA binding and induced gene transcription of adhesion molecules ICAM-1, VCAM-1, and E-selectin in HUVEC (Goebeler *et al.*, 1995). It also induced mRNA production and protein secretion of the NF-κB–controlled proinflammatory cytokine IL-6 in a dose-dependent manner. Ni-induced activation of NF-κB and adhesion molecule expression was inhibited by the antioxidant pyrrolidine dithiocarbamate, indicating some involvement of redox-dependent mechanisms (Goebeler *et al.*, 1995). It has also been shown that Ni phosphorylated IκB and NF-κB in human monocyte–derived dendritic cells (Aiba *et al.*, 2003). NF-κB activity was also induced by Ni exposure in 3T3 and BEAS-2B cells, where NF-κB played a role in the induction of Cap43 by Ni. Conversely, similar treatment of cells with soluble Ni salts did not induce AP-1 activity (Huang *et al.*, 2002b). The effect of Ni on AP-1 is controversial though. It has also been shown that Ni-induced *c-jun* and *c-fos* mRNA levels, as well as increased phospho- and total c-Jun protein levels in BEAS/2B cells. This Ni-dependent activation of AP-1 was through an oxidant-independent pathway, and AP-1 was necessary for Ni-induced expression of plasminogen activator inhibitor (PAI-1) (Andrew *et al.*, 2001a). The Ni-induced NFAT activation seemed to be mediated by the generation of H_2O_2 by Ni, because the scavenging of Ni-induced H_2O_2 with N-acetyl-L-cysteine (a general antioxidant) or catalase (a H_2O_2 scavenger) abolished this activation. In contrast, pretreatment of cells with sodium formate (an OH radical scavenger) or SOD (an O_2^- radical scavenger) did not show any inhibitory effects (Huang *et al.*, 2001a).

6.3.6 Other Metals

In addition, some other metal compounds, such as vanadate (V), copper (Cu (II)), and iron (Fe (II)), have also been shown to impact signal transduction pathways. For example, V induced HIF-1α and VEGF by a PI3K/Akt-dependent, but a MAPK-independent, pathway in DU145 cells (Gao *et al.*, 2002). It also affected the expression of NFAT through H_2O_2 in JB6 mouse epidermal cells (Huang *et al.*, 2001a). V exposure activated AP-1 dose dependently, and O_2^-/H_2O_2 were involved in this activation (Ding *et al.*, 1999). It has been shown that Cu generated ROS in cells, but it activated PI3K independent of ROS (Ostrakhovitch *et al.*, 2002). Cu has also been shown to induce HIF-1α and VEGF levels (Martin *et al.*, 2005). NFAT and AP-1 could be induced in JB6 cells exposed with coal containing high levels of bioavailable iron or ferrous sulfate (Huang *et al.*, 2002a). Table 2 summarizes the signaling pathways and transcription factors induced by all of the metals discussed in this section.

CHAPTER

6

General Considerations of Dose-Effect and Dose-Response Relationships*

DAPHNE B. MOFFETT, HISHAM A. EL-MASRI, AND BRUCE A. FOWLER

ABSTRACT

In 2003, the International Union of Pure and Applied Chemistry (IUPAC) issued a glossary of terms that included the definition of dose-effect and dose-response relationships (Nordberg *et al.*, 2004). Dose-effect relationship is defined as an association between dose and the resulting magnitude of a continuously graded change, either in an individual or in a population. Dose-response relationship is an association between dose and the incidence of a defined biological effect in an exposed population usually expressed as a percentage.

In this chapter, we introduce the concepts of dose, response, effect, and the relationships between them and the curves that illustrate them. Modeling the dose-response relationships, comparing the shapes of the curves, and modeling the data are also addressed. Thoughtful discussion is given to species extrapolations, including the complexities of gaining statistical power with limited-sized animal experiments. Benchmark dose is also introduced as an alternative metric to NOAEL (no observed adverse effect level) to determine an allowable exposure to toxic chemicals.

*This chapter is based on the chapter with the same title by Emil A. Pfitzer and Velimir Vouk in the 2nd edition of the Handbook.

Disclaimer: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention/Agency for Toxic Substances and Disease Registry or the Environmental Protection Agency.

1 GENERAL ASPECTS OF DOSE-RESPONSE RELATIONSHIPS

A dose-effect relationship exists if a change in dose of a chemical causes a quantifiable change in the effect observed. When the observed effect does not have a variable level within an individual, but is either present or not present (often called all-or-none effect), a dose-response relationship exists if the percentage of a population responding with that effect depends on the dose of a chemical. These statements are basic concepts of pharmacology and toxicology. Whether we are concerned with beneficial effects, as in pharmacology, or with adverse effects, as in toxicology, an increased dose of a chemical is expected to cause either an increased *effect* in an individual or an increased *response* in a population.

1.1 Use of the Terms Effect and Response

It is useful to apply the terms *effect* and *response* in the manner just specified, although semantic considerations could allow the two terms to be used as synonyms. This specialized use should not cause confusion but rather should provide a focus on a relationship with dose that is given either (1) by a graduated change

in a continuum of biological changes that can be quantitatively measured to provide an "effect" or (2) by the presence of a specified change in a certain proportion of the individuals in a population providing "response."

This distinction in terminology is needed for a clear and precise description of changes resulting from a dose or doses of a chemical. When a population of individuals receives a dose of a chemical, both effect and response occur simultaneously (i.e., some individuals respond with an effect of a certain magnitude, whereas other individuals respond with a greater or lesser effect). Furthermore, more than one kind of effect may occur at the same time. The need to differentiate the variations in magnitude and kind of effect from the variations in the number of individuals responding makes this use of the terms *effect* and *response* valuable. A set of hypothetical data is used to illustrate the interrelationships between effect and response.

1.2 Interrelationships Among Dose, Effect, and Response

First, consider the simplest situation for the observation of a dose-effect relationship. This would be for an individual subject in which a series of doses of a chemical would be administered; after each dose, a single kind of effect would be quantitatively determined. One could then plot the magnitude of the dose against the magnitude of the effect. This situation assumes that each successive dose is independent (i.e., the subject returns completely to the original state between doses). However, in most situations the effect has some residue that may change the magnitude, and possibly the kind, of effect resulting from the next dose. Therefore, it is generally necessary to use populations of individual subjects to quantity changes due to individual doses where each time the subject is naive.

Next, consider a study in which a population of 40 subjects is randomly distributed into four groups of 10 each, and each group of 10 is given a different dose of a chemical. The effect on each subject is then measured on a quantitative scale, and the values are plotted with dose as in Figure 1.

With such data as in Figure 1, it may be useful to make general statements (either graphical or mathematical) about the relationship with dose. Specifically, it is useful to interpolate between doses. Thus, one may plot (see Figure 2) a curvilinear relationship using the median effect at each dose (the term "median effect" meaning that 50% of the population responded with this or a lesser effect). Alternately, one could determine the percent responding at each dose by a defined level of effect and plot the relationships as shown in Figure 3. In addition, one could plot the distribution of effect for the population at a specific dose level, as shown in Figure 4.

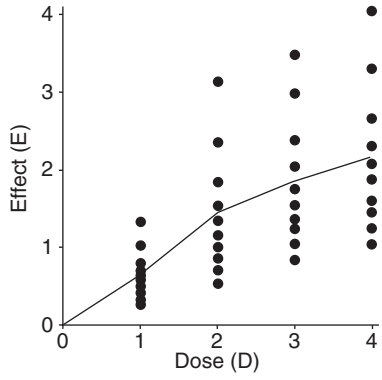

FIGURE 1 Hypothetical observations of effect on 10 subjects at each dose. The line is point-to-point based on the arithmetic mean of the values for effect.

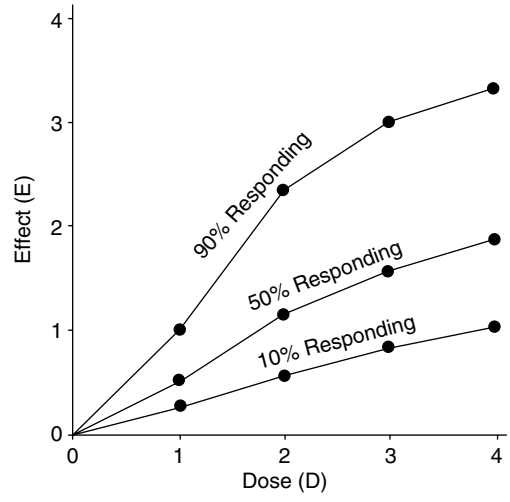

FIGURE 2 Point-to-point plots for the dose-effect relationships at equi-response based on data from Figure 1.

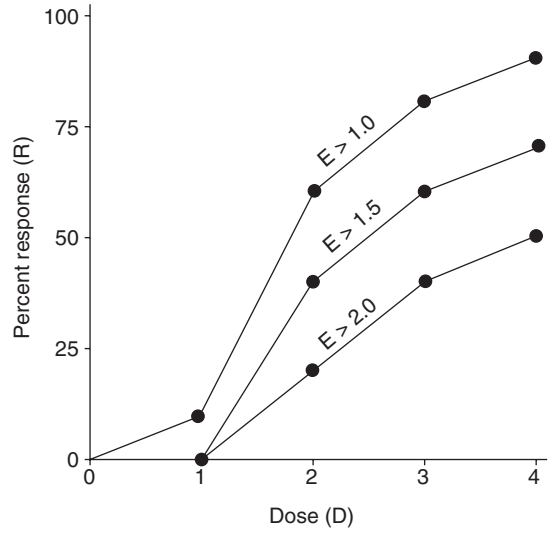

FIGURE 3 Point-to-point plots for the dose-response relationships at equi-effect based on data from Figure 1.

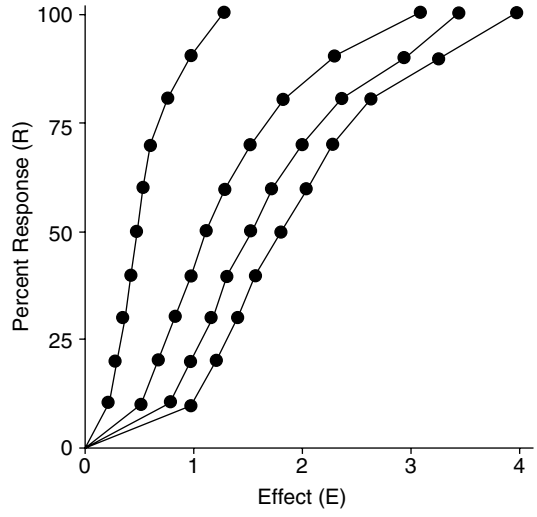

FIGURE 4 Point-to-point plots for the relationships between effect and percent response at equi-dose levels based on data from Figure 1, using dose levels of D = 1, 2, 3, and 4.

The interrelationship among dose, effect, and response has been presented as a three-dimensional model by Loewe (1959) and Hatch (1968). Although three-dimensional models are conceptually useful, the data necessary to construct them are not usually available, and such models are not considered further here.

Quantitatively, the generated relationship can then be used, after the application of several uncertainty factors, in estimating risk guidance values to humans when exposed to the same chemical. For example, the animal-derived dose-response relationship can be used to estimate the dose level at which no significant increase in response over background occurs. This dose level is referred to as the "No Observed Adverse Effect Level" (NOAEL) that is fundamental in the application of risk assessment to hazardous chemicals. Dose-response modeling in occupational epidemiology is usually motivated by questions of causal inference (e.g., Is there a monotonic increase of risk with increasing exposure?) or risk assessment (e.g., How much excess risk exists at any given level of exposure?).

Qualitatively, the shape of the dose-response curve can be indicative of underlying mechanisms. Usually, the shape of the curve varies along the dose ranges applied. In some instances, no response is observed until a dose large enough is applied to elicit a significant response. This dose is referred to as a "threshold." In other cases, there may be a gradual increase in the response as the dose increases. This increase may follow a linear or curvilinear relationship at a low dose. The magnitude of this increase may shrink as the dose range is elevated. At high enough doses, a further increase of response is observed as the dose gets larger. This describes "saturable" phenomena at higher doses, typical of many chemicals that require bioactivation by metabolism. Whether we assume that a dose-response has a threshold or follows a linear relationship at a low dose usually follows from our understanding of mechanism of toxicity. For example, low-dose linear responses are assumed when a chemical is found to be mutagenic. Instances of a "threshold" effect at a low dose are assumed whenever a chemical depletes the body's natural capacity to fight toxicity, perhaps by the inactivation of critical proteins as the chemical dose increases.

1.3 Definitions of Dose and Response

Determination of the dose-response relationship, which is the association between dose and the incidence of a defined biological effect in an exposed population usually expressed as percentage (Nordberg et al, 2004), depends on the numerical evaluation of both dose and response. Dose is defined as the total quantity of a substance administered to, taken up, or absorbed by an organism, organ, or tissue (Nordberg *et al.*, 2004) and can be measured with *in vitro* or *in vivo* experiments. When measured *in vivo*, doses are usually expressed as milligrams per kilogram of body weight in the case of oral exposure, as parts per million or billion (ppm/ppb*) in cases of inhalation exposure, or milligrams per square meter in cases of dermal exposures. *In vitro* dosing units will depend on the experiment that is usually described as concentrations (e.g., ppm or μg/L) in the medium where the experiment is conducted.

Effect can be defined as a graduated biological change in a continuum of changes that can be quantitatively measured. For biological effect to be useful in dose-response relationships it has to be readily quantifiable. It is common for a chemical to cause multiple effects, some effects occurring simultaneously in time, and some effects interacting with each other. The measured effect in the dose-response relationship has to also be independent from other exposures. This assumption of independence is important because it ensures the direct relationship between the dose and the measured response. If response depends on other responses caused by the chemical, it will be difficult to associate the response with the delivered dose.

The measured effect can quantitatively fall within one of the following:

*The SI unit for concentration of a substance in air is mg/m^3, which is ppm multiplied by molecular weight in grams divided by 24.45 (at 25°C and 1 atmosphere).

• Dichotomous (Quantal)—A dichotomous effect may be reported as either the presence or absence of an effect or change.

• Continuous—A continuous effect may be reported as an actual measurement or as a contrast (absolute change from control or relative change from control). In the case of continuous data, when individual data are not available, the number of subjects, mean of the response variable, and a measure of response variability (e.g., standard deviation [SD], standard error [SE], or variance) are needed for each group.

• Categorical—For categorical data, the responses in the treatment groups are often characterized in terms of the severity of effect (e.g., mild, moderate, or severe histological change).

Categorical variables represent data that may be divided into groups. The grouping is either nonordered (nominal) such as gender or race or ordered (ordinal) such as high, medium, or low temperature. Most effects of acute chemical poisoning can be cast into a categorical classification. This obviously applies to binary response data (e.g., mortality: dead vs. alive subjects; irreversible vs. reversible toxicity: presence or absence of congenital abnormalities, infertility, blindness, severe burns, necrosis). Categorical variables also applies to graded responses (e.g., a toxicological effect might have four levels of severity: no effect, mild effects, severe effects, and death).

2 MODELING OF DOSE-RESPONSE RELATIONSHIPS

The interrelationship among dose, time of exposure, and response is fundamental to the quantitative analysis of the dose-response relationship. Standard dose-response models are generally based on Haber's law or its generalizations. Dose (or concentration) and time of exposure are both important in determining the intensity of response to a toxic agent. For a given response intensity, Haber's rule ($c \times t = K$) has been proposed as a law of toxicology, but this rule is just one special case of a more general relationship $c \times t^m = K$, where *c* is the concentration, *t* equals time, and the exponent *m* is quite variable. For non-carcinogens, *m* generally has a value between 0 and 1, whereas for carcinogens, *m* is usually between 1 and 5. The absence of a universal value for *m*, or one that is generally applicable to different classes of toxicants, makes it not yet possible to develop a Haber-type rule with which to extrapolate successfully between exposure scenarios (Bunce and Remillard, 2003).

A common type of dose-effect relationship is one in which successive equal increments of dose cause a smaller and smaller increment of effect. Three examples of this type of relationship are illustrated by the logarithmic model, the power function model, and the equilibrium model (Figures 5, 6, and 7).

The logarithmic model is illustrated in Figure 5. There are several features of interest in this curvilinear relationship. First, the value for *b*, the base of the logarithm, must be greater than one and is most commonly equal to 10, as in the common (or Briggsian) system, or e (= 2.71828…), as in the natural (Napierian) system. Another feature is that for the simple logarithmic expression represented by curve 5A—whenever the dose is equal to one—the effect will always be equal to zero. If the model requires that the effect is zero when the dose is zero, the model can be amended by adding the constant 1 to the dose as illustrated by curve 5B. It may also be noted that curve 5A, but not curve 5B, will be a straight line when dose is plotted on the log scale of semilogarithmic graph paper.

The power-function model is also commonly used for dose-effect relationships. Figure 6 illustrates the power-function model for relationships in which the value for *n* is less than 1 but greater than zero (i.e., a positive fraction less than 1). Several features of the power-function model are noteworthy. First, the simple model described by $E = K(D)^n$ will always show a zero effect with a zero dose. A shift away from the origin may be accomplished by altering the model to $E = K(D + a)^n$, where *a* is some constant. Second, the power function model may be plotted as a straight line when both dose and effect are on a log scale or when they are plotted on a log–log scale. Thus, $E = K(D)^n$ becomes $\log E = \log K + n(\log D)$, where *n* can be seen to be the slope of the straight line and *E* is equal to *K* when the dose is equal to 1. Note that the zero dose–zero effect

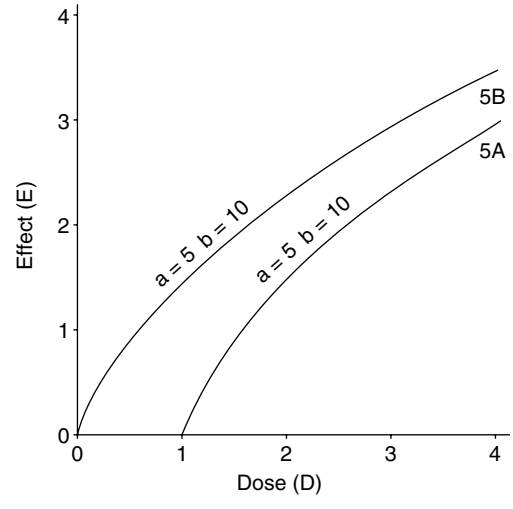

FIGURE 5 Examples of logarithmic models. Curve 5A, $E = \log_b D$. Curve 5B, $E = a\log_b(D + 1)$.

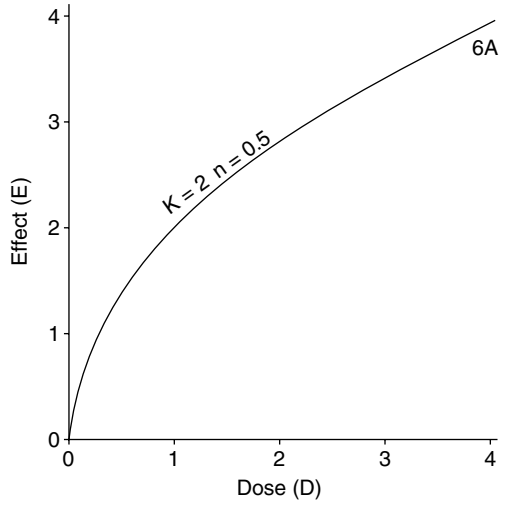

FIGURE 6 Example of a power-function model when 0<n<1. $E = KD^n$.

point cannot be plotted on log–log paper but nevertheless exists as a condition of the model. When = 0.5 as in curve 6A, the expression becomes $E = K(D)^{0.5}$.

Both the logarithmic and the power-function model share the feature that as the dose becomes infinitely large, the effect also becomes infinitely large. Many, if not all, biological systems have some maximum effect that they are capable of demonstrating and the maximum response in any population can be no more than 100%. Figure 7 illustrates two curvilinear relationships in which a maximum effect is approached asymptotically with increasing dose. These relationships may be described as steady-state models, because the effect approaches a steady state with increasing dose.

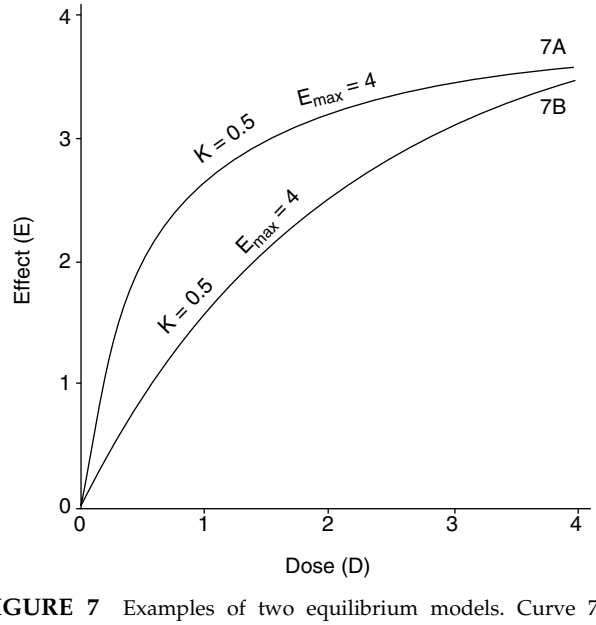

FIGURE 7 Examples of two equilibrium models. Curve 7A, $E = E_{max}[D/(D + K)]$. Curve 7B, $E = E_{max}[1-\exp(-KD)]$.

Curves 7A and 7B have three factors in common; they both originate from the origin (i.e., the zero dose–zero effect point) they both approach a maximum effect of four units asymptotically, and they both contain a single constant, *K*, with a value of 0.5. The difference between the two curves is obvious from their mathematical expressions. The derivation of the mathematical expressions is discussed in Section 3 dealing with possible biological bases for the relationships. It is of interest that curve 7A can be constructed as a straight line by plotting 1/D against 1/E. This is because $E = E_{max}[D/(D + K)]$ may be rewritten as $1/E = 1/E_{max} + [K/E_{max}][1/D]$. This plot allows the experimental determination of E_{max} from the y-intercept and subsequently also the value for *K* from the slope. This expression and procedure is identical to the Lineweaver–Burk plot used in the study of enzyme-substrate kinetics. Curve 7B may also be plotted as a straight line by plotting dose on a linear scale against the value of $E_{max}/[E_{max} - E]$ on a logarithmic scale. However, to do this, E_{max} must be known, and the value is often difficult to determine experimentally.

An additional important feature of curves 7A and 7B is that if dose is plotted on a logarithmic scale, the curves become sigmoid in shape, being asymptotic to zero effect and to the maximum effect. Additionally, the effect axis may be presented as a percent value. Thus, in Figure 7, effect values of 0, 1, 2, 3, and 4 would become 0, 25, 50, 75, and 100% effect values.

2.1 The Shape of Dose-Response Curves: S, Hormesis, U-Shaped

When successive equal increments of dose cause greater and greater increment in effect, the curvilinear relationship swings upward instead of downward. The exponential model and the power-function model are examples of such relationships.

The exponential model is illustrated in Figure 8. As with the logarithmic curves in Figure 5, the value for b must be greater than 1. At zero dose, the effect will always have a value of 1 for the simple exponential model described by $E = b^{a(D)}$ or $\log_b E = a(D)$ as seen with curve 8A. Curve 8A, but not curve 8B, will be a straight line when plotted on semilogarithmic graph paper with effect on the log scale.

The power-function model represented in Figure 9 requires that the value of *n* be greater than 1, whereas the previous power-function model illustrated in Figure 6 requires that the value of *n* be less than 1 but greater than 0. Curve 9, as well as curve 6A, will become a straight line when the data for dose and effect are plotted on log–log scale.

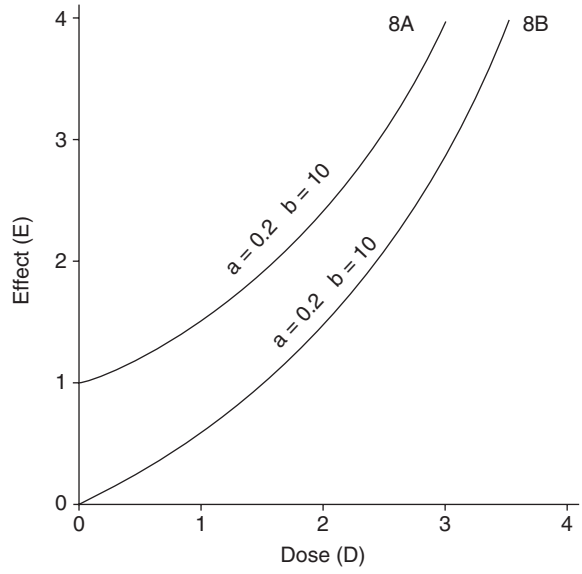

FIGURE 8 Examples of exponential models when b>1. Curve 8A, $\log_b E = a(D)$. Curve 8B, $\log_b (E + 1) = a(D)$.

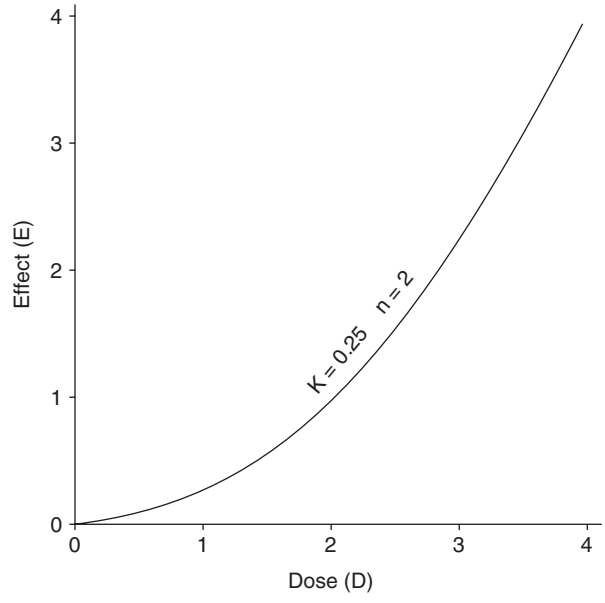

FIGURE 9 Example of a power-function model when n>1. $E = KD^n$.

2.2 The Sigmoid Curve

The sigmoid (or ogive) curvilinear relationship is often observed with dose-effect data and is almost always observed with dose-response data. This model as illustrated in Figure 10 has to have an upward swing (curvature) at the lower dose levels and a downward swing (curvature) at the higher dose levels. The middle range seems to be close to linearity and these curves may or may not be symmetrical.

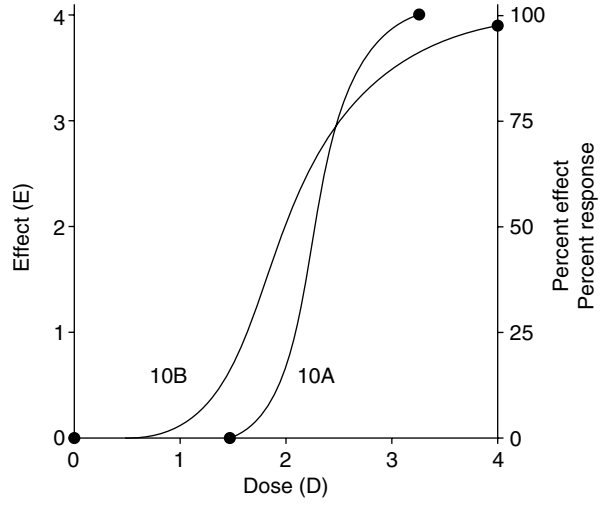

FIGURE 10 Examples of sigmoid models.

Two types of sigmoid curves are illustrated in Figure 10. The nature of the model is that there is an initial slow increase in effect with increasing dose, followed by a relatively linear or directly proportional increase in effect with dose, and finally another slow increase in effect with increasing dose, up to the maximum effect that the system can demonstrate. In curve l0A, the effect is zero until the value of the dose becomes greater than 1.5, and the maximum effect of 4 units is observed at a dose of 3.25; further increases in dose will produce only the same maximum effect of 4 units.

In contrast, curve l0B has characteristics similar to curve l0A, except that the curve begins at the origin (zero dose–zero effect) and is asymptotic to the maximum effect of 4 units. The graphical representation of Figure 10 does not provide a clear picture of a quantifiable value for effect at the lower dose levels, but the model for curve 10B requires that there is an extremely small, but finite, value for effect at infinitely small values for dose. The significance of this feature and the consequence of this contrast with curve 10A are discussed in later sections.

One of the most common explanations of the sigmoid or ogive curve is that a value on the effect scale includes the summation of all of the effects occurring at dose levels up to and including that dose. This explanation is particularly appropriate for the dose-response relationship. It was noted earlier that models with a maximum effect provide the possibility of converting the effect scale with graded units to a percent effect scale as illustrated in the right hand margin (Figure 10). The percent scale may alternately be defined as a percent response scale that would be necessary if the curves l0A and l0B are to be considered as dose-

response relationships rather than dose-effect relationships. For the dose-response relationship the sigmoid model, therefore, represents the cumulative frequency distribution of subjects showing an effect as a function of dose. A graphical representation of this statement is given in Figure 11. It is obvious that biological systems may include complexities that prevent any simple generalization by a graph or mathematical expression. On the other hand, understanding and communication of scientific observations are greatly enhanced by the presentation of general principles and models or mechanisms for observations.

2.3 Hormesis—Inverted U- or J-Shaped Curves

There is evidence to suggest that some toxic substances may also impart beneficial or stimulatory effects at low doses, but that at higher doses they produce adverse effects. This term "hormesis" (meaning to excite) was first coined in 1943 by Southam and Ehrlich (1943) in studies dealing with the effects of red cedar extracts on fungal metabolism and was later used more extensively to describe radiation effects. Numerous articles have been published that indicate that the hormetic dose-reponse model, which is characterized by a low-dose stimulation and a high-dose inhibition and is seen as either an inverted U- or J-shaped curve is common in the biomedical/toxicological literature, and is highly generalizable according to biological model tested, endpoint measured, and chemical class/physical agent used (Calabrese, 2002).

The form of this dose-response curve may be either of an inverted U or a J shape, depending on the endpoint measured. In cases of endpoints such as growth, longevity, fecundity, and cognitive function, the response would be seen as an inverted U shape. In the case of disease incidence, it would be seen as a J shape (Figure 12) (Calabrese, 2005).

In some situations, hormetic dose response is a normal component of the array of traditional dose-response relationships. Above NO(A)EL doses the hormetic dose response and the traditional sigmoidal dose response are the same. At below NO(A)EL doses the threshold response model assumes there is no real treatment-related difference between the control group response and the exposed group response below the NO(A)EL treatment.

2.4 U-Shaped Curves and Essentiality

The dose-response relationship for an essential substance such as vitamin or essential trace element

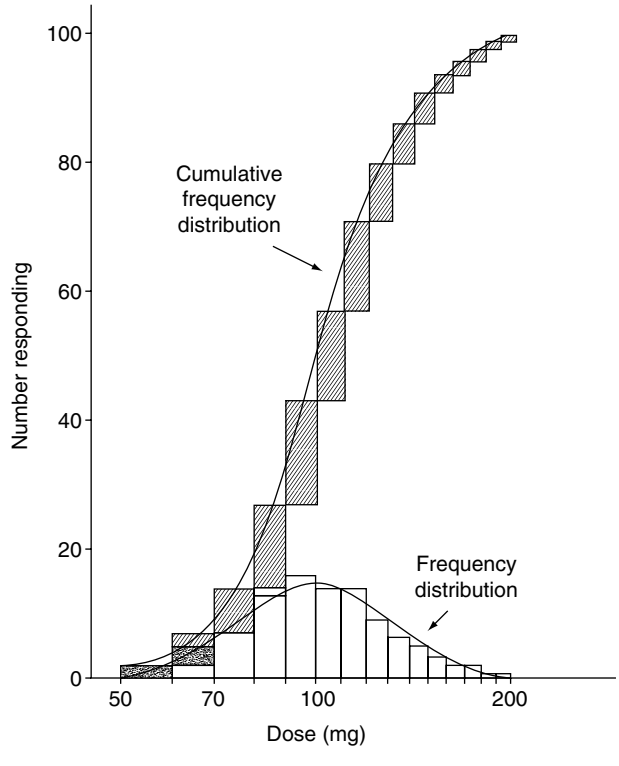

FIGURE 11 The relationship between the frequency distribution curve and the S-shaped cumulative frequency distribution curve (from Goodman and Gilman, 1975).

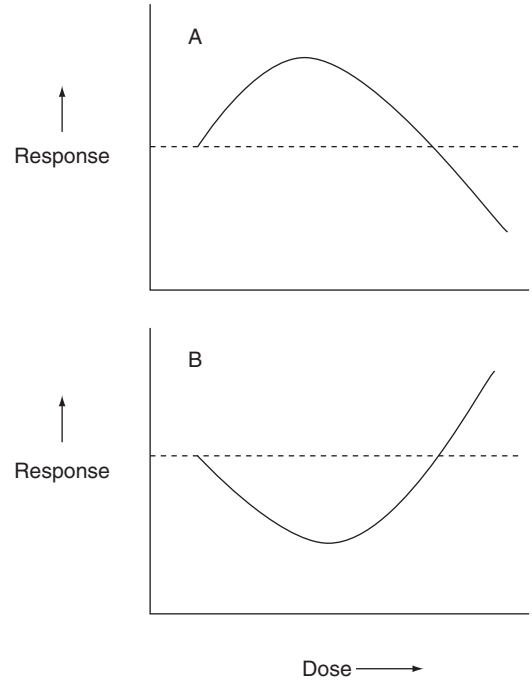

FIGURE 12 (A) The most common form of the hormetic dose-response curve depicting low-dose stimulatory and high-dose inhibitory response, the inverted U-shaped curve. Endpoints displaying this curve include growth, fecundity, and longevity. (B) The hormetic dose-response curve depicting low-dose reduction and high-dose enhancement of adverse effects. Endpoints displaying this curve include carcinogenesis, mutagenesis, and disease incidence.

is U shaped. At very low doses, there is a high level of adverse effect, which decreases with an increasing dose and similarly at very high doses there is a high level adverse effect, which decreases with decreasing doses. The region of the dose-response relationship at very low doses for essential nutrients is commonly referred to as a "deficiency" (Eaton and Klaasen, 2001, Chapter 9). As the dose is increased, the deficiency no longer exists, and no adverse response is detected, the organism reaches a state of homeostasis.

There are eight metals generally accepted as essential: cobalt, copper, iron, magnesium, manganese, molybdenum, selenium, and zinc. The dose-response relationships for these substances are all U shaped; however, the point at which deficiencies and contrarily poisoning occurs is specific to each metal (Nordberg *et al.*, 2000).

3 MODELING THE DATA

The strength of a scientifically based model is that it provides some understanding of possible mechanisms for the observed relationships. This provides confidence for extrapolations to other experimental conditions. In addition, one can intelligently design experiments to verify or to refine the proposed mechanism for the observed relationships. Difficulties in the use of models are: (1) inherent assumptions in the model may be false for the specific data; (2) the model may fit only a narrow range of values for either variable; (3) the data may actually fit one or more models equally well and; (4) the complexities of some biological systems may not be currently amenable systematic description.

When a model has been selected as appropriate for a given set of data, it is necessary to obtain the best fit of the data to the chosen curvilinear relationship. Best fit, in general, means that the variation of the actual data points from the curve will be at a minimum. There is also the implication that, because the data points do not usually fall exactly on the curve, some estimate of the variability, such as confidence limits, should be made.

The standard procedure for describing a set of data is the use of statistical descriptors such as mean and standard deviation (SD) or standard error. From these calculated quantities, additional statistical measures may be estimated such as the 95% confidence limits. The method for these procedures is well described in standard texts. Specifically, these statistical descriptors help in predicting events for a "large" population from a small sample, or subset, of the population. In the case of a simple linear model where one requires the curve to originate from the zero dose–zero effect point, a hypothetical set of data might provide the basis for the following statement: From the experimental set of data, the estimated slope of the dose-effect relationship for the true population is 1.0, and the true slope of the dose-effect relationship should be between 0.8 and 1.2, unless the experimental set of data was a random sample, which would not be expected more than once in 20 times.

It is important for the presentation of a dose-effect relationship to show the best fit, if a model is assumed, and to show the variation of the data in statistical terms. The preceding example expresses the variation over the full dose range in terms of the slope. When one has made multiple observations at the same dose, it is also possible to illustrate the statistical variation in effect at that dose. This is usually expressed as a mean and standard error and is often shown graphically as a vertical line on either side of the mean at the appropriate dose value. This is particularly useful for empirical curvilinear relationships and for visualization of the comparison of differences between several curvilinear relationships.

A frequently used metric for fitting a straight line to a series of data points is the least squares error function. Use of this metric leads to calculation of a slope that will make the sum of the square of the differences between observed effect and predicted effect a minimum. This square is used to simplify calculations by avoiding negative values for those points falling below the line. The simplicity of this method and the ease of calculations for a straight line rather than for a curved line provide the reasons why emphasis has been given to the ability to plot the various models as straight line relationships.

The previously described relationship between the sigmoid model and the probability curve has provided a basis for converting the sigmoid curve into a straight line. The SD, or normal deviate, of the dose (or log dose) provides an arithmetic progression on the dose scale relative to the mean ($\bar{x}$), i.e., $\bar{x}$ – 2 SD, $\bar{x}$ – 1 SD, $\bar{x}$, $\bar{x}$ + 1 SD, $\bar{x}$ + 2 SD, etc.

The cumulative frequency is a percentage that increases as the dose increases. Specifically, for a normal probability distribution, the approximate cumulative number of responders at a given dose will be 2.3% at $\bar{x}$ – 2 SD, 15.9% at $\bar{x}$ – 1 SD, 50% at $\bar{x}$, 84.1% at $\bar{x}$ + 1 SD, and 97.7% at $\bar{x}$ +2 SD, where $\bar{x}$ is the mean response at that dose.

For convenience in calculations, a unit called the *probit* was invented. The probit has a value of 5 $\bar{x}$, where the normal deviate is zero and the number of responders is 50%, a value of 6 at $\bar{x}$ +1 SD, where there are 84.1 % of the responders, a value of 4 at $\bar{x}$ – 1 SD, where there are 15.9% responders, etc. The probability or probit graph may have either a linear scale on the x-axis for normal frequency distributions or a logarithmic scale for

log-normal frequency distributions. Thus, the probit or log probit model is identical to the sigmoid model but has been transformed to a straight line (Finney, 1971).

In the earlier example of making the best fit of data to a model, it was assumed that variations at different doses had equal importance or weight. In the probit model, however, the observations are precise at the 50% response point and lose precision as response either increases or decreases. The least squares method has, therefore, been modified to provide a variable weight to the deviation as a function of the level of response and is called the "maximum likelihood" method. This method allows similar statistical statements of variation for the sigmoid or probit models, as was described for the linear model.

The logistic model is very similar to the probit model except that the frequency distribution follows the logistic curve rather than the probability curve. Further reference to the logistic model is made in the next section. The equation of the logistic function reads $P = 1/[1 + \exp(-(a + bx))]$.

With some of the simple curvilinear relationships, it was noted that simple adaptations could amend the model to fit a given experimental requirement. For example, the simple logarithmic model may be amended by adding the value of one to the dose so that the curve will include the zero dose–zero effect point. In a similar manner, the power-function model could be amended to account for a baseline effect by simply adding the value for the baseline effect as a constant to the experimentally expected effect. Models may also be amended to account for a threshold dose if the simple model required the zero dose–zero effect point.

It is also possible that a dose-effect relationship will not fit the same model over the entire dose range. There could be many biological reasons for the need to adapt the model at one dose range to a different model at another dose range, or at least to amend the constants of the model as a function of dose. For example, the homeostatic mechanism that alters effect may be exhausted and inoperable at higher dose levels. Enzymes may be inducible over certain dose ranges, leading to altered metabolism and altered effects. The chemical may be stored in depots with differing affinities for the chemical and different elimination rates, causing a multiphase change with time and/or dose.

Heterogeneity in the population being studied may cause an abnormal frequency distribution. For example, two populations differing in susceptibility may overlap in such a way that a composite of the two dose-response relationships would be required. Clearly, the dose-effect or dose-response relationship may be based on complex mechanisms that are not adaptable to modifications in a practical biological model. The experimenter must be alert to conditions that should not be forced into a simple model.

The problem of adapting a model to provide either for a threshold or for a zero dose–zero effect point requires particular care. In many cases, the experimental data itself will not be adequate to provide support for either possibility. In such cases, it is necessary to rely on the theory underlying the model or to refuse to extrapolate to conditions that cannot be experimentally validated.

The problem of the baseline effect is in large part the problem of the "normal" range. An individual may exhibit some range of effect values when tested repeatedly in the absence of a dose. The normal range may be considerably expanded when the experiment includes many different individuals. For most clinical laboratory measurements, the normal range is considered to be the 95% confidence limits around the mean value for a population sample that is considered to be either "healthy" or representative of the total population. The gray area between "normal" and "abnormal" may be subjective at times, and the limits of normality require careful definition.

The variation and magnitude of effect or response at zero dose can greatly confound interpretations of experiments. For example, an incremental increase of 5% response on top of a 0% response at zero dose may be relatively easily validated on statistical grounds. However, the same 5% incremental increase on top of an existing baseline response of 50% may be very difficult to differentiate from the "normal" variation around the 50% baseline value.

Figure 11 illustrates the relationships between the frequency distribution and the sigmoid model of a dose-response relationship. The biological basis for this model is the observed variability among individuals within a given population. The frequency distribution shows that a given effect will be demonstrated by a few individuals in the population at low doses and that a few individuals will be more resistant and will require very high doses before demonstrating the same effect. Most individuals will, however, demonstrate the effect in the middle range of doses as illustrated in Figure 13. The relative susceptibility or resistance is considered to be related to genetic differences, health status, differences in detoxification or elimination rates, differences in absorption rates, different volumes of distribution, or other biological variables that make one individual different from another. These differences are not sufficiently great to consider any individual as not belonging to the population, and the variation in a large population will approximate that predicted by a probability curve.

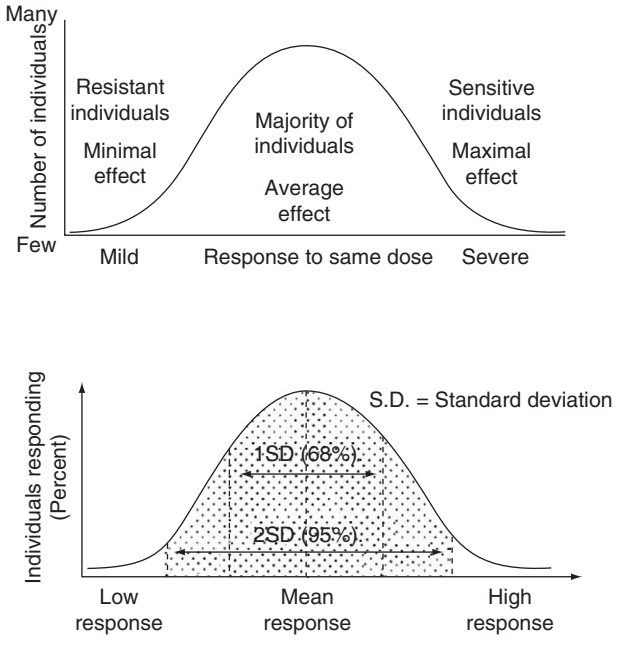

FIGURE 13 The top graph illustrates that within a population, most responses to a toxicant are similar; however, a wide variance of responses may be encountered, some individuals are susceptible and others are resistant. As demonstrated above, a graph of individual responses can be depicted as a bell-shaped standard distribution curve. As illustrated in the bottom curve, dose responses are commonly presented as mean + 1 SD (standard deviation), which incorporates 68% of the individuals. The variance may also be presented as two standard deviations, which incorporates 95% of the responses. A large standard deviation indicates great variability of response.

The frequency distribution may fit a symmetrical curve given by the equation, $y = \exp(-x^2)$, and is then known as a normal distribution. However, many frequency distributions in nature are observed to have a distribution skewed in the direction of higher doses. This skewness is particularly evident for effects caused by a mean dose that is close to zero. The restriction that zero dose is limiting for zero effect creates an inherent skewness to the frequency distribution. When dose is plotted on a log scale, however, the restriction of the zero dose is removed from the dose scale, and it is observed that many distribution frequencies in nature become normalized (i.e., more symmetrical) when log dose is used. Such frequency distributions are often called log-normal distributions.

Thus, the sigmoid model of the dose-response relationship has a biological basis depending on a normal or log-normal distribution of susceptibility of individuals to a given effect at different doses. It is important to remember that the effect in this case is an all-or-none event (i.e., the individual is either showing the effect or not: there is no gradation of the effect under consideration).

When a dose-effect relationship is observed to fit the sigmoid model, it might be postulated that the effect results from the cumulative reaction of many individual receptors having a frequency distribution of susceptibility. In other words, individual receptors, cells, or fibers may each demonstrate an all-or-none reaction at a given dose. If the cumulative reactions produce a type of effect that can be graded in a continuum, a dose-effect relationship of the sigmoid type may be constructed. If, however, the cumulative responses produce an effect in the individual that is also all-or-none, a population of individuals will be required to produce a dose-response relationship for the effect.

A feature of the probability curve, and consequently the corresponding frequency distribution, is that the response is asymptotic to the dose scale (x-axis). That is, by definition, a small fraction of the population will respond to even the smallest of doses, and, conversely, a small fraction that will never respond, even to the highest of doses. In practice, such observations may not exist, or they may not be seen because of limitations in the size of the population. This feature is illustrated in curves 10A and 10B. In curve 10A, there is a finite dose, often called the threshold dose, that must be exceeded before any response is observed, whereas curve l0B begins at zero dose–zero response.

3.1 Biological Basis for Modeling

The biological basis for the threshold is usually considered to be one or more of the following mechanisms:

1. The specific biological mechanism is not capable of producing the effect at or below the threshold dose.
2. Homeostatic, defense, and/or repair mechanisms are capable of countering the effect at the threshold dose in even the most susceptible subject.
3. The biological factors of absorption, transport, metabolism, and elimination do not allow a sufficient dose to reach the site of effect for the most susceptible subject of the population.
4. Any quantitative effect smaller than the effect of the threshold dose will not subsequently progress to that effect.

The biological basis for the no-threshold model is that the smallest possible dose (i.e., one molecule or one particle) may interact with a cell or cellular component, initiating a chain of events that ultimately produces the effect of concern. Pathogenetic mechanisms involving such a chain of events, usually involving self-replication, have been described for carcinogenesis and mutagenesis.

The basic problem of low-dose extrapolation is the selection of a mathematical model that is biologically

appropriate, so that we can have some assurance of its applicability both within and outside the range of measured dose-response values. The models currently used for low-dose extrapolation of data on carcinogenicity are of two kinds: dichotomous models and "time-to-occurrence" models. The dichotomous models relate dose to the probability of the occurrence (expected response) of a particular effect. The second group of models relates "time-to-occurrence" of an effect (i.e., duration of latency period) to dose.

The simplest dichotomous model that has found practical application and that has a biological basis for some effects is the linear or one-hit model. This model is based on the concept "that the effect can be induced after a single susceptible target has been hit by a single biologically effective unit of dose" (Hoel *et al.*, 1975). This concept leads to the following equation linking the probability (P) of an effect to the dose (D):

$$P(D) = 1 - \exp(-yD)$$

where y is an unknown parameter that has to be determined from experimental data, if possible. For small values of yD (i.e., for low doses) the equation reduces to a simple expression;

$$P(D) \approx yD$$

because exp(−x) can be expanded into a series $\exp(-x) = 1 - x + x^2/2! - x^3/3! + \ldots$, and when x is small, all terms involving x can be neglected except the first (i.e., x). A procedure for low-dose extrapolation based on this model has been described, for example, by Hoel *et al.* (1975).

A closely related model is based on the multievent theory of carcinogenesis proposed by Armitage and Doll (1961) and leads to the following equation relating the probability of effect (P_D) to the dose (D):

$$P(D) = 1 - e^{-(\lambda_0 + \lambda_1 D + \lambda_2 D_2 + \ldots \lambda_k D!}$$

where k is the number of transitional events in the carcinogenic process and λ_0, λ_1,…are unknown positive parameters. At low doses, the higher order terms in D^2, D^3, etc. may be neglected, and P(D) reduces to

$$P(D) \cong 1 - e^{-(\lambda_0 + \lambda_1 D)} \cong \lambda_0 + \lambda_1 D$$

where λ_o now represents the background response. A procedure for low-dose extrapolation based on this model has been suggested in an International Symposium on General Air Pollution and Human Health with Special Reference to Long-Term Effects, held in Stockholm, 8–11 March 1977 (Task Group on Air Pollution and Cancer, 1978) and was also used by the Safe Drinking Water Committee (NAS, 1977).

There are several other dichotomous models that have been proposed for low-dose extrapolation, the best known being the log-probit model of Mantel and Bryan (1961), the logistic model, and the model based on the Weibull distribution (see, e.g., Chand and Hoel, 1974). These models have, however, little biological basis, which is a serious limitation.

The use of such models involves a high degree of uncertainty, as is well illustrated by a comparison made by the FDA Advisory Committee on Protocols for Safety Evaluation (1971) (see Table 1). Three models, the probit, logit, and one-hit model, were compared under conditions of essentially equally good fit to experimental data. All three models gave identical responses of 50 and 16% at doses of 1 and 0.25, respectively; however, when extrapolation was made to responses as low as 1 in 10,000 or 1 in 1 million, the predicted doses differed by factors of approximately 10^3 and 3×10^4. Of all the models of this type, the one-hit model is the most conservative and will give the lowest doses corresponding to predetermined low responses. This may give rise to great practical problems when using the one-hit model, particularly if the substance considered has not been well established as a carcinogen.

The "time-to-occurrence of effect" models are based on the observation that the median latency period for some effects, for example, cancer, induced by some chemicals depends on the dose and increases with decreasing dose, whereas the individual latency

TABLE 1 Comparison of Three Models for Expected Response as a Function of Dose

Adapted from FDA (1971).

periods are statistically distributed, either log normally (Blum, 1959; Druckrey, 1967) or according to the Weibull distribution function (see, for example, Pike, 1966). Albert and Altshuller (1973) have applied the Blum–Druckrey model to a variety of carcinogenesis data assuming that the dose (D) is related to the median "time-to-occurrence" of cancer (t) by the equation $t^nD = C$, where n is a positive parameter greater than 1, and C is a constant. The model based on the Weibull distribution seems to be better justified than the log-normal model used by Albert and Altshuller because of the theoretical basis given by Pike (1966). However, it seems that different data on cancer incidence would require different models and that there is no single model that could be applied to all types of data. The low-dose extrapolation should not be attempted unless the experimental data are biologically appropriate for such extrapolation. The following aspects should be given particular attention: the types of animal models used, the number of animals used both in the experimental and in the control group, the route of administration, the toxicity of the agent and side effects, the survival of animals in the course of the experiment, the availability of detailed pathological analysis of individual animals, and the possible presence of synergistic factors that can greatly modify the outcome of the experiment. The quality standards for long-term bioassays have been discussed in several publications (FDA, 1971; Health and Welfare, Canada, 1973; NAS, 1961; WHO, 1978).

4 SPECIES-TO-SPECIES EXTRAPOLATIONS

The relevance of experimental data to the assessment of the carcinogenic risk to man was discussed by an *ad hoc* working group of the International Agency for Research on Cancer (IARC, 1977). Information in the first 16 IARC monographs on the evaluation of the carcinogenic risk of chemicals to man showed that of approximately 25 chemicals or manufacturing processes generally accepted as being causally related to cancer in man, all of those that have been adequately tested produced cancer in at least one animal species. At present, 95 agents, mixtures, and exposures have been evaluated as being in Group 1: Carcinogenic to humans (IARC, 2005). For several chemicals the evidence for carcinogenicity was first obtained in experimental animals (IARC, 1977). Thus, there seems to be adequate evidence that chemicals carcinogenic in laboratory animals are carcinogenic in man. There is also tentative evidence for a quantitative relationship between the dose of a chemical that is carcinogenic in animals and the dose that is carcinogenic in man (Rall, 1979). There is no reason to assume that the same is not true for other toxic effects produced by chemicals. Thus, it seems justifiable to use animal data for predicting health risk in man.

The difficulties in quantitatively translating the toxicological information obtained from one species to another are many. The first problem is the large number of experimental animals that can be used. Normally, 100–1000 experimental animals are used in one experiment; the size of the human population to be protected may be as large as 10^6–10^8. Also, animal populations used in experiments are usually homogeneous, whereas human populations are largely heterogeneous. Laboratory animals are healthy, whereas the human populations to be protected include subpopulations that are ill and weak and that may, therefore, be particularly susceptible to the effects of a chemical. There are also differences regarding nutrition and the presence of other factors in the human environment that can modify the response to toxic chemicals. Furthermore, there may be differences in receptor sites. The size of different animals is also of concern, because it determines the number of susceptible cells and the residence time of the chemical in the organism. Thus, for the same dose in terms of mg/kg body weight, human tissues may be exposed much longer than mouse tissues. For this reason, it was recommended (Hoel *et al.*, 1975) the dose be expressed per unit body surface rather than body weight. This conversion of doses reduces the species differences considerably (NAS, 1977). The length of life is another variable that may largely influence the response. Man lives 35 times longer than a mouse, and, therefore, in man there are many more cell divisions and a better chance for neoplastic change. Thus, generally it seems that man is more susceptible to the effects of chemicals than the small rodents routinely used in the laboratory, although exceptions for some toxic effects exist.

Despite these difficulties in applying the information obtained in laboratory experiments to man, there seems at present no alternative to the current practice of using laboratory test results as a basis for human safety evaluation of chemicals, particularly as regards new products. Also, there are at present no generally valid criteria on which to base the interpretation of laboratory experiments in terms of human health risk, and we have to continue to rely on the experience and the expert judgment of trained toxicologists.

In addition to animal experiments, it is important to include the evidence from epidemiological studies in the evaluation of chemicals and their affects on man. Clear epidemiological evidence is often difficult to obtain because of questions of exposure amounts, duration, chemical mixtures, etc. In the past, most

epidemiological studies were limited to early worker exposure studies, which were cited as foundational for most toxicological and epidemiological studies for assessing dose-effect and dose-response relationships. More recently, however, community-based epidemiological studies have become more available and have yielded revealing results (i.e., Trasande *et al.*'s 2005 study of mercury emissions and blood mercury levels). A detailed discussion of epidemiological methods is found in Chapter 8.

Recent cancer risk assessment guidelines (USEPA, 2005) recommend that different approaches be adopted for determining an allowable exposure level for a carcinogen depending on whether it is thought to exert its carcinogenic effects in animals by a mode of action that has a threshold or nonlinear dose-response in the low-dose region. Part of that weight-of-evidence narrative includes consideration of the results from genetic toxicity studies. Although some of the reactions leading to genetic toxicity and tumor induction have biological thresholds (e.g., because of DNA repair or metabolic activation) or are nonlinear in the low-dose region, it has been generally assumed that the carcinogenicity dose-response is linear and without a threshold for chemicals testing positive in genetic toxicity studies. Furthermore, such a mechanistic assumption is predicated on having data to answer the question of genetic toxicity; however, discordant outcomes from genetic toxicity tests complicate the interpretation. The "positive/negative" interpretation of these tests must be considered in conjunction with the fundamental toxicological concept of dose-response and all additional mechanistic research to better determine relevance to human health. Moreover, USEPA guidelines for human cancer risk assessment (USEPA, 2005) acknowledge that a nonlinear dose response may be operable even when there are positive genetic toxicity data.

5 RISK ASSESSMENT AND DOSE-RESPONSE RELATIONSHIPS

5.1 NOAEL/LOAEL

Approaches for characterizing threshold dose-response relationships include identification of "no observed adverse effect levels" (NOAELs) or "lowest observed adverse effect levels" (LOAELs).

In Figure 14, the threshold represents the dose below which no additional increase in response is observed. The NOAEL is identified as the highest nonstatistically significant dose tested. The LOAEL is the lowest dose tested with statistically significant effect.

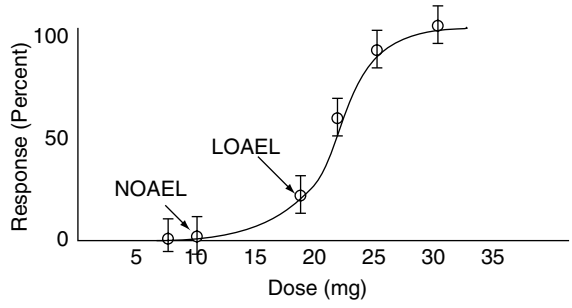

FIGURE 14 Dose-response curve.

5.2 Benchmark Dose

The benchmark approach is gaining attention as an alternative to the NOAEL approach. A benchmark dose (BMD) is defined as the statistical lower confidence limit on the dose producing a predetermined level of change in adverse response compared with the response in untreated animals (the benchmark response, or BMR) (Crump, 1995). It is determined by modeling a dose-response curve in the region of the dose-response relationship where biologically observable data are available. The BMR is generally set near the lower limit of responses that can be measured directly in animal experiments of typical size. There are multiple advantages to using BMD in place of NOAEL. The BMD method does not extrapolate to doses far below the experimental range. BMD is not constrained to using only one experimental dose. BMD accounts for variability in the data and incorporates response data from groups other than the experimental group determining the NOAEL. A BMD can be defined even when all experimentally observed responses would be considered effect levels (i.e., there is no NOAEL), and thus can avoid application of additional uncertainty factors. However, current guidelines for the design of toxicity tests are based on assessing a NOAEL. It has been suggested that the current study design may not be optimal for assessing a BMD.

To further investigate three simulation studies in which a large number of designs were compared focusing on continuous endpoints were performed (Crump, 1995). Four fictitious endpoints were considered, their underlying dose-response curves having a linear, sublinear, supralinear, or sigmoidal shape. In each simulation run, the BMD was derived from a model fitted to the generated data, where the selection of the model was based on that particular data set (according to a formal likelihood ratio test procedure). Thus, the model used for fitting the BMD in a single generated data set may not be the same as the one used for generating the data. In this way, model uncertainty is taken into account as well. The results show that the performance

of a design is first of all determined by the total number of animals used. Distributing them over more dose groups does not result in a poorer performance of the study, despite the smaller number of animals per dose group. Dose placement is another crucial factor, and to minimize the risk of inadequate dose placement, the use of multiple dose studies is favorable. As a concomitant advantage, the use of multiple doses mitigates the disturbing effect of potential systematic errors in single dose groups. However, for endpoints with large residual variation (CV≥18%), there is a substantial probability of not detecting the overall dose response, and this probability increases in designs with increasing number of dose groups. In such situations, six dose groups may be used as a compromise. Designs with high dose levels (i.e., associated with relatively high effects) are helpful in estimating doses with smaller effects (such as the BMD), and it seems bad practice to omit higher dose groups to improve the fit at lower doses. The typical 28-days study design of four dose groups with five animals (per sex) may not be adequate to assess endpoints with large residual variation (CV ≥ 18%), both in assessing a benchmark dose and in assessing a NOAEL (Bokkers *et al.*, 2005).

5.3 Data Types and Benchmark Dose

Although software for several continuous models is available (USEPA, 2005), there may be occasions when it is advantageous to convert continuous data to quantal data, for example, before applying a BMD analysis (an alternative to the NOAEL approach for assessing noncancer risks associated with hazardous compounds). In some cases, converting continuous data into quantal data may more directly address a specific definition of adverse response. For example, body weight measurements for individual animals could be converted to the incidence of animals that have more than 10% lowering of body weight, if this is the criterion for a significant response. Rendering data quantal may also facilitate comparisons among data sets if the majorities are in quantal form. A major disadvantage of continuous to quantal conversion is the loss of information about the magnitude of response.

For quantal data, an excess risk of 10% is the default BMR, because the 10% response is at or near the limit of sensitivity in most cancer bioassays and in some noncancer bioassays as well. If a study has greater than usual sensitivity, a lower BMR can be used, although the ED10 (the dose corresponding to a 10% increase in an adverse effect, relative to the control response) and LED10 (the 95% lower confidence limit of the dose of a chemical needed to produce an adverse effect in 10% of those exposed to the chemical, relative to control) should always be presented for comparison purposes. For example, reproductive and developmental studies having generational nested study designs often have greater sensitivity, and for such studies a BMR of 5% has typically been used; similarly, epidemiology studies often have greater sensitivities, and a BMR of 1% has typically been used for quantal human data.

For continuous data with a minimal level of change in the endpoint that is generally considered to be biologically significant (for example, a change in average adult body weight of 10%, or the doubling of average level for some liver enzyme), that amount of change can be used to define the BMR. The BMD and the benchmark dose level [BMDL] corresponding to a change in the mean response equal to one control standard deviation from the control mean should also be presented for comparison purposes; if individual data are available and a decision can be made about which individual levels can be reasonably considered adverse (perhaps on the basis of a quantile of the control distribution, for example), the data can be "dichotomized" on the basis of that cutoff value, and the BMR can be set as previously for quantal data.

In the absence of any other idea of what level of response to consider adverse, a change in the mean equal to one control standard deviation from the control mean can be used. The control standard deviation can be computed including historical control data, but the control mean must be from data concurrent with the treatments being considered (Crump, 1995). Crump (1995) found that this gives an excess risk of approximately 10% for the proportion of individuals below the 2nd percentile or above the 98th percentile of controls for normally distributed effects.

6.0 DOSE-RESPONSE IN AN ERA OF -OMICS

Dose response and dose effect are fundamental descriptors of events occurring after an exposure. Although the field of toxicology continues to explode with the development of new techniques, models, and "-omics" areas of study, these underlying concepts remain invaluable and are the common threads that link these areas together. Newer terms including "biological monitoring" and "biomarkers," which have become more common in recent years, incorporate the responses to exposures and include information on dose response and effect. An in-depth discussion of these terms is found in Chapter 4 (Fowler, 2005).

Interactions in Metal Toxicology

GUNNAR F. NORDBERG, LARS GERHARDSSON, KARIN BROBERG,
MOIZ MUMTAZ, PATRICIA RUIZ, AND BRUCE A. FOWLER

ABSTRACT

Human exposures to metals and metalloids such as arsenic frequently occur as mixtures, and hence it is important to consider interactions among these elements in terms of both mechanisms of action and for risk assessment purposes. Interactions among these elements may produce additive, synergistic/potentiative, or antagonistic effects that may be manifested as direct cellular toxicity (necrosis or apoptosis) or carcinogenicity. Dose-response relationships may further be influenced by constitutive factors such as age, sex, and the expression of specific proteins. The roles of molecular factors regulated by specific genes (so called gene–environment interactions) for the expression of metal toxicity are known only to a limited extent for most metals. However, for chronic beryllium disease causing fibrosis of the lung, it has been shown that beryllium sensitization, a prerequisite for developing the disease, depends on an antigen-specific immune response occurring predominantly among persons with a specific HLA–DBP1 genotype. Some gene–environment interactions in terms of genetic polymorphisms have been demonstrated such as those involving ALAD and arsenic methyl transferases, but the importance of these observations for development of human diseases has not been fully explored. Mechanisms of importance for interactions and the development of toxicity are the expression of metal-binding proteins (metallothioneins or lead-binding proteins). In many cases, direct primary data on interactions among toxic or essential elements are lacking, and so innovative derivative methods such as the binary weight of evidence (BINWOE) method have been used to predict potential interactions among groups of metals and metalloids. At present, there is much to be learned about interactions among both toxic and essential elements, but this is clearly a critical area of research.

1 INTRODUCTION

Toxic effects of metallic compounds may be modified in a number of ways by various factors, changing the character of effects or dose-effect and dose-response relationships. Nutritional and physiological factors may affect susceptibility. Constitutional factors like age, sex, and other genetically determined factors, often called host factors, may also be of importance. Toxicokinetics of metals can also be modified by simultaneous or previous exposure to certain environmental agents. Direct interaction with the metal in question at the molecular level explains some interactions, whereas in other cases, an indirect metabolic change is induced by the interfering environmental factor that gives rise to the change in dose-response relationship. Such indirect interactions are sometimes of considerable interest even though the mechanism may not be known. Important interactions may also occur in the general environment and exposure media (i.e., air, water, and food), and they are dealt with in Chapter 13. These interactions and environmental transformations, to a large extent, determine the type of exposure for human beings. Such interactions are not discussed in this chapter.

For several decades, chemical and physical interactions of metals have been studied in experiments both *in vitro* and *in vivo*. There is an abundance of data on

such interactions, and no attempt will be made in this chapter to review all these data. Many results from such studies have found practical application in the field of animal nutrition, but their significance for imbalance of trace elements and for toxic effects of some metals in the human being has been difficult to evaluate. The experimental work has usually been performed in healthy animals of the same strain in carefully controlled environments. Often, the doses or exposure routes have been of little relevance to the human situation. Nevertheless, such studies may sometimes be indications of what might happen in man and may form a basis for further studies with more relevance to human beings.

At meetings in Tokyo in 1974 (Nordberg, 1976) and in Stockholm in 1977 of the Task Group on Metal Interactions (Nordberg, 1978), results from such animal studies were discussed, and several interactions of possible importance for humans were recognized. Further considerations of interactions important for carcinogenicity were discussed during a meeting in Atlanta in 1980 (Belman and Nordberg, 1981; Nordberg and Andersen, 1981) and in Geneva in 1983 (Nordberg and Pershagen, 1984). Considerations discussed during these working group meetings are summarized in this chapter and complemented by more recent information from a meeting in Atlanta in 2004 (Fowler, 2005). This latest meeting in Atlanta focused on reports of original scientific contributions, and joint consensus conclusions were not developed. There is a need for an in-depth discussion of public health implications of exposure to mixtures of metals and the role of metal interactions in risk assessment of such exposures with an aim to reach consensus conclusions. The lack of such a document makes it difficult for the present authors to present a review that fills this gap, and this chapter can only give the views of the present authors. There is hence a pressing need for an international meeting to discuss interactions among metals and to reach a consensus, if possible.

Host factors such as age, sex, race, and other genetic factors are well recognized as modifying factors for the occurrence of adverse effects in humans. The following text gives a brief general discussion of such well-recognized factors. Emerging knowledge is reviewed about the influence of variation (i.e., genetic polymorphism) in specific identified genes for the occurrence of disease and other adverse health effects of metal exposures; a section on risk assessment of mixtures is included. As an introduction to these sections, some fundamental concepts will be introduced.

At the Tokyo meeting, the term "interaction" in the present context was considered to be a process by which metals in their various forms, or other factors, change the critical concentration or a critical effect of a metal under consideration. At the Stockholm meeting, this definition was accepted, and it was emphasized that the term "interaction" should be used to also describe the influence of these other substances, host factors, and external factors such climate. In the section of this chapter dealing with gene–environment interactions, the term interaction is used in a similar way, meaning how variation in specific genes may modify the dose-response relationship (describing the relationship between exposure or dose of a metal and the occurrence of disease or other adverse effects).

Finney (1971) described the classical mathematical interpretation of joint action of chemicals.

An example of a joint action (i.e., not a true interaction) occurs when two metals exert their action at the same site and when their modes of action are similar, but they do not influence the action of each other. The result of such joint action is an *addition* of effects that can be estimated from the dose-effect and dose-response relationships of the constituents of a mixture. Such types of joint action seem to apply to arsenic and lead in relation to coproporphyrin excretion (Fowler and Mahaffey, 1978). There are other types of joint actions in which the dose-effect or dose-response curve of the combination cannot be assessed from those of the individual chemicals (e.g., synergism and antagonism). Models have been developed later to describe the interaction between different factors (Breslow and Day, 1980). Under the assumption of an additive model and linear dose-response relationships, synergism takes place when the response of a combined exposure is greater than additive. A multiplicative action represents a special form of synergism. Further considerations on statistical aspects are given by Greenland and Rothman (1998) and in Section 6 of this chapter.

2 AGE, SEX, DRUGS, AND SOME OTHER FACTORS

2.1 Influence of Drugs, Alcohol, and Tobacco on Metal Metabolism and Toxicity

2.1.1 Drugs

Oral contraceptives are among the drugs taken by a large number of healthy women. Intake of such synthetic hormones is known to cause changes in copper metabolism, influencing the synthesis of ceruloplasmin and bringing about higher serum concentrations of copper. Zinc metabolism and iron metabolism are also influenced by oral contraceptives. In studies on women exposed to metals such as cadmium and lead, which might interfere with the metabolism of essential

metals, the use of contraceptive pills should be taken into account. Some of the drugs for the treatment of hypertension, which essentially act as chelating agents, also affect metal metabolism. Prolonged treatment with some of these may increase zinc excretion, but not cadmium excretion. Thus, such treatment may, in the long run, cause changes in the cadmium/zinc ratios. The use of chelating agents such as DMSA and penicillamine in the treatment of metal poisoning is a way of using interactions for therapeutic purposes (for details, see Chapter 15). Attempts have also been made to change the kinetics of methylmercury by the use of resins that prevent the reabsorption of methylmercury excreted through the bile (Chapter 15).

2.1.2 Alcohol and Tobacco

Ethyl alcohol has been shown to cause an increase in the absorption of lead. This might be of importance when evaluating dose-effect relationships in people exposed to lead in illicitly distilled alcohol. In cases of lead poisoning caused by such consumption, the symptoms in the central nervous system (CNS) seem to be more severe than what would be expected from lead exposure alone. Thus, some synergistic action between alcohol and lead might exist.

Consumption of large amounts of alcohol can temporarily depress ALA-dehydratase activity, which is also a sign of lead toxicity. However, it has also been shown that ALA-dehydratase activity may increase in animals exposed to both lead and alcohol. The depression caused by either of the substances is partially reversed when the two substances are combined (Chapter 31).

Alcohol influences the metabolism of mercury after exposure to mercury vapor. This is thought to be due to the interference of alcohol with some of the enzymes taking part in the conversion of mercury vapor to mercury (II) (Nielsen-Kudsk, 1965; Chapter 33). Simultaneous exposure to cobalt and alcohol has caused so-called beer drinker cardiomyopathy, where the effect was greater than would be expected from the single action of the compounds (see Chapter 25).

Smoking may affect the uptake and effects of metals in several ways. A discussion in relation to carcinogenesis of arsenic compounds is given in Section 3. The content of carbon monoxide, various organic compounds, and a number of toxic metals (e.g., cadmium, nickel, mercury, and lead) are probably of importance in explaining the increased carcinogenicity of combined exposures to carcinogenic metals/metalloids and smoking, compared with single exposures, as show in several studies performed in the working environment (e.g., Lundstrom *et al.*, 2006).

2.2 Influence of Age and Sex on Metal Toxicity

2.2.1 Age

It has long been claimed that certain age groups are at increased risk (i.e., young children and the elderly). During the past decade, quantitative data have become available to document these claims. Several investigations have dealt with young animals and children, and data on elderly people are also forthcoming. The fetus is regarded as especially vulnerable, because many functions are not fully developed until after birth, and several possibilities exist for contact between the fetus and toxic metals. The toxic effects caused by metals on development of the fetus are discussed in Chapter 12. Methylmercury is known to cross the placental barrier and to accumulate in the fetus. It is well documented that fetal exposure to methylmercury can cause intrauterine methylmercury poisoning (Chapter 33). Lead crosses the placental barrier, and prenatal lead exposure may play a role for later development. The fetal brain does not tolerate lead to the same extent as the adult brain does (cf Chapters 16 and 31). Extensive animal studies have shown that newborn and suckling animals have higher absorption of certain toxic metals, like lead and cadmium, because of their dependence on a milk diet. The neonate also has higher whole-body retention, higher blood levels, and a much higher accumulation in the brain compared with the adult exposed to similar doses (cf Chapters 12 and 31). Exposure of animals to lead in the early neonatal stages can cause changes in behavior, learning deficits, and increased motor activity. There are also data demonstrating that children develop signs and symptoms at lower blood-lead concentrations and have a higher absorption of lead than adults. Because the calorie intake per person increases rapidly during the period 6–20 years of age, it follows that the daily intake of a metal (e.g., cadmium) also increases during this time (cf Chapter 3). The urinary excretion of cadmium has a peak in the age range 6–12 years, followed by a second peak at ages 50– 70. The first peak is explained by the increase in per person intake in the mentioned age range and the growth rate of the kidney, implying that a peak in kidney cadmium concentration occurs. The later higher peak at age 50 is explained by the gradual accumulation of cadmium by age because of the long biological half-life of this metal in the human kidney (Choudhury *et al.*, 2001).

2.2.2 Sex

When women are referred to as a high-risk group, it is often meant that the exposure of pregnant women results in the exposure of the fetus. Such aspects are discussed in Chapter 12. The influences to be dealt

with here concern only those directly related to the differences in sex. Data from animal experiments are to some extent conflicting. Lead acetate (Kostial *et al.*, 1974) and cadmium chloride (Engstrom and Nordberg, 1978) have been shown to have higher acute toxicity in male than in female animals. On the other hand, compared with male rats, female rats were shown to retain twice as much cadmium after a single oral dose (Kello *et al.*, 1979). Because castrated males absorbed as much as the females, it was then concluded that male sex hormones were responsible for the decreased retention of cadmium in males. Pregnancy may create a change in sensitivity to metal exposure. Parizek (1965) found that pregnant rats were more susceptible to the action of injected cadmium than nonpregnant rats. These and other aspects on pregnant animals are discussed in Chapter 12.

Adult women before menopause lose iron with menstrual blood, and there is a high prevalence of low iron stores in this population group. Because it is known (cf Chapter 23) that persons with low iron stores have an increased gastrointestinal uptake of cadmium, women often accumulate more cadmium than men. Higher blood cadmium values have been reported among women than men in many epidemiological studies.

2.3 Influence of Some Other Factors on Metal Metabolism and Toxicity

There are important interactions between metals and nutritional factors, but this chapter cannot review all these interactions. Nutritional factors in terms of intake of essential metals will be discussed in Section 4 of this chapter. Several other dietary components have been shown to have a considerable influence on metal toxicology. Phytate in certain diets causes a reduction in the absorption of zinc and renders zinc less available from vegetable diets than from diets based mainly on meat. The protein content of the diet has been shown to play a role in cadmium and lead toxicity (i.e., the lower the protein content, the higher the absorption and the more severe the signs of toxicity), but these and other factors will not be reviewed here. The reader is referred to general textbooks of trace elements and nutrition (Mertz, 1987).

Because sweat is an important route of excretion for some metals (e.g., zinc and nickel), metal losses through sweat might influence metabolism and toxicity. Workers exposed to nickel in a hot environment had considerably lower nickel levels in blood than expected (Szadkowski *et al.*, 1969). The clearance of inhaled particles from the lung depends on the proper function of the mucociliary transport system. Smoking cigarettes over a long period and bacterial and viral diseases can impair this transport system (see Chapter 3). A decreased clearance of inhaled particles might increase the absorption of certain metals or prolong their retention time in the lungs. Simultaneous exposure to irritant gases, like SO_2, and metals may affect the distribution and toxicity of these metals. Another part of the pulmonary defense system consists of the alveolar macrophage, the function of which might be depressed by exposure to nitrogen dioxide. This might result in prolonged retention time and thus a greater absorption of slowly soluble metallocompounds in the alveoli.

3 GENE–ENVIRONMENT INTERACTIONS FOR METALS

It is generally known that there is a large interindividual variation within species in sensitivity to metal exposure. Different types of studies have shown that part of this variation in susceptibility is due to genetic causal components (e.g., studies of human twins, families, or epidemiological associations), as well as animal studies on knockout mice or inbred rodent strains (examples are given in the following for the different metals). This type of interaction in which a genetic component is thought to modify the exposure-disease relationship is often referred to as *gene–environment interaction* and the genes involved as *susceptibility genes*.

For most metals it is still totally unknown to what extent genetic components predispose for susceptibility to toxicity and which specific genetic factors are responsible. This is mainly due to the shortage of studies addressing these questions, which in turn is the result of lack of knowledge about mechanisms of metal action. Another reason for limited data is previous technical limitations. However, the molecular genetic technology has lately developed greatly, and there are now many fast tools for detecting genetic variation and performing association studies.

3.1 Genes of Concern

The metal susceptibility genes differ in several aspects from the so-called high penetrance genes that have been identified for some rare metal-associated hereditary diseases (e.g., Wilson or Menkes diseases) characterized by impaired copper homeostasis. Typically, high penetrance gene mutations associated with disease are rare (i.e., they have a frequency lower than 1% in the population). For example, the gene frequency for Wilson disease varies between 0.3 and 0.7% worldwide (Gollan and Gollan, 1998) and is the result of mutations in the *ATP7B* gene (Bull *et al.*,

1993; Tanzi *et al.*, 1993). This type of mutation has high penetrance, meaning that it confers a high absolute risk, irrespective of environmental factors. Hereditary hemochromatosis is a more common (gene frequency of approximately 5% in the Caucasian population) genetic disease (Cartwright *et al.*, 1979; Lalouel *et al.*, 1985). It is caused by mutations in the *HFE* gene, which leads to increased iron uptake from the gastrointestinal tract (Feder *et al.*, 1996). However, a recent study suggests that *HFE* mutations have much lower penetrance than what have previously been estimated (Beutler *et al.*, 2002). These aforementioned genetic diseases will be covered elsewhere in this handbook (namely, Chapter 26 on copper and Wilson and Menkes diseases and Chapter 30 on iron (hemochromatosis) (apart from some aspects on hemochromatosis, which will be mentioned here in relation to lead and cadmium).

In contrast, genetic variants of susceptibility genes generally have a low penetrance but are more frequent. Genetic variants that are present in greater than 1% of the population are called polymorphisms. When reviewing the literature, risk effects of odd ratios of 2–3 or less for different diseases are found for most susceptibility genetic variants, and, thus, there is much greater scope for interaction with specific exposures. However, although the individual risk for carrying a susceptibility variant might be increased by a small amount, a common polymorphism in the population may result in a substantial proportion of toxic effects attributable to this type of genetic trait.

The genetic variants influencing susceptibility to toxic effects by metals could be of many different kinds: they might affect the metal biotransformation by absorption—as suggested for lead and *HFE* polymorphisms (Wright *et al.*, 2004), metabolism—as exemplified for arsenic and genetic variants of the methyltransferase gene *CYT19* (Meza *et al.*, 2005), or excretion. They could also alter the cellular import and export of metals. Genetic differences in the defense against oxidative stress or DNA repair capacity probably modify the toxic effects of different metals as well. Because many metals are provoking hypersensitivity reactions (e.g., gold, mercury, beryllium, and nickel) (Garner, 2004), major histocompatability complex genes involved in presenting metals to the immune system are presumably of relevance, as has been shown for beryllium and the human leukocyte antigen (HLA) variant *HLA-DBP1* (Richeldi *et al.*, 1993), as well as other parts of the immune system.

Another type of genetic factors that might be important for individual susceptibility to metal toxicity is mediated by so-called epigenetic elements that can change genome function under exogenous influence. Epigenetic factors regulate changes in gene expression that are not transmitted by the DNA sequence itself, but by different modifications of the DNA nucleotides or DNA-associated proteins like the histones. DNA methylation patterns of the cytosines are the most studied epigenetic markers. Arsenic, cadmium, and nickel are affecting the methylation pattern of DNA (Chen *et al.*, 2004; Costa *et al.*, 2001; Takiguchi *et al.*, 2003). However, the impact of epigenetic factors on predisposition for metal toxicity is at present completely unknown.

3.2 Design of Gene–Environment Interaction Studies

There are many aspects of how to design a gene–environment interaction study; a few are mentioned in the following. For a more comprehensive overview, Vineis and Malats (1999) is recommended. Today, many gene–environment studies are based on the genotype for information of the phenotype (i.e., characteristics of an individual). Genotyping has several advantages over phenotypic analyses: the genotype is stable over time and not influenced by environmental factors, very small amounts of DNA are needed, and the technique is not as cumbersome. However, the genotype–phenotype association is not established for most polymorphisms. Probably, many genetic variants result in no or very limited effect on the phenotype. Thus, when no phenotypic information is present, careful selection of polymorphisms should be conducted based on position within the gene sequence (e.g., whether or not it results in an amino acid exchange or might regulate the expression of the protein). It is also important to note that the geographical distribution of polymorphisms varies worldwide, and thus, gene–environment interactions can differ between ethnic groups. For example, the frequency of the F allele of the *Fok*1 polymorphism of *VDR* was much higher among the African-American children than the non-African-American children in a study on *VDR* polymorphisms (Haynes *et al.*, 2003). The interaction observed for this *VDR* genotype and floor dust lead was not significant for African-American children, but it was significant for non-African-American children. In general, genetic effects are more easily observed in homogenous rather than mixed populations, and ethnic origin should, when possible, be taken into consideration.

Genetic factors for metal toxicity are most often handled as effect modifiers of the exposure-disease relationship. The interpretation of genotype as an effect modifier implies that studies should be planned to have sufficient power for detecting interactions and that an interactive term should be modeled into the statistical analysis. (However, it is important to note that interaction with one genetic variant does not warrant

conclusions on a causal relationship with the biochemical mechanism, because the genetic variant may be linked with the causal gene.) Another fact that stresses the importance of sufficient statistical power is that, in general, genes act in concert to exert effects. Therefore, effects on one gene may induce compensatory changes in others. Moreover, many metabolic enzymes have overlapping substrate specificities. Thus, there are several grounds for analyzing interactions between different gene loci, so-called gene–gene interactions. However, only a limited number of studies have until now examined the combined effects of two or more genes in relation to metal toxicity. One example is beryllium in which the combined effect of specific variants of HLA DPB1 and DRB1 and tumor necrosis alpha (TNF) have been analyzed in relation to clinical severity (Maier *et al.*, 2001). Considering multiple genes is more biologically relevant, but for these studies, a large number of individuals are needed. Moreover, it is necessary to formulate a strategy for handling the problem of multiple comparisons that very quickly arise when analyzing the effects of a large number of polymorphisms in different exposure groups, in different subgroups, or for different markers of effect. Simple corrections for multiple testing (e.g., Bonferroni correction) are not very fruitful when analyzing several hundreds of polymorphisms, rather it has been suggested that the prior credibility of the hypothesis is important for interpreting a set of observations. New statistical methods for genetic association studies are needed, and a recent article illustrates how a Bayesian approach can be used to estimate the probability that a positive association is false (Wacholder *et al.*, 2004).

3.3 Interactions for Specific Metals

A review of what presently is known about gene–environment interactions for different metals follows. For most metals apart from a few exceptions (i.e. beryllium, lead, and to some extent arsenic) there are no or only a few reports on gene–environment interactions. However, the literature within this field is rapidly growing.

3.3.1 Arsenic

Gene–environment interaction studies for this element have mainly focused on genes involved in the metabolism of inorganic arsenic. Of the total amount of arsenic excreted through the urine, 10–30% is usually inorganic, 10–20% monomethylated arsenic (MMA), and 60–70% dimethylated arsenic (DMA). However, there is a marked variability in metabolism of inorganic arsenic within and between population groups (Vahter, 2000). In some areas of Taiwan, people excrete an unusually high percentage as MMA in the urine (20–30%), whereas certain populations in Argentina and Chile only excrete a few percent as MMA. Support for the idea that part of this variation is determined by genetic causal components comes from a correlation study for arsenic performed within families (Chung *et al.*, 2002), showing that siblings have a higher correlation of arsenic methylation capacity than their parents. Moreover, there are two studies addressing intraindividual variability in arsenic methylation pattern, showing that arsenic methylation pattern remains relatively stable over time, suggesting that the predominant factors are either genetically influenced or associated with long-term environmental factors, such as dietary habits (Concha *et al.*, 2002; Steinmaus *et al.*, 2005).

Evidence for genetic effect modification on arsenic metabolism comes from studies on the methyltransferase CYT19 (also labelled AS3MT) that is believed to catalyze the methylation of arsenic to MMA and further to DMA. This enzyme is best characterized in rat (cyt19) (Lin *et al.*, 2002; Thomas *et al.*, 2004) but is not well defined in humans (Hayakawa *et al.*, 2005). Meza and colleagues showed in a study from Mexico that *CYT19* displayed three variants that were strongly associated with the second methylation index (DMA/MMA) among children but not in adults (Meza *et al.*, 2005). This finding suggests a role for polymorphisms regulating developmental differences in arsenic biotransformation. However, there was a difference in ethnicity between the groups: the children were to a larger degree of Indigenous and the adults of European ancestry. Wood *et al.* (2006) estimated the functional impact on AS3MT enzyme activity of genetic variants occurring in exons. However, for intronic polymorphisms, like those reported in Meza *et al.* (2005), their function on AS3MT activity is still completely unknown.

It is generally thought that many of the toxic effects associated with arsenic exposure were mediated through arsenic-induced oxidative stress. Thus, Ahsan *et al.* analyzed whether polymorphisms in the oxidative stress–scavenging enzyme catalase and the phase I metabolic enzyme myeloperoxidase (MPO) are associated with increased risks of hyperkeratosis in a highly arsenic-exposed population in Bangladesh (Ahsan *et al.*, 2003). The results indicated that the low-activity variant of the catalase was overrepresented among the cases of hyperkeratosis. Similarly, the variant of MPO producing an increased amount of the reactive oxygen species hypochlorous acid was overrepresented among the cases. Ahsan and coworkers also published data suggesting that genes involved in DNA repair, removing oxidative stress–induced DNA damage, may influence the risk of arsenic-induced

premalignant hyperkeratotic skin lesions (Ahsan *et al.*, 2003). However, in both studies the results were based on very small study populations. Genes involved in oxidative stress have also been shown to modify the risk for arsenic-related cardiovascular effects (Hsueh *et al.*, 2005, Wang *et al.*, 2006).

3.3.2 Beryllium and Cobalt

Genetic susceptibility for beryllium-associated sensitization and subsequent chronic beryllium disease (CBD) has been described and is maybe the clearest example of a gene–environment interaction for a metal. The immunopathogenesis of CBD and beryllium sensitization depends on the development of an antigen-specific, cell-mediated immune response (Saltini *et al.*, 1989). Beryllium-specific $CD4^+$ T cells probably recognize a form of beryllium as an antigen, acting in combination with MHC class II molecules on antigen-presenting cells. In a key study, Richeldi *et al.* (1993) reported an increased prevalence of HLA-DPB1 with glutamic acid in position 69 (Glu^{69}) in cases of CBD (97%) compared with beryllium-exposed nondiseased controls (30%). These results were later confirmed by further studies, although the frequency of the Glu^{69} variant was somewhat lower (Maier *et al.*, 2003; Rossman *et al.*, 2002; Saltini *et al.*, 2001). The results from these studies show that specific Glu^{69}-containing alleles and their copy number (homozygous or heterozygous) confer the greatest susceptibility to CBD in exposed individuals. However, because 15–20% of CBD patients lack Glu^{69}, other class II markers are likely to be involved in the Be-specific response as well. Recently, Amicosante and coworkers identified the HLA-DRPhebeta47 marker to be associated with beryllium sensitivity in Glu^{69}-negative subjects (Amicosante *et al.*, 2005).

Beryllium antigen stimulates tumor necrosis factor alfa (TNFα) from bronchoalveolar lavage cells in CBD. Thus, functional gene polymorphisms of this gene are suspected to modify the course of CBD. Several studies suggest that the −308 allele in the promoter region of TNFα determines susceptibility for CBD (Dotti *et al.*, 2004; Gaede *et al.*, 2005; Maier *et al.*, 2001). Moreover, the antiinflammatory cytokine transforming growth factor beta (TGFβ) is able to inhibit production of alveolar macrophages and monocytes, and it has recently been demonstrated that the frequency of a polymorphism associated with a low TGFβ release (labeled $TGF\beta_1$, codon 25) was strongly associated with CBD (Gaede *et al.*, 2005). However, this phenomenon was only seen among individuals from the United States, suggesting that different genetic factors are important in different populations.

Hard metal disease is a pulmonary disorder associated with occupational exposure to inhalation of cobalt ions, sintered or not to other metals. A strong association with hard metal disease and HLA-DP sharing a Glu at position 69 has been reported (Potolicchio *et al.*, 1997, 1999). On the other hand, no influence of Glu^{69} was observed in relation to lung function changes among workers from a cobalt-producing plant (Verougstraete *et al.*, 2004).

3.3.3 Cadmium

Support for genetic influences comes from a large number of studies performed on different inbred strains of rodents that differ greatly in metal susceptibility. As an example, for cadmium-induced testicular toxicity, more than 30 mice strains are sensitive at very low cadmium levels, whereas approximately 10 are resistant, even at very high cadmium concentrations (Liu *et al.*, 2001). Differences in the cadmium-binding protein metallothionein have generally been thought to be responsible for the strain susceptibility to cadmium toxicity. Metallothionein null mice, indeed, are more sensitive to certain effects of cadmium (e.g., nephrotoxic or testicular injuries) (Liu *et al.*, 2000). However, a study on cadmium-induced testicular damage showed that the genetic mouse strain and not the metallothionein genotype determined susceptibility to testicular injury (Liu *et al.*, 2001). Therefore, the resistance to cadmium-induced testicular injury among certain strains has been sought in other factors, most probably including genetic differences in the recently reported transporter ZIP8, located at mouse chromosome 3 (Dalton *et al.*, 2000; 2005).

Although cadmium is one of the major toxic metals, so far strikingly little is known about what extent and which genetic factors influence its toxicity among humans. One twin study has been performed for quantifying the genetic influence of variation in blood concentrations of cadmium and lead (Björkman *et al.*, 2000). Heredity had a substantial impact on blood cadmium and lead levels, but a striking sex difference was observed. Among nonsmoking women, the hereditary impact was 65%, whereas for nonsmoking men it was only 13%.

3.3.4 Lead

3.3.4.1 ALAD

It is now 20 years since the first study by Ziemsen *et al.* describing differences in blood lead levels by genotype of the gene δ-amino levulinic acid dehydratase (ALAD) (Ziemsen *et al.*, 1986). Since then, there have been a large number of studies performed focusing on

interactions for *ALAD* genotype, lead metabolism, and toxicity (reviewed in Kelada *et al.*, 2001). ALAD is the major binding site for lead in red blood cells (Bergdahl *et al.*, 1997; 1998). This protein is polymorphic, and the main variant analyzed is the Lys/Asn substitution at amino acid position 59. The two alleles are traditionally labeled *ALAD*-1 for the Lys variant and *ALAD*-2 for the Asn variant, and the resulting genotypes are named *ALAD* 1-1 for Lys/Lys carriers, *ALAD* 1-2 for Lys/Asn, and *ALAD* 2-2 for Asn/Asn. The frequency of the ALAD-2 allele varies considerably worldwide: the highest frequency is found in Northern Europe (up to 20%), whereas this allele is rarer among Asian populations and almost absent among Africans (Packer *et al.*, 2006). The Lys59Asn amino acid position is not positioned near the Zn-binding sites, where lead probably binds (Jaffe *et al.*, 2000; 2001). However, because asparagine is a neutral amino acid whereas lysine is positively charged, this amino acid substitution results in a more electronegative enzyme. This fact has generated the hypothesis that the ALAD-2 protein binds positively charged lead more tightly than the ALAD-1 protein and that a protective effect of ALAD-2 exists because of this tight binding, maintaining lead in the intravascular space in a less bioavailable form (Wetmur, 1994; Wetmur *et al.*, 1991). It is important to stress that, so far, limited proof exists of molecular differences between the two isozymes. Jaffe *et al.* have constructed recombinant ALAD variants in *E. coli*. They found no functional dissimilarities, apart from a small difference in the half-time for recovery from lead inhibition between ALAD-1 and ALAD-2 *in vitro* (Jaffe *et al.*, 2000; 2001).

In early studies of effect modification of *ALAD* on lead, the individuals analyzed were from populations with relatively high levels of exposure from occupational or home environment. These studies displayed association of the *ALAD*-2 genotype with higher blood lead levels. Wetmur and colleagues demonstrated in a study based on more than 1000 children from New York City that *ALAD*-2 individuals had higher lead levels in blood (Wetmur 1994; Wetmur *et al.*, 1991). However, conclusions of this large study are hampered by the selection of study subjects: they all had high protoporphyrin levels in an initial screening. This means that the conclusion may either be that *ALAD*-2 carriers demonstrate higher lead levels, which in turn result in higher protoporphyrin levels, or alternately, that *ALAD*-2 carries more lead relative to *ALAD*-1 but is protected from the negative effects of lead. Several other studies have shown an effect of *ALAD* genotype on blood lead levels among individuals with a high lead exposure (Alexander *et al.*, 1998; Fleming *et al.*, 1998), whereas others have not (Bergdahl *et al.*, 1997; Sakai *et al.*, 2000; Schwartz *et al.*, 1995; 1997; Sithisarankul *et al.*, 1997; Süzen *et al.*, 2003). Epidemiological studies of blood lead levels at background exposure levels show no clear association of effect of *ALAD* genotype (Bergdahl *et al.*, 1997; Hu *et al.*, 2001; Smith *et al.*, 1995), although Hsieh *et al.* found nonsignificant higher levels among *ALAD*-2 individuals in a Taiwanese population (Hsieh *et al.*, 2000).

Schwartz and colleagues found that the 1–2 genotype (Lys/Asn carriers) was associated with occupational exposures of more than 6 years (Schwartz *et al.*, 1995). This genotype distribution could be the result of genotype selection, and the authors suggested that *ALAD*-2 subjects were protected from effects of lead and could tolerate longer exposures to lead than *ALAD* 1-1. This is in line with the alternative conclusion of the New York study mentioned previously.

Kim *et al.* analyzed whether Korean lead workers with the *ALAD* 1-1 genotype were more susceptible to the hematological effects of lead exposure (Kim *et al.*, 2004). They found that *ALAD* 1-2/2-2 was associated with lower log zinc protoporphyrin (ZPP) and higher hemoglobin levels. Moreover, among individuals with normal iron status, those with the *ALAD* 1-1 genotype were more likely to be anemic. Alexander *et al.* (1998) found significantly lower levels of ZPP at high blood lead levels among *ALAD*-2 genotypes as well, and lower but nonsignificant ZPP levels among carriers of the *ALAD*-2 allele have been reported elsewhere (Sakai *et al.*, 2000; Schwartz *et al.*, 1997; Sithisarankul *et al.*, 1997). Reduced levels of plasma aminolevulinic acid among *ALAD*-2 carriers have also been seen in the studies on the Korean battery workers (Sakai *et al.*, 2000; Schwartz *et al.*, 1997; Sithisarankul *et al.*, 1997), as well as among Japanese workers (Sakai *et al.*, 2000). Accumulation of plasma aminolevulinic acid has been suggested to confer a greater risk for neurotoxic effects of lead. Bioavailable lead has also been analyzed by measuring the amount of dimercaptosuccinic acid (DMSA)–chelatable lead in urine. There is some evidence that *ALAD*-2 individuals display lower levels of DMSA-chelatable lead levels (Schwartz *et al.*, 1997; 2000).

ALAD genotype has been analyzed in relation to kinetics of bone lead as well. However, the results are difficult to interpret; some studies suggest an impact of *ALAD* on bone lead (Bellinger *et al.*, 1994; Hu *et al.*, 2001; Kamel *et al.*, 2003), whereas others do not find any effect modification of the polymorphism (Bergdahl *et al.*, 1997; Fleming *et al.*, 1998; Schwartz *et al.*, 2000). Moreover, a few studies have analyzed effect modification of *ALAD* on lead's effects on kidney parameters (Bergdahl *et al.*, 1997; Smith *et al.*, 1995; Weaver *et al.*, 2003). Also the results of these studies are contradictive.

The inconsistent findings of the impact of this ALAD polymorphism on lead levels and toxicity between different studies could be the result of different ways of selecting study subjects (e.g., from highly exposed environments or the general population, from lead levels in blood, or biomarkers of effect). Another problem regarding study design is the use of different statistical methods for analyzing interaction, which makes it difficult to compare the different studies. Thus, these data should still be interpreted with caution. Another reason for contrasting findings could be that *ALAD* may have impact, depending on the genetic background, and incoherent observations are made when different populations are studied. To explain the differences between populations, more genes related to lead metabolism and effects have to be analyzed in association with lead markers of toxicity.

In summary, at high levels of exposure and in comparison with *ALAD*-1 subjects, heterozygous or homozygous *ALAD*-2 carriers seem to have increased blood levels, lower levels of ZPP and plasma aminolevulinic acid, and perhaps lower amounts of chelatable lead. Theses associations are consistent with those reported by Scinicariello and colleagues (2006), who used meta-analyses to summarize the current state of knowledge. Still, much is unknown of genotypic effect modifications of lead on the bone, kidney, and the neurological system, and whether or not there are similar effects of *ALAD* genotype in the general low-exposed population as seen for high levels of exposure.

3.3.4.2 VDR

Lead uptake increases when calcium resources are limited (Mahaffey *et al.*, 1986). Thus, genetic differences in calcium absorption might, in turn, modify lead levels. Lead binds to calcium proteins, which are regulated by the vitamin D endocrine system and the vitamin D receptor (VDR). VDR displays polymorphisms, and Ames *et al.* (1999) demonstrated that the *VDR Fok1* genotype FF increases bone mineral density and calcium absorption by 30–40% among healthy children 7–12 years of age. Haynes and coworkers (2003) have shown that children from New York with the Ff genotype displayed lower blood lead than the FF genotype after exposure to floor dust lead, suggesting that this genotype is an effect modifier of the relationship of floor dust lead and blood lead concentrations.

Another polymorphism of *VDR*, labeled *Bsm*I, is affecting the bone mineral density: decreased density has been reported in those with the BB compared with the bb genotype (Cooper and Umbach, 1996). In Korean battery workers, individuals with the BB and Bb genotypes displayed higher blood and tibia lead levels (Schwartz *et al.*, 2000), as well as diastolic blood pressure, compared with participants with the bb genotype (Lee *et al.*, 2001). Also Theppeang and coworkers reported higher patella lead levels among VDR BB carriers compared with bb carriers (Theppeang *et al.*, 2004). In a study on renal function in Korean lead workers, the *Bsm*I polymorphism of *VDR*, as well as endothelial nitric oxide synthase (*NOS3*), involved in nitric oxide production were analyzed for possible effect modification (Weaver *et al.*, 2003). However, no obvious association was present for *VDR* and either lead levels or markers for renal function.

Studies analyzing gene–gene interactions for *ALAD* and *VDR* or different polymorphisms within *VDR* are very few in the literature. However, in the aforementioned study on Korean battery workers (Schwartz *et al.*, 2000), the authors analyzed the frequency of combined genotypes of *ALAD* and *VDR* among exposed subjects and controls and found that there was a tendency among exposed subjects homozygous for *ALAD*-1 to lack the *VDR Bsm*I bb genotype. Among the controls, the opposite genotype distribution was seen. This finding could indicate a genotype selection among the exposed workers.

3.3.4.3 HFE

Lead is also linked to the uptake of iron in the gastrointestinal tract: when the sources of iron are limited, lead absorption is increased (Cheng *et al.*, 1998). As previously mentioned, the autosomal genetic disease hemochromatosis is caused by mutations in the *HFE* gene. The *HFE* gene is mutated at amino acid position 282, which leads to a cysteine-tyrosine exchange, among 85% of the affected. Another variant of this gene, His63Asp, is also associated with hemochromatosis, but with a lower penetrance (Waheed *et al.*, 1997). Because mutations in the *HFE* gene affect iron uptake, variants of this gene or others affecting the iron status might have a modifying effect on the levels of lead as well. Barton *et al.* (1994) showed that subjects who were homozygous for the Cys282Tyr mutation had increased blood lead and that there was an allele-dosage effect. On the other hand, in a Swedish study, the blood lead levels were lower among hemochromatosis-affected subjects than among the controls (Åkesson *et al.*, 2000). Similarly, Wright *et al.* (2004) showed among elderly men that carriers of at least one variant *HFE* allele from Cys282Tyr or His63Asp were associated with lower levels of blood or bone lead. Adjusted analysis showed that one *HFE* variant was independent factor for significantly lower levels of lead in patella.

3.3.5 Mercury

There is substantial evidence for strain differences among mice in susceptibility to immune toxic effects of inorganic, methylmercury, as well as ethylmercury (Häggqvist *et al.*, 2005; Havarinasab *et al.*, 2005; Warfvinge *et al.*, 1995). The differences in predisposition to mercury-associated autoimmune diseases have been linked to genes in the major histocompatability complex (H-2), but genes outside this region also seem to be important (Hultman *et al.*, 1992; 1993). Kono and coworkers found evidence for a locus on mouse chromosome 1 determining susceptibility toward inorganic mercury-associated autoimmunity (Kono *et al.*, 2001). However, the candidate gene(s) has not yet been identified.

Glutathione (GSH) plays a central role in mercury metabolism, and there are also indications that the activity of glutathione S-transferases (GST) is involved in the conjugation of Hg^{2+} (Brambila *et al.*, 2002; McGuire *et al.*, 1997). A possibility for variation in toxic effect of mercury is genetic differences in mercury metabolism, because of polymorphism in genes that conjugate GSH to mercury (i.e., GSTs) or synthesize GSH (e.g., glutamyl-cysteine ligase encoded by *GCLC* and *GCLM*).

Westphal *et al.* showed that among individuals exposed to ethylmercury, those carrying the low-activity null genotypes of *GSTM1* and *GSTT1* were overrepresented among patients who had contact dermatitis develop (Westphal *et al.*, 2000). The mechanism for this observation could be that ethylmercury-sensitized individuals have a slower elimination of ethylmercury by GSH conjugation or even lack this route of elimination, and thus have a greater tendency for ethylmercury accumulation and sensitization. For methylmercury, a recent study tested the hypothesis that polymorphisms in GCL and GST genes could modify methylmercury elimination (Custodio *et al.*, 2004). Erythrocyte mercury concentration and plasma polyunsaturated fatty acids (a proxy for fish intake) were measured. The presence of one rare variant allele for either of the polymorphisms *GCLC*-129 or *GSTP1*-114 was associated with both higher EryHg levels and a steeper regression slope for the association between Ery-Hg and PPUFA. This is consistent with slower methylmercury elimination in these genotypes.

Also for inorganic mercury, the genotypes of GSH-related genes seem to modify the metabolism. Data from a study on gold miners and gold buyers in Ecuador, highly exposed to elemental mercury vapor, shows that the presence of the less GSH-producing *GCLM*-588T allele was associated with increased blood, plasma, and urine mercury levels and that it modifies the effect of exposure (Custodio *et al.*, in 2005). These results indicate that genotypes with decreased GSH availability for mercury conjugation affect the metabolism of inorganic mercury.

Inorganic mercury gives a porphyrinogenic response, which can be detected by increases of different coproporphyrins in urine, and this response has been suggested as a biomarker of mercury exposure and toxicity. A polymorphism in the coproporphyrinogen oxidase gene (*CPOX4*) was found to be overrepresented among subjects showing highly elevated levels of coproporphyrins in urine in response to mercury (Woods *et al.*, 2005). The *CPOX4* polymorphism and mercury exposure seem to exert negative effects in an additive manner on neurobehavioral tests among dentists and dental assistants (Echeverria *et al.*, 2006). However, no CPOX4-mercury interaction was investigated.

3.3.6 Nickel

Nickel allergy has been suggested to have a genetic causal component, partly from earlier twin and familial studies (Fleming *et al.*, 1999; Menne and Holm 1983), but also from the past finding of an association of an HLA-DQA polymorphism and nickel allergy (Olerup and Emtestam, 1988). However, associations with this or other HLA-types have not been confirmed (Emtestam *et al.*, 1993; Ikaheimo *et al.*, 1993). Recent data suggest that nickel mainly interacts with HLA-DR, but then with a conserved amino acid in the beta chain (Gamerdinger *et al.*, 2003). Still, other genetic factors not related to the HLA-system might have importance for the risk of developing nickel allergy. On the other hand, a more recent study based on female twins indicates that nickel contact dermatitis is mainly determined by environmental and only to a lesser degree to genetic factors (Bryld *et al.*, 2004).

3.3.7 Platinum

Interestingly, for platinum-containing substances like cisplatin and oxaliplatin used in high doses in chemotherapy, gene-exposure interactions have been reported that have an impact on treatment outcome and survival (Kweekel *et al.*, 2005). Variants in genes involved in cellular defense mechanisms that prevent platinum-DNA adduct formation (e.g., glutathione S-transferase *GSTP1*) or remove DNA adducts (base or nucleotide excision repair genes *XPD* and *ERCC1*) have been shown to affect the response of chemotherapy. These variants might as well have an impact on susceptibility toward platinum-related health effects from low-level occupational or environmental exposures.

3.4 Conclusions

Gene–environment interactions are unknown for most metals. So far, presence of *HLA-DPB1* and toxic effects of exposure to beryllium seem to be the strongest example of a genetic effect modification. *ALAD* genotype and lead exposure is the most studied interaction, but its impact on health effects of lead is still unclear. The heterogeneous results of studies of *ALAD*-lead stresses problems with gene–environment interaction studies, such as uncharacterized biological mechanisms, use of different biomarkers or markers of effect, small studies with low power, as well as the lack of a "gold standard" for statistical analysis for this study type. However, it is important to try to solve these problems for the identification of subpopulations that are more vulnerable to metal-induced toxic effects. Moreover, genetic variants may be significant in relation to low-level exposures, influencing the risk assessment and of setting tolerable limits of exposure.

4 METAL–METAL INTERACTIONS (NONCARCINOGENIC EFFECTS)

4.1 Arsenic and Other Metals

Lead, cadmium, and arsenic are among the most commonly encountered toxic trace elements to which humans may be exposed, but toxicity studies of interactions among these elements are relatively limited. Early *in vivo* studies concerning interactions between toxic trace elements (Fowler and Mahaffey, 1978; Mahaffey and Fowler, 1977; Mahaffey *et al.*, 1981) used "stressor dose levels'" of these elements in semipurified diets fed to rats for 10 weeks in a factorial design study, demonstrated additivity as the most common type of interaction among these elements for a variety of clinical and elemental concentration parameters. The organelle and biochemical aspects of interactions among these elements, as well as mercury, were reviewed and future research needs identified for understanding the molecular bases among these elements. Subsequent *in vivo* mechanistic studies evaluated interactions between gallium and arsenic (Goering *et al.*, 1988) and indium and arsenic (Conner *et al.*, 1993; 1995; Fowler *et al.*, 2005) semiconductors. More recent *in vitro* studies (Madden and Fowler, 2000; Madden *et al.*, 2002) compared cadmium and arsenic interactions in both rat and human cell lines and observed more than additive effects and documented differences in species sensitivity. These studies explained a number of the mechanistic molecular factors (e.g., stress proteins) that contribute to cellular resistance to toxicity until the cellular capacity is exceeded by either dose level or combined interactive toxic effects. Complementary *in vivo* studies (Fowler *et al.*, 2004) in rats exposed to lead, cadmium, or arsenic at LOEL dose levels in drinking water and fed semipurified diets for 30, 90, or 180 days also demonstrated additive, or more than additive, effects as a function of duration of exposure. As with the *in vitro* studies, biomarkers of cell injury showed clear responses when the capacities of cellular protective mechanisms were exceeded as a function of duration of exposure. Analogous studies on human populations exposed to Cd and As in China (Nordberg *et al.*, 2005) also showed positive interactive effects using biomarker endpoints with regard to increased renal toxicity among groups with combined exposures to both cadmium and arsenic relative to groups with increased exposures to only cadmium or arsenic.

Interactions between arsenic and selenium have been documented by a number of investigators. Previous studies (Kraus and Ganther, 1989) reported synergistic toxicity between arsenic and methylated selenium compounds. Studies by others (Csanky and Gregus, 2003) demonstrated alterations in the disposition of arsenate or arsenite in rats treated with selenite and demonstrated decreased tissue concentrations of MMA(III) and MMA(V) and altered biliary excretion of MMA(III) and DMA metabolites. The investigators also noted a pronounced dose effect with regard to these observations. Mechanistic studies by others (Styblo and Thomas, 2001; Walton *et al.*, 2003) using *in vitro* hepatocyte culture systems showed that selenite rather than its methylated metabolites was responsible for the observed inhibition of arsenical methylation and may stimulate the observed increases in cellular toxicity of inorganic arsenic. Studies by others (Zakharyan *et al.*, 2005) showed that three Se atoms and three GSH molecules were covalently bound to the monomeric form of human glutathione-S-transferase (hGST01-01), which also acts a the arsenical methyl transferase. The investigators conclude that the mechanism of Se inhibition of arsenical methylation involves complexation of Se with glutathionylated cysteines at the active site of the enzyme. Se–As interactions have also been reported (Davis *et al.*, 2001) to produce alterations in the methylated pathway and to alter DNA methylation in Caco-2 cells *in vitro*.

There is also a pressing need to consider the impact of factors such as age and gender on interactions among toxic trace elements. Such intrinsic biological factors are clearly important for assessing risks to sensitive subpopulations or groups of workers exposed to mixtures of these elements such as those found in the semiconductor industry (Fowler and Sexton, 2002;

Fowler and Silbergeld; 1989), because they may influence target molecular and cellular responses to mixtures of gallium and arsenic or indium and arsenic (Conner *et al.*, 1994).

4.2 Interactions Between Cadmium and Other Metals

Many studies show that zinc can counteract toxic effects of cadmium. Cadmium and zinc belong to the same group of the Periodic Table. It has been speculated that cadmium can displace or replace zinc in some essential systems in the organism, thus causing functional changes. Metallothionein, a low-molecular-weight cysteine-rich protein, can bind cadmium, copper, and zinc; and this protein will bind most of the cadmium stored and kidneys, being inert in this form and preventing cadmium ions from interfering with the essential metals. Some parts of the reproductive system have particularly high concentrations of zinc, which is of great functional importance. Lethal toxicity from injection of Cd compounds can be protected by pretreatment by Zn or Cd (Leber and Miya 1977; Nordberg, 1972). The induction of MT by the pretreatment, shown to take place in the liver, most probably is the explanation for such protective effects. Studies using MT transgenic and MT null mice have demonstrated lower lethality and lower liver toxicity from Cd in mice expressing increased levels of MT (Liu *et al.*, 1995) and increased such toxicity in MT-null mice (Liu *et al.*, 1998). Cadmium in single doses may cause testicular destruction, but this damage may be prevented by injection of large amounts of zinc (Parizek, 1957), selenium, or even pretreatment with smaller doses of cadmium. The latter phenomenon is likely to be due to the induction of a small cadmium-binding protein (Nordberg, 1971) protecting against the deleterious effect of the large dose. Although it has been speculated that this protein might be metallothionein, the fact that various strains of mice with variable susceptibility to this effect are not related to MT, makes it likely that the protective protein is different from metallothionein (see Section 3.2 of this chapter). Gunnarsson *et al.* (2004) showed that pretreatment with zinc protected against Cd-induced testicular prostaglandin increase, a probable mechanism by which Cd inhibits testosterone synthesis. In many studies on the relationships between zinc and cadmium, animals exposed to cadmium were given diets with extremely high concentrations of zinc, which might have prevented some of the expected effects of cadmium. Of greater interest are the studies in which animals have been exposed to cadmium, but the dietary concentrations of zinc have been just adequate or suboptimal. In such experiments, it has been shown that exposure to small amounts of cadmium may cause a redistribution of zinc in the organism (Petering *et al.*, 1971). Zinc concentrations increase in liver and kidney and might decrease in other organs where cadmium does not accumulate to the same extent (e.g., in the testes). It has also been shown that if pregnant animals are exposed to cadmium, the fetal concentrations of zinc and of copper may become lower (Pond and Walker, 1975). Cadmium, a potent inhibitor of iron uptake in mice fed a low iron diet, impaired zinc uptake under these conditions (Hamilton *et al.*, 1978). Such interactions influencing the fetal levels of essential elements may be important components for the explanation of the effects of low-level Cd exposures on the fetal brain (cf Chapter 23).

In rats, cadmium (Cd2+) and chromium (Cr3+) inhibited zinc (Zn2+) uptake, but chromium (Cr6+) did not show any affinity for the transport process (Lyall *et al.*, 1979). In animals exposed to cadmium over a long period of time, there is a marked accumulation of cadmium in the liver and kidneys; in addition, there is an increase in zinc and a decrease in iron in these organs, whereas the concentration of copper is usually unchanged (Sugawara, 1984). It could be expected that cadmium would cause changes in the activities of some enzymes that require zinc. It has been shown that the renal activity of leucine aminopeptidase, which is a zinc-requiring enzyme, is reduced in animals exposed to cadmium (Cousins *et al.*, 1973).

It is known from animal experiments that the dietary intake of iron, zinc, and calcium is of importance for the gastrointestinal uptake of Cd (see reviews by Andersen *et al.* [2004] and Chaney *et al.* [2004]).

There are indications that contributing factors for Itai-Itai disease were low intakes of calcium and other minerals, vitamin D, and protein. The poor nutritional conditions in many areas of Japan during World War II were discussed and a comparison between diets in the endemic region of Itai- , Toyama prefecture, Japan as a whole and Sweden was presented by Kjellstrom in 1986. Lower dietary intakes calcium and of fat-soluble vitamins compared with Sweden and the practice by women in the endemic area of wearing clothes covering their whole body, including hands and face, may have provided only marginally adequate calcium intake and marginal or less than marginal vitamin D activity. Such conditions most probably made this population more sensitive to the development of bone effects of Cd than populations in other countries (Kjellstrom, 1986; Nordberg, 1974). Although it is clear that the high cadmium intake in the endemic area was the main causal factor for development of the disease (cf Chapter 23), these other factors may have contributed to the development of severe osteomalacia and osteoporosis with many

fractures. Severe cases of bone disease with osteomalacia have not been observed in other countries (China) where exposures started in the 1960s, nutritional factors are similar to Japan in the 1960s–1990s (but better than in Japan during WWII), and where cadmium intakes have been almost as high as in the endemic area for Itai–Itai disease in Japan (Nordberg *et al.*, 2002).

The important interaction between iron and cadmium in the intestinal mucosa has also been shown in humans. Iron deficiency or low iron stores (indicated by low serum ferritin values) increases Cd uptake in humans (Flanagan *et al.*, 1978). Higher blood and urine values of Cd were found among Swedish women with iron deficiency compared with women without such deficiency (Akesson *et al.*, 2002). The probable mechanism of this interaction is the competition between Fe and Cd for the common transporter DMT-1 (divalent metal transporter 1) in the intestinal mucosa. Findings in human enterocytes of a close correlation between the expression of DMT-1 and Cd absorption (Tallkvist *et al.*, 2001) supports such a mechanism.

In a study in metal-contaminated areas in China, interactions between cadmium and inorganic arsenic exposure were demonstrated (Hong *et al.*, 2004, Nordberg *et al.*, 2005). Although there was a lack of persons with low arsenic exposure and concomitant high cadmium exposure, a multiplicative interaction is still indicated with regard to the prevalence of renal tubular dysfunction in subgroups exposed to various combinations of the two metals (Figure 1).

4.3 Interactions Between Lead and Other Metals

Zinc, a nutritionally essential metal, may affect both the absorption and toxicity of lead. Lead exposure in both humans and animals may lead to a decrease in the activity of the zinc-requiring enzyme ALA-dehydratase. Simultaneous administration of zinc can counteract this decrease. Soil and dust measurements of environmental lead were positively associated with the blood lead concentrations, regardless of the corresponding zinc concentrations in these samples. The strength of association was 20–46% lower in areas with high environmental concentrations of zinc. The findings suggest that zinc influences the relationship between soil and dust lead and the corresponding blood lead levels (Noonan *et al.*, 2003). Lead has been shown to interfere with the DNA-binding properties of Sp1 and Egr-1, both *in vivo* and *in vitro*, and also with the zinc finger protein transcription factor IIIA. Thus, by targeting zinc finger proteins (ZFP), lead may cause multiple responses through its action on a common site that is present in enzymes, channels, and receptors (Zawia *et al.*, 2000). Lead may also replace zinc on heme enzymes (Goyer, 1997).

Experiments in laboratory animals have shown that nutritional iron deficiency may increase the gastrointestinal lead absorption, thereby promoting lead toxicity (Mahaffey 1981), particularly in pregnant women and young children. Similar findings have been shown in epidemiological studies among children, suggesting that

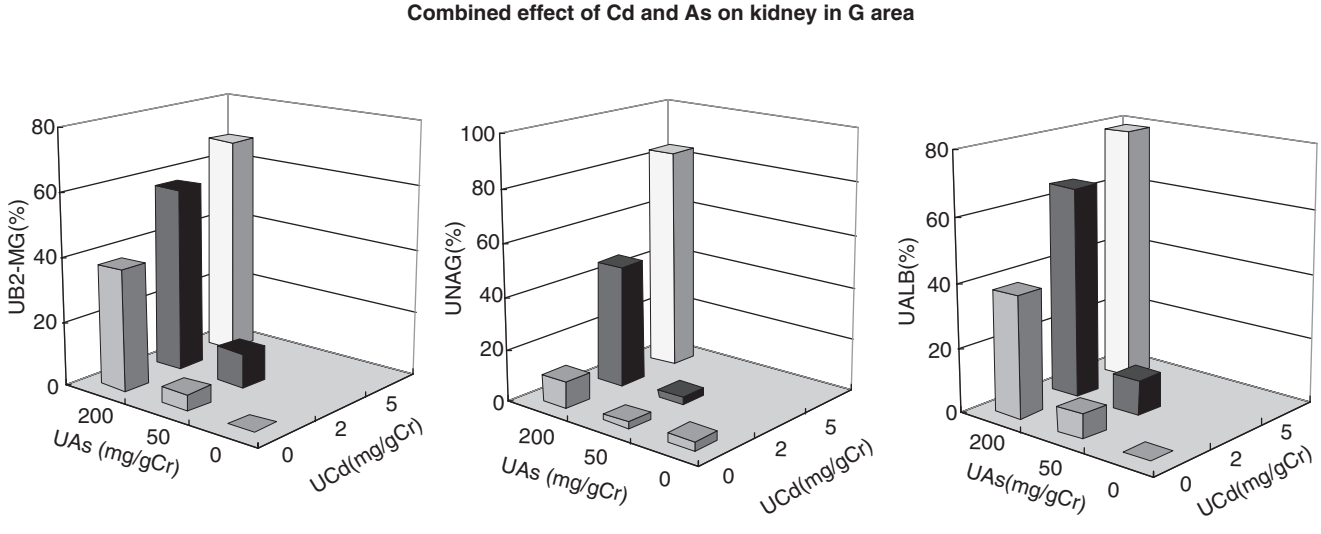

FIGURE 1 Prevalence (%) of elevated excretion for three biomarker proteins in a metal-contaminated area of China in relation to combined exposure to Cd and As as indicated by urinary As and Cd excretion. UB2MG, urinary beta2-microglobulin; UNAG, urinary N-acetylglucosaminidase; UALB, urinary albumin. Reproduced from Nordberg *et al.* (2005).

iron deficiency may increase the susceptibility to lead poisoning. This risk can be counteracted by high iron intake and sufficient iron stores (Kwong *et al.*, 2004).

In a study of 157 children from Katowice, and industrial area in Poland, blood lead concentrations showed a negative relationship with selenium levels in whole blood and serum. The relationship was mainly appearing at low blood lead levels, which was interpreted as an influence of selenium on the kinetics of lead, rather than an impact of lead on the selenium status. In the study, children with low serum ferritin concentrations showed a tendency to higher blood lead levels. Thus, the kinetics of lead may be influenced by both the iron and selenium status (Osman *et al.*, 1998).

Lead may interact with calcium in the nervous system, which can impair the cognitive development (Goyer, 1997). Lead competes with calcium, inhibiting the release of neurotransmitters, and interferes with the regulation of cell metabolism by binding to second-messenger calcium receptors, blocking calcium transport by calcium channels and calcium-sodium ATP pumps, and by competing for calcium-binding protein sites and uptake by mitochondria (Goyer, 1995). The capacity of lead to promote oxidative stress, affect cell signals, and induce cell death by apoptosis has been mostly attributed to its effect on different calcium-mediated cellular events (Oteiza *et al.*, 2004). Low concentrations of inorganic lead ions (Pb^{2+}) can disrupt transmitter release by causing aberrant augmentation of spontaneous and suppression of evoked release. These effects are probably caused by high-affinity interactions of Pb^{2+} with the voltage-gated calcium channels, as well as with Ca^{2+} binding proteins involved in the regulation of synaptic vesicle mobilization, docking, and exocytosis processes. In contrast to intracellularly mediated actions of Pb^{2+} causing an augmentation of spontaneous release, the inhibition of evoked transmitter release by Pb^{2+} is largely attributable to extracellular block of the voltage-gated calcium channels (Suszkiw, 2004).

In experiments on rats, the results indicated an interaction between arsenic and lead on lipid peroxidation of the erythrocyte membrane. The results showed that in the arsenic-lead–treated rats, the levels of lipid peroxidation did not change significantly. However, the concentration of blood glutathione and superoxide dismutase (SOD) activity decreased significantly. A synergistic effect of arsenic-lead on SOD activity was observed (An *et al.*, 1998).

4.4 Hg and Other Metals

The influence of metals and metalloids on the toxicity of inorganic mercury has been studied in animal experiments (Magos and Webb, 1980; Nordberg, 1978) and is also reviewed in Chapter 33. Selenite and other compounds that are metabolized to selenite have been shown to reduce the lethal effect of inorganic mercury in rats, preventing the development of renal tubular and intestinal necrosis (Parizek and Ostadalov, 1967). Dietary selenate prevents the depression of growth in rats receiving mercuric chloride by mouth (Potter and Matrone, 1974). In long-term experiments, dietary selenate reduces the chronic renal tubular damage produced by oral mercuric chloride in rats (Groth *et al.*, 1973; 1976). Parizek *et al.* (1969; 1974) demonstrated that administration of selenite to rats gives rise to a marked increase in mercury in blood and a reduced excretion of mercury. Similar distribution changes have been observed in rabbits (Imura and Naganuma, 1978) and in pigs (Hansen *et al.*, 1981). Both mercury and selenium are bound to a plasma protein with an atomic ratio of 1 (Burk *et al.*, 1974). The formation of a mercury-selenoprotein complex may explain these alterations in the kinetics and toxicity of mercury (Parizek, 1976; Parizek *et al.*, 1971; 1974), and it may also be related to the observation by Groth *et al.* (1976) and Carmichael and Fowler (1979) of intranuclear inclusion bodies containing mercury and selenium. A high-molecular-weight selenium–protein complex could be involved (Chen and Fang, 1974; Imura and Naganuma, 1978). The decreased passage of mercury and selenium across the placenta and into milk, when inorganic mercury and selenite are administered simultaneously, may also be explained by the formation of a mercury–selenium–protein complex (Parizek *et al.*, 1974). The formation of such a complex diminishes the binding of mercury to metallothionein in tissues (Mengel and Karlog, 1980).

More recent studies by a number of investigators have examined the role selenoproteins in mediating the binding and transport of mercury in blood and tissues. Yoneda and Suzuki (1997) first reported the detoxification of mercury by selenium via binding in an equimolar complex with a specific plasma protein in rats. They observed that both elements appeared to first from a complex and then bind to basic amino acids in the protein. This binding was inhibited by addition of polylysine. Subsequent studies using extended X-ray absorption fine structure (EXAFS) by Gailer *et al.* (2000) using plasma from rabbits demonstrated the formation of an Hg–Se–S chemical species.

More recent studies (Chen *et al.*, 2006a, b) have further examined the roles of selenoprotein P in serum samples from miners with occupational exposure to mercury and in porcine liver and kidney using pigs raised in an area of China with extensive mercury contamination. They found increased binding of Hg

to selenoprotein P and glutathione peroxidase in miners. In the pig tissues, they observed increased binding of mercury to metallothionein and both mercury and selenium binding in higher molecular weight protein fractions in a ratio of 1:1.

An indication that processes similar to those demonstrated in animals might occur in man is provided by the observations of elevated concentrations of mercury and selenium in organs of mercury miners many years after cessation of exposure (Rossi *et al.*, 1976).

The influence of other metals on the toxicity of inorganic mercury has not been adequately documented. One observation showed that pretreatment with cadmium protected (male) rats from the nephrotoxic effect of inorganic mercury (Magos *et al.*, 1974). This action is regarded to be mediated through induction of metallothionein. The Cd–Hg–Se interaction is limited by mercury, with respect to the distribution of both cadmium and selenium. Results from animals concomitantly exposed to inorganic salts of the three elements (Cd, Hg, Se) suggest that an observed increase in the whole-body retention of selenium is due to the mercury exposure. Mercury significantly increases the retention of selenium in the kidneys—all fractions—and liver—nuclear and mitochondrial fractions (Chmielnicka *et al.*, 1983). The toxic effect of methylmercury has been shown to be influenced by selenite in several animal species (Nordberg *et al.*, 1978; Skerfving, 1978). Thus, 0.5–8.0 mg/kg of selenite in the diet protected chicks, quail, and rats from the toxic effects of up to 40 mg/kg of methylmercury in the diet. Although it has been suggested that selenium present in marine fish might decrease the toxicity of dietary methylmercury (Ganther and Sunde, 1974; Ganther *et al.*, 1972; Ohi *et al.*, 1976), the evidence that selenium is the responsible factor is inconclusive; for instance, the difference in toxicity could be explained by differences in methylmercury intake or by the quantity and quality of protein in the diet (Nordberg *et al.*, 1978; Stillings *et al.*, 1974). However, selenium probably does have an influence. It has been shown (Kasuya, 1976; Naganuma and Imura, 1980) that bismethyl-Hg selenite ([CH3Hg]2Se) is formed in blood and that this compound more readily penetrates into the brain than methylmercury (Naganuma and Nobumasa, 1980). An increased mercury concentration in brain and even in fetal brain has been reported after combined exposure to methylmercury and selenium (Iijima *et al.*, 1978; Satoh and Suzuki, 1979). Bismethyl-Hg selenite seems to decompose readily in tissues. Selenium may also be involved in demethylation of methylmercury (Yamane *et al.*, 1977).

Dietary selenite and vitamin E diminished mortality in methylmercury-exposed quail (Welsh and Scares, 1976). Welsh (1976) showed that, in rats, vitamin E and other antioxidants had a protective effect. More recent neurodevelopmental studies in rats fed semipurified diets (Beyrouty and Chan, 2006; Newland *et al.*, 2006; Reed *et al.*, 2006) have reported alterations in the neurotoxic effects after methylmercury exposure that seem to be influenced by dose levels of both selenium and methylmercury.

In rats, the whole-body retention of mercury under the influence of zinc and cadmium was slightly lower than that observed in animals treated with mercury alone; however, copper decreased whole-body retention by more than 50% (Komsa Szumska and Chmielnicka, 1983). Urano *et al.* (1997) reported that selenite exposure reduced the biliary secretion of methylmercury in rats. More recent studies (Juresa *et al.*, 2005) reported that selenite treatment decreased the efficacy of DMSA and DMPS on facilitating mercury elimination in rats after concomitant treatment with mercuric chloride. Conversely, Gregus *et al.* (2001) reported that exposure of rats to methyl mercury, merbromin, mercuribenzene sulfonic acid, or mercuribenzoic acid alter selenium tissue concentrations in rats injected with selenite. Studies by Frisk *et al.* (2001a,b) reported that concomitant *in vitro* exposure of K-562 cells to selenium protected against the toxicity of mercuric chloride but had a lesser effect on methylmercury. Subsequent studies (Frisk *et al.*, 2003) showed that selenium protected against mercuric chloride–induced apoptosis in this cell line.

In a study on humans exposed to methylmercury, multiple regression analyses revealed an inhibition of ALA-dehydratase in red cells related to concentrations of both mercury and lead in blood (Schutz and Skerfving, 1975). The effects of equimolar concentrations of mercury and lead were similar. More recent studies (Farina *et al.*, 2003a,b; Perottoni *et al.*, 2004 a,b) demonstrated Se–Hg interactions with regard to increased inhibition of this enzyme with concomitant exposure to both these elements.

4.5 Molybdenum–Copper–Zinc Interactions

There is an interaction between copper and molybdenum studied for many years in animals and humans (cf Chapter 34). Thiomolybdates are formed by ruminants after oral intake of molybdenum causing copper depletion. This is the biochemical explanation of molybdenosis (Mason, 1986). Sheep and cows are more susceptible to imbalances between Cu and Mo than other animals like pigs and rats. Copper deficiency has been observed in ruminants grazing on pastures where the Mo content is high (Bremner, 1979). In human volunteers with an increased dietary intake

of Mo, increased Cu excretion was found (Deostahle and Gopalan, 1974). Copper toxicity in humans with Wilson's disease has been successfully treated with tetrathiomolybdate (Brewer and Yuzbasiyan-Gurkan, 1992).

Another efficient treatment of Wilson's disease is by oral doses of zinc salts (Brewer, 2000). This treatment is based on the findings that oral zinc intake induces the synthesis of metallothionein in the intestinal mucosa. Cu binds more readily to metallothionein than zinc, and thus Cu is sequestered in the mucosa and not taken up systemically but eliminated by the fecal route when the mucosal cells are shed. It has also been shown in groups of the general population that several manifestations of Cu deficiency can be induced by high oral Zn intakes in the form of supplements. When taking such supplements, it is important to make sure that there is a balance between intakes of Zn and Cu (Chapter 47).

4.6 Interactions Between Thallium and Potassium

Thallium and potassium seem to have some common receptor sites where they compete and thus undergo direct interaction. Potassium has been proposed for use in the treatment of thallium poisoning, because the administration of potassium increases excretion of thallium. For further data, see Chapter 41.

5 METAL–METAL INTERACTIONS IN CARCINOGENESIS

5.1 Arsenic

Arsenic is a known human carcinogen (see Chapter 10 for a detailed review) that seems to elicit the carcinogenic response via production of reactive oxygen species (ROS) with subsequent DNA damage secondary to oxidative stress, alteration of DNA methylation processes, gene expression patterns, and inhibition of DNA repair (NAS/NRC, 1999). Concomitant exposure to other metals that produce toxicity by oxidative stress such as cadmium (Hong *et al.*, 2004; Nordberg *et al.*, 2005) create a situation with additive or more than additive interactive effects. Such interactions are likely to exist for cancer but have so far only been demonstrated for noncancer effects among human populations exposed to both these elements in China (Figure 1).

5.2 Chromium

Crosslinking of DNA can be caused by chromium metabolites. The concentrations of chromium bound to DNA are related to the levels and stabilities of the chromium (V) species formed on reaction of chromium (VI) with various thiols. Thus, chromium–thiol interactions may play an important role in chromium (VI) genotoxicity (Borges *et al.*, 1991).

Exposure to lead chromate can induce chromosomal damage after extracellular dissolution, producing solubilized chromium and lead. Even if lead (II) is weakly clastogenic at high doses, hexavalent chromium seems to be the proximate clastogen in lead-chromate–induced clastogenesis. Pretreatment of cells with vitamin E can block clastogenesis induced by particulate chromates (Wise *et al.*, 1994).

Apoptosis in Chinese hamster ovary cells was observed 48 hours after treatment with 300 µmol/L chromium (Na_2CrO_4) for 2 hours. Cadmium alone at concentrations of 1, 5, or 10 µmol/L (as $CdCl_2$) did not induce apoptosis in these cells at times up to 72 hours after treatment. When these cells, however, were concurrently exposed to cadmium and chromium, chromium-induced apoptosis was markedly suppressed in a cadmium concentration–related fashion. The experimental findings indicate that cadmium can block chromium-induced apoptosis (Shimada *et al.*, 1998). The activation of the JNK, p38, and ERK mitogen-activated protein kinases by Cr (VI) is mediated through oxidative stress, but their activation does not affect cytotoxicity. In the experiments, the p38 activation by Cr(VI) showed a positive relationship to oxidative stress, whereas the JNK activity was enhanced by either a quencher (e.g., mannitol) or activator (H_2O_2) of redox reactions in Cr(VI)-exposed human non-small cell lung carcinoma CL3 cells (Chuang *et al.*, 2000).

At the genomic level, Cr genotoxicity manifests as gene mutations, several types of DNA lesions, and inhibition of macromolecular synthesis. At the cellular level, Cr exposure may lead to cell cycle arrest, apoptosis, premature terminal growth arrest, or neoplastic transformation. Cr-induced DNA–DNA interstrand crosslinks, the tumor suppressor gene p53, and oxidative processes are some of the major factors that may play a significant role in determining the cellular outcome in response to Cr exposure (Singh *et al.*, 1998). Chromium (VI) may induce cell growth arrest through hydrogen peroxide–mediated reactions in experiments on human lung epithelial A549 cells. The authors found that ROS were generated in Cr (VI)-stimulated A549 cells through reduction of molecular oxygen. Among the reactive oxygen species generated, H_2O_2 played a major role in causing G2/M phase arrest in the human lung epithelial cells (Zhang *et al.*, 2001).

N-acetylcysteine (NAC) and ascorbic acid (AsA) showed additive effects in reducing chromium (VI) and reverting its mutagenicity in experiments on mice

(D'Agostini *et al.*, 2000). NAC prevented the adverse effects of AsA on spontaneous mutagenicity. At the same time, this thiol and AsA showed additive effects, inhibiting the mutagenicity of Cr (VI) and the lung tumorigenicity of urethane in mice (D'Agostini *et al.*, 2000).

Experiments on Chinese hamster ovary cells using a host cell reactivation assay showed that the repair of BPDE-DNA adduct in a luciferase reporter gene was greatly inhibited after Cr(VI) exposure in NER-proficient cells but not in NER-deficient cells. Accordingly, Cr(VI) exposure can greatly enhance the mutagenicity and cytotoxicity of PAHs by inhibiting the cellular NER pathway, and this may constitute an important mechanism for Cr(VI)-induced human carcinogenesis (Hu *et al.*, 2004).

5.3 Iron

Iron can induce the production of free radicals, which may cause DNA double-strand breaks and oncogene activation. Iron can also maintain the growth of malignant cells, as well as the growth of pathogens. Breast cancer cells have been shown to display 5–15 times more transferrin receptors than normal breast tissue cells. On the other hand, iron chelators can counteract cell damage (Reizenstein, 1991). Animal experiments have shown that magnesium antagonizes nickel-induced carcinogenesis in the rat kidney, whereas iron tends to enhance it (Kasprzak *et al.*, 1994). Experiments on hamsters have shown that estrogen treatment increased the non-heme iron in liver of both high and low iron treatment groups and in kidney of the hamsters on the low-iron diet. Thus, the dietary iron enrichment may enhance the incidence and severity of estrogen-induced tumor induction (Wyllie and Liehr, 1998).

Iron may act as a promoter of dimethylnitrosamine-initiated hepatocytes in rats. Fibrogenesis was not an absolute requirement for this promotion. The authors suggest that iron may also act as a promoter of already initiated hepatocytes in the development of liver cancer in humans (Carthew *et al.*, 1997).

In experimental studies, 2-butoxyethanol increased liver tumors in B6C3F1mice after chronic exposure. Continued treatment with 2-butoxyethanol resulted in hemosiderin deposition in the liver, indicating that the liver tumors were mediated by oxidative iron catalyzed stress and Kupffer cell activation (Park *et al.*, 2002). Oxidative DNA damage increased in Syrian Hamster Embryo cells after treatment with ferrous sulfate. On the other hand, the DNA lesions decreased by cotreatment of ferrous sulfate with antioxidants. The authors suggested that iron, produced indirectly through hemolysis and not 2-butoxyethanol or its metabolites, might be responsible for the observed carcinogenicity (Park *et al.*, 2002).

An elevated dietary iron intake enhances the incidence of carcinogen-induced mammary tumors in rats and estrogen-induced kidney tumors in Syrian hamsters. Estrogen administration increases iron accumulation in hamsters and facilitates iron uptake by cells in culture. In humans, increased body stores of iron have been shown to increase the risk of several estrogen-induced cancers (e.g., breast cancer; Liehr and Jones [2001]).

In cell experiments, addition of catalase, which can increase Fe^{2+} concentrations, further increased the plasmid-induced DNA damage; on the other hand, diethylenetriaminepentaacetic acid (an iron chelator) significantly inhibited DNA damage. Thus, iron-dependent DNA damage has been suggested as one mechanism of action of human arsenic carcinogenesis (Ahmad *et al.*, 2002). The iron chelator phenanthroline suppressed the sodium chloride–enhanced gastric carcinogenesis induced by N-methyl-*N*′-nitro-*N*-nitrosoguanidine in experiments on Wistar rats (Tatsuta *et al.*, 2003). Intraperitoneal administration of ferric iron-ATP (FeATP) has been studied in an animal model. The morbidity and mortality rate were higher with FeATP, indicating two different interactions (intensity and duration) with the cell plasma membrane (Anghileri *et al.*, 2002).

Ex vivo and *in vitro* protective effects of kolaviron against oxygen-derived radical-induced DNA damage and oxidative stress have been found in human lymphocytes and rat liver cells. One mechanism behind the protective effects versus oxidative damage to molecular targets may be by means of scavenging of free radicals and iron binding (Farombi *et al.*, 2004).

5.4 Lead

Lead chromate can induce chromosomal damage. In cell experiments, high doses of lead glutamate were weakly clastogenic. It induced a different spectrum of chromosomal aberrations compared with lead chromate. Pretreatment of cells with vitamin E reduced the lead chromate–induced clastogenesis by 54–93% (Wise *et al.*, 1994).

Lead, as well as cadmium, may act as a tumor promoter in diploid human fibroblasts. In the experiments, ROS had a greater impact on cadmium than on lead-induced cytotoxicity and anchorage independence (Hwua and Yang, 1998).

It has been suggested that lead on a cellular and molecular level may permit or enhance carcinogenic events involved in DNA damage, DNA repair, and regulation of tumor suppressor and promoter genes

(Silbergeld, 2003). The formation of lead inclusion bodies in normal human lung cells exposed to lead chromate indicates that ionic lead is released from the particles and thereafter may contribute to the cell toxicity caused by lead chromate. Internalization and dissolution of lead chromate particles and the interaction of ionic chromium and lead with DNA may be components of the mechanism of lead chromate carcinogenesis. Lead chromate–induced apoptosis may be one mechanism to eliminate cells with chromium- and/or lead-damaged DNA (Singh *et al.*, 1999).

Lead in blood can, together with other parameters, influence the level of DNA single-strand breaks (DNA-SSB) in human mononuclear blood cells. Although lead alone did not increase the level of DNA-SSB, an increase of the lead air concentrations for the exposed workers from 1.5–50 $\mu g/m^3$ in the presence of constant exposures to cobalt ($8 \mu g/m^3$) and cadmium ($3.8 \mu g/m^3$) caused an almost fivefold increase in the odds ratio. The mechanism behind these interactions might be repair inhibition of oxidative DNA damage, because a decrease in repair capacity will increase susceptibility to ROS generated by cadmium or cobalt (Hengstler *et al.*, 2003).

5.5 Nickel

Nickel is a human and animal carcinogen that primarily affects the initiation process in the lung cancer development (Chiu *et al.*, 2004). Transition metals can damage DNA by free radicals generated by the Fenton reaction. Zinc finger proteins act as transcription factors binding specifically to short DNA sequences and controlling the transcription of a number of genes. Experiments have shown that metals like cobalt, cadmium, copper, nickel, and iron may substitute for zinc in zinc finger proteins. An important mechanism of the metal-mediated carcinogenesis is the enhancement of cellular redox processing by metals. A redox metal substituted for zinc in the zinc finger protein is expected to generate free radicals that may cause DNA damage (Sarkar, 1995). Another mechanism may include mediation of promutagenic oxidative DNA damage that depends on Ni (II) binding to chromatin (Bal *et al.*, 1995). Nickel ($NiCl_2$) may also inhibit specific DNA–protein interactions (Coogan *et al.*, 1989). In experiments on rat kidney, magnesium antagonizes nickel carcinogenesis, whereas iron tends to enhance it. The findings may be caused by the attenuating or enhancing effects of magnesium and iron on the inflammatory response to nickel compounds (Kasprzak *et al.*, 1994).

Nickel (II) and cadmium (II) can both inhibit the incision step of nucleotide excision repair. By applying a gel-mobility-shift assay and HeLa nuclear extracts, the effects of both metals on the damage recognition step of the repair process was studied. When applying nuclear extracts from HeLa cells treated with 50 µmol/L Ni (II) and higher, there was a dose-dependent decrease in protein binding. This effect, however, was largely reversible by addition of magnesium (II) to the binding reaction. Nickel compounds seem to disturb DNA–protein interactions essential for the initiation of the nucleotide excision repair, probably by the displacement of essential metal ions (Hartmann and Hartwig, 1998). A molecular mechanism of nickel carcinogenesis has also been suggested, involving oxidative damage processes catalyzed by weak Ni (II) complexes with cellular components (Bal *et al.*, 1996).

Nickel compounds can increase UV-induced cytotoxicity and mutagenicity and interfere with the repair of UV-induced DNA lesions by disrupting DNA–protein interactions involved in DNA damage recognition. Experiments suggest that Ni (II) at noncytotoxic concentrations inhibits nucleotide excision repair and possibly crosslink repair by interference with distinct steps of the respective repair pathways (Krueger *et al.*, 1999).

Oxidative stress induced by nickel sulfide caused loss of the tumor suppressor gene p16 and activation of the mitogen activated protein kinase (MAP kinase) signaling in experiments on mice. The findings indicate that there may be synergistic interactions between MAP kinase activation and p16 loss in carcinogenesis (Govindarajan *et al.*, 2002). The mechanism of DNA damage induced by carcinogenic Ni (II) in the presence of SH compounds has been studied for several compounds. The intensity of Ni (II)-mediated DNA damage that was induced by dithiothreitol (DTT) was stronger in comparison with other tested model endogenous SH compounds, 1,4-dithio-L-threitol and dithioerythritol. The finding that DNA damage induced by Ni (II) in combination with DTT was only evident when DNA was treated with piperidine suggests that Ni (II) and DTT caused only base damage. The results indicate that Ni (II) and DTT form reactive species that might be responsible for the observed guanine-specific DNA damage. Endogenous SH compounds, which have similar chemical structures as DTT, would participate in nickel carcinogenesis through causing oxidative DNA damage (Oikawa *et al.*, 2002).

Ni (II) genotoxicity may be enhanced through the generation of DNA-damaging ROS and the inhibition of DNA repair. Epigenetic effects of nickel include alterations in gene expression resulting from DNA hypermethylation and histone hypoacetylation, as well as activation or silencing of certain genes and transcription factors, particularly those that are involved in the cellular response to hypoxia (Kasprzak *et al.*, 2003a).

Several pathogenetic effects of nickel are due to the interference with the metabolism of essential metals such as Fe (II), Mn (II), Ca (II), Zn (II), or Mg (II). One way of treatment would be to find ways to inhibit or prevent nickel (II) interactions with critical target molecules and ions, Fe (II) in particular, and thus avert the respiratory tract cancer and other adverse health effects in nickel-exposed workers (Kasprzak *et al.*, 2003a). Ni (II) binding to some chromatin proteins in somatic as well as in sperm cells may cause oxidative and structural damage to the proteins and DNA. These effects may alter the fidelity of DNA replication and gene expression and thus facilitate carcinogenesis, including paternally mediated cancer in the progeny (Kasprzak *et al.*, 2003b).

5.6 Selenium

In an animal experiment, Ip (1986) studied the interaction between vitamin C and selenium supplementation in the modification of mammary carcinogenesis in rats. The protective effect of selenite in tumorigenesis was counteracted by vitamin C, whereas the chemopreventive action of seleno-DL-methionine was not affected. One hypothesis is that vitamin C reduces selenite to elemental selenium, which is not available for uptake by tissues. The results indicate that high concentrations of vitamin C can interfere with the accumulation of tissue selenium and that an increased level of selenium in cells is essential for hampering tumor development (Ip, 1986). In another experiment, the chemopreventive effect by a synthetic retinoid, selenium, and the combination of these elements during the postinitiation stages of carcinogenesis induced in rats by azaserine was investigated (Curphey *et al.*, 1988). Retinoid inhibited the progression of pancreatic carcinogenesis in a dose-related way, but selenium alone showed no effect. The combination of retinoid and selenium, however, was more effective than retinoid alone (Curphey *et al.*, 1988). Ip and Ganther (1988) compared the efficacy of trimethylselenenium versus selenite in cancer chemoprevention and its modulation by arsenite, using the dimethylbenz(a)anthracene-induced mammary tumor model in rats. Supplementation of selenite (3 ppm Se) alone caused approximately a 50% reduction in tumor yield. Arsenite (5 ppm As) reduced the response to selenite. On the other hand, arsenite greatly enhanced the protective effect of trimethylselenium (40 ppm Se). This combination proved to be nearly as effective as selenite. Thus, arsenite seems to be able to influence the anticarcinogenic properties of selenium. It can either potentiate or attenuate the protective effect, depending on the methylation state of the selenium compound (Ip and Ganther, 1988). It has been suggested that arsenite increases the production of a critical metabolite from methylated selenides (Ip and Ganther, 1992).

The effect of deficiencies of selenium and vitamin E alone or in combination on the induction of mammary carcinogenesis by 1-methyl-1-nitrosourea was studied in 21-day-old female Sprague–Dawley rats. Compared with rats fed the adequate diet, final cancer incidence and number were higher and cancer latency time shortened in rats consuming the diet deficient in both selenium and vitamin E. Single deficiencies of either nutrient failed to significantly alter the tumorigenic response (Thompson, 1991). Ip and Ganther (1991) investigated the dimethylbenz(a)anthracene (DMBA)-induced mammary tumor model in rats using three sets of combinations of blocking and suppressing agents (diallyl sulfide/Se-methylselenocysteine; ellagic acid/selenomethionine; diallyl sulfide/quercetin). In all three cases the combination regimen was much more effective than the single-agent treatment in tumor suppression (Ip and Ganther, 1991). Similar results have been reported by Rao *et al.* (1990) studying the chemopreventive effects of six agents (tamoxifen, 10 mg/kg; retinyl acetate, 50 mg/kg; tocopherol, 200 mg/kg; aminoglutethimide, 1 mg/kg; ergocryptine, 5 mg/kg; sodium selenite, 1 mg/kg) when given singly or in combinations on the initiation of mammary carcinogenesis induced by 20 mg of DMBA in virgin female rats. When modulators were given singly or in combinations of two, tumor incidences were not altered significantly. The range of tumor incidences was between 13 and 30% when the agents were given in combinations of three, four, or five. When all six modulators were given together, the tumor incidence decreased significantly to 8.3% (Rao *et al.*, 1990). High selenium intake significantly reduced the tumor incidence of pancreatic cancer, induced by *N*′-nitroso bis(2-oxopropyl)amine in female Syrian golden hamsters (Kise *et al.*, 1990). McGarrity and Peiffer (1993) studied the effects of difluoromethylornithine (DFMO), an inhibitor of ornithine decarboxylase (ODC), and selenium supplementation on tumor formation induced by the carcinogen 1,2-dimethylhydrazine (DMH) in Sprague–Dawley rats fed a fiber-free diet. In distal colon, 19 tumors developed in the DFMO group, 22 tumors in the high selenium group, and only 12 tumors in the combined high selenium/DFMO treatment group compared with 32 tumors in the regular diet group. Thus, selenium supplementation in combination with DFMO treatment selectively inhibited distal colon tumor formation in an additive way (McGarrity and Peiffer, 1993).

Inhibition of experimental benzo(a)pyrene-induced carcinogenesis by vitamin C alone and by vitamin C/vitamin E and selenium/glutathione was studied in

224 female Wistar rats (Charalabopoulos *et al.*, 2003). By calculating the carcinogenic potency of benzo(a)pyrene and the anticarcinogenic potency of substances used, as well as histological examination of developed tumors and survival time of treated animals, it was shown that vitamin C exerts a significant anticarcinogenic effect of 8.3 units. The combination of the two studied anticarcinogens produced a significant prolongation of the animals' survival time with anticarcinogenic potencies of 22.1 and 22.2 units, respectively (Charalabopoulos *et al.*, 2003). In another experiment, it was found that there is a synergy between sulforaphane and selenium in the induction of the enzyme thioredoxin reductase 1. The synergy can result from a combination of induction at the levels of transcription, as well as translation (Zhang *et al.*, 2003).

Oxidative stress may increase the risk of prostatic carcinogenesis. In a nested case-control study from the prospective Physician's Health Study, 567 cases and 764 controls were investigated, including baseline determinations of plasma antioxidant concentrations (selenium, lycopene, alpha-tocopherol) and beta-carotene. Among men with the AA genotype, high selenium levels (quartile 4 vs. 1) were associated with a relative risk (RR) of 0.3 (95% confidence interval [CI], 0.2–0.7) for total prostate cancer, and a RR of 0.2 (95% CI, 0.1–0.5) for clinically aggressive prostate cancer. In contrast, among men with the VV/VA genotype, the corresponding RRs were 0.6 (0.4–1.0) and 0.7 (0.4–1.2), respectively. Similar patterns were observed for lycopene and alpha-tocopherol. The protective effect was particularly strong when these antioxidants and selenium were combined. Men with the AA genotype had a 10-fold gradient in risk for aggressive prostate cancer across quartiles of antioxidant status (Li *et al.*, 2005).

5.7 Zinc

Zinc supplementation tends to inhibit carcinogenesis based on a systemic effect (Kasprzak and Waalkes, 1986). The binding of cadmium to DNA *in vitro* and the effect of calcium, magnesium, and zinc on the cadmium binding have been investigated by Waalkes and Poirier (1984). All three metals were competitive antagonists of the cadmium binding to high-affinity sites in double-stranded DNA. Zinc had the highest antagonizing capacity followed by magnesium and calcium. The relative capability of these metals to antagonize high-affinity Cd-DNA binding probably parallels their *in vivo* capacity to antagonize Cd-induced carcinogenesis (Waalkes and Poirier, 1984). Esophageal carcinogenesis in rats induced by methylbenzylnitrosamine (MBN) was enhanced by zinc deficiency. Zinc deficiency also caused esophageal tumors in rats exposed to the hepatocarcinogen dimethylnitrosamine (Newberne *et al.*, 1986). Zinc may prevent cadmium-induced testicular tumors of interstitial cell (IC) origin in rats. One mechanism may be zinc-induced synthesis of metallothionein (MT), a metal-binding protein with high affinity for cadmium. Thus, sequestration of cadmium may account for cadmium tolerance in most tissues (Waalkes and Perantoni, 1988). In experiments on isolated interstitial cells of the rat testes, the nonpassive component of the cadmium accumulation was markedly reduced by addition of zinc *in vitro*, indicating a competition for uptake at the cellular level (Waalkes and Perantoni, 1988). Further experiments by Wahba *et al.* (1994) showed that zinc pretreatment had little effect on metallothionein RNA in the testes and did not alter the testicular cadmium-binding protein capacity. In contrast, zinc-pretreated rats showed marked increases in MT RNA and MT protein in liver cells. Thus, the testicular MT gene did not seem to play a major role in the zinc-induced tolerance to cadmium toxicity and carcinogenesis (Wahba *et al.*, 1994).

Zinc finger proteins is a class of DNA-binding proteins, which act as transcription factors binding specifically to short DNA sequences and controlling the transcription of a number of genes. Several metals (e.g., cobalt, cadmium, copper, nickel, and iron) may substitute for zinc in zinc finger proteins. A redox metal substituted for zinc in the zinc finger protein is expected to generate free radicals to cause DNA damage (Sarkar, 1995). The disturbance of DNA damage recognition after ultraviolet (UV) irradiation by nickel (II) and cadmium (II) has been studied in mammalian cells (Hartmann and Hartwig, 1998). In the case of cadmium (II), a dose-dependent inhibition of DNA–protein interactions was detected at a level of 0.5 μmol/L and higher, which was almost completely reversible by the addition of zinc (II) (Hartmann and Hartwig, 1998).

The p53 protein is a zinc-binding protein containing several reactive cysteines. The protein seems to control the timely production of reactive oxygen intermediates, which may initiate apoptosis. The activity, however, is under the control of changes in metal levels and in cellular redox status. This redox sensitivity may be one of the biochemical mechanisms by which p53 acts as a sensor of multiple stress (Hainaut and Mann, 2001). It has been shown that alpha-difluoromethylornithine (DFMO), a highly effective chemopreventive agent in esophageal carcinogenesis, reverses and counteracts esophageal cell proliferation/cancer initiation in zinc-deficient rats by way of stimulating apoptosis (Fong *et al.*, 2001).

The dietary intake and micronucleus index survey in South Australia have been used to study whether supplementation with beta-carotene, vitamin C, and

vitamin E together with zinc (ACEZn) improved genome stability in a randomized trial for 6 months in 190 healthy subjects. Supplementation with zinc significantly reduced the micronuclei assay index by 18% ($P = 0.038$) (Fenech *et al.*, 2005).

6 RISK ASSESSMENT OF MIXTURES OF METALS

6.1 Introduction

Risk assessment of chemical(s) is the practice of evaluating the degree of danger (risk) associated with chemical exposure. Assessing the risks associated with exposure to chemicals involves acquisition and interpretation of appropriate data; drawing and integration of conclusions from such data; and formulation of overall recommendations for the management of potential risks (Mumtaz *et al.*, 1993). Thus, the risk assessment process determines the kind and degree of hazard posed by a chemical(s), thereby permitting an estimate of the present or potential health risk. Typically, it involves four steps: exposure assessment, hazard identification, dose-response assessment, and risk characterization. In itself this process is a real challenge, but when applied to chemicals and/or their mixtures, it becomes that much more formidable. This section focuses on the major principles underlying metal toxicity and provides some basic risk assessment guidance to account for metal-specific toxicity assessment. Metals have a number of characteristics that should be carefully considered throughout the risk assessment process. Some metals are essential because they serve as macronutrients or micronutrients. Also, in contrast to other pollutants, metals are naturally occurring constituents of the environment. These characteristics of metals present additional challenges to risk assessors than those posed by environmental pollutants or other xenobiotics.

6.2 Toxicity Assessment of Mixtures

Metals can affect multiple organs and hence there exists potential of more than one metal occurring at the same time in a given target organ (Table 1). Thus, there exists a need for consideration of joint toxicity assessment of metal mixtures. Three different approaches, riddled with varying uncertainties and assumptions, are described for the toxicity assessment of metal mixtures (ATSDR, 2001; U.S. EPA, 1986). Selection of an appropriate assessment method depends on known toxic effects of chemicals comprising a mixture, availability of toxicity data, and quality of available exposure data.

6.2.1 The Mixture of Concern

The first approach is the "mixture of concern" approach, in which risk is estimated using toxicity data from the same mixture. It is the most direct and simplest method and entails the fewest uncertainties. This approach, however, is the least frequently applied, because very few mixtures have been studied adequately for this type of assessment. Some such mixtures for which MRLs could be derived include fuel oils, jet fuels, mixtures of polychlorinated biphenyls (PCBs), and polybrominated biphenyls (PBBs) (ATSDR,

2006). Similarly, a few occupational exposure limits (OELs) for asphalt fumes (0.5 mg/m^3), cotton dust (0.2 mg/m^3), coal dust (0.4 mg/m^3), and Stoddard solvent (100 ppm) have been established (*http://www.acgih.org*; *http://www.cdc.gov/niosh/homepage.html*; NIOSH, 2006).

6.2.2 The Similar Mixture Approach

The second approach used is the "similar mixture" approach and can be applied on a case-by-case basis to a candidate mixture or groups of mixtures that could act similarly (Durkin *et al.*, 1995). It is used when adequate information is not available for the mixture of concern and is often applied to complex mixtures that have been extensively investigated, such as coke oven emissions, diesel exhaust, and wood stove emissions. However, a minimum of information should be available to consider a mixture sufficiently similar to the mixture of concern. For example, if a risk assessment is needed for gasoline contamination of groundwater and information is available on the chronic toxic effects of gasoline, it may be possible to use the available information to assess risks from the contaminated groundwater. However, there are no set criteria to help decide when a mixture is sufficiently similar. Hence, the health assessor is left to determine whether the two chemical mixtures are sufficiently similar and whether this similarity justifies use of surrogate risk or toxicity data. The first two approaches, the mixture of concern and the similar mixture approach, are used for those mixtures that have been experimentally tested as a whole to some extent.

6.2.3 The Hazard Index Approach

The third approach, the hazard index (HI) approach, is the method most often used. This approach integrates the exposure level and the related toxicity into a single value by use of potency-weighted dose or response addition. The goal of the HI approach is to approximate the toxicity index that would have been determined had the mixture itself been tested (Mumtaz *et al.*, 2002b). Initially, the potential health hazard from exposure to each chemical is estimated by calculating its individual hazard quotient (HQ). The HQ is derived by dividing a chemical's actual exposure level (E) through an environmental medium by its acceptable/allowable exposure level (AE) such as a minimal risk level (MRL) or a reference dose (RfD). The hazard index (HI) of the mixture is then calculated by adding together all the component hazard quotients, as illustrated below for three chemicals in a mixture:

$$\mathrm{HI} = \frac{\text{Chem. Exposure}_1}{\mathrm{AE}_1} + \frac{\text{Chem. Exposure}_2}{\mathrm{AE}_2} + \frac{\text{Chem. Exposure}_3}{\mathrm{AE}_3}$$

In a manner analogous to the hazard index approach for noncarcinogens, a hazard index for carcinogens can be estimated by dividing chemical exposure levels by doses (DR) associated with a set level of cancer risk (U.S. EPA, 1986; 2000a):

$$\mathrm{HI} = \frac{\text{Chem. Exposure}_1}{\mathrm{DR}_1} + \frac{\text{Chem. Exposure}_2}{\mathrm{DR}_2} + \frac{\text{Chem. Exposure}_3}{\mathrm{DR}_3}$$

In terms of estimating risk, the HI values obtained using the HI approach should be interpreted carefully. For example, if chemical mixture "X" yields an HI value of 4, it need not be interpreted as twice as toxic as mixture "Y" that yields a value of 2. However, it can be said that mixture "X" is more toxic than mixture "Y". Thus the HI approach can be used for priority setting of mixtures. As the value of the HI increases toward unity, the concern for the potential hazard of a mixture increases. The potential health effects of a mixture are further analyzed and investigated if the HI value is equal to or greater than 1. The HI approach assumes that all components have similar joint action, that is their uptake, pharmacokinetics, and dose-response curves have similar shape (Teuschler and Hertzberg; 1995; U.S EPA, 2000). For carcinogens, the preceding equation assumes that each carcinogen has a linear dose-response curve and that each carcinogen is acting independently (U.S. EPA, 1986).

6.2.4 The Target-Organ Toxicity Dose (TTD)

In terms of estimating risk, it is important that the estimates be realistic. The use of acceptable exposure levels (MRLs or RfDs) that are based on a critical effect to assess secondary effects could lead to overestimation of risk (U.S. EPA, 1989). To circumvent this problem, target-organ toxicity doses (TTDs) can be used (Mumtaz *et al.*, 1997). TTDs, in essence, are effect- or organ-specific MRLs and are calculated by use of the same method and process. Thus, for a given chemical, there could be an MRL for hepatotoxicity and a series of TTDs for nephrotoxicity, neurotoxicity, and reproductive toxicity (ATSDR, 2001a). The TTD method is a simple modification of the HI approach and yields a series of HIs for various toxic effects. The values of endpoint-specific hazard indices are treated the same as that of a HI of a mixture (Mumtaz *et al.*, 1997).

The hazard index approach is a simple approach to implement but somewhat limited in its scope and, as a result, may either underpredict or overpredict risk estimates of mixtures of industrial, occupational, and environmental chemicals if synergistic and antagonistic interactions occur (Feron and Groten, 2002; U.S. E.PA.,1986; 2000a). It is important that the risk

assessment values with the HI approach also express the available information on chemical interactions. But, there is little guidance on how the interactions should be evaluated or incorporated into the overall risk assessment (Feron and Groten, 2002; Mumtaz and Hertzberg, 1993). The National Academy of Sciences has proposed the use of additional safety factors if synergistic interactions are of concern (NAS, 1989).

6.3 A Weight-of-Evidence (WOE) Method

To provide further guidance on this issue, a weight-of-evidence (WOE) method was developed (De Rosa *et al.*, 2002; Mumtaz and Durkin, 1992). The WOE method yields a composite representation of all the toxicological interaction evidence from animal bioassay data and human studies data; relevance of route; duration and sequence; and the significance of interactions. The method consists of a classification scheme used to provide a qualitative and, if needed, a quantitative estimation of the effect of interactions on the aggregate toxicity of a mixture (Table 2). The first two components of the scheme are major ranking factors for the quality of the mechanistic information that supports the assessment and the toxicological significance of the information. The last three components of the WOE are modifiers that express how well the available data correspond to the conditions of the specific risk assessment in terms of the duration, sequence, routes of exposure, as well as the animal models. This method evaluates data relevant to joint action for each possible pair of components of a mixture, and, as such, requires mechanistic information and direct observation of toxicologically significant interactions. Initially, for each pair of component chemicals of a mixture, two binary weight-of-evidence (BINWOE) determinations are made to estimate the effect of the first chemical on the second chemical's toxicity and to estimate the effect of the second chemical on the toxicity of the first chemical. A BINWOE determination is a qualitative judgment based on empirical observations and mechanistic considerations, which categorizes the most plausible nature of any potential influence of one compound on the toxicity of another for a given exposure scenario (ATSDR, 2001a; Mumtaz and Durkin, 1992).

Once all of the qualitative WOE determinations have been made for each pair of compounds in the mixture, these are arrayed in a qualitative WOE matrix (Table 3). This matrix lists each potential binary classification along both axes. The diagonal line running from the upper lefthand corner to the lower righthand corner corresponds to chemical identities. These are, by definition, dose additive and are left blank in the interaction matrix. The column headings indicate the chemicals that are affected by

TABLE 2 Weight-of-Evidence Scheme for the Qualitative Assessment of Chemical Interactions

Determine whether the interaction of the mixture is additive (=), greater than additive (>), or less than additive(<).

Classification of Mechanistic Understanding

I. Direct and Unambiguous Mechanistic Data

The mechanism(s) by which the interactions could occur has been well characterized and leads to an unambiguous interpretation of the direction of the interaction.

II. Mechanistic Data on Related Compounds

The mechanism(s) by which the interactions could occur is not well characterized for the compounds of concern, but structure/activity relationships, either quantitative or informal, can be used to infer the likely mechanisms and the direction of the interaction.

III. Inadequate or Ambiguous Mechanistic Data

The mechanism(s) by which the interactions could occur have not been well characterized, or information on the mechanism(s) does not clearly indicate the direction that the interaction will have.

Classification of Toxicological Significance

A. The toxicological significance of the interaction has been directly demonstrated.
B. The toxicological significance of the interaction can be inferred or has been demonstrated in related compounds.
C. The toxicological significance of the interaction is unclear.

Modifiers

1. Anticipated exposure duration and sequence
2. A different exposure duration or sequence
   a. *In vivo* data
   b. *In vitro* data
      i. The anticipated route of exposure
      ii. A different route of exposure

Source: Modified from Mumtaz and Durkin (1992).

TABLE 3 Matrix of BINWOE Determinations for Intermediate or Chronic Simultaneous Oral Exposure to Chemicals of Concern

Effect of	On toxicity of			
	Lead	*Manganese*	*Zinc*	*Copper*
Lead		=IIICii n	=IIB h	=IIIC p
Manganese	>ICii n >IIB2ii h		? h	? p
Zinc	<IB n <IA h	? n		<IB p
Copper	<IC n <IB h	? n	<IIA h	

n, Neurological; h, hematological; p, hepatic. Direction of interaction: =, additive; >, greater than additive; <, less than additive; ?, indeterminate. Mechanistic understanding: I, clear; II, inferred; III, unclear. Toxicologic significance: A, clear; B, inferred; C, unclear. Modifying factors: 2, different exposure duration or sequence than anticipated; ii, different route of exposure than anticipated.

the compounds listed in the row headings. For example, the classification for the effect of zinc on the toxicity of lead is given in the first column (lead) of the third row (zinc). Similarly, the classification for the effect of copper on the toxicity of zinc is given in row four (copper) column three (Zn). Binary classifications starting with an "=" indicate an additivity; those starting with a ">" indicate a greater than additive interaction; and those starting with a "<" indicate a less than additive interaction.

The qualitative WOE matrix may then be used as a tool to quantify the risk assessment for a particular site. The quantitative BINWOE can have an absolute value of 0 to 1, with 1 indicating the highest degree of confidence in the assessment. Ultimately, this WOE method can be used so as to modify the HI and include the role of chemical interactions (ATSDR, 2001a, De Rosa *et al.*, 2002; Mumtaz and Durkin, 1992). Improvements in assessing human health risks from chemical mixtures can only come about by reducing inherent uncertainties in risk assessment methods. This will require an understanding of how chemicals behave in biological systems, as well as explaining their collective mechanisms of action.

When performing an exposure-based assessment of joint toxic action of the mixture, the BINWOEs developed for the endpoints of concern can be used qualitatively to predict the impact of interactions. An analysis to evaluate neurological, hematological, and hepatic effects of varying pairs of lead (Pb), manganese (Mn), zinc (Zn), and copper (Cu) yielded the following WOE matrix (Table 3). The BINWOE for the hematological effect of zinc on lead is <IA. The qualitative interpretation will be as follows:

6.3.1 Direction of Interaction

The direction of interaction is predicted to be less than additive based on a study in orally exposed children indicating a protective effect of zinc on the hematological effects of lead (Chisolm, 1981). This is supported by several intermediate-duration oral studies in rats that show supplemental zinc protects against a number of hematological effects of lead related to heme synthesis, particularly at higher lead doses (Cerklewski and Forbes, 1976; Flora *et al.*, 1982). The evidence for zinc inhibition of lead hematotoxicity is clear and toxicologically significant and is supported by clear mechanistic understanding that excess zinc protects and reactivates lead-inhibited ALAD (delta-aminolevulinic acid dehydratase), decreases the absorption and tissue distribution of lead, and may induce proteins that sequester lead and donate zinc to ALAD and for other tissue needs.

6.3.2 Mechanistic Understanding

A characteristic and sensitive effect of lead is the inhibition of ALAD, a zinc-containing enzyme in the heme synthesis pathway. Zinc protects the enzyme from inactivation by lead *in vivo* and *in vitro* (Abdulla *et al.*, 1979; Mauras and Allain, 1979), as assayed directly or by the appearance of greater amounts of ALA (delta-aminolevulinic acid) in the urine. Supplemental zinc decreased the gastrointestinal absorption of lead and decreased blood, bone, liver, kidney, and spleen concentrations of lead in rats in intermediate-duration studies (Cerklewski and Forbes, 1976; El-Gazzar *et al.*, 1978; Flora *et al.*, 1982; 1989). This effect was seen at higher, but not lower, doses and was not seen in humans at lower doses of both metals than those used in the rat studies. The evidence in general suggests that oral coexposure to zinc at levels significantly above essentiality decreases lead absorption and body burden at higher lead exposures. Zinc induces a metallothionein that has been shown to sequester lead *in vitro*, protecting against its cytotoxicity (Goering and Fowler, 1987; Liu *et al.*, 1991). A metallothionein-like protein in erythrocytes binds lead *in vitro* and was present in higher concentrations in lead-exposed workers than in controls. This protein was also present at exceptionally high levels in a worker with very high blood lead (180 μg/dL), but no signs of lead poisoning, compared with another worker with high blood lead (160 μg/dL) who was symptomatic (Church *et al.*, 1993a; 1993b). An acidic, soluble lead-binding protein in erythrocytes (and brain and kidney) that normally binds zinc is postulated to attenuate lead toxicity to ALAD through lead binding and zinc donation (Fowler, 1998). The preceding mechanistic data indicate that under conditions in which an interaction occurs, the effect of zinc on the hematological toxicity of lead will be less than additive.

6.3.3 Toxicological Significance

A study in occupationally exposed men given a low oral dose of zinc did not provide evidence of an effect on blood lead or urinary ALA. However, the inhalation route of exposure for lead circumvents potential interactions at the level of absorption, and the dose of zinc was very low in this study. In another study, an increase in urinary ALA above the normal range was significantly associated with a decrease in the chelatable zinc/lead ratio to 18.45 or less in children given chelation therapy for lead poisoning (Chisolm, 1981). Supplemental zinc protected against the inhibiting effects of lead on ALAD activity and against lead-induced increases in zinc protoporphyrin and urinary ALA excretion in rats given both metals orally for intermediate durations (Cerklewski and Forbes, 1976; El-Gazzar *et al.*, 1978; Flora *et al.*, 1982; 1989). These protective effects were seen at higher but not lower lead doses and when basal levels of zinc in the diet were adequate. The potential public health hazard of the joint toxic action of this mixture must also recommend inclusion of estimation of endpoint-specific hazard indexes (HIs) for neurological effects of lead and manganese and for hematological effects of lead and zinc. The HIs are estimated by use of exposure data and health guidance values:

$$\mathrm{HI}_{\mathrm{neuro}} = \frac{\mathrm{Exposure}_{\mathrm{Pb}}}{\mathrm{Guidance\ value}_{\mathrm{Pb}}} + \frac{\mathrm{Exposure}_{\mathrm{Mn}}}{\mathrm{Guidance\ value}_{\mathrm{Mn}}}$$

This HI approach should be used when the hazard quotients (HQ) of at least two of the components equal or exceed 0.1. If only one or if none of the mixture components has a hazard quotient that equals or exceeds 0.1, further assessment of the joint toxic action is not needed, because additivity and/or interactions are unlikely to result in significant health hazard (ATSDR, 2001a). With the information from the WOE matrix, the following summarizations can be made regarding the impact of interactions on some specific toxicities.

A deductive method such as the WOE should have built-in capabilities to integrate all observations on interactions, reflect the underlying principles and mechanisms that are operative, allow the users to express uncertainty comparable to existing methods, be able to be applied consistently in varying exposure scenarios, be used qualitatively and if possible quantitatively, and, most importantly, be able to be verified and validated through experimental studies.

6.4 Perspectives and Future Needs

The best measurement of exposure comes through biomonitoring, the measurement of chemicals in human tissues and fluids. This age-old practice has been used by the Centers for Disease Control and Prevention (CDC) to study the presence of natural and synthetic chemicals in human populations (CDC, 2005 the NHANES report). This has led to the development of programs to control emission of certain environmental pollutants such as lead, when the cause and effect has been established. The measurement of metals in biological fluids is the primary means of quantifying exposure for metals by occupational health organizations, such as the American Congress of Governmental Industrial Hygienists, and is the basic tool for population or molecular epidemiology studies of effects of exposure to humans of various metals.

CHAPTER

8

Epidemiological Methods for Assessing Dose-Response and Dose-Effect Relationships

TORD KJELLSTRÖM AND PHILIPPE GRANDJEAN

By the term *epidemiology*, we mean the science of the occurrence of health and illness in *human* populations. The formal definition is "the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to control health problems" (Last *et al.*, 2000). Although the focal point in clinical practice is the *individual* and changes in the individual's health status, in epidemiology the interest is extended to *groups (populations)*. However, in modern evidence-based medicine, clinical decision making uses integrated epidemiological and clinical observations.

In this chapter, we will introduce basic concepts of epidemiology and discuss how they are applied in assessing dose-response or dose-effect relationships for metals. The chapter will not systematically explain all concepts and methods in epidemiology as such. The reader who is seeking more detailed information about epidemiology is referred to standard textbooks, such as *Basic Epidemiology* (Beaglehole *et al.*, 2000) (or one of the 20 translations), *Environmental Epidemiology* (Baker *et al.*, 1999), *Epidemiology Beyond the Basics* (Szklo and Nieto, 2004), or *Modern Epidemiology* (Rothman and Greenland, 1998). The terminology in this chapter is based on the *Dictionary of Epidemiology* (Last *et al.*, 2000), sponsored by the International Epidemiology Association. The structure of the chapter is inspired by Beaglehole *et al.* (2000), listing measurement concepts and terms in an early section. Systematic research on the dose-response and dose-effect relationships for metals developed in the 1970s, and we will make reference to the early studies, as well as recent studies, to highlight that useful evidence was accumulating long before we could do literature searches in *Google Scholar*.

1 EPIDEMIOLOGICAL MEASUREMENT OF OCCURRENCE OF HEALTH EFFECTS

Epidemiological studies are essential for assessing dose-response or dose-effect relationships for toxic metals (see Chapter 6), because humans and laboratory animals may differ in the metabolism and toxicity of metals. Results of animal experiments can, therefore, seldom be used directly to draw quantitative conclusions about human effects and responses. On the other hand, epidemiological studies can be used in this way, because they measure health effects of metals in groups of people with different exposure levels, different vulnerability, or other relevant characteristics. The measurement of health effects in these groups would focus on the *population at risk*. This population includes only the people who are actually able to suffer from the health effects under study. For instance, congenital malformations can only occur among newborn children who would thus be defined as the population at risk in a study of such malformations. If prostate cancer is being studied, only men are included in the population at risk.

The study population is the selected part of the total population that is actually studied. It should include people with a range of different metal exposure levels in the population at risk, but it may be restricted to selected age, gender, or occupation groups to reduce the number of variables that potentially influence the health effect and to draw more focused conclusions from the study.

The different approaches and terms used in expressing the results of epidemiological measurements will be presented here, because these terms will be referred to in the subsequent sections. Issues concerning the analysis of differences between groups with different levels of metal exposure will be discussed in Section 5.

The occurrence of disease or toxic effects is measured either as *incidence*, which is the number of newly developed cases during a defined period, or as *prevalence*, which is the number of existing cases at a defined point in time. Incidence and prevalence are usually calculated as rates in the population at risk (e.g., number of cases per 1000 persons at risk). Depending on the type of disease or effect that is measured, the time unit used for incidence rates may vary. The most common unit for chronic effects is years. For acute effects, days or even hours may be more appropriate. The time unit is included in the incidence rate. The rate may be expressed as cases per 1000 persons per year or cases per 1000 persons per day, depending on the type of disease or toxic effect studied. The size of the population at risk is often determined as the average population during a defined period. In epidemiological studies of groups with a rapid turnover of individuals entering and leaving the population at risk, the average population can vary greatly with time. For each individual, the *number of person-years of follow-up* can then be calculated, and the incidence would be expressed as the number of cases per 1000 person-years.

Incidence and prevalence rates are interdependent, because the number of existing cases depends on how many new cases occur and how many disappear because they die or are cured. The *duration* of the disease and the time unit for incidence are the factors on which this interdependence is based. A low incidence may give a high prevalence if the duration of the disease is longer than the time unit for incidence. If the time unit for incidence is very long, the calculation should be corrected for the increasing number of prevalent cases that cannot experience the effect again. The correction is made by calculating the *cumulative incidence rate* (Beaglehole *et al.*, 2000). This measure is particularly valuable in studies of chronic diseases such as cancer. In these studies, interest is often directed to the cumulative incidence over a 30- or 40-year period, and increasing incidence rates with age need to be taken into consideration. The cumulative incidence in the population at risk can be described as the *risk* (or probability) of an individual contracting the disease.

The occurrence measures mentioned previously are absolute measures. It is common to calculate relative measures when the occurrence of effects in the population at risk is compared with the occurrence in some defined *control population* (or *reference population)* without excessive exposure to the metal under study. If the population at risk for metal exposure is very small in comparison with the entire population of the country or the area, then this entire population can be used as a control population.

In mortality and cancer-morbidity studies, the *life-table method* for calculating relative risks has been used (e.g., studies on arsenic and heart disease mortality; Chen *et al.*, 1996). From death registers and cancer registers, the age-specific incidence rates for dying of a particular disease or of contracting cancer at a particular site are calculated for an entire country or province (the control population). For each individual in the population at risk, these rates are used to estimate the risk of dying or of contracting cancer within the period under study. The *expected number of cases* is calculated as the sum of the individual risks, and this number is compared with the *observed number of cases* to calculate the *risk ratio* (relative risk) and the *risk difference* (Beaglehole *et al.*, 2000). If the risk ratio is 2, this means that the effect is twice as common in the population at risk as in the control population. The risk difference is expressed in the same unit as the risk itself (e.g., cases per 1000 persons).

Two other important measures of the occurrence of effects are the *attributable risk among the exposed* and the *attributable risk in the population.* The former expresses the part of risk of the effect occurring among the exposed that is thought to be caused by the exposure. It can be computed as the risk difference divided by the total risk in the exposed group (Beaglehole *et al.*, 2000). The latter takes into consideration the fact that in any given population, only a fraction may be exposed. Thus, the attributable risk in the population is the part of the measured risk of the effect on the entire population that is thought to be caused by exposure to the metal.

Epidemiological studies for assessing dose-effect and dose-response relationships of metal toxicity have the advantage that they are usually dealing with only one specific exposure—the metal ion (or metal compound), which is not metabolized into any other substance. However, the speciation or oxidation state may change, which, in some cases, may be of toxicological importance. Another crucial factor is the measurement

of dose at the appropriate time or time span. It is often necessary to estimate long-term doses that take into account long half-times of the metal in the critical organ. This may involve the use of kinetic models (see Section 4.1), because direct measurements may not be possible.

Measurement of effects requires a clear case definition and attention to the timing of the effect (see Section 4.2). From the viewpoint of prevention, emphasis should be placed on early or subclinical effects that may occur in the most sensitive part of a population at risk. Measurements of relatively high response rates can be made in studies of limited size. Very low response rates (e.g., 1 case per 1000 persons) may, however, necessitate large-scale studies that are not always feasible because of cost or because the population at risk is not large enough to provide valid findings.

2 OBSERVATIONAL STUDIES AND MODELING STUDIES OF DOSE-RESPONSE RELATIONSHIPS

Dose-effect and dose-response relationships for humans can be ascertained in two different ways. *Observational studies* involve measurement of exposure and dose in groups within the study population and measurement of occurrence of effects and response in the same groups by use of clearly described methods. In the analysis, the relationship between dose and severity of effect and between dose and response are ascertained (Figure 1). *Modeling studies* do not assess the exposure at an individual level but involve the use of metabolic models, statistical distributions of the occurrence of the toxic metal in tissues or the daily intake, as well as estimates of critical concentrations in the critical organ to calculate the proportions of groups in the population at risk that are likely to have the effect (Figure 2). Another term for modeling studies would be health risk assessment or health impact assessment (Yassi *et al.*, 2001). In such cases in which a direct exposure at an individual level is not available, a variety of *proxy variables* (e.g., questionnaire data or survey results) may be applied.

Observational studies are more straightforward and avoid assumptions about the metabolism of the metal compound, which may increase the uncertainties of the dose-response evaluations. Even low incidence rates can be studied from routine records of deaths or of specific diseases. Less prominent effects, such as lead toxicity on hemoglobin synthesis (Roels *et al.*, 1975), have also been established through observational studies. In designing and evaluating these studies, the background occurrence of the effect in question must be taken into account. For instance, renal tubular damage of the type seen in chronic cadmium poisoning (Chapter 23) is rare in the general population, whereas paresthesias, an early symptom of methylmercury poisoning (Chapter 33), is not uncommon and mostly from other causes.

Modeling studies may be used as an extension of data from observational studies for parts of the dose-response relationship where no observations exist or as a complete substitute for observation studies. The metabolic model is the key (Figure 2). The models used range in complexity from the one-compartment model of methylmercury metabolism proposed by Berglund *et al.* (1971) to the eight-compartment model of cadmium metabolism (see Chapter 23) proposed by Kjellstrom and Nordberg (1978). The model is a means of linking together data on metal intake, metal concentrations in different tissues, and metal excretion. Data from groups with relatively low exposure levels

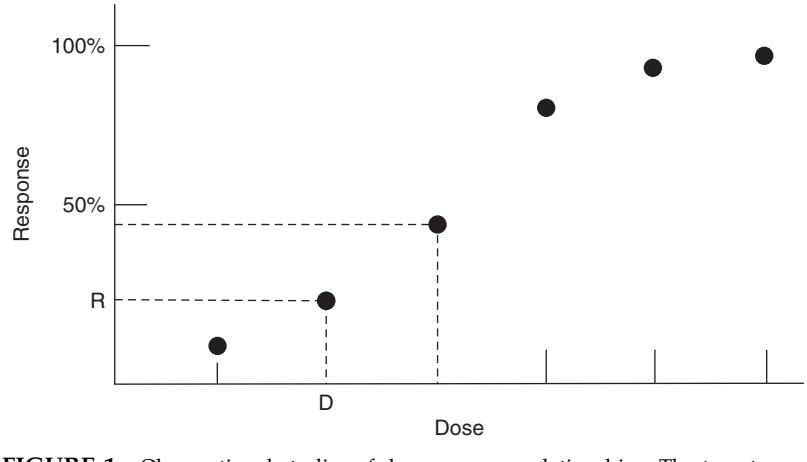

FIGURE 1 Observational studies of dose-response relationships. The target population is stratified into groups according to dose. The mean dose and the mean response are measured for each stratum, giving one combined point on the dose-response curve.

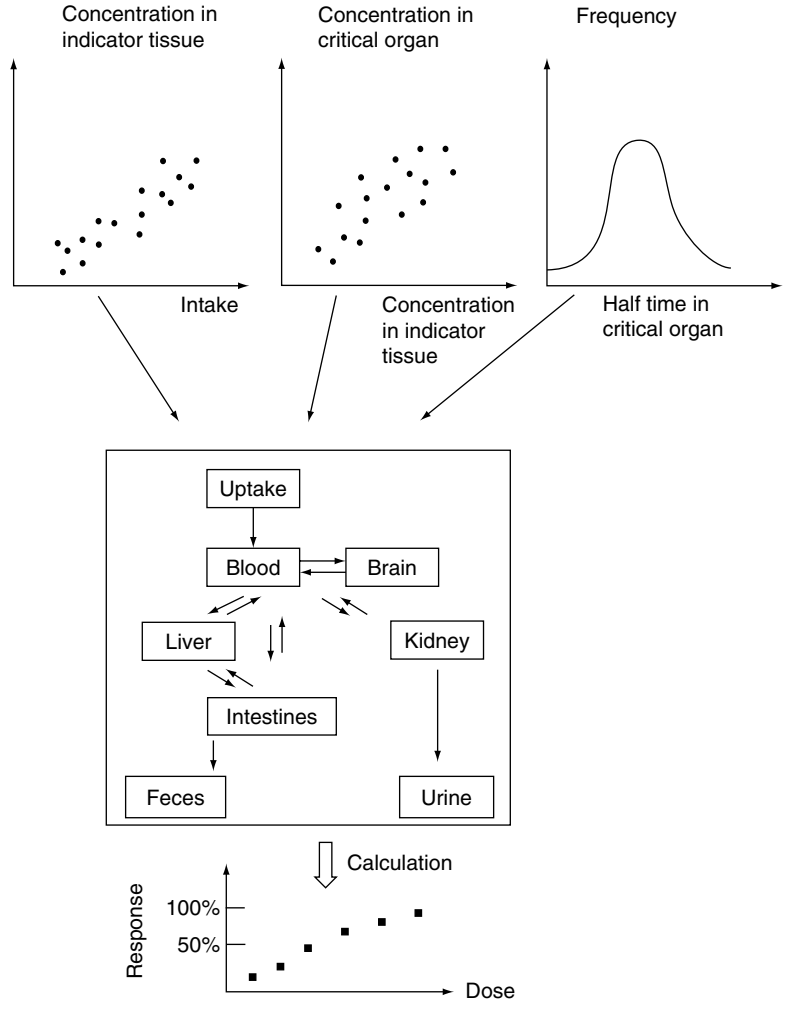

FIGURE 2 Modeling studies of dose-response relationships. Data on human metabolism of the metal and distribution of half-times, etc. are used to establish a metabolic model. The model calculates the proportion of a group with a particular dose that would have metal concentrations in critical organs above an estimated critical concentration. This is used as an estimate of response rate in each dose group.

can be used to quantify rates of transfer between compartments in the model. If it can be assumed that these rates are independent of the exposure levels (within the range of interest), critical organ concentrations under particular exposure conditions can be predicted. Individual variation in dose within the population at risk, as well as the individual variation in half-times of the metal compound in the main body compartments, can be expressed as statistical distributions. In the case of cadmium, for instance, it has been shown that both daily intake and renal cortex cadmium concentrations follow log-normal distributions, which coincide remarkably well with calculations that use a metabolic model (Kjellstrom, 1977).

The critical organ concentration is defined as a threshold level above which "adverse" changes occur in the cells of the critical organ (TGMT, 1976) in an individual. For most metals, it can be assumed that there is considerable individual variation in the sensitivity of the critical organ. This has been shown clearly by *in vivo* neutron activation studies of cadmium in renal cortex (Ellis *et al.*, 1984). Some controversy about critical concentrations for cadmium has developed, because of the application of the term to populations without consideration of individual variations. To overcome this problem, the term population critical concentration (PCC) has been proposed (Friberg and Kjellstrom, 1981; Kjellstrom *et al.*, 1984). The PCC-50 is the concentration in the critical organ at which 50% of the population has exceeded the individual critical concentrations; the PCC-10 applies to 10% of the population and so on. This approach to assess risk is similar to the benchmark dose concept (see later).

By use of metabolic models based on epidemiological data on metal intake, tissue distribution, and excretion, as well as statistical distributions and estimates of critical organ concentrations, the proportion of a population at risk that develops the critical effect (the response rate) can be calculated. Calculated dose-response relationships, such as those for methylmercury (Nordberg and Strangert, 1976) and for cadmium (Kjellstrom, 1977; 1985), can be of value to indicate what response rates can be expected at different doses. This information can be used to decide on sample size in direct studies and to decide on provisional hygienic standards for primary prevention.

Health risk assessments have provided new insights into the potential epidemiological impact of metal compounds. For instance, Trasande *et al.* (2005) analyzed the impact of mercury emissions from coal-powered electricity generation plants in the United States. The frequency distributions of different blood mercury levels were combined with estimates of dose-response functions (from other epidemiological studies) to calculate that between 300,000 and 600,000 children each year would be exposed to methylmercury levels in maternal blood high enough to cause loss of IQ.

3 STUDY DESIGN

Epidemiological study designs can be classified into three types (Beaglehole *et al.*, 2000) (Table 1). Descriptive studies provide data on the occurrence of exposures, dose, or effects with no specific comparison between dose and effects or dose and response. Studies on metal intake through food in a population or on the incidence of stomach cancer in different age and sex groups would be descriptive studies. Data from this type of study are commonly used for dose estimation in modeling studies of dose-response relationships (see Section 2). Analytical studies combine data on exposures or doses with data on effects or responses to estimate the causative role for a particular exposure. Intervention studies involve manipulation (or intervention) of metal exposure in a randomized group in the population and follow-up of the influence of intervention on the occurrence of effects. Intervention studies are, in a sense, equivalent to human experiments and can be used only for studying effects that are reversible and not injurious to the persons exposed. They are, therefore, primarily used to evaluate preventive interventions (e.g., Lanphear *et al.*, 1999; Markowitz *et al.*, 2004; Weihe *et al.*, 2005). Data from analytical studies are the basis of most observational studies of dose-response relationships. Epidemiological studies can also be classified with regard to data specificity as either macroepidemiological (ecological, population level) or microepidemiological (individual level) (Table 1).

The studies can also be classified with regard to the time relationship of observations as either longitudinal or cross-sectional (Table 1). In the longitudinal studies, data about exposures and effects are collected at more than one point in time, and antecedent–postcedent relationships can be analyzed. A cross-sectional study collects data on exposures and effects at only one point in time, which is often a disadvantage from the point of view of analysis. Longitudinal data can be collected either retrospectively or prospectively. Retrospective data collection involves the use of information about the past (usually from existing data), whereas prospective data collection makes it possible to design more precise and standardized data sets that fit the needs of the study. When the half-time in the critical organ is very long, as it is for cadmium (see Chapter 23), retrospective exposure estimates are essential for achieving reasonably rapid results.

If there is a good indicator of internal dose—for instance, blood lead for inorganic lead exposure (see Chapter 31) and hair mercury for methylmercury exposure (see Chapter 33)—data on dose and effects may be collected at the same time (cross-sectional study), because the indicator reflects exposures in the past. However, irregular exposure and other types of imprecision may render this measure unreliable. Thus, data often have to be collected longitudinally over time.

TABLE 1 Classification of Observational Epidemiological Studies

Type		
Descriptive	Describing the occurrence of exposures and effects	
Analytical	Testing associations between exposures and effects	
Intervention	"Experiments" in which exposures are assigned (includes randomized controlled trials)	
Direction		
Case-control	Start from cases with effect and probe into their exposures	
Cohort (follow-up)	Start from exposed people and see whether they get the effect	
Timing		
Cross-sectional	All data collected referring to one point in time	
Longitudinal	Retrospective	Data collected regarding the present and the past
	Prospective	Data collected regarding the present and the future

The study can either focus on cases with the effect as compared with a control group without the effect, or it can focus on persons with the metal exposure and compare them with people without exposure. The first type of study is called a case-control study (Table 1). The cases and non-cases are compared concerning their metal exposures in the past or the present based on analysis of indicator tissues. Higher doses in the group of cases may be interpreted as an association between the metal and the effect. *Absolute* occurrence and dose-response relationships cannot be measured using a case-control study alone, but a *relative* occurrence between groups with different dose levels can be calculated in the form of an *odds ratio*. If both the cases and the controls are stratified into groups according to metal dose, the odds ratio for each stratum can be calculated; this ratio can be expressed as a dose-response relationship. Case-control studies are often retrospective, because the analysis starts out from the people with effects, and their relevant metal exposure for these effects must have occurred in the past. The term retrospective study has, therefore, often been used in the past as a synonym (Beaglehole *et al.*, 2000). It should be pointed out that retrospective data collection might increase errors in exposure estimations, because of the inherent difficulties in "reconstructing the past."

To measure the *absolute* incidence or prevalence rates needed to establish complete dose-effect or dose-response relationships in different dose groups, a cohort study (follow-up study) would be the most suitable. In this type of study, an exposed group and a nonexposed group (controls) are selected. The occurrence of effects of the metal is measured in each group. The exposed group can be stratified into groups according to dose level. The measurement of incidence or prevalence of effects in each group forms the basis for dose-effect and dose-response relationships.

One of the most important steps in an epidemiological study is the selection of the groups under study. In both descriptive and analytical (follow-up) studies, it should be ascertained that the people in the exposed group are really exposed and belong to the population at risk. Ideally, the entire group that is and has been exposed should be studied, or if the group is too large, a randomly selected sample from this group should be studied. In an industrial environment, this means that all workers who were ever exposed in the factory under study should be included. An operational definition for "exposed" may be used such that an exposure duration limit is set (e.g., having worked in a metal-exposed area of a factory for 1 year or longer). If only workers actively working at the time of the study are included, those with the effect may be selectively excluded, because they had to stop working when they contracted the effect. In a dose-response study of cadmium-induced tubular proteinuria (Kjellstrom, 1977), it was shown that the possible underestimation of response because of selective exclusion might be considerable. A similar bias may occur in studies based on population screenings where only those healthy enough to come to the screening can participate. Selection bias may also be introduced in studies of industrial workers by the procedure of preemployment selection of workers. Mainly healthy young men would be selected for the work that involves metal exposure, and the results of such a study may not be applicable to the general population. This is called the *healthy worker effect* and is a problem in, for example, retrospective follow-up studies of mortality (Kitagawa and Hansen, 1973; McMichael, 1976).

The selection of the control group in analytical follow-up studies is as important as the selection of the exposed group. Selection bias caused by, for example, sick people who are not able to participate, should be avoided. If any sampling of the exposed group takes place, the same criteria for sampling should be used for the control group.

In case-control studies, similar problems of selection occur as in follow-up studies. A clear definition of "a case" is needed, and often this has to be based on an operational definition from symptoms, signs, and biochemical or physiological measurements. The selection of a "control" in a case-control study is sometimes a problem, because it is necessary to find cases and controls in the same source population, the study base (Rothman and Greenland, 1998) (which may be restricted by age, gender, etc.). For example, if cancer is the effect studied, ideally the wider population in which the cancer cases occur should be the source of the controls. In some studies of hospitalized cancer cases, other hospital patients without cancer have been selected as controls. These controls naturally have some other disease, because they are also hospital patients, and if this disease is also associated with the metal exposure, the epidemiological analysis may be invalid. In the choice between follow-up and case-control at the design stage of the study, it should also be pointed out that the size of the study group needed for a particular statistical power in the conclusions depends on whether the exposure or the effect is rare. If the exposure is rare, but the exposed people can be identified, a follow-up study needs a smaller group than a case-control study. If the effect is rare, the opposite is true. If both exposure and effect are relatively common (e.g., in more than 10% of groups studied), either type of study can effectively be used.

Confounding factors can interfere with epidemiological analyses. A confounding factor is something that is associated with both metal exposure and the effect; for example, heavy drinking is associated with

gout. If the exposed group in a study of molybdenum and gout had a greater proportion of heavy drinkers than the control group, the drinking habits would be a confounding factor. At the stage of selection of target groups for the study, confounding can be controlled by stratification of the target group to subgroups of the population at risk according to drinking habits (stratified samples). Confounding can also be controlled by restriction. If drinking is a confounding factor, the study could be restricted to nondrinkers only, but the results may then only apply to the selected group (nondrinkers). One way of stratifying (and restricting) the sample in cohort studies is matching. For each exposed person, one or more controls are selected that have the same characteristics (age, gender, occupation, etc.) as the exposed person. Confounding can also be controlled for at the analysis stage of the study.

By controlling the confounders, a more precise estimate of the metal effects will be expected. However, this may not be true when the exposure parameter is imprecise (Budtz-Jørgensen *et al.*, 2003). Also, even when information on several suspected confounders has been collected, some residual confounding may remain. An important question is, therefore, whether the estimated effect of the metal exposure should be considered reliable. Although smoking has often been invoked as a confounder that may explain occupational lung cancer risks, simulations have clearly shown that any residual confounding because of unmeasured differences in smoking patterns is unlikely to explain risks that are above a certain level (Axelson, 1989). A balance, therefore, needs to be achieved, without invoking unjustified "ghost" confounders.

A study design often used in studies of subjective symptoms, for example to study short-term symptoms of air pollution, is the panel method. Groups of people in an area with anticipated variations in exposure to air pollutants are asked to keep a diary of symptoms as they occur each day. During the same period, exposure levels are measured, and any association between exposure and effects on a day-to-day basis is analyzed. The people studied serve as their own controls during periods of low exposure. This approach is also the basis for time-series studies and case crossover studies (Szklo and Nieto, 2004).

4 DATA COLLECTION

4.1 Measurement of Dose

Ideally, the metal dose should be measured in the tissue where the metal elicits its earliest effect, the critical organ (TGMT, 1976). In many cases, this is not possible, and, instead, indirect measurements of varying degree of accuracy have to be made (Figure 3). The critical organ is often an internal organ that is not directly accessible for metal measurements. During autopsy, samples may be collected and analyzed, and in some cases biopsy specimens have been used (e.g., renal biopsies from cadmium workers—Axelson and Piscator, 1971). Autopsy data (or stored organ analysis data) may be compared with earlier data on effects, as was done in some early studies of Minamata disease (methylmercury poisoning) (Harada *et al.*, 1977) and Itai–Itai disease (cadmium poisoning) (Kjellstrom, 1985). For certain metals, the *in vivo* neutron activation technique (Ellis *et al.*, 1984; Harvey *et al.*, 1975; Morgan *et al.*, 1990) can be used to measure excessive doses. *In vivo* methods have been used primarily for cadmium and lead (see, Chapters 23 and 31).

Indicator tissues, such as blood (for lead), urine (for cadmium), or hair (for methylmercury), can be used to estimate the dose in the critical organ. To translate

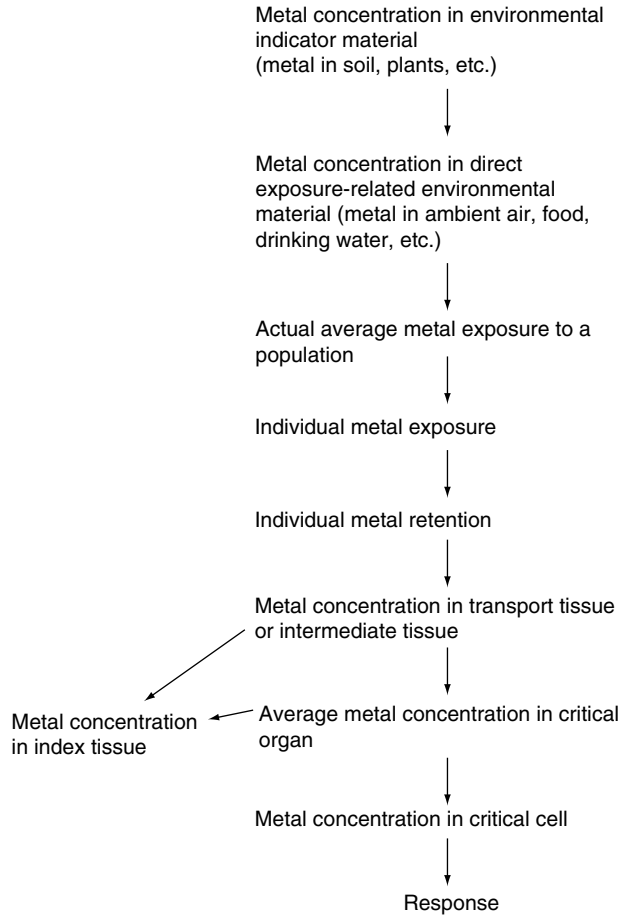

FIGURE 3 Sequential relationship between dose variables and a specific response. (From Kjellstrom, 1976).

indicator tissue concentrations into critical organ dose, metabolic models (see Section 2) are useful. The amount of a metal in feces is a good indicator of daily intake by ingestion when the gastrointestinal absorption is low. In Chapter 23, a comparison between cadmium body burden and daily fecal and urinary amounts of cadmium is given, which shows good agreement between body burden and urine cadmium on a group basis after long-term low-level exposure. Body burden and kidney burden are also well correlated (Kjellstrom, 1977). Hair mercury is a good indicator of body burden of methylmercury (Friberg and Vostal, 1972), and because of the relatively even distribution of methylmercury in the body (see Chapter 33), it is also assumed to be a good indicator of the amount of methylmercury in the brain. Hair has the advantage that it may be a source of retrospective dose data, because the metals stay in the hair as the hair grows. It was shown after the methylmercury poisoning outbreak in Iraq (Bakir *et al.*, 1973), sectional analysis of hair could pinpoint the time when mercury consumption started and the time when it reached its maximum.

The measurement of dose by analyzing indicator tissues or the critical organ itself involves analysis of the metal compound in the tissue. The concentrations are usually very low, in the order of μg/kg to mg/kg, which may make accurate analysis difficult. The problems of getting accurate chemical analysis results have been highlighted by interlaboratory comparisons (Kjellstrom, 1979; Nordberg *et al.*, 2000). Alternately, the dose may be estimated from exposure data if uptake kinetics and half-time in the critical organ are known. The product of exposure level and exposure duration, corrected for the ratio between duration and half-time and also for the absorption rate, can give an estimate of dose. The calculation of dose should be based on the exposure that is relevant for uptake. Measurements of exposure to metals, particularly through air, should ideally include an estimate of particle size distribution and the metal concentration in each size fraction. The absorption of metals in the intestines can be affected by other elements in the diet (see Chapter 3). Therefore, additional information on diet content would be necessary to calculate dose from metal levels in different foodstuffs.

Other ways of estimating the dose involve "proxy variables," which can reasonably be expected to be associated with actual exposures. One example is the use of the number of amalgam surfaces on teeth to estimate past exposures to inorganic mercury (Bates *et al.*, 2004). Because they are elements, most metals occur naturally in air, food, and drinking water. Whichever particular exposure conditions are being studied, the total exposure by adding all possible uptakes must normally be considered. Skin exposure may be significant in occupational environments.

Smoking can increase exposure both through the natural metal content of cigarettes and pipe tobacco and through external contamination of the smoking gear from hands, overalls, or the workroom air (Hassler, 1983; Piscator *et al.*, 1976). A smoker may be sensitive to airborne metal exposures in other ways. Smoking is associated with chronic bronchitis and emphysema (which can also be caused by cadmium inhalation), and it slows down lung clearance (Albert *et al.*, 1969; see also Chapter 3).

For acute effects of metals, the peak exposure levels will determine the risk of effect. We can assume that in some cases, for chronic effects also, the dose may not be a function of exposure level times the exposure duration, but rather a function of the frequency of peak exposures above a certain level (impulse exposures).

As indicated previously, all exposure measures involve some element of imprecision. None of the exposure biomarkers or other variables amply reflect the concentration profile occurring in the critical organ during the time period of relevance. In general, such imprecision is random, although it may sometimes be relatively greater at low concentrations. Random or nondifferential exposure measurement error results in underestimation of the risk. The larger the imprecision of the exposure parameter, the greater the underestimation. Unfortunately, a "gold standard" is rarely available, and the degree of misclassification is, therefore, seldom known for sure, and its magnitude must therefore be assumed (e.g., from comparisons between exposure indicators). Recent studies suggest that such comparisons result in an underestimate of the total imprecision (Grandjean *et al.*, 2004).

Although imprecision is generally expressed as the coefficient of variation (CV) obtained from laboratory quality assurance studies, other factors may play a role as well. For example, the degree to which an exposure parameter reflects the concentration at the sensitive target or compartment within the body may vary, and the laboratory accuracy and precision will not reflect the total degree of uncertainty associated with a particular exposure parameter. In studies on methylmercury toxicity, the laboratory CV was approximately 5% or less (i.e., of minimal significance for the outcome of the studies). However, an exposure indicator can be expressed as a function of the "true" exposure plus an intercept and an error function. This equation has three unknowns, but it can be modeled (e.g., by factor analysis) if at least three exposure variables are available from each subject. Using this approach, the

hair-mercury result obtained in a large population study was found to have a total CV of approximately 50% (Grandjean *et al.*, 2004). The laboratory variability alone was a small contributor. Irregular exposures, external contamination of the hair, leaching of mercury because of hair treatment, and differences in hair structure and hair growth rates may all have contributed to this large imprecision. These findings suggest that efforts to minimize laboratory imprecision need to be seen in regard to their contribution to total error levels. A greater impact may be achieved by collecting samples that better reflect the dose level (e.g., the cord-blood mercury concentration).

4.2 Measurement of Effect and Response

Whenever health effects are measured, biological variation and random errors in the measurement procedure will affect the results so that false-negative and false-positive results will occur. The ideal test of effects gives only true-positive and true-negative results, but such tests are difficult to find. A clinical sign or symptom, which is typical for a particular exposure, is called pathognomonic. Under certain circumstances, the skin granulomas seen in beryllium exposure, the cardiopathy and polycythemia associated with cobalt, and the characteristic breath after tellurium exposure may be considered pathognomonic (Grandjean *et al*, 1991). If the test yields very few false-negative results, it will have found almost all of those who had the effect (positives) and can then be called a *sensitive* test. Some of those who were classified as having the effect would be wrongly classified (i.e., the false-positive results). If the test, on the other hand, results in very few false-positive results, it is almost certain that a person classified as having the effect in fact has this effect. Such a test is called a *specific* test. Sensitivity and specificity are important qualities of health effect measurements in epidemiological studies (Beaglehole *et al.*, 2000). In studies of persons affected by a metal compound present in the environment, a sensitive measurement of the health effect is important to find all affected cases. However, in an epidemiological study aimed at quantifying a dose-response relationship, it may be more advantageous to have a specific measurement, so as not to "dilute" the analysis with false-positive results. The concepts of sensitivity and specificity can also be applied to exposure variables that are dichotomous (i.e., each person is classified as either exposed or unexposed).

Effects can be classified as subjective symptoms, psychological effects or learning deficiencies, social or behavioral changes, biochemical or physiological changes, clinical disease, and death. Subjective symptoms can be, for example, the shortness of breath associated with beryllium exposure (Chapter 21) or the weakness, fatigue, and anorexia associated with mercury-vapor exposure (Chapter 33). In this group of effects, we can also include subjective psychological changes, mood changes, and annoyance reactions to dust, skin irritation, and smell. Data may be collected through standardized interviews or self-completed questionnaires. When interviews are carried out, it is important to avoid observer bias caused by, for example, different interviewers in the exposed group and the reference group. The way questions asked may affect the answers. Ideally, the interviews should be blind (i.e., the interviewer should not know to which group a particular person belongs). In a double-blind study, neither the interviewer nor the person studied knows the exposure status of this person.

Psychological effects or learning deficiencies have been measured as effects of, for example, lead (Chapter 31). Many standardized "psychometric" tests are available, but problems of validity may arise when effects are measured in populations with a language or cultural background different from those of the population the test was designed for. Quality-assurance procedures incorporated into the testing program are, therefore, essential and should preferably be complemented with studies of case groups that are known from independent evidence to suffer the particular deficits that are sought in the exposed group. The problems of observer bias may be limited by standardized instructions for how the test should be carried out, but it is still desirable that the tests are carried out on a double-blind basis.

By social and behavioral effects we mean, for example, family strife caused by behavioral changes in the affected person, decreased work efficiency, lagging behind in school work, absenteeism, and workers compensation or other insurance claims. The latter two effects are usually based on diagnosed clinical disease, but this is not always the case, and absenteeism may be an unspecific "annoyance" effect of metal exposure in the workplace. Data collection can be carried out in a way similar to collection of subjective symptoms or by using existing records of absenteeism at school or work, school results, insurance claims, etc. Using this method, it was found that high arsenic exposure during early life affected children's school results 15 years later (Ohira and Aoyama, 1973). The effects mentioned here are quite nonspecific, and the risk of confounding may be greater than for other effects.

Biochemical and physiological changes are likely to be the critical and subcritical effects of metal compounds (see Chapter 6). Only a few have been established—for example, decreased erythrocyte ALA-dehydratase

activity after lead exposure (Chapter 31) and increased urinary beta$_2$-microglobulin excretion after cadmium exposure (Chapter 23). Histopathological changes may also be included in this type of effect. Measurement problems are related to finding the specific type of change caused by a metal compound. Animal studies can be of great value here, but species differences have been shown, for instance, for the type of proteins excreted in urine as an effect of cadmium poisoning. Another problem concerns the possibility of taking samples of the tissue where the effect occurs. The biochemical change we measure may be an indirect measure of the effect, as it is for cadmium-induced urinary β_2-microglobulin excretion, or a direct measure, as in lead-induced ALA-dehydratase inhibition.

When the effect is measured as changes in a normally occurring tissue compound or physiological variable, the dose-effect relationship can be evaluated from the quantitative increase in the variable with dose. For calculations of dose-response relationships it is necessary to have an operational definition of what level of the variable constitutes the effect. The distribution of the variable in the control group may be used to calculate a certain percentile as the cutoff level. When urinary concentrations of specific compounds are used for measuring effects, it is necessary to correct the individual concentrations for variations in urinary dilution. When compounds in whole blood are measured, it may be necessary to correct for percentage of packed cell volume (PCV).

Another problem with biochemical, physiological, and histopathological changes as measures of effects is whether the changes measured should be interpreted as an "adverse" toxic effect, adaptation to the metal, or just physiological variations influenced by the metal. There is no metal for which we have detailed knowledge about all the chemical steps in its toxicity from the first changes observed to severe clinical disease. Any change occurring in the critical organ that may be related to more severe effects in this organ should be considered at least as a subcritical effect (TGMT, 1976). In support of this notion, lead exposure is known to adversely affect the formation of hemoglobin, but the hematological parameters of most subjects will remain within normal ranges. However, significant differences in the rate of blood regeneration may occur when the subjects have been exposed to a blood loss (*in casu*, donation for a blood bank) (Grandjean *et al.*, 1989a). Decreases in reserve functions may not be apparent from most cross-sectional studies but are revealed during the additional stress of a blood loss.

Effects of metals can also be measured as clinically diagnosed disease. Medical practice records, hospital records, and data registers, such as a cancer register, may be used as information sources. Such records or registers may not be complete, however, which may result in an underestimation of response. There may be factors that cause a biased selection of the people in the records or the register, for example, economic barriers or social class-dependent attitudes to medical care. A complete clinical examination of the entire group under study may overcome such shortcomings of existing records. In industrialized countries where reporting systems are good and where autopsy rates are high, cancer registers or congenital malformation registers are becoming more and more complete and accurate. Cancers with a relatively short and characteristic course, such as lung cancer or breast cancer, would be more completely recorded than, for example, prostatic cancers, which occur at older ages and may be overshadowed by other diseases that cause death. When this type of effect is measured, it is necessary to collect data for the exposed group and the control group in an identical fashion. If a cancer register is used for calculating national reference rates for a "life-table study," all cancer cases in the exposed group should also be picked up through the cancer register. Whether the exposure itself makes it more likely for the cancers to be diagnosed and recorded in the cancer register must also be taken into account (e.g., metal-exposed factory workers may have an autopsy rate higher than normal, because of the suspicion of occupational cancer).

Finally, the type of effect that is most easily defined (death) has been used in some studies as an indicator of long-term prognosis after metal exposure (e.g., Cooper and Gaffey, 1975; McMichael and Johnson, 1982; Sorahan and Waterhouse, 1983). After very high exposures to metal compounds, death can be one of the main effects (Bakir *et al.*, 1973). Depending on the character of the recording system and autopsy rates, data on causes of death vary in quality. Mortality studies need long-term follow-up, which poses problems of tracing the place of death of the target group and problems of identification. Case-control studies of mortality involve finding data on exposures of people one cannot interview. One study has shown, however, that interviews with next of kin can produce valid data (Pershagen and Axelson, 1982). The major difficulty in mortality studies is linking up individual dose data with the effect data rather than measuring the effect itself.

When the target group is well defined and the effect has been measured accurately, the measurement of response is straightforward; the proportion of the group that contracts the effect in a specific period (incidence response), or the proportion that has the effect at a specific point in time (prevalence response). Selection bias (see Section 3) would be the most likely cause for errors in response measurement.

5 DATA ANALYSIS

Data analysis is the stage in an epidemiological study where the data are arranged and calculations made so that conclusions can be drawn. In descriptive studies, the conclusion would be in the form of a description of the occurrence of a variable in the population group studied. In an analytical or intervention study it would be in the form of rejecting or accepting a hypothesis about an association between an exposure and an effect. If the study was designed for ascertaining a dose-effect or dose-response relationship, the conclusion may be that this has or has not been found, and the result is often expressed as a mathematical relationship with confidence intervals. In drawing these conclusions, a number of statistical techniques are used, which will not be discussed in detail here. The reader is referred to more detailed texts, such as Jewell (2004).

We can express the dose as population dose, which is the sum of all individual doses in a population. This is the approach often used in radiation protection, and basically it assumes a linear dose-response relationship down to very low doses. A certain population dose is assumed to be associated with a certain number of affected cases. If the dose data are in the form of environmental measurements of emissions, it may also be relevant to estimate the dose commitment. This is the estimated total future population dose that will arise from the emissions. Quantitative effect data can also be expressed as distributions.

When the effects are measured as the number of cases of a particular disease (e.g., primary liver cancer) and incidence data based on a total population are available, the life-table method (see Section 1) can be used to estimate incidence rate ratios between the exposed group and the total population. The rate ratios for groups with different dose levels are compared with the average dose in the groups to yield a dose-response relationship.

If the data show an apparent increase in the response with increasing dose, a statistical test is used to determine whether it is likely that the data have emerged this way just by chance. A confidence interval for the dose-response relationship can also be calculated. These calculations are simplified if any of the three mathematical transformations mentioned in the following are used. The shape of the dose-response curve is often sigmoidal as a cumulative normal distribution. Such a curve can be transformed to a straight line by probit transformation. Another method of mathematical transformation that produces a sigmoidal dose-response curve for binary data is the logit transformation (Ashton, 1972; Cox, 1970). This has been used to assess the prevalence of prenatally induced CNS effects of methylmercury (Figure 4). It can be adjusted for a background prevalence. However, the dose range may represent only part of this curve, which would then be either concave or convex. For some outcome variables, there may be a "ceiling," so that a result cannot exceed a certain level. Vice versa, other outcomes may exhibit a "floor" effect, where the result cannot be recorded below a certain level. These properties may affect the shape of the dose-effect curve. The assumption of a"floor" and a straight line dose-response is the basis for the "hockey stick" method (Figure 4).

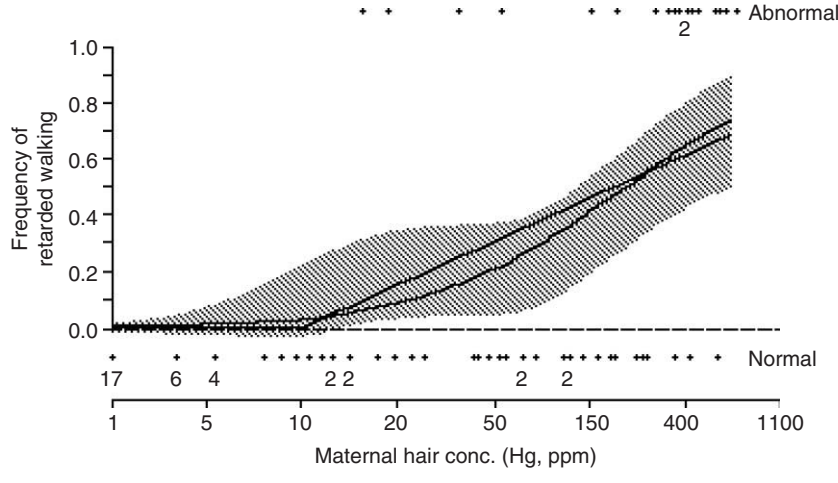

FIGURE 4 The frequency of retarded walking in prenatally exposed children versus the estimated maximum body burden in the mother during pregnancy, as expressed in terms of the hair-mercury concentration: (Straight line) "Hockey stick" method. (Curve) Logit analysis. The data are taken from Marsh *et al.* (1979) and clarkson *et al.* (1981). +, Motor retardation is defined as failure to walk by the age of 18 months.

When the shape of the dose-response curve is unknown, as is often the case in studies of, for example, metal-induced cancer, the margin of exposure (MoE) concept may be used. This approach is based on the calculation of a predefined dose, which is associated with a defined acceptable risk (e.g., a 0.001% cancer risk) or a benchmark dose (see later). The MoE is then calculated as the ratio between this parameter and the average exposure of the population at risk. The MoE is meant as a tool for risk assessors and needs to be interpreted with care, because the risk associated with a particular MoE is unlikely to be the same for different carcinogenic metals.

Of particular interest in regard to risk assessment is the existence of a threshold. However, this concept rests on limited theoretical grounds, and empirical studies have often found lower and lower "thresholds" using more sensitive measures and larger populations. For practical purposes, dose measures that represent the level at which certain changes begin to occur would be useful as a guide for preventive efforts. One simple approach is the so-called hockey-stick method of expressing a dose-response relationship (Figure 4). It is based on the assumption that there is a background prevalence and at a certain threshold dose, the response rate starts increasing linearly. The dose-response function is fitted to the data with a maximum likelihood method (Yanagimoto and Yamamoto, 1979).

Regulatory agencies have more recently started to apply the so-called benchmark dose (BMD), as originally proposed by Crump (1984). This parameter is statistically well defined and has several advantages to approaches that aim at identifying a possible threshold. The BMD is the dose that increases the risk of an abnormal response by a benchmark response (BMR) (i.e., from P_0 (most frequently 5%) for an unexposed subject to P_0+BMR for a subject exposed at the BMD). A BMR of 5% is often used, so that an exposure at exposure at the BMD doubles the risk of an abnormal response. To take the statistical uncertainty into account, a lower 95% confidence limit (BMDL) for the BMD is then determined. The BMDL is, therefore, not a threshold, but the statistical definition has the advantage of taking into account the variability of the dose-response relationship. It has sometimes been compared with LOAELs (Lowest Observed Adversed Effect Level) or NOAELs (No Observed Adversed Effect Level) no obtained in experimental toxicology studies. The benchmark approach has more recently been extended so that it can be used with continuous data, also those obtained in epidemiological studies, where confounder adjustment is needed (Budtz-Jorgensen *et al.*, 2001; Crump, 1995).

Measurement imprecision in the dose scale will, of course, also affect the BMD. At greater imprecision levels, the BMD is overestimated. However, if the imprecision level is known, an adjustment can be made (Budtz-Joergensen *et al.*, 2004). Interestingly, a comparison of different approaches showed that the hockey-stick method is less vulnerable to imprecision (Keiding and Budtz-Jorgensen, 2004).

For metals, exposures generally take place over time, and the effects may vary over time. Time-series analyses may be used to explore such relationships. In ecological or aggregate-level studies, the population exposures are drawn from centrally located pollution monitors, whereas the individual-level studies obtain exposure estimates for individual participants from monitors, perhaps in combination with personal records of environments where participants spend time. Geographical information systems (GIS) may be a helpful tool for such studies (Scoggins *et al.*, 2004). Measurement error is of particular importance to consider (Zeger *et al.*, 2000).

As a new approach to data analysis recently introduced, structural equation models provide several advantages (Bollen, 1989), although these methods require substantial statistical expertise and software experience. This multivariate approach is potentially more powerful than traditional statistical methods, because it may incorporate all data available; it includes adjustment for imprecision in the exposure variable, and it will eliminate the need for adjustment for multiple comparisons. The principle is that all exposure variables—and similarly the outcome variables—are joined into a latent composite variable. After confounder adjustment, the effect of the latent exposure on the latent outcome variable(s) is then computed. Figure 5 shows how the model is constructed. If more than one exposure parameter is used (e.g., prenatal and postnatal), the relative contributions by these exposures to the effects can be estimated. This technique has now been applied in studies of methylmercury toxicity (Budtz-Joergensen *et al.*, 2002; 2004).

To facilitate different approaches in the evaluation of dose-response data in metal toxicity studies, it is of value that the original detailed data are published rather than that data are just aggregated from groups. This will clearly show the individual variations, which are often great. Even the most sophisticated statistical methods can seldom prove or disprove that a particular mathematical dose-response function is the "correct" one.

It should also be pointed out that metal exposures may cause effects in combination with other exposures, and various factors can modify the dose-response relationship. For instance, the lung effects of cadmium exposure through air can be exacerbated by tobacco smoking, and the bone effects are influenced by dietary vitamin D or calcium intake. These interactions can be

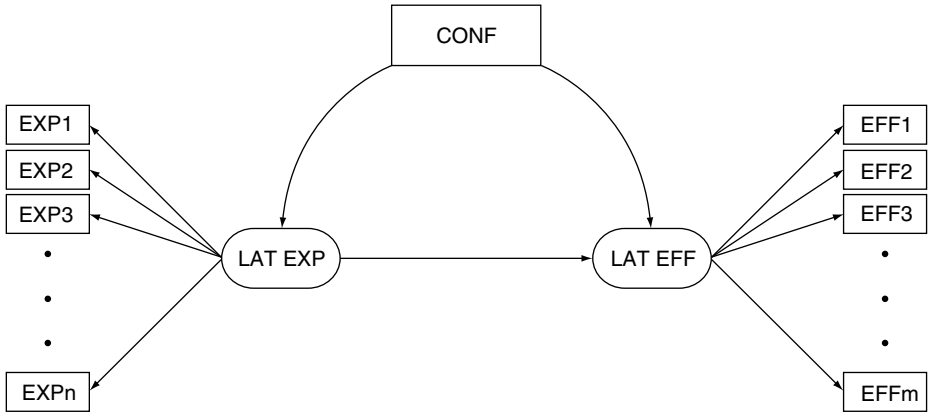

FIGURE 5 Structural equation model that includes a latent exposure variable modeled on the basis of several exposure parameters, and a latent effect variable based on a series of related parameters that reflect the same outcome. Confounder adjustment is included. This technique allows incorporation of incomplete cases.

studied at the analysis stage of a study, if the required data about other exposures are collected. The methods for analysis of interactions can be found in most textbooks of epidemiology or biostatistics (e.g., Rothman and Greenland, 1998).

6 INFERENCE

Epidemiological evidence often presents associations between frequency or severity of disease on the one hand and levels of metal exposures on the other. In human experimental studies, the exposure may be tightly controlled, but in most population studies, the exposure is not a matter of design, and it must instead be judged from various measurements, each of which is imprecise to some degree. Because all circumstances cannot be taken into account in the data analysis, each study will by necessity underdetermine the causal association.

One recent controversy relates to the possible effects of low-level lead exposure on blood pressure, where findings seem to differ between population subgroups (den Hond *et al.*, 2003). However, some variability in findings is only to be expected. First, most studies have used assessments of blood pressure and blood-lead concentration only at one point in time, and temporal changes have been ignored. Second, several factors, such as the blood-hemoglobin concentration, tobacco smoking, and alcohol drinking (Grandjean *et al.*, 1989b), can affect both blood pressure and the lead concentration in blood, thereby complicating scrutiny of the cause-effect relationships. Particularly when the causative exposure has been measured with some imprecision (and perhaps not at the right point in time), problems with confounding and possible adjustments may become insurmountable.

Scientific inference in regard to disease causation is a hotly debated issue in epidemiology, also in philosophical terms (Rothman and Greenland, 2005). Although most philosophers agree that a cause cannot be proven, certain criteria may be applied for logical analysis of the strengths and weaknesses of a hypothesis in light of the results available. The most frequently cited criteria are those developed by Bradford Hill. However, this list should not be applied too stringently, because very few environmental exposures seem to satisfy every single criterion. Because metal-associated adverse health effects are affected by dose level, timing, and vulnerability factors, each study of this association should not be interpreted as a test whether or not the association is true, but rather as a relative contribution to the understanding of this possible relationship.

Given that data quality may be far from ideal, that too few subjects have been followed for too short a time, and other limitations, epidemiology can only provide insight into causal associations to the extent allowed by the underlying information. In addition to critical scrutiny of an epidemiological study, the full perspective also needs to be appreciated: What is it possible to know, given the types of data that would be accessible for epidemiological study of this particular topic? For example, blood pressure is thought to be affected by prenatal programming and, therefore, also by developmental lead exposure. Studies of current blood-lead concentrations may show only weak associations with blood pressure, but this evidence has to be interpreted in light of the fact that the true underlying cause may be the unknown lead exposure some time in the past, of which the current blood-lead concentration is only a mere reflection.

In addition, a public-health angle is frequently relevant and deserves separate consideration (Grandjean, 1999). Thus, the scientist may conclude that the

difference in blood pressure between exposed and unexposed subjects may be less than the normal imprecision for repeated blood pressure readings. However, from a population viewpoint, even a small average increase may push a substantial number of subjects into the hypertension range with its associated increases in risk of disease and mortality. For a full interpretation of the findings, one, therefore, also needs to consider the possible effects at the extremes of the distributions. Furthermore, adjustments for imprecision of the data should explore how large the true difference between the two groups may be (e.g., the upper 95% confidence limit). Such calculations are particularly relevant for studies that report a high *P* value (>0.05) normally interpreted as denoting a lack of statistical significance. Although such studies are often called "negative," the lack of significance needs to be supplemented with a statement that some difference between the two groups would be in agreement with the results. Thus, the statistical power of the study, along with its other characteristics, needs to be taken into account when exploring whether or not the study adds support to a causal hypothesis.

CHAPTER

9

Essential Metals: Assessing Risks from Deficiency and Toxicity

GEORGE C. BECKING, MONICA NORDBERG, AND GUNNAR F. NORDBERG

ABSTRACT

Recommendations aimed at protecting the public from toxicity of essential elements have usually been developed separately from those recommendations aimed at protection from deficiency. Because of the uncertainties involved in the evaluations, these recommendations have sometimes been in conflict, emphasizing the need for a new approach, including a balanced consideration of nutritional and toxicological data.

In developing these new principles of evaluation, some basic concepts based on interindividual variability in sensitivity to deficiency and toxicity must be considered. Such variation translates into one interval of (low) daily intakes, at which there is risk of developing deficiency, and another interval of (high) dietary intakes at which toxicity may occur. In most instances, there is a third set of intakes in between, which represents the acceptable range of oral intakes (AROI) in which no adverse effects occur. It must be noted, however, that such a range cannot be found that protects all persons from adverse effects. Those persons with genetically determined sensitivity may require higher intakes to avoid deficiency or lower intakes to avoid toxicity than those defined by the AROI. AROI is defined as protecting 95% of an unselected human population from minimal adverse effects of deficiency or toxicity.

1 INTRODUCTION

Risk assessment of essential metals (EMs) in human health involves methods for analyzing the limits of deficient and excess intakes or exposures of EMs. Risk assessment of EMs needs a multidisciplinary scientific approach. Only a combination of data on required nutritive intakes, deficiency, and excess exposure can give appropriate intake recommendations from both the nutritional and toxicological point of view. Principles and methods for developing such recommendations will be described in this chapter. Assessing risks includes evaluation of the essentiality of metals, nutritional requirements and related adverse effects of deficiencies, homeostasis, maximum allowable concentration, and the critical adverse effects of intakes above this concentration.

The traditional criteria for essentiality for human health is that the absence or deficiency of the element from the diet produces either functional or structural abnormalities and that the abnormalities are related to, or a consequence of, specific biochemical changes that can be reversed by the presence of the essential metal (WHO, 1996). At present, the following trace elements are regarded as essential for human health: iron, zinc, copper, chromium, cobalt, molybdenum, and selenium (WHO, 1996). Details of their essentiality and toxicity are reviewed in the respective chapters in this Handbook. As explained in Chapter 32, a basic intake of this metal through the diet is required by humans to maintain health, and based on this information manganese should be added to the list of essential metals.

In this chapter the principles for risk assessment of EMs are outlined and discussed. For the assessment of risks from toxic effects, methods are similar to those used for metals in general (cf Chapter 14) with the addition that the essential nature of the metal has

to be balanced against its toxic effects. In the past, risk assessment of the toxic effects of EMs has sometimes been developed separately from those for deficiency, and conflicting recommendations have occurred. To avoid such a situation, explicit methods that use a combined approach have been developed and discussed by Mertz (1994), Nordberg and Skerfving (1993), WHO (1996), (Oskarsson, 1995), Mertz (1998), Olin (1998), Sandstrom (1998), Nordberg *et al.* (2000), IOM (1998, 2001), and WHO/IPCS (2002). Some aspects from those documents will be summarized and discussed in this chapter. Considerable weight is given to the principles described by WHO/IPCS in the Environmental Health Criteria Document on Principles and Methods for Assessment of Risk From Essential Trace Elements (WHO/IPCS, 2002).

The acceptable range of oral intake (AROI) is designed to limit deficient and excess intakes in healthy populations and is set for different age-sex groups and physiological states such as pregnancy and lactation. To facilitate comparisons, AROIs are discussed in relation to other risk assessment approaches. The principles and methods used to develop an AROI for an EM are not necessarily applicable to toxic nonessential metals or other chemicals.

A number of abbreviations and acronyms used in this chapter are given in Table 1. IUPAC official recommendations (Nordberg *et al.*, 2004) for defining some of these key terms are given below.

TABLE 1 List of Abbreviations and Acronyms

ADI	acceptable daily intake
AROI	acceptable range of oral intake
BMD	benchmark dose
CV	coefficient of variation
DRI	dietary reference intakes
EM	essential metal
FAO	Food and Agriculture Organization, United Nations
IUPAC	International Union of Pure and Applied Chemistry
JECFA	Joint Expert Committee on Food Additives, United Nations
LOAEL	lowest- observed-adverse-effect level
PRI	population reference intake
PTDI	provisional maximum tolerable daily intake
PTWI	provisional tolerable weekly intake
RDA	recommended dietary allowance
RfD	reference dose (oral)
SCF	EU Scientific Committee on Food
SD	standard deviation
SF	safety factor
SRPMI	safe range of population mean intake
TDI	tolerable daily intake
TI	tolerable intake
TWI	tolerable weekly intake
UL	tolerable upper intake level

Acceptable daily intake, ADI

Estimate by JECFA of the amount of a food additive, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk.

Note 1: For calculation of ADI, a standard body mass of 60 kg is used.

Note 2: Tolerable daily intake (TDI) is the analogous term used for contaminants.

Tolerable daily intake, TDI

Estimate of the amount of a potentially harmful substance (e.g., contaminant) in food or drinking water that can be ingested daily over a lifetime without appreciable health risk.

Note: Acceptable daily intake (ADI) is normally used for substances not known to be harmful, such as food additives.

Tolerable weekly intake, TWI

Estimate of the amount of a potentially harmful substance (e.g., contaminant) in food or drinking water that can be ingested weekly over a lifetime without appreciable health risk.

Toxicity

1. **Capacity to cause injury to a living organism defined with reference to the quantity of substance administered or absorbed, the way in which the substance is administered and distributed in time (single or repeated doses), the type and severity of injury, the time needed to produce the injury, the nature of the organism(s) affected, and other relevant conditions.**
2. **Adverse effects of a substance on a living organism defined as in 1.**
3. **Measure of incompatibility of a substance with life: this quantity may be expressed as the reciprocal of the absolute value of median lethal dose ($1/LD_{50}$) or concentration ($1/LC_{50}$).**

2 BASIC CONCEPTS

2.1 Definition of an AROI (Acceptable Range of Oral Intake)

Considerable interindividual variation exists in the human population. For an essential metal, this applies to the expression of toxic effects from higher doses and the expression of adverse effects of deficiency from too low intakes. In Figure 1, this interindividual distribution of sensitivity is shown

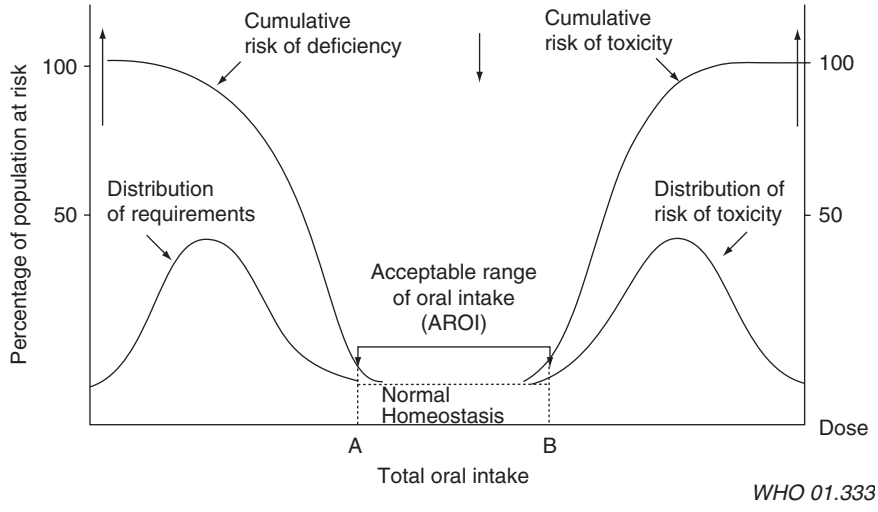

FIGURE 1 Percentage of population at risk of deficiency and toxicity effects according to oral Intake. As ETE intakes drop below A (lower limit of AROI where 2.5% of the population under consideration will be at risk of deficiency), an increasing proportion will be at risk of deficiency. At extremely low intakes all subjects will manifest deficiency. As ETE intakes exceed B (where 2.5% of the population under consideration will be at risk of toxicity), a progressively larger proportion of the population will be at risk of toxicity. From WHO/IPCS (2002) with permission.

for nutritional requirements and for expression of toxicity. For a specific adverse effect of deficiency, there are individuals in a population who display average sensitivity to developing symptoms. There are, as well, more sensitive individuals, that is, those who develop deficiency symptoms at somewhat higher intakes and, those with less sensitivity, that is, people who develop deficiency symptoms first when intakes are lower than the average. The same applies for a specific toxic effect. Some individuals develop symptoms from doses lower than those that cause symptoms in people of average sensitivity. In addition, some people have less than average sensitivity and require higher doses before they develop symptoms. In summary, neither the upper or lower boundaries of the AROI are absolute values below or above which adverse effects will occur. This situation can be shown as two bell-shaped curves describing the distribution of sensitivity to deficiency and toxicity (Figure 1 lower curves). In most cases, an interval between these two curves describes the acceptable range of oral intake (AROI) in which no adverse effects occur. If these conditions are, instead, shown with curves in cumulative forms, a U-shaped curve occurs, and the AROI appears at the bottom of the U, between points A and B in Figure 1.

2.1.1 Groups with Special Sensitivity/Resistance

2.1.1.1 Genetically Determined

The low limit of the AROI covers the requirement of most of the population, and the high limit should protect most people from toxic effects. Special population subgroups, such as those with Wilson's disease, may exhibit toxicity at relatively low intakes of copper, lower than AROI for normal persons. In contrast, some population subgroups may have requirements higher than the upper limit of acceptable range (e.g., zinc intake in subjects with acrodermatitis enteropathica). Further aspects on genetically determined variation in sensitivity are given by WHO (WHO, 1996; WHO/IPCS, 2002).

2.1.1.2 Nongenetically Determined

Many diseases are genetically determined, but this is not considered here if the disease is not known to involve a specific metabolic defect related to essential elements. In celiac disease, there is a deficient uptake of several nutrients including essential elements such as iron (Kushner, 1988) and zinc (Solomons *et al.*, 1976). In addition, gastrointestinal losses of trace elements can be increased because of diarrhea. If the disease is not well controlled by exclusion of gluten from the diet and/or the decreased uptake is not compensated by

an increased intake of these elements, iron and/or zinc deficiency may develop.

Increased urinary losses of zinc are observed in patients with alcoholic cirrhosis (Vallee *et al.*, 1957) and diabetes (Cunningham *et al.*, 1994).

It has been shown that iron deficiency gives rise to an increased uptake of manganese (Mena *et al.*, 1969). It can, therefore, be assumed that there would be an increased risk of manganese toxicity if persons with iron deficiency were exposed to high oral intakes of manganese.

Sensitivity to manifestations of zinc deficiency is known to be dependent on certain metabolic situations. When discussing effects of deficiency or toxicity of an essential element, it is, therefore, of fundamental importance to specify the background conditions of the group under consideration. Such conditions can be all determining for dose-response relationships. For example, at a certain low zinc intake (e.g., under conditions of total parenteral nutrition), clinical symptoms of zinc deficiency may not develop in a group of individuals who are in metabolic balance but may be clinically manifest in persons who undergo growth or who are in an anabolic phase (Kay *et al.*, 1976). Dose-response relationships for zinc deficiency thus can be quite different depending on metabolic state.

2.2 Other Concepts Used in Risk Assessment of Essential Metals

Terms and definitions used in this chapter are taken from IPCS Environmental Health Criteria 170, 210, and 228 (WHO/IPCS, 1994; 1999; 2002), "Trace Elements in Human Nutrition and Health" (WHO, 1996), (IOM, 1998), and (SCF 1993, 2000a,b,c). To avoid ambiguity and ensure scientific accuracy, these principles and definitions are often presented here as written in references with appropriate attribution

2.2.1 Toxicological Terms

IUPAC recommendations defining ADI (acceptable daily intake), TDI (tolerable daily intake), TWI (tolerable weekly intake), and toxicity were given in the Introduction. ADI is used for food additives and TDI for contaminants. Other terms of interest in relation to risk assessment of EMs are "reference dose" and "upper level of tolerable intake (UL). The US Environmental Protection Agency has replaced ADI and TDI with the single term, reference dose (RfD), which is defined as: "an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure for the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime." The term RfD is intended to avoid any implication that exposure to the chemical is completely "safe" or "acceptable," as may be implied by use of the term ADI (Barnes and Dourson, 1988). A basic assumption when using the terms ADI, TDI, and RfD in risk assessment is that zero exposure to the element of concern poses no health risk. For EMs, this is not an appropriate default position. For the upper intake level of the AROI (toxicity), the United States Food and Nutrition Board/Institute of Medicine (IOM, 1998) and the European Scientific Committee on Food (SCF, 2000a,b,c) have replaced the term TDI with "tolerable upper intake level (UL)."

2.2.2 Nutritional Terms: Definitions and Approaches Used to Assess Individual and Population Requirements for EMs

In developing AROIs, the term "population" does not refer to geographically or culturally defined groups or to groups with genetic abnormalities in the metabolism of EMs. Rather, the term population refers to a group that is homogeneous in terms of age, sex, and other characteristics that might affect nutrient requirements or alter toxicity (WHO/IPCS, 2002; WHO, 1996).

2.2.2.1 Factorial Estimation of Nutrient Requirement

The factorial approach calculates nutrient requirements by summarizing the minimum amounts of a nutrient needed to maintain growth and for maintenance of body stores at low intakes. Such intakes are usually sufficient for the prevention of clinical deficiencies in adults. These maintenance requirements are derived from the estimation of unavoidable losses in urine, sweat, hair, and so on. There are complex interrelationships between such losses, dietary intakes, nitrogen metabolism, and other interdependent nutrients. A lack of understanding of these interrelationships can lead to much uncertainty in the results of factorial methods. In general, they are used only as a first approximation for the assessment of individual requirements (WHO, 1996)

2.2.2.2 Requirements for the Individual

Requirement for the individual, as stated in WHO (1996), is the lowest continuing level of nutrient intake that, at a specified efficiency of utilization, will maintain the defined level of nutriture in the individual. The defined level of nutriture may be given as a basal requirement or a normative requirement or both. The level of intake needed to prevent pathologically relevant and clinically detectable signs of impaired function attributable to inadequacy of the nutrient is termed the basal requirement, whereas the normative

requirement refers to the level of intake that serves to maintain a level of tissue storage or other reserves that are judged to be desirable. Because intakes meeting the normative requirement provide for systemic stores, homeostatic adaptation resulting in mobilization of such stores when intakes are below the normative requirement would be considered evidence of "deficiency." Below the basal level, homeostatic adaptation is more likely to be inadequate, and metabolic and other disturbances would be expected.

2.2.2.3 Dietary Reference Intakes (DRI), Population Reference Intakes (PRI), Recommended Dietary Allowance (RDA), and Safe Range of Population Mean Intake (SRPMI)

Many different terms, definitions, and values are used by various countries and organizations in developing recommendations for dietary intakes of EMs. The recommended dietary allowances (RDA) developed by US National Research Council are set to maintain normal physiological functions from a nutritional point of view, and they have been widely used and discussed (IOM, 2001; Mertz *et al.*, 1994; SCF, 1993). Where adequate data are available, the dietary reference intakes (DRI) (IOM, 2006) will include, for a defined population, one or more of the following intake estimates: estimated average requirement (EAR); recommended dietary allowance (RDA); adequate intake (AI), and tolerable upper intake level (UL). The RDA and UL represent the boundaries of an AROI (see Section 2.1). The population reference intake (PRI) estimated in the European Union (SCF, 1993) is conceptually similar to the RDA, that is, the average requirement for a defined population plus 2 SD. The tolerable upper intake levels (UL) estimated by the IOM (1998) and the SCF (2000a,b,c) are conceptually the same and are based on the use of a risk assessment method similar to that discussed in Chapter 14. Although the terms DRI, AROI, PRI, and SRPMI used in North America, Europe, and within WHO have similarities, there are often subtle differences in their meaning and application. There is an urgent need to harmonize universally the terms and definitions used to describe recommended dietary intakes, including the upper level of intake based on toxicological data, and the methods used in nutrition and toxicological risk assessment.

Before 1996, most recommendations for the intake of EMs provided estimates that applied to individuals with the assumption that the average intake of a defined population plus 2 SDs would protect the majority (97.5%) of the individuals in the group. However, in estimating the "safe range of population mean intake" (SRPMI), WHO (1996) is concerned with population (group) mean intakes rather than intakes of individuals. The lower limit of the SRPMI is set so that very few (less than 3% of individuals in the defined population) would be expected to have intakes below their requirement. The upper limit of the SRPMI is set to protect most persons in the population from (minimal) adverse effects. The concept of SRPMI and the problems involved in its derivation are discussed fully in WHO (1996).

3 EFFECTS OF DEFICIENCY AND TOXICITY

3.1 Factors Affecting Dose-Response Relationships

The early literature on factors affecting dose response relationships of metals was reviewed by Nordberg (1976). A review by WHO (1996) highlights factors affecting nutrient dose-response relationships. Such alterations in dose-response will markedly affect the intake level of an EM at which signs of toxicity and deficiency will be observed.

3.1.1 Homeostatic Mechanisms

A defining characteristic of EMs is that there are homeostatic mechanisms that maintain optimum tissue levels over a wide range of intakes. Homeostatic mechanisms involve regulation of absorption, tissue retention, and excretion. There are specific homeostatic mechanisms for each EM that may vary in efficiency within individuals of defined populations (WHO, 1996; WHO/IPCS, 2002). For EMs handled as cations (zinc, iron, copper, manganese, and chromium) homeostatic mechanisms operate largely via gastrointestinal absorption and the liver, whereas the more soluble anionic EMs (molybdenum and selenium) are absorbed rather efficiently and total body burden regulated by alterations in oxidative state, level of methylation, and renal excretion. A third category of homeostatic mechanism is illustrated by cobalt. It is a highly reactive element with several oxidative states and can effectively compete with other cationic EMs. Such interactions are avoided, because the physiologically active form is the highly regulated bio-inorganic complex cobalamin. There is no evidence that humans require inorganic cobalt.

3.1.2 Bioavailability, Speciation, and Interactions

One important aspect determining both the likelihoods of deficiency symptoms and toxic manifestations is the bioavailability of the essential element in question. Variation in uptake and use of EMs varies, depending on chemical form, salt or ionic form, food source or dietary matrices, age, gender, interactions with other

nutrients, and nutritional state. Of these factors, nutritional status is most critical. It influences adaptive processes or biokinetics in response to deficiency or excess and needs to be taken into account when developing an AROI (WHO/IPCS, 2002). These aspects are discussed in detail elsewhere (Mertz *et al.*, 1994; Nordberg and Skerfving, 1993; WHO, 1996; WHO/IPCS, 2002).

Another aspect of fundamental importance is the chemical species of the EM ingested. Variations in solubility between chemical species of an EM may markedly alter its solubility and thus its bioavailability, in many cases altering the risks from deficient or excess intakes. Examples of EMs where speciation plays an important role in determining bioavailability and use are iron (ferrous/ferric), copper, and selenium (WHO, 1996; WHO/IPCS, 1998; 2002).

In addition to bioavailability and speciation, interactions between EMs and interactions between EMs and nonessential metals need to be considered during the development of an AROI. These interactions have been summarized by WHO (1996), and only a few examples are given here. There is a competitive interaction for absorption between copper and zinc (WHO/IPCS, 1998; 2001a). Also, copper can interact with a number of other nutrients (e.g., molybdenum, manganese, selenium, and iron), leading to a decreased copper availability. With regard to zinc toxicity, groups with a high dietary copper intake may not develop adverse effects of high zinc intakes to the same extent as persons with low dietary copper intake. The critical effects of zinc toxicity are considered to be related to induced copper deficiency (WHO/IPCS, 2001a).

3.2 Basic Principles for Classifying Effect

Evaluation principles concerning adverse effects from metal toxicity have been previously developed by the ICOH Scientific Committee on the Toxicology of Metals—Task Group on Metal Toxicity 1976 (Nordberg, 1976; 1992; Nordberg *et al.*, 2000) and Chapter 14 in this Handbook). Adverse effects can occur from too low or too high an intake of an EM. As mentioned (see Section 2), it may not be possible to arrive at recommendations that protect *all* individuals in a population from such adverse effects, because some individuals with genetically determined metabolic disorders may require intakes that are higher or lower than those that represent AROI for normal persons in a defined population (cf Section 4 and Chapter 7). AROI can, therefore, only be applicable for persons without such disorders. It is further considered that the use of sensitive indicators of adverse effects with limited functional significance as markers of critical effect will provide further safety from more severe clinical disease caused by deficiency or toxicity. Based on present knowledge, it seems possible in most cases to define an AROI for the essential elements that will protect 95–98% of the population from adverse effects (i.e., the protective level at each end of the U-shaped curve would be 97.5–99%) (cf Nordberg *et al.*, 2000, WHO/IPCS, 2002).

These considerations are based on the assumption that adverse effects from deficiency or toxicity follow an S-shaped (or Z-shaped for deficiency) dose-response curve. As mentioned, such curves represent the cumulative conversion of a Gaussian distribution (or other defined distribution) of individual thresholds of effect in a population. Such effects, which occur when a threshold concentration is exceeded in a specific tissue of an individual, are termed *deterministic effects*. Many adverse effects, which result from for example enzyme inhibition and similar biochemical mechanisms, are considered to be of this nature.

In Figure 2 (right hand side), theoretical examples of dose-response curves for a metallic compound are illustrated. Effects of increasing severity occur when the daily oral intake increases above a certain level (curves 5–8). Slight changes in biochemical markers that have been shown in epidemiological studies to be without functional or clinical significance (curve 5) are of limited importance in relation to public health. Subclinical markers of effects that are related to functional deficits or that signal the development of clinical disease are more relevant to public health, and such markers are often crucial for preventive action. These effects and their dose-response curves can be regarded as critical pieces of information when discussing preventive measures such as exposure limits and recommendations of safe intakes. Such effects are termed *critical effects* (for further discussion of the "critical effect" concept see Chapter 14). Sometimes subclinical biomarkers of effects have not been identified, and the clinical effect that occurs at the lowest dose must be used as the critical effect.

These evaluation principles focusing on the critical effect (i.e., the adverse effect that occurs at relatively low exposures and which implies some kind of clinical or functional impairment) have been adopted by several international bodies and has been used by WHO/IPCS (1994) and WHO/IPCS (2001b).

In toxicological cancer research and in radiation biology, considerable research efforts have been devoted to characterizing another type of effects, so called *stochastic effects*, which are considered to occur as a result of a random process of interaction between the agent and DNA in the cell nucleus. Cancer induction is considered to be such a stochastic effect. For such effects it has been assumed that the dose-response curve has

a linear component in the low-dose range, and for safety reasons it has been the policy in some situations to set very low acceptable exposures, because only extremely low risks have been considered as acceptable for cancer from environmental pollution with chemical substances. Because carcinogenic effects of this stochastic nature are unlikely to appear as a result of exposure to essential metals, except in persons with specific genetically determined susceptibility (cf Chapter 30), stochastic effects of essential EMs will not be discussed in this chapter.

3.3 Examples of Effects of Varying Severity

In the following text, examples of effects of deficiency and of toxicity are given, explaining the various theoretical curves in Figure 2.

3.3.1 Lethal Deficiency

Severe deficiency sometimes with lethal outcome may result from situations in which individuals are completely devoid of the nutritional element in question. Severe iron deficiency when combined with otherwise benign conditions may lead to severe anemia with lethal outcome in rare cases (Solomons *et al.*, 1976). In China, Keshan disease, with myocardial abnormalities and sometimes death, may occur as a result of selenium deficiency, possibly in combination with viral disease (Chen *et al.*, 1980; Keshan Disease Group, 1979). Lethal outcomes in deficiency cases are often related to some interacting agent or intercurrent disease and can then be considered as deficiency in a sensitive subgroup of the population.

3.3.2 Deficiency—Clinical Disease

Iron deficiency with clinically observable anemia with pallor and fatigue is still not uncommon among women in child-bearing age (Frey, 1995). Psychomotor development has been shown to be impaired in children whose mothers were iron deficient during pregnancy (Walter, 1989).

Clinical deficiency as a result of copper deficiency is more rare, but anemia unresponsive to iron therapy sometimes can be ascribed to copper deficiency (Pettersson and Sandstrom, 1995; Sandstead, 1993). Growth failure, poor immunity, impaired wound healing, and impairment of special senses and cognition are clinical signs of zinc deficiency (Sandstead, 1993; WHO/IPCS, 2001a; Chapter 47). Selenium deficiency has been shown to be related to an endemic disease in China with cardiomyopathy and sometimes changes in the thyroid called Keshan disease, and also to Kashin Beck disease, a joint and muscle disease occurring in the same area (Alexander and Meltzer, 1995). Muscular symptoms have been reported in patients on total parenteral nutrition (WHO, 1996).

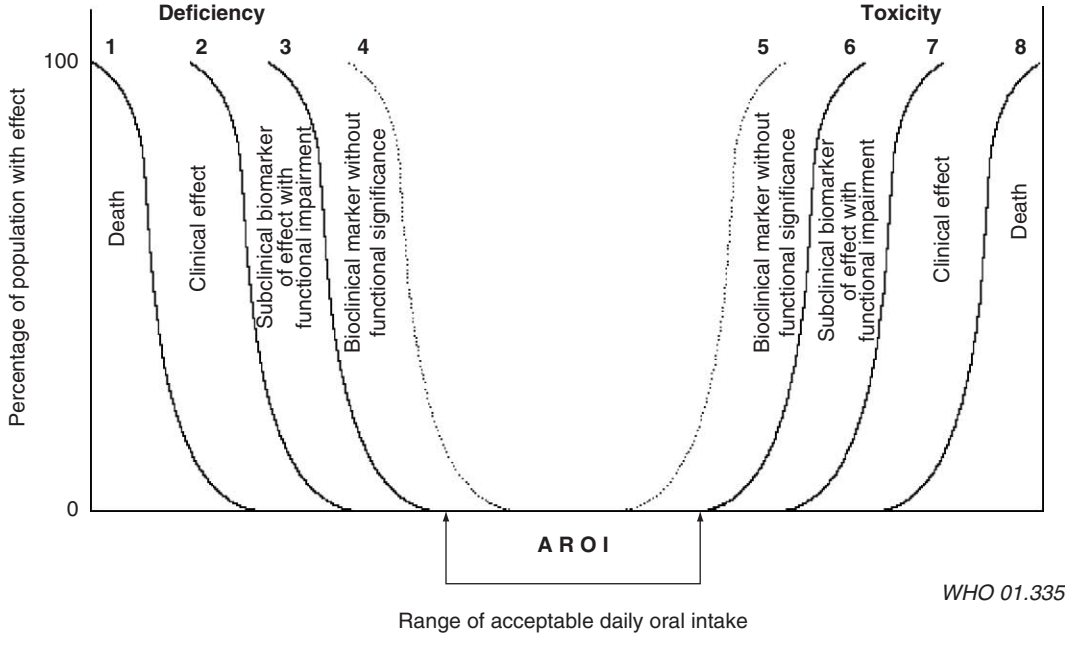

FIGURE 2 Theoretical dose-response curves for various effects occurring in a population at various levels of intake (doses) of an ETE. The lower end of the dose-response curve for such critical effects related to deficiency (curve 3) and toxicity (curve 6) defines the range of acceptable daily oral intakes. From WHO/IPCS (2002) with permission.

3.3.3 Subclinical Biomarkers of Deficiency with or without Clinical Significance

A number of markers related to decrease in enzyme levels have been shown to occur in persons with low intakes of some essential metals. In some cases, such an influence on enzyme levels is believed to be of functional significance and may even be a precursor of clinical disease. In other cases, a slight decrease in an enzyme level may be tolerated without any functional significance, namely, if there is a great surplus of this enzyme in the medium in which it is measured.

An example of such a subclinical marker of deficiency is the saturation of glutathione peroxidase (GSHPx) in plasma, erythrocytes, and platelets that is impaired when selenium intakes are low. Incomplete GSHPx saturation in plasma does not occur until Se intakes fall below approximately 40 μg/day (Yang *et al.*, 1989a,b). For saturation of GSHPx in erythrocytes higher intakes are required, and for saturation in platelets more than 100 μg/day is required (Whanger *et al.*, 1988). The clinical or health importance of such incomplete GSHPx saturation is debated, particularly in the most sensitive compartment (i.e., platelets).

For some essential metals (e.g., zinc) specific and sensitive biochemical indicators of deficiency are lacking. In absence of such indicators, the estimates of requirements have to be evaluated by a factorial technique (i.e., by adding together the requirements for tissue growth, metabolism, and endogenous losses). It is notable that the activity of zinc-dependent processes and plasma and tissue zinc concentrations can be maintained over long periods of time at low intakes by substantial reductions in endogenous losses of zinc. This adaptive ability was taken into account by WHO (1996) for estimates of the physiological requirement of absorbed zinc using data from long-term balance studies at very low intakes (Baer and King, 1984; Hess *et al.*, 1977). At the basal requirement level, the ability to increase the efficiency of zinc retention has been fully exploited. Observations made during the early phase of the same studies of zinc depletion were used to estimate the normative physiological requirement. For adult males, an uptake of 1.4 mg/day was judged to maintain zinc equilibrium without the need of adaptive changes in endogenous losses. With 30% fractional uptake from the diet, this corresponds to a daily normative dietary requirement of 4.7 mg/day. Lacking corresponding long-term studies in other age groups, endogenous losses in relation to basal metabolic rates were used as the basis for extrapolation.

A reduction of maximal oxygen consumption has been demonstrated in physical performance tests in young women with low serum-ferritin concentrations without anemia, suggesting effects on tissue level unrelated to oxygen-transport capacity (Zhu and Haas, 1997).

Another example is a decrease in ceruloplasmin levels in low copper intakes and decreased erythrocyte superoxide dismutase (ESOD) when copper intakes are low (WHO/IPCS, 1998). Although these changes are considered useful indicators of decreased biological copper activity, their clinical significance has not been well defined.

When iron intakes are low, serum ferritin levels decrease, and transferring saturation and increased erythrocyte protoporphyrin are decreased. Although these indicators are excellent indicators of low body iron stores, slight decreases in iron stores are of debatable clinical significance.

3.3.4 Lethal Toxic Effects

Excessive doses of soluble salts of iron or copper by the oral route that may be ingested by accident or with suicidal intent give rise to extensive and severe gastrointestinal manifestations, systemic toxicity, shock, and death (Borch-Johnsen and Petersson-Grawé, 1995; WHO, 1998).

3.3.5 Toxic Effects with Clinical Significance

Clinical disease (without fatal outcome) may occur as a result of ingestion of high doses of soluble selenium salts. Such poisoning cases display nausea, vomiting, and subsequently hair and nail changes and skin lesions (Alexander, 1993; Chapter 38). Persons ingesting large doses of copper may develop hematuria and jaundice in addition to vomiting, nausea, and diarrhea (WHO/IPCS, 1998; Chapter 26). Also ingestion of soluble iron salts may give rise to gastrointestinal manifestations with vomiting and diarrhea often with bloody stools, and later cirrhosis may occur (Borch-Johnsen and Peterson-Grawé, 1995; Chapter 30).

3.3.6 Subclinical Toxic Effects with or without Functional Significance—Biomarkers of Critical Effect

Like the situation with biochemical markers of deficiency, subclinical markers of toxicity have been identified in the form of changes in enzyme levels. To use such a biomarker as a critical effect, it is of great importance to be able to determine the extent to which increased levels of such biomarkers in media easily accessible for analysis (blood, urine, hair) signals a subclinical stage of a disease or abnormality in organ function. Unfortunately, for several potentially useful markers, there is a lack of such information, and further definition of the clinical and functional

significance of biomarkers is needed. ESOD levels may occur as a result of excessive zinc intakes. Most probably, this is a result of interference by zinc with uptake of copper, and the balance between zinc and copper is of fundamental importance for the expression of this effect (WHO/IPCS, 1998). For excessive iron intakes, excessive transferrin saturation and excessive levels of serum ferritin can be used as markers of iron overload (Borch-Johnsen and Peterson-Grawé, 1995; Chapter 30). The clinical significance of marginally increased iron overload is still under discussion. Large excesses like those occurring in persons with hemochromatosis are clearly of clinical importance. Homozygotes for hemochromatosis are at several hundred fold increased risk of liver cancer and an increased risk of coronary heart disease (Bradbear *et al.*, 1985; Niederau *et al.*, 1985; Chapter 30). Moderate levels of iron overload may also be related to increased risks for carcinogenicity in several organs, including the liver, but such effects are not well documented. A relatively large proportion of the population is heterozygotic for the hemochromatosis gene and potentially at risk for iron overload.

High selenium intakes may give rise to prolonged plasma prothrombin time and increased ALAT (see also Chapter 38).

TABLE 2 Principles Underlying Use of the Homeostatic Model in Human Health Risk Assessment of EMs (From WHO/IPCS 2002 with Permission.)

- Homeostatic mechanisms should be identified for the selected ETE.
- Variations of the population's homeostatic adaptation must be considered.
- There is a "zone of safe and adequate exposure for each defined age and gender groups" for all EMs – a zone compatible with good health. This is the acceptable range of oral intake (AROI).
- All appropriate scientific disciplines must be involved in developing an AROI.
- Data on toxicity and deficiency should receive equal critical evaluation.
- Bioavailability should be considered in assessing the effects of deficiency and toxicity.
- Nutrient interactions should be considered when known.
- Chemical species and the route and duration of exposure should be fully described.
- Biological end-points used to define the lower (RDA) and upper (toxic) boundaries of the AROI should ideally have similar degrees of functional significance. This is particularly relevant where there is a potentially narrow AROI as a result of one end-point being of negligible clinical significance.
- All appropriate data should be used to determine the dose–response curve for establishing the boundaries of the AROI.

4 SUMMARY OF PRINCIPLES FOR HUMAN RISK ASSESSMENT OF EXPOSURES TO EMs

WHO (WHO/IPCS, 2002) developed a set of principles for the use of the "homeostatic model" in the assessment of human health risks from exposure to essential trace nutrients. These are presented, with permission, in Table 2. Many of these principles were examined at a workshop in 1992 (Mertz, 1993; Mertz *et al.*, 1994) and have been discussed briefly elsewhere in this chapter or in the references provided.

It is beyond the scope of this chapter to discuss in detail the known physiological adaptation to changing levels of intake of EMs and the variables affecting this adaptation. However, as noted by WHO (WHO, 1996; WHO/IPCS, 2002), this will play an important role in the risk assessment of essential trace nutrients, including EMs.

4.1 Application of Principles for Determination of AROI

A proposed scheme for the application of the principles in Table 2 for the determination of an AROI has been presented by WHO (WHO/IPCS, 2002). This scheme is reproduced with permission in Figure 3.

The scheme in Figure 3 should not be considered a new paradigm for assessing human health risks from exposure to EMs. In fact, the steps shown are essentially the same as those shown for the risk assessment of metals in general (see Chapter 14). One major difference is the need to apply each step to data related to essentiality and toxicity for the EM. This requires a multidisciplinary team of scientists, applying the principles in Table 2, and using a weight of evidence approach, applying sound scientific judgement at each step. The entire scheme is an iterative process.

In step 6, risk characterization, data on exposure and the AROI are integrated. This process takes into consideration the variability in exposure and dose-response for multiple subpopulations, evaluating the strengths and weaknesses of the evaluations at each step (WHO/IPCS, 1999). Transparency during each step is important but particularly so during the risk characterization. It is essential to ensure scientific conclusions are identified separately from policy judgments. Also, the use of default values or methods during the risk assessment must be clearly identified and discussed (WHO/IPCS, 2002). Based on the wide-ranging expertise of groups carrying out risk assessments of EMs, an important role of risk characterization is the identification of research

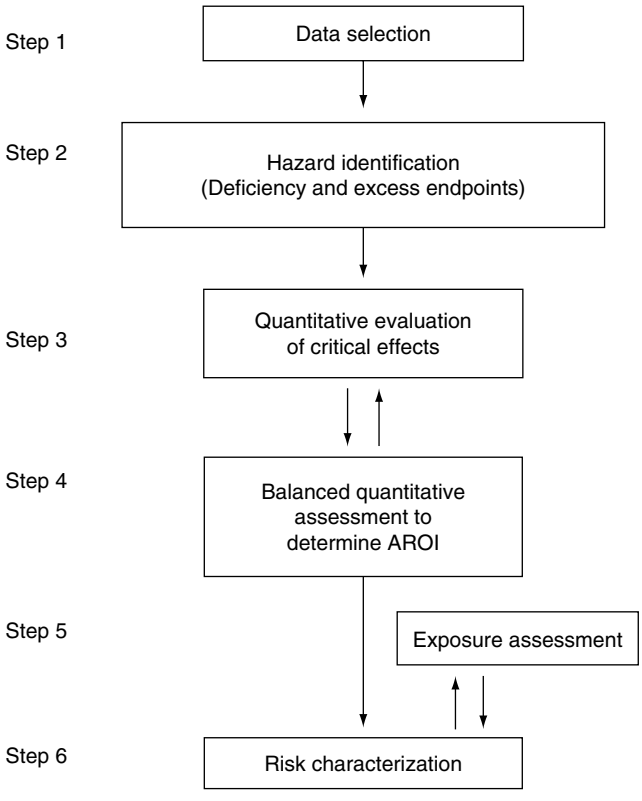

FIGURE 3 Application of the principles for the assessment of risk from essential trace elements. From WHO/IPCS (2002) with permission

needs that could lessen the uncertainty of any recommendation for an AROI.

With appropriate consideration of physiological adaptation during the application of the scientific principles in Table 2, and following the steps outlined in Figure 3, it should be possible to develop a range of intakes that meet nutritional requirements and identify intakes associated with toxicity in specific age-gender groups that do not overlap. However, as with any recommendation based on the evaluation of scientific data, the AROI should not be considered a static number over time. As new data on exposure, mechanism of action, and toxic effects of an EM become available, there needs to be national and, hopefully, international mechanisms developed to review the new data in a timely manner and, if necessary, to update the AROI.

5 ESTIMATION OF AROI

The overall goal in developing an AROI for an EM, or a SRPMI, is to make recommendations on a range of intakes necessary to maintain adequate nutrition in healthy members of a defined population while preventing signs of toxicity and avoiding conflicts between these two intake values. Such conflicts have occurred previously (e.g., zinc), largely the result of scientists evaluating the toxic risks from EMs in isolation from those developing the recommended nutritive requirement without consideration of the human requirements and, as discussed in Section 3 of this chapter, using biological markers of toxicity with markedly different biological significance than those used for the assessment of deficiency in humans (Mertz *et al.*, 1994).

When developed by a multidisciplinary group of experts using the principles and methods summarized in Section 4 of this chapter, an AROI or SRPMI affords an equal level of protection against deficiency and toxicity. Generally, an AROI and a SRPMI afford protection of 97–98% to the members of a defined population, that is, 2 SD from the mean of the distributions for nutritional requirements and risks of toxicity (IOM, 2001; WHO, 1996; WHO/IPCS, 2002). Although the AROI and SRPMI are based on different concepts, the scientific method used to evaluate the data on nutrition and toxicity is very similar, if not identical (WHO, 1996; WHO/IPCS, 2002). Also, the method used by the European Commission SCF to derive PRIs and UL (equivalent to an AROI) is that suggested in this chapter (SCF, 1993; 2000a). All groups have used a weight of evidence approach, whereby the full data base on nutritional requirements and toxicity of any EM is evaluated to identify possible hazards to human health. A critical step in this method is the balancing of endpoints for deficiency and toxicity to ensure the chosen biomarkers have comparable health significance (Section 3 of this chapter). Choosing as a critical effect the inhibition by an EM of an enzyme without known clinical significance with respect to deficiency and/or toxicity should be avoided.

In developing the UL for EMs, both the European Union Scientific Committee on Food (SCF, 2000a) and the US Institute of Medicine/Food & Nutrition Board (IOM, 1998; 2001) followed the principles and method described in this chapter and in WHO/IPCS (2002), that is, the generic risk assessment model having a long history of use for the assessment of chemicals in food. The model assumes nutrients, including EMs, work through threshold mechanisms, where no adverse health effects are assumed to occur below the threshold dose (intake). In deriving an UL, a NOAEL (considered an approximation for the threshold dose) or LOAEL is identified and modified by use of UFs to take into account the uncertainty within the data. Although the BMD method uses the complete dose-response curve, rather than the point estimate of the NOAEL, and considers the variation in response within the studied population, its use in deriving ULs for nutrients is very limited. As discussed in the report from the FAO/WHO Consultation (FAO/WHO, 2006), the data on the adverse effects of high intakes of

nutrients are usually not suitable for the derivation of a BMD. The mathematical modeling used in the derivation of a BMD requires high-quality studies with multiple intakes showing graded responses at different levels of intake. Such studies on EMs in humans are usually not available. Even animal studies that might be useful in deriving the UL provide limited dose-response data. Therefore, the UL for the AROI of EMs is presently based on the use of NOAEL or LOAELs and the application of appropriate UFs based on expert scientific judgement (FAO/WHO, 2006; IOM, 1998; SCF, 2000a; WHO/IPCS, 2002). This risk assessment approach is necessitated by the quality of data now available. However, it is strongly recommended that research efforts be intensified to generate data on the toxicity of EMs that would permit the application of the BMD model. As pointed out by WHO/IPCS (2002), this approach provides a more precise estimation of the UL, because it analyzes the complete dose-response curve, including the confidence interval around the central estimate. Although the NOAEL/UF approach is a very useful risk assessment tool, where adequate dose-response data are available, the BMD model can decrease the level of uncertainty in risk evaluations and is thus a preferable approach for dose-response evaluation (WHO/IPCS, 2002). The BMD approach for risk assessment of metals is discussed in Chapter 14.

Although neither the USIOM/FNB nor the EU/SCF used the term AROI, the recommendations for RDAs, AI, and PRIs, when combined with the recommended UL, is equivalent to the AROI described in Section 2 of this chapter. The method described by each of these organizations follows the principles and steps described in Section 4 of this chapter.

The derivation of a SRPMI (WHO, 1996) used many of the steps described in this chapter, particularly the use of a weight of evidence approach. It can be considered similar to an AROI but based on observations of the distributions of population mean intakes and their distribution. The difference in percentage of a particular population at risk from the choice of the SRPMI compared with an AROI will be affected by the slope (shape) of the relevant intake distributions and the slope of the risk of toxicity or deficiency curves. Theoretically, if the same criteria for safety are used for both the SRPMI and the AROI, the SRPMI will cover a narrower range of intakes; however, this difference may be very small in practice as indicated in Table 3.

A summary of recommended intake ranges (considered here as AROIs) by the EU/SCF, USIOM/FNB, and WHO for five EMs in adult men is shown in Table 3. In comparing these ranges it must be remembered that the recommended intake for nutrition (RDA, AI, PRI) represents the amount from dietary sources only, whereas the UL and PMTDI represent the oral intake from all sources (food, water, and supplements) (IOM, 2001; SCF, 1993). The SRPMI represents dietary intakes only. However, when developing specific SRPMIs, it was realized water and supplements might provide added exposure that might result in toxicity. In those cases, the upper boundary of the SRPMI was adjusted to reflect such exposures (WHO, 1996). Although values are given for adult men only, all three organizations developed recommendations for intakes by other defined populations.

An examination of the intake ranges (considered as AROIs) for any one of the five EMs in Table 3 indicates they are very similar, with a few significant

TABLE 3 Comparison of Intake Recommendations for Five Essential Metals in Adult Males from Europe[a], North America[b] and WHO[c]

Essential Metal	SCF		IOM		WHO
	PRI	UL	RDA	UL	SRPMI
Copper (mg/day)	1.1	5	0.9	10	1.3–12
Iron (mg/day)	9	ND	8	45	ND (see note[d])
Manganese (mg/day)	1–10 (a safe & acceptable range)	ND	2.3 (an AI)	11	ND
Selenium (ug/day)	55	300	55	400	40–400
Zinc (mg/day) (moderately available)	9.5	25	11	40	9.4–45

[a] European Union Scientific Committee on Food [PRIs (SCF, 1993); manganese (SCF 2000b); selenium (SFC 2000c); copper (SCF 2003a); zinc (SCF 2003b)].
[b] United States Institute of Medicine/Food & Nutrition Board [selenium (IOM, 2000); copper, manganese & zinc (IOM 2001); DRI summaries (IOM 2006)]
[c] World Health Organization (WHO 1996)
[d] FAO/WHO recommended a requirement of 9 mg Fe/day for an adult male (WHO/FAO 2002) and WHO (1983) calculated a PMTDI of 48 mg Fe/day (0.8 mg/kg bw). The range 9 to 48 can be considered as an AROI for iron in adult males.
AI = Adequate Intake
ND = Not determined

differences that need to be examined. It is hoped this analysis will lead to further refinement of the method for EMs discussed in this chapter. The fact that a few significant differences in recommendations occurred is not surprising given the fact they resulted from the deliberations of five different groups of experts meeting over a span of 20 years.

For copper, the SRPMI (WHO, 1996), PRI (SCF, 1993), and RDA (IOM, 2001) were not markedly different. The variation in recommendations arises from the fact that the SRPMI and the PRI were based on normative and average requirement of 0.8 mg/day and a CV in intakes of 20%. The RDA of 0.9 mg/day was derived from an EAR of 0.7 mg/day assuming a CV of 15%. This evaluation was made on the basis of additional well-controlled deletion/repletion studies not available to WHO and the SCF experts. The most significant difference in the AROIs for copper is the UL recommended. The upper boundary of the SRPMI of 12 mg copper/day was derived from an analysis of the database on adverse effects of copper in food, where no effects were seen at intakes of around 10 mg/day. The SCF (2003a) and the IOM/FNB (IOM, 2001) both considered potential liver damage as the critical effect and evaluated the same small double-blind study in humans given 10 mg copper/day as a soluble supplement. No adverse effects on liver function were reported. In the professional judgement of the SCF, an UF of 2 was required to take into account potential variability of response within the normal population. The IOM/FNB concluded an UF of 1 was adequate, given the large international database indicating a lack of adverse effects in humans consuming 10–12 mg/day of copper in foods and the rarity of observed liver damage from copper exposures in human populations with normal copper homeostasis.

Iron is an example of an EM in which the intakes within the general population are skewed by the requirements for growth in children and adolescents, as well as the losses in females through menstruation. Also, the bioavailability of the iron consumed will markedly affect the determination of the AROI boundaries. Taking these facts into account, very similar lower boundaries of the AROI were recommended by SCF (SCF, 1993), WHO (FAO/WHO, 2002), and the IOM/FNB (IOM, 2001). All determined the basal losses and modeled the components of iron requirements to determine an average requirement. Based on a CV in losses of 15% and assuming 15% as the upper limit of iron absorption, both WHO and the SCF recommended 9 mg iron/day as the lower boundary of the AROI. The value of 8 mg/day, derived by the IOM/FNB results from the assumption of 18% as the upper limit of iron absorption. The UL of 48 mg/day recommended by WHO in 1983 was derived by the examination of data on the gastrointestinal effects from consumption of soluble iron supplements by humans, whereas the UL of 45 mg iron/day recommended by the IOM/FNB in 2001 was based on the determination of a LOAEL for gastrointestinal distress of 70 mg iron/day (60 mg as iron fumarate) in a controlled double-blind study and applying an UF of 1.5 to account for extrapolation from a LOAEL to a NOAEL.

Manganese is an example of an EM in which there are limited data of sufficient quality to support the development of an AROI. As shown in Table 3, WHO concluded that data on manganese requirements and toxicity were not sufficient to set a SRPMI, and the SCF (1993) concluded it was preferable to give a safe and acceptable range of intakes rather than a definitive AROI. Given the limitations of the human data and the fact that NOAELs are lacking for critical toxic endpoints in animal studies (particularly neurotoxicity after oral intake), the SCF (2000b) concluded it was not possible to set a UL of intake for manganese. The IOM/FNB concluded that balance studies for manganese were inadequate to set an EAR and thus a RDA. The mean intake of manganese in adult men within the United States is 2.1–2.3 mg/day (IOM, 2001). Because symptoms of manganese deficiency are not found in this population, the recommendation of an AI of 2.3 mg manganese/day was appropriate at this time. The UL of 11 mg/day was set on the basis of no adverse effects found in humans consuming Western-style diets containing up to 11 mg manganese/day and supported by a LOAEL of 15 mg/day reported from a study in humans where significant increases in serum manganese were found after 25 days of supplementation. A UF of 1 applied to the NOAEL was considered appropriate.

As shown in Table 3, the AROIs for selenium derived by the three organizations are very similar. All three groups considered the enzyme plasma glutathione peroxidase as an appropriate indicator of minimal selenium deficiency and for toxicity, the threshold where biochemical disturbances in selenium metabolism were seen in humans (850 µg/day). The differences shown can be explained by different scientific judgments made with regard to whether maximal peroxidase activity was the most appropriate indicator of nutrient need and the level of uncertainty in the epidemiological data that indicated a threshold of toxicity at intakes of 850 µg selenium/day. The lower boundary of the AROI recommended by WHO was 40 µg selenium/day based on the intake required to provide two thirds of the maximum glutathione peroxidase activity and a 16% interindividual variation in selenium intakes. However, experts advising SCF (2000c) and the IOM (2000) considered it more

appropriate to recommend intakes of selenium that resulted in maximum peroxidase activity, namely 55 μg/day. The differences noted in the UL were a result of applying an UF of 2 to the threshold for selenosis by WHO (1996) and the IOM/FNB (2000), whereas the SCF (2000c) thought an UF of 3 was more appropriate.

As for iron, the bioavailability of dietary and supplemental zinc must be considered in deriving an AROI. The values in Table 3 are the intakes for adult men consuming a diet in which zinc was moderately available (defined by WHO [1996] as 30–35%). All three groups used factorial modeling to determine the minimal quantity of absorbed zinc required to replace endogenous losses. The lower boundary of the SRPMI was based on a CV of intakes of 25%, and the IOM assumed a 10% CV in requirements to calculate the RDA from the EAR of 9.4 mg zinc/day. The upper boundary of the AROIs in Table 3 indicate a marked difference between the ULs derived by WHO and the IOM/FNB and that recommended by the SCF. The three ULs for zinc are based on the intake of zinc that affects relevant indicators of copper status as the critical effect. In all studies evaluated, humans were given extremely soluble (highly bioavailable) zinc supplements while consuming diets containing approximately 10 mg of zinc. The IOM/FNB used a study in which 50 mg of supplemental zinc was provided to humans for 10 weeks. Decreased activity of ESOD was noted at this total intake of 60 mg zinc/day. A UF of 1.5 was considered adequate to account for interindividual variability in response and the fact that a LOAEL was used. The SCF (2003b) evaluated four studies in humans in which several relevant indicators of copper status were measured after zinc supplementation. No adverse effects were observed at total zinc intakes between 40 and 53 mg/day for 90 days. An intake of 50 mg zinc/day was considered a NOAEL, and an UF of 2 was applied because of the small number of subjects in relatively short-term studies. The recommended UL of 25 mg total zinc/day raises an important point mentioned earlier, namely, recommending intakes without full consideration of nutritional needs, or as in this case, the fact that thousands of humans worldwide have daily intakes of zinc well above the recommended UL without any signs of adverse health effects. It was mentioned (SCF, 2003b) that the 97.5 percentile of total zinc intakes of all age groups are close to the UL. However, it should be noted that the 95th percentile intake of total zinc of adult men in the United States is 30.5 mg/day, pregnant women 39.7 mg/day, and lactating women 46.7 mg/day (IOM, 2001).

6 CONCLUSIONS

From this review, we recommend the following:

1. A set of principles and methods for the assessment of risks from essential metals.
2. The use of these principles and methods for the development of AROIs for EMs and other nutrients be expanded globally whenever such risk assessments are carried out.
3. Nutritional and toxicological information should be considered in a balanced approach on the basis of adequate human data.
4. Speciation, bioavailability, and homeostatic mechanisms should be taken into account.
5. Critical effects of deficiency and toxicity should have similar clinical significance.
6. During the risk assessment process for EMs, greater emphasis should be given to the risk characterization step to increase the transparency of the process and to provide guidance to those using the evaluations of the strengths and weaknesses of each step in the process.
7. An acceptable range of oral (individual) intakes (AROI) and a safe range of population mean intakes (SRPMI) can be defined if adequate data are available.

CHAPTER

10

Carcinogenicity of Metal Compounds

QINGDONG KE, MAX COSTA, AND GEORGE KAZANTZIS

ABSTRACT

Epidemiological studies have demonstrated that nickel, chromium, arsenic, cadmium, and beryllium compounds are human carcinogens. Most of these epidemiological studies were retrospective in humans occupationally exposed to compounds of these metals. There are few environmental studies in humans exposed to any of these metal compounds, when possible speciation of the metal compound is considered in the epidemiological studies. Of compounds of the five metals, those of nickel, chromium, cadmium, and beryllium have been confirmed as carcinogens in experimental animals, although there was recent evidence in the case of arsenic. However, it should be noted that in many cases animal bioassays were conducted with exposure routes that were not relevant to human exposure such as intramuscular injection of insoluble metal compounds. The genotoxicity and mutagenic activity of metals is also discussed briefly; however, the reader is referred to more detail in chapters on individual metals and to the chapter on the mechanisms of metal toxicity and carcinogenicity. Cell transformation in tissue culture and other mechanistic information for each metal ion is included in summary style.

1 PRINCIPAL METALS SHOWING CARCINOGENIC EFFECTS

Exposure to compounds of five metals has been shown in epidemiological studies to correlate with increased incidences of cancer in humans. These metals are nickel, chromium, arsenic, cadmium, and beryllium. However, adequate epidemiological studies, and in particular prospective studies, have not been performed with other metals; at present, there is a great lack of human data. Most of the available epidemiological data have been retrospectively obtained on occupationally exposed groups. Of the five metals, compounds of nickel, chromium, cadmium, and beryllium have been confirmed as carcinogens in experimental animals; there was recent evidence in the case of the metalloid arsenic (Burns *et al.*, 2004; Rossman *et al.*, 2004; Uddin *et al.*, 2005). Some compounds of cadmium and beryllium have been shown to have an unequivocal carcinogenic effect in animals, although the exposure situations have not been comparable to humans. In addition to the preceding, certain compounds of cobalt, iron, lead, manganese, platinum, titanium, and zinc have produced tumors in experimental animals, but the doses used and modes of administration have been different from any known human exposure situation. In further consideration of these 12 metals, their speciation should be kept in mind. A number of compounds of nickel are carcinogenic in animal bioassay, but with manganese and titanium only one organic compound of each has been shown to have such a potential. Currently, there is inadequate evidence with regard to a metal itself as carcinogenic; only a limited number of compounds have been shown to give rise to tumors in an experimental situation. It should further be noted that in both the general and occupational environment, exposure situations are complex, giving opportunity for enhancement or inhibition of a carcinogenic effect by interactions among metals and between metals and organic compounds (Nordberg and Andersen, 1981). Those metals for which there is some epidemiological evidence for a

carcinogenic effect in humans are considered first, followed by those for which there is evidence of such an effect only in animal bioassay. Brief reference is made to their genotoxic effects only when this seems to be relevant to a consideration of carcinogenicity. Reference is also made to the property of these metals to transform cultured mammalian cells *in vitro* and to affect the fidelity of DNA synthesis in a cell-free system.

1.1 Nickel

1.1.1 Epidemiological Observations

A highly significant excess of both lung cancer and cancer of the nasal sinuses has been found in nickel-refinery workers in several countries (Doll, 1958; Mastromatteo, 1967; Morgan, 1958; Pedersen *et al.*, 1973). In the Mond Nickel Works in South Wales, where exposure to nickel carbonyl gas had occurred in the past, Doll *et al.* (1970) estimated the excess mortality from lung cancer at 10 times the incidence expected for men first employed before 1914, and at about five times that expected for those first employed between 1915 and 1924 (Doll *et al.*, 1970). For nasal cancer, those first employed between 1910 and 1914 experienced an almost 900-fold increase; at the same time as in those first employed between 1920 and 1924, the mortality was almost 100 times the national average (Doll *et al.*, 1970). Observations by Doll *et al.* (1977) showed that the risk to the refinery workers continued until 1930, after which time major changes occurred in the refinery processes (Doll *et al.*, 1977). More recently, the Landolph laboratory has shown that reduction, or elimination, of the sulfuric acid in the refinery process in 1923 reduced the amount of nickel arsenide (orcelite) present in the Clydach refinery, in Wales, operated by the International Nickel Company (INCO), which led to a reduction in the incidence of nasal and lung cancers. Furthermore, it has also been shown that the 1920 refinery dust sample (25% orcelite) did, but that the 1929 sample (2.5% orcelite) did not, induce morphological transformation in C3H/10T1/2 cells, consistent with the high nasal and respiratory cancer incidence from 1901–1923 and the reduced cancer incidence after 1925 (Clemens and Landolph, 2003). All the men studied were manual workers in the refinery, but only some of them were employed on the specific nickel carbonyl process at the same time; others were general laborers who changed jobs frequently. Thus, it was not possible to collect detailed information on exposure.

The theory that nickel carbonyl alone acted as a carcinogen had to be discarded when a similar risk was found in nickel-refinery workers in Ontario, where the electrolytic process was used. Mastromatteo (1967) and Sunderman (1973) collected data on 327 cases of lung cancer and 115 cases of cancer of the nasal sinuses in nickel-refinery workers with a variety of exposures to nickel in Norway, France, Germany, the United States, and Japan, as well as in Wales and Canada (Mastromatteo, 1967; Sunderman, 1973).

Apart from nickel-refinery workers, isolated cases of lung and nasal cancer have been reported in workers in nickel-plating, nickel-grinding, and nickel-polishing operations, but the significance of these cases cannot be assessed, because no definitive epidemiological study has yet been performed. However, from the extent of exposure in the old nickel-refining processes and from the decrease in cancer mortality when the exposure was reduced, it seems unlikely that the much lower levels of exposure encountered in nickel plating would constitute a risk.

Although Morgan (1958) gave a detailed account of the nickel-refining process in South Wales, no information was given on exposure levels encountered by the workers who experienced an increased cancer mortality rate except that they were exposed to dusty rather than to gaseous compounds (Morgan, 1958). Similarly, Mastromatteo (1967) referred to the association between furnace operations involving the inhalation of freshly treated insoluble dust or fumes and the increased risk of cancer, but he gave no exposure concentrations (Mastromatteo, 1967). No data are available on exposure levels in workers with an increased mortality experience of respiratory cancer, except that exposure to nickel-containing dusts was heavy in the past; thus, no observations can be made on a dose-response relationship.

The carcinogenic agent(s) in nickel refining is (are) likely to be related to dust exposure from the preliminary processes of calcination, but the exact identity of the carcinogenic nickel-containing species is open to speculation. Sunderman and Mastromatteo (1975) considered that fresh nickel dusts from sintering and roasting processes were especially carcinogenic, and focus on respirable particles of metallic nickel, nickel subsulfide, and nickel oxide as significant carcinogens. An increased lung, nasal, and laryngeal cancer risk was found in men who had worked in the roasting, smelting, and electrolysis departments in a Norwegian nickel refinery before 1953 (Pedersen *et al.*, 1973). This study adds to the evidence incriminating exposure to furnace fumes and dust from the high-temperature sintering or calcining of impure nickel mattes. However, a case-control study from New Caledonia showed increased lung cancer mortality not only in workers but also in residents in the vicinity of a refinery processing laterite, an ore-containing nickel oxide (Lessard *et al.*, 1978). Available data suggest that the cancer risk is greater in heavy cigarette

smokers, with an interaction between two carcinogens, as with asbestos and smoking (Kreyberg, 1978).

A long-term cohort study of 814 workers with substantial exposure to airborne metallic nickel at a gaseous diffusion plant showed no increase in mortality from cancer of the respiratory tract (Godbold and Tompkins, 1979). Similarly negative results were obtained in a mortality study of 1925 men employed for a minimum period of 5 years who were exposed to average concentrations of metallic nickel of between 0.5 and 0.9 mg Ni/m^3, half by weight being of respirable size (Cox *et al.*, 1981). From these studies, it seems less likely that metallic nickel is a human carcinogen; the active, carcinogenic agent must be a compound of nickel, probably nickel subsulfide.

An epidemiological report on cancer mortality in 10 cohorts of occupationally exposed workers aimed at identifying the chemical forms of nickel responsible for the elevated cancer risk. Mortality from lung and nasal sinus cancer was associated with exposure to high levels of oxidic nickel compounds, sulfidic nickel in combination with oxidic nickel, and exposure to water-soluble nickel alone or together with less soluble nickel compounds (Doll *et al.*, 1990). In a case-control study of Norwegian nickel-refinery workers, Grimsrud *et al.* (2002) examined dose-related association between lung cancer and cumulative exposure to four forms of nickel: water soluble, sulfidic, oxidic, and metallic nickel. The study positively correlated a dose-related association between lung cancer and cumulative exposure to water-soluble nickel compounds (Grimsrud *et al.*, 2002a).

The latent period from first exposure to nickel compounds to diagnosis of the cancer is long, averaging approximately 25 years, with a range of 10–40 years. In those cases for which information is available, epithelial tumors predominated, but anaplastic and pleomorphic tumors have also been observed (Sunderman, 1973).

Significant abnormalities have been found in nickel-refinery workers subjected to routine cytological screening. Nasal cancer and a high rate of epithelial dysplasia compared with controls were found after biopsy of the nasal mucosa. Sputum cytology has revealed epithelial dysplasia, and in 16 of a group of the 583 refinery workers from a nickel-sinter plant, malignant cells were found without clinical or radiological evidence of cancer (McEwan, 1978). The routine use of such screening procedures should be considered when any risk of nickel-induced cancer is believed to exist.

1.1.2 Animal Models

The experimental models that have been used to study nickel carcinogenesis have been reviewed by Sunderman (1973) and by the IARC (1976) (IARC, 1976; Sunderman, 1973). Carcinogenesis has been adequately demonstrated in several animal species after subcutaneous or intramuscular injection, but with the exception of nickel subsulfide, the results after inhalational exposure have been less conclusive. Nickel subsulfide, Ni_3S_2, has given rise to fibrosarcomas and to rhabdomyosarcomas in numerous experiments after subcutaneous or intramuscular injection. Gilman (1966) found a dose-response relationship with injections of 10 mg nickel subsulfide giving an 80% tumor incidence in Wistar rats (Gilman, 1966). Sunderman *et al.* (1975) also found a dose-response relationship, with 7 of 30 rats developing sarcomas after a dose of 0.63 mg, rising to 28 of 30 rats developing sarcomas with a dose of 2.5 mg nickel subsulfide. Heath and Daniel (1964a) injected powdered nickel suspended in fowl serum into the thigh muscle in rats, all of which developed rhabdomyosarcoma at the injection site within 17 to 41 weeks (Heath and Daniel, 1964a; 1964b). Tumors have also been produced after the intrarenal and intratesticular injection of nickel subsulfide (Damjanov *et al.*, 1978; Sunderman *et al.*, 1979).

Prolonged inhalation of nickel subsulfide, of fine particle size (70% smaller than 1 μm diameter), at a concentration of 1 μg/m^3, produced 14 malignant neoplasms of the lung in 226 exposed rats compared with only 1 neoplasm in 241 control animals (Ottolenghi *et al.*, 1975). Inhalation of nickel carbonyl resulted in only two pulmonary adenocarcinomas in a series of experiments on rats (Sunderman and Donnelly, 1965). The repeated intravenous injection of nickel carbonyl resulted in malignant tumors in 19 of 21 survivors, or 16% of the injected rats. In addition to the sarcomas, one cholangiosarcoma, one carcinoma of the kidney, one mammary carcinoma, and five pulmonary lymphomas were observed (Lau *et al.*, 1972).

Comparison of the relative poteny of the various nickel compounds tested is difficult because of the variation is experimental design is different studies(r) Potenic seems to be inversel related to solubility of the nickel compound is aqueoue media with the highly soluble salts suce as nickel chloride having no apparent carcinogeni activity(r). The carcinogenic activity of nickel subsulfide (α-Ni_2S_3) is greater than that of any other metallic compound so far investigated in animal bioassay. The variety of animal species, routes of administration, and high yield of tumors has made nickel subsulfide particularly useful for experimental tumor induction. However, bacterial mutagenesis tests for nickel compounds have been consistently negative. Nickel subsulfide and nickel sulfate induced dose-related morphological transformation and enhanced viral transformation in cultured hamster embryo cells

(Casto *et al.*, 1979; DiPaolo and Casto, 1979), and divalent nickel decreased the fidelity of DNA synthesis in the cell-free system of Sirover and Loeb (1976) (Sirover and Loeb, 1976b) and induced morphological transformation in cultured C3H/10T1/2 Cl 8 mouse embryo fibroblasts (Miura *et al.*, 1989). The laboratory of Landolph has found that in nickel compound–induced transformed 10T1/2 mouse embryo fibroblast cell lines, there are aberrations in the expression of 130 genes, with approximately 65 genes, including oncogenes, such as the ect-2 oncogene, being expressed at higher steady-state levels and 65 genes, such as the DRIP/TRAP80 gene, being reduced in expression or not expressed at all (Clemens *et al.*, 2005; Landolph *et al.*, 2002; Verma *et al.*, 2004).

Possible mechanisms of nickel carcinogenesis have been reviewed by Sunderman (1976, 1977) (Costa, 2002; Costa *et al.*, 2003; 2005; Sunderman, 1976; 1977). An inhibition by nickel carbonyl of RNA synthesis in hepatocytes has been demonstrated (Beach and Sunderman, 1970; Witschi, 1972). This is believed to be due to an inhibitory effect of nickel on RNA polymerase activity, thus altering the expression of genetic information. Manganese has been shown to inhibit the carcinogenicity of nickel subsulfide in the rat without altering the mobilization or excretion of nickel or the initial inflammatory reaction at the injection site. In keeping with the preceding hypothesis, manganese may antagonize the nickel inhibition of RNA polymerase activity (Sunderman, 1975). Nickel subsulfide also produces disordered patterns of cell proliferation in fetal cell cultures. This effect, too, can be prevented by the addition of manganese dust (Costa, 1978). The current issue of this handbook has a chapter on the mechanisms of metal carcinogenesis and toxicity and a separate chapter on nickel, and the reader is referred to this chapter for further information on mechanisms of nickel carcinogenesis.

1.1.3 Evaluation

The IARC (1990) concluded there is sufficient evidence in humans for the carcinogenicity of nickel sulfate and of combinations of nickel sulfides and oxides encountered in the nickel-refining industry. There is inadequate evidence in humans for the carcinogenicity of metallic nickel and nickel alloys (IARC, 1990).

There is sufficient evidence in experimental animals for the carcinogenicity of metallic nickel, nickel monoxides and hydroxides, and crystalline nickel sulfides. There is limited evidence in experimental animals for the carcinogenicity of nickel alloys, nickelocene, nickel carbonyl, nickel salts, nickel arsenides, nickel antimonide, nickel selinides, and nickel telluride. The data on the carcinogenicity of soluble nickel compounds such as nickel sulfate, is equivocal, although they are generally not carcinogenic in animals, it is difficult to get data on nickel sulfate alone in humans.

The overall evaluation of nickel compounds as a group as a basis of combined results of epidemiological studies, carcinogenicity studies, studies in experimental animals, and several types of other relevant data was supported by the underlying concept that nickel compounds can generate nickel ions at critical sites in their target cells. Overall, IARC classified nickel compounds to be carcinogenic to humans (group 1), and metallic nickel is possibly carcinogenic to humans (group 2B).

1.2 Chromium

1.2.1 Epidemiological Observations

Lung cancer in workers producing dichromates from the raw material, chromite, or chrome iron ore was first reported in Germany in the 1930s, and these reports have been reviewed by Baetjer (1950). The reader is also referred to the review of chromium by Costa (1997). The observation was confirmed in the United States by Machle and Gregorius (1948) and in Britain by Bidstrup and Case (1956). In the American series, the observed mortality for lung cancer was approximately 30 times the expected number from national mortality data of that time, but in the British series (a 6-year follow-up mortality study), the increased risk was computed at a little over three times that expected. Similar observations were made in other countries. An increased risk of dying from lung cancer with duration of exposure in the chromate industry was observed by Taylor (1966). In his cohort study, the death rate from respiratory cancer increased from 106 for men with 5–9 years' exposure, to 400 per hundred thousand for men with 20–24 years' exposure; this study provides the only evidence for a dose-response relationship (Taylor, 1966).

Langård and Norseth (1975) found three cases of bronchial carcinoma in a cohort study of 24 workers with more than three years' exposure to chromate pigments, including zinc chromate (Langard and Norseth, 1975). The average age of those with cancer was 50 years and the risk ratio, based on general population experience, was computed at 38. Exposure levels were estimated to have been between 0.5 and 1.5 mg Cr/m^3 over a 6- to 9-year period and occurred mainly in filling sacks and in the mixing of raw materials. By 1983, six cases of lung cancer had occurred among these 24 men, where only 0.13 had been expected, an excess large enough for smoking cigarettes not to be considered an important confounder (Langard and Vigander, 1983).

A mortality study in three English factories manufacturing chromate pigments showed a significant increase in lung cancer in the two factories producing zinc chromate pigments. The excess mortality was observed in those departments where exposure to dust occurred and was rated as high; it was also noticed in the less dusty, wet departments, where exposure was rated as being of medium intensity. Exposure for as little as 1 year was associated with a raised mortality, and induction times were found to be fairly short, with a ratio of observed deaths/expected deaths fairly constant at about 4/1 during 5–24 years after first exposure. This short induction time contrasts with the longer latent interval found in the dichromate-producing industry (Davies, 1978).

In an updated cohort mortality study of lung cancer in these three chromate pigment factories (Davies, 1984), workers exposed to lead chromate experienced normal mortality, even under conditions conducive to lead poisoning. Those workers who had low exposure to both lead and zinc chromate also had no increase in lung cancer. However, workers with high or medium exposure for at least 1 year to both lead and zinc chromate had significantly raised lung cancer mortality, with 32 observed deaths whereas 12 were expected. Again, latent intervals for the development of cancer were unusually short. The results indicate that moderate or heavy exposure to zinc chromate may give rise to a severe risk of lung cancer developing, but relatively mild exposure lasting less than 1 year may not constitute an effective risk.

In the industrial process, raw chromite is dried, crushed, mixed with soda ash, and roasted in a rotary furnace in an oxidizing atmosphere. The insoluble oxide is converted to a water-soluble monochromate and from this the dichromate and other chromium compounds are produced. The lung cancer hazard in the chromate production industry has been attributed to carcinogenic agents present in the primary ore or in one of the furnace products, either as an intermediate or as a component of the residue. Secondary users of chromates and chrome pigments may be at increased risk, but the epidemiological evidence is inconclusive. Exposed groups include welders and grinders and those engaged in chrome-alloy production, such as ferrochromium. An increased lung cancer risk in chrome-alloy workers was observed by Langård *et al.* (1980) but not by Axelsson *et al.* (1980) in a similar investigation (Axelsson *et al.*, 1980). The Federal Security Agency, U.S. Public Health Service (1963) did not demonstrate excess of lung cancer over a 14-year period in a refractory plant using chromite ore to make chromite brick. The investigators concluded that acid-soluble and water-soluble derivatives of chromite ore were the suspect carcinogens. With regard to the large population of platers exposed to soluble chromium compounds, the evidence for an increased lung cancer risk is again inconclusive (Norseth, 1981). A pilot cohort mortality study in nine small chrome-plating plants found 3 cases of lung cancer among hard-chrome platers who had heavy exposure, whereas 0.7 was expected (Franchini *et al.*, 1983). Because of the small size of the cohort, the effect of confounding variables could not be assessed, and further studies on the possible carcinogenicity of chromic acid are required. Thus, the epidemiological evidence at present shows a clear increased risk of lung cancer only in the primary chromate production and in the zinc chromate pigment production industries, consistent with the concept that slightly soluble hexavalent chromium compounds are carcinogenic.

In more than 50 epidemiological studies on chromium exposure and lung cancer, the major investigations have been performed on chromium production workers, chromate paint makers, and chrome platers (IARC, 1990). The overall relative risk for lung cancer in these studies has been estimated at 2.78 (95% confidence interval, 2.47–3.52). In those studies where asbestos, nickel exposure, and smoking were assessed, confounding was rejected as the major source of the observed elevated risk (Steenland *et al.*, 1996).

The time interval for lung cancer from first exposure to chromium compounds has varied from 4–47 years, with a mean latent interval from 10.6–21 years in different studies. Enterline (1974), reviewing the American data, concluded that the risk of respiratory cancer in chromate workers remained high in the period 1937–1960, with a higher risk in younger age groups; this suggests only a short latent period after exposure to a potent carcinogen (Enterline, 1974). Approximately 80% of the lung cancers examined were squamous cell carcinomas, but undifferentiated cancers and adenocarcinomas have also been seen. A few cases of nasal cancer have also been reported in chromate workers, but an increase in incidence has not been confirmed.

1.2.2 Animal Models

Animal models have so far not contributed to the precise identification of the carcinogen in the chromate-production industry, although they confirm the carcinogenic potential of chromium (VI). A small number of tumors have been observed in the rat after the intramuscular or intrapleural administration of chromite-ore roast (Hueper, 1958). The intramuscular implantation of pellets of 25 mg calcium chromate produced local sarcomas in 8 of 35 treated rats; and implantation of 25 mg sintered chromic trioxide gave rise to sarcomas in 15 of 35 rats (Hueper and Payne, 1959). The carcinogenic

activity of calcium chromate has been convincingly demonstrated by Roe and Carter (1969), who obtained a 75% tumor yield in 24 rats injected subcutaneously over a period of 20 weeks with 19 mg calcium chromate suspended in arachis oil (Roe and Carter, 1969). Laskin *et al.* (1970) introduced into the rat bronchus a small capsule saturated with the test material, thus providing continuous, long-term exposure to the bronchial epithelium (Laskin and Drew, 1970). Squamous cell carcinoma at the impaction site developed in six rats and adenocarcinoma developed in another 2 of 100 rats exposed to calcium chromate. Chromic chromate, chromic oxide, and chromic trioxide were without effect. Inhalational exposure to calcium chromate dust at a concentration of 13 mg/m^3 for 35 hours/week for life produced alveolar adenocarcinoma in mice in a single experiment (Nettesheim *et al.*, 1971). Levy and Venitt (1975) produced squamous cell carcinoma in the rat lung by implanting calcium chromate and zinc potassium chromate, both medium-soluble hexavalent chromium salts, into the bronchial tree. The tumor yield was low and the incubation period long, but adequate control groups were also examined, and the tumors were considered to be causally related to the chromium implants. In the animals without lung tumors, a significant increase in squamous metaplasia was seen in rats exposed to the pure hexavalent compounds only (Levy and Venitt, 1975). There has been considerable controversy over the carcinogenic activity of hexavalent chromium by ingestion. Hexavalent chromium resembles sulfate and phosphate and is able to penetrate all cells of the body. Thus, on the basis of molecular mimicry, human exposure to chromates has broad carcinogenic potential. Recent studies of hairless mice have demonstrated that when combined with ultraviolet (UV) exposure there was a dose-dependent induction of skin cancer in hairless mice that were given 0.5, 2.5, and 5 mg/l of chromate in the drinking water (Davidson *et al.*, 2004). These cancers were squamous cell carcinomas, and because this type of cancer is not recorded in humans, it is difficult to assess whether chromate can induce it in humans.

1.2.3 Short-Term Tests

Chromium in hexavalent form is the most active of the metals in giving rise to mutations in both the S. *typhimurium* and *E. coli* bacterial test systems, where it seems to act directly without prior activation. After reduction to trivalent chromium, the mutagenic effect was no longer observed (Nishioka, 1975). Soluble hexavalent chromium salts produce both chromosomal aberrations in mammalian cells *in vitro* and morphological transformation of hamster embryo cells in culture (DiPaolo and Casto, 1979). However, in the cell-free system of Sirover and Loeb (1976), trivalent chromium was shown to be more potent than hexavalent chromium in the induction of genetic miscoding (Sirover and Loeb, 1976b). A possible mechanism for chromium carcinogenesis has been proposed from these and other observations. In this model, hexavalent chromium readily traverses cell membranes and in the process it is reduced to the trivalent form. Within the cell, trivalent chromium binds to nucleotide bases in DNA to give rise to genotoxic effects (Levis *et al.*, 1978; Lofroth, 1978). Thus, although the cancer hazard seems to follow environmental exposure to hexavalent chromium, trivalent chromium seems to be the agent that initiates the changes within the cell. Of all the metals studied, chromium best fits the hypothesis that carcinogenesis entails mutagenic initiation of somatic cells as a result of direct interaction with DNA. The handbook has a separate chapter on mechanisms of metal toxicity and carcinogenicity and a separate chapter on chromium, and the reader is referred to these chapters for further information.

1.2.4 Evaluation

IARC (1990) concluded there was sufficient evidence in humans for the carcinogenicity of chromium (VI) compounds as encountered in the chromate production, chromate pigment, and chromium plating industries (IARC, 1990). There is inadequate evidence in humans for the carcinogenicity of metallic chromium and of chromium (III) compounds.

There is adequate evidence in experimental animals for the carcinogenicity of calcium chromate, zinc chromates, strontium chromate, and lead chromates. There is limited evidence in experimental animals for the carcinogenicity of chromium trioxide and sodium dichromate.

The IARC Working Group made its overall evaluation on chromium (VI) compounds on the basis of the combined results of epidemiological studies, carcinogenicity studies in experimental animals, and several types of other relevant data that support the underlying concept that hexavalent chromium ions generated at critical sites in the target cells are responsible for the observed carcinogenic action. Overall, the Working Group concluded that hexavalent chromium is carcinogenic to humans (Group 1). Metallic chromium and trivalent chromium compounds are not classifiable as to their carcinogenicity to humans (Group 3).

1.3 Arsenic

1.3.1 Epidemiological Observations

Evidence for the carcinogenicity of arsenic is based on observations made in occupational groups and also

in general population groups exposed to arsenic after absorption from food, water, or drugs. A number of different occupational groups with exposure to arsenic have shown a greater cancer risk. An increase in cancer deaths was found in chemical process workers engaged in the production of inorganic arsenicals (Ott *et al.*, 1974), in smelter workers (Lee and Fraumeni, 1969; Pershagen *et al.*, 1977; Pinto *et al.*, 1977; Tokudome and Kuratsune, 1976), and in miners (Osburn, 1969).

In Hill and Faning's study, a proportional excess of deaths mainly from lung and skin cancer was demonstrated (29% observed compared with 13% expected). Exposure to arsenical dust was heavy, ranging from a mean atmospheric concentration of 1034 $\mu g/m^3$ by the kibbler to 78 $\mu g/m^3$ in the packing rooms. A significant increase in lung cancer was found in another proportional mortality study in chemical workers producing a variety of inorganic arsenicals, mainly lead and calcium arsenate (Ott *et al.*, 1974). Lung cancer accounted for 16% of deaths in the exposed group compared with 6% in the controls. Exposure levels were calculated as the product of the time-weighted average concentration with months of exposure. A dose-response relationship was demonstrated, the ratio of observed to expected deaths from lung cancer increased from 0.6 in the lowest to 7.0 in the highest exposure category. In the study reported by Pinto *et al.* (1977), a time-weighted index of total lifetime exposure to arsenic trioxide in copper-smelter workers was linearly related to lung-cancer mortality, ranging from a standardized mortality ratio (SMR) of 111 at the lowest exposure to 833 at the highest. It has been estimated that 25 years' exposure to arsenic at a concentration of about 50 $\mu g/m^3$ could lead to a nearly threefold excess mortality in lung cancer. The exposure in the past was probably underestimated, however, and the conclusions with regard to a dose-response relationship should be regarded as tentative. Axelson *et al.* (1978), in a case-control study in a Swedish copper-smelter, found a fivefold increase in lung cancer mortality with a trend toward a dose-response relationship (Axelson *et al.*, 1978).

It should be noted that very high exposures to arsenic in copper smelters might have occurred in the past. Thus, Kuratsune *et al.* (1974) refer to their workers as having been engaged in the "dirtiest prewar operations" where arsenic trioxide was a major by-product of the smelter (Kuratsune *et al.*, 1974). Although occupational exposure to a variety of arsenic compounds may occur, smelter workers are predominantly exposed to airborne arsenic trioxide. Arsenic may be present in copper, lead, zinc, nickel, and other metal ores. Exposure patterns are, therefore, complex and may involve other suspected carcinogens. Sulfur dioxide is another pollutant with which arsenic exposure is frequently associated. Thus, Lee and Fraumeni (1969) found that deaths from lung cancer increased not only with increasing arsenic trioxide exposure but also with increasing exposure to sulfur dioxide (Lee and Fraumeni, 1969). Axelson *et al.* (1978) also referred to the high correlation between exposure to arsenic, sulfur dioxide, and copper and pointed out the difficulty in distinguishing the interaction in such mixed exposures (Axelson *et al.*, 1978). A case-control study among smelter workers examined the effect of both arsenic trioxide exposure and smoking cigarettes on mortality from lung cancer (Pershagen *et al.*, 1981). The age-standardized ratio for death from lung cancer was 3.0 for arsenic-exposed nonsmokers, 4.9 for non-arsenic–exposed smokers, and 14.6 for arsenic-exposed smokers in relation to subjects without exposure to these putative carcinogens, indicating a multiplicative effect of the two exposures. The authors drew attention to the preventive measures that could be taken with regard to smoking in such an exposure situation.

A cohort study of 1462 tin smelter workers potentially exposed to lead, arsenic, and cadmium showed a statistically significant excess mortality from lung cancer (Binks *et al.*, 2005). The mortality pattern was considered to be similar to that in copper smelter studies (Enterline *et al.*, 1987; Jarup *et al.*, 1989) in which lung cancer excess was attributed to arsenic exposure. Arsenic has been identified as a major causative factor for lung cancer mortality in the copper smelter cohorts (IARC, 1987).

German and French vineyard workers who used pesticide spray containing arsenic had chronic arsenic poisoning develop over a 12- to 14-year exposure period. Roth (1958) investigated 27 deaths and found among these workers 12 cases of lung cancer, one of which was bilateral, occurring 8–14 years after the pesticides had been banned. Exposure had been heavy, with intake estimated at >5.0 g over a 12-year period (Roth, 1958).

The total daily intake of arsenic is greatly influenced by the amount of seafood in the diet, usually <200 μg/day and normally <50 μg/day (WHO, 1981). The arsenic content of tobacco has fallen as a result of the decreased use of arsenicals in agriculture. Arsenic is usually present in its pentavalent form, although traces of trivalent arsenic derived from pesticides may also be found. Contamination of food and drinking water from natural and industrial sources giving rise to chronic arsenic poisoning has been widely reported (see Volume II, Chapter 3). In one such episode in Taiwan where artesian well water with a high arsenic content has been used for more than 60 years (Tseng, 1977), clinical manifestations of chronic arsenicism were seen in the exposed population, including Blackfoot

disease and hyperkeratotic skin lesions. Arsenic levels in drinking water were designated "low" (<0.3 mg/l), "medium" (0.3–0.6 mg/l), and "high" > 0.6 mg/l). The rate of skin cancer was very high, at 10.6 per 1000 persons, and evidence of a dose-response relationship was found in the form of a clearcut ascending gradient of the prevalence of skin cancer from low to high for both sexes in all age groups.

IARC (2004) evaluated the extensive evidence available for the carcinogenicity of arsenic in drinking water (IARC, 2004). The Working Group evaluated ecological studies in Taiwan, Chile, Argentina, Australia, cohort studies in Taiwan, Japan, and the United States, and case-control studies in Taiwan, the United States, and Finland. Studies that involved long-term high exposures showed substantial increases in the risk for bladder cancer, with evidence for a dose-response relationship. Similarly, an increased risk for lung cancer was observed, with evidence for a dose-response relationship. The potential confounding effect of cigarette smoking was excluded. It was considered that the findings for both bladder and lung cancer cannot be attributed to chance or confounding, are consistent, and demonstrate strong associations in populations with high exposure. Furthermore, ecological studies have indicated substantially elevated incidence, prevalence, and mortality rates for skin cancer associated with drinking water highly contaminated with arsenic, with evidence of a dose-response relationship.

An increased mortality from liver cancer and for kidney cancer in populations with high, long-term exposure to arsenic was also reported by the IARC Working Group; however, there was potential confounding for liver cancer, and relative risk estimates for kidney cancer were much lower than those for urinary bladder cancer.

As with nickel and chromium, the latent interval between first exposure to arsenic and development of cancer is long. Average latent intervals of 34, 39, and 41 years were estimated for heavy, medium, and light exposure categories (Lee and Fraumeni, 1969).

Chronic exposure to arsenic has been implicated in the etiology of hemangiosarcoma (hemangioepithelioma) of the liver, in some cases associated with hepatic cirrhosis (Lander *et al.*, 1975; Popper and Thomas, 1975). Cancers of the lymphatic and hemopoietic systems, bladder cancer, and cancers of other organs have also been reported to occur more frequently after arsenic exposure, both with and without skin cancer (IARC 2004).

1.3.2 Animal Models

Evidence is limited for carcinogenesis by arsenic in experimental animal studies. An increased incidence of lymphocytic leukemia and lymphoma was observed in female Swiss mice and their young after the subcutaneous injection of sodium arsenate during pregnancy (Osswald and Goerttler, 1971). Arsenic trioxide, sodium and potassium arsenite, and sodium arsenate have been extensively tested by oral administration and by skin application with negative results. A number of organic arsenicals have also been tested with similar findings. Lung tumors in rats have been produced after a single intratracheal instillation of a mixture of calcium arsenate, copper sulfate, and calcium oxide, a preparation similar to that formerly used in vineyards, indicating a carcinogenic potential at least for the mixture given (Ivankovic *et al.*, 1979). Multifocal bronchogenic adenocarcinomas and bronchiolar alveolar cell carcinomas were induced in 9 of 15 surviving rats, the mean induction time being 470 days. Intratracheal instillations with calcium arsenate alone induced only benign lung tumors in hamsters (Pershagen and Bjorklund, 1985). A small number of lung cancers developed in hamsters given arsenic trioxide together with charcoal carbon as a carrier dust. There was, in addition, a significant increase in adenomas and papillomas in the treated animals compared with the controls given only carbon dust.

Combined exposure to arsenic trioxide and benzo(a)pyrene by the same route markedly increased the incidence of pulmonary adenomas, papillomas, and adenomatoid lesions compared with benzo(a)pyrene alone (Pershagen *et al.*, 1984a). In a further study three carcinomas and a number of adenomas and papillomas were identified in 47 hamsters exposed to arsenic trioxide and charcoal, but no carcinomas and few other tumors in 53 hamsters without arsenic trioxide exposure (Pershagen *et al.*, 1984b). Benign pulmonary tumors and/or carcinomas have also been induced with arsenic trioxide in some other studies on experimental animals (Ishinishi *et al.*, 1977; 1980; 1983).

To explain the apparent contradiction between epidemiological and animal experimental data, it has been proposed that arsenic may act as a cocarcinogen or potentiator of the carcinogenic process rather than as a direct carcinogen. A number of studies have been performed on the effect of arsenic on tumor incidence and growth with contradictory results, and Squibb and Fowler (1983) have reviewed these.

1.3.3 Short-Term Tests

Chromosome aberrations have been observed in workers exposed to arsenic compounds (Nordenson *et al.*, 1978), and both aberrations and an increase in SCE have been noted after arsenic medication (Burgdorf *et al.*, 1977; Petres *et al.*, 1977). Although mutagenicity

could not be demonstrated with the *S. typhimurium* plate test (Lofroth, 1978), arsenic compounds gave positive results indicative of DNA damage in bacterial assay (Nishioka, 1975). Morphological transformation of hamster embryo cells in culture could be induced with sodium arsenate; and enhancement of viral transformation in the same system was obtained with arsenic trichloride (Casto *et al.*, 1979; DiPaolo and Casto, 1979). However, arsenic did not affect the fidelity of DNA synthesis (Sirover and Loeb, 1976a). Squibb and Fowler (1983) in their review concluded that arsenic compounds are not generally mutagenic, but that certain compounds have shown a potential for inducing DNA damage and inhibition of DNA repair enzymes (Squibb, 1983). Possible mechanisms to explain the carcinogenicity of arsenic have been discussed by Sunderman (Sunderman *et al.*, 1979). Again the reader is referred to the mechanism chapter in this handbook as well as the chapter on arsenic for further information.

1.3.4 Evaluation

The IARC (1980) concluded that there was sufficient evidence that inorganic arsenic compounds are skin and lung carcinogens, but the data suggesting an increased risk for cancer at other sites were inadequate for evaluation. They found the evidence for the carcinogenicity of arsenic compounds in animals to be insufficient.

The IARC (2004) concluded there is sufficient evidence in humans that arsenic in drinking water causes cancer in the urinary bladder, lung, and skin (IARC, 2004). It was considered that there is sufficient evidence in experimental animals for the carcinogenicity of dimethyl arsenic acid; limited evidence for the carcinogenicity of sodium arsenite, calcium arsenate, and arsenic trioxide; and inadequate evidence for the carcinogenicity of sodium arsenate and arsenic trisulfide. It was considered that, taken together, the studies on inorganic arsenic provide limited evidence for carcinogenicity in experimental animals. Overall, it was considered that arsenic in drinking water is carcinogenic to humans (Group 1).

1.4 Cadmium

1.4.1 Epidemiological Observations

Studies have been performed principally on industrial workers who have been exposed in the past to high concentrations, in particular, of cadmium oxide fume and dust.

Three of eight deaths in 74 nickel-cadmium battery workers with at least 10 years' exposure to cadmium oxide dust were noted by Potts (1965) to be from cancer of the prostate (Potts, 1965). In the past, exposure to cadmium oxide dust and fume had been heavy. For example, in 1949, concentrations in two work areas ranged from 0.6–2.8 mg Cd/m^3, and in a third up to 236 mg/m^3 (Potts, 1965). Improvements in ventilation reduced these levels to below 0.5 mg/m^3 by 1950 and to 0.1 mg/m^3 by 1956. Kipling and Waterhouse (1967) surveyed the records of nickel-cadmium battery workers exposed to cadmium oxide dust for a minimum period of 1 year. They found four cases of prostatic cancer for which the expected figure was computed at 0.58 from regional incidence rates. They concluded that the increase in prostatic cancer was highly significant, whereas the occurrence of other forms of cancer was close to that expected. However, the numbers involved were not large (they included the three cases noted by Potts), and they were unable to infer the existence of an industrial hazard.

Since then, another study has supported the preceding findings, a cohort mortality investigation of smelter workers heavily exposed to cadmium fume and cadmium oxide dusts (Lemen *et al.*, 1976). The study involved 292 smelter workers with a minimum of 2 years' exposure during a 30-year period starting in 1940. A significantly excessive risk was demonstrated for malignant neoplasms, with 27 cases observed and 17.6 expected. Twelve of the deaths were due to respiratory cancer, a significant increase, because only 5.11 were expected; and 4 were due to prostatic cancer, whereas 1.15 were expected, a difference that was not significant. The greatest risk for respiratory cancer was apparent 30 years after initial employment and for prostatic cancer 20 years after initial exposure, at which time the increased risk of prostatic cancer had attained significance. However, in this study there was concomitant exposure to arsenic, and smoking histories were not available.

Kjellstrom *et al.* (1979) have presented data on cancer mortality and cancer morbidity among 269 cadmium-nickel battery workers and 94 cadmium-copper alloy workers in Sweden (Kjellstrom *et al.*, 1979). All workers had at least 5 years' heavy past exposure to cadmium oxide dust or fume. Before 1947, the exposure levels in the battery plant were on average above 1 mg/m^3. An internal reference group of 328 alloy factory workers without cadmium exposure was also studied. The cumulative observed and expected number of prostatic cancer deaths in 1940–1975 among the alloy factory workers was 4 against 2.69, whereas the corresponding number in the reference group was 4 of 6.42. In the battery factory, there were two observed cases of prostatic cancer against 1.2 expected. In the combined cohort study, there were two cases of cancer of

the nasopharynx against an expected 0.2, with a risk ratio of 10; however, heavy exposure to nickel had also occurred. In a follow-up and an extension of the study in the nickel-cadmium battery workers, many of whom had been heavily exposed to both cadmium and nickel, in a subgroup exposed for more than 15 years, there were now 3 deaths from prostatic cancer with 1.6 expected and 3 deaths from lung cancer where 2.5 had been expected from Swedish male mortality rates. Thus, the small, no significant excess mortality from prostatic cancer in this cohort has been maintained (Andersson *et al.*, 1984). In a further analysis of the total cohort, the standardized mortality ratio for both prostatic and lung cancer increased with increasing dose and latency but did not attain statistical significance (Elinder *et al.*, 1985).

In copper-cadmium alloy workers in Britain, again with heavy past exposure exceeding 1 mg Cd/m^3, a total of 7 cases of lung cancer was observed compared with 3.9 expected in men exposed for more than 10 years (Holden, 1980). Among vicinity workers not directly involved in cadmium processes, 8 cases of prostatic cancer were observed compared with 3 expected, although only 3 of these 8 had had more than 15 years' exposure (Holden, 1980). With no evidence of a dose-response relationship, their association with past cadmium exposure might be questioned. No new evidence of any relation between occupational exposure to cadmium oxide dust and cancer of the prostate was found in a mortality study of more than 3000 nickel-cadmium battery workers in Britain, which included the 4 cases previously observed by Kipling and Waterhouse (1967). There was some indication of an increased risk from cancers of the respiratory system, because 89 deaths were observed, whereas only 70.2 were expected, although exposure to welding fumes and nickel hydroxide was considered an important confounding factor (Sorahan and Waterhouse, 1983).

In an extended follow-up study of the cohort described by Lemen *et al.* (1976), mortality experience has been investigated through 5 additional years and the cohort extended to include white men with at least 6 months' employment in a production area (Thun *et al.*, 1985). Since 1925, the plant had refined cadmium and a number of other trace metals from "baghouse" dust, a by-product of lead smelting. Previously, the plant had functioned as an arsenic smelter and initially as a lead smelter. Exposure to cadmium had been heavy; more than 80% of the workers measured had a mean urine cadmium concentration of at least 20 µg/l. Mortality from lung cancer was significantly greater among the workers employed for 2 years or more than would have been expected from US white male rates, with 20 observed deaths where 11.43 were expected. In addition, the study showed a significant dose-response relationship between lung cancer mortality and cumulative exposure to cadmium (Stayner *et al.*, 1992a; 1992b). No further deaths from prostatic cancer have been reported since the earlier study, thus weakening the original observation by Lemen *et al.* (1976) of a possible association between prostatic cancer and cadmium exposure. With regard to lung cancer, Thun *et al.* (1985) made certain assumptions from which they concluded that the two confounding factors, smoking cigarettes and past arsenic exposure, were unlikely to account for the observed excess lung cancer risk. However, arsenic exposures after 1926 may have been higher than estimated, and no account was taken of the possible combined effect of smoking cigarettes and arsenic exposure (Pershagen *et al.*, 1981).

To investigate mortality on a scale larger than available in earlier studies, the mortality of almost 7000 cadmium-exposed male workers from 17 cadmium processing plants in England, born before 1940 and exposed to cadmium for more than 1 year between 1942 and 1970, was examined initially until the end of 1979 (Armstrong and Kazantzis, 1983), followed up for an initial 5-year period from 1980–1984 (Kazantzis *et al.*, 1988), and for a second 5-year period to the end of 1989 (Kazantzis *et al.*, 1992). Jobs were assessed for each year as involving high, medium, or low exposure to cadmium. The years at risk of the study population were divided into three groups, "ever high" (minimum of 1 year), "ever medium" (minimum of 1 year), and "always low." Significant excess lung cancer mortality was observed in both the 5-year and the total study periods. The SMR increased with intensity of exposure in both the 5-year and the total study periods, being significantly raised in the "ever high" exposure groups. The increased risk was most marked in men first employed before 1940 with long exposure and a long period of follow-up. However, in attributing this apparent dose-response relationship to cadmium, account has to be taken of multiple confounding factors, including arsenic, in the study population (Ades and Kazantzis, 1988). No increased risk from prostatic cancer was observed in the overall cohort, with one case in the "ever high" exposure group where one was expected.

In a systematic review of studies since the IARC (1993) classification of cadmium as a human carcinogen, several cohorts of cadmium workers have been updated with additional data available regarding environmental exposure to cadmium and cancer risk (IARC, 1993). A lower relative risk of lung cancer in occupational groups exposed to cadmium in the absence of arsenic and nickel is indicated in some studies. No evidence was found that nonmalignant respiratory

disease represents a competing cause reducing mortality from lung cancer. The association between cadmium exposure and prostate cancer was not confirmed in the latest available updates. Although studies in environmentally exposed populations have not indicated an increased relative risk of cancer (Verougstraete *et al.*, 2003), the most recent study has shown that overall cancer risk, especially lung cancer, was significantly associated with the environmental exposure to cadmium (Nawrot *et al.,* 2006; Nordberg, 2006).

1.4.2 Animal Models

Finely divided cadmium metal suspended in fowl serum injected into the thigh muscle of the rat gave rise to rhabdomyosarcoma and fibrosarcoma (Heath *et al.*, 1962). Similar tumors followed the intramuscular and subcutaneous injection of cadmium sulfide and cadmium oxide suspensions (Kazantzis, 1963; Kazantzis and Hanbury, 1966). The tumors developed at the site of one of two subcutaneous injections of 25 mg cadmium sulfide or of cadmium oxide suspended in physiological saline, or after a single intramuscular injection of 50 mg cadmium sulfide in saline, after an interval of 4 months after subcutaneous injection and 9 months after intramuscular injection. The tumors were metastasizing and pleomorphic, and the tumor yield was high. In their series with cadmium oxide, this tumor yield was comparable with the nickel sulfide–induced tumors described earlier. Subcutaneous and intramuscular injection of soluble cadmium chloride or sulfate, in addition to producing sarcomas at the injection site, also induced hyperplasia interpreted as interstitial cell tumors of the testis (Haddow *et al.*, 1964; Reddy *et al.*, 1973; Roe *et al.*, 1964) and even after a single dose (Gunn *et al.*, 1963). However, the interpretation of the specific role of cadmium in initiating these changes in the testis is difficult. The initial effect of cadmium is a necrotizing one on the interstitial cells, probably acting through the vascular supply to the testis (Parizek, 1957), and it is possible that the hyperplastic or possible neoplastic change is secondary to this. However, zinc protects against the action of cadmium on the testis (Parizek, 1957). Zinc acetate given as three subcutaneous injections inhibited the development of both interstitial cell tumors of the testis and local sarcomas after the injection of cadmium chloride in rats (Gunn *et al.*, 1964).

In a study in which cadmium sulfate was given by subcutaneous injection or by stomach tube repeatedly over a period between 18 months and 2 years to rats and mice—in the latter by stomach tube only—no malignancy or other morphological change attributable to cadmium was seen in the prostate gland or in other systems. The dose range was based on exposure levels calculated to produce low-molecular-weight proteinuria in man. However, only the rats in the highest exposure group given cadmium sulfate parenterally had liver and kidney concentrations of the same order of magnitude as occupationally exposed workers (Levy *et al.*, 1973).

Striking results were obtained in an experiment by Takenaka *et al.* (1983), who exposed inbred male rats to cadmium chloride aerosols at concentrations of 12.5, 25, and 50 $\mu g/m^3$ continuously for a period of 18 months followed by 13 months' observation (Takenaka *et al.*, 1983). A dose-related incidence of lung cancer of varying histological types was seen, ranging from 15% in the low-exposure group to 71% in the high-exposure group.

1.4.3 Short-Term Tests

Chromosomal abnormalities have been noted in mammalian cells treated *in vitro* with cadmium chloride and with cadmium sulfate, but in high dosage. Observations on chromosome aberrations in cadmium-exposed persons are conflicting. Aberrations were noted in workers in a zinc smelter who had raised blood levels of cadmium and lead (Bauchinger *et al.*, 1976); and aberrations have also been seen in Japanese patients with *Itai-Itai* disease (Shiraishi, 1975). However, other studies on cadmium-exposed workers found no such abnormalities. Mutagenic effects are considered further in Section 1. Cadmium acetate was as potent as sodium chromate in producing morphological transformation of Syrian hamster embryo cells, and both compounds enhanced transformation of these cells by simian adenovirus (Casto *et al.*, 1979; DiPaolo and Casto, 1979). Cadmium also decreased the fidelity of DNA synthesis in the cell-free system of Sirover and Loeb (1976) (Sirover and Loeb, 1976a). The mutagenic effects of cadmium demonstrated in plants and insects, and the effects of cadmium on the metabolism of nucleic acids, have been reviewed by Degraeve (1981); a further review on mutagenic and carcinogenic effects of cadmium has been supplied by Kazantzis (Kazantzis and Armstrong, 1984). Again, the reader is referred to the mechanism chapter in this handbook and the chapter on cadmium for further information

1.4.4 Evaluation

An evaluation made by the IARC (1993) on the carcinogenic risk of cadmium may be summarized as follows (IARC, 1993). In two inhalation studies in rats, malignant lung tumors were produced by cadmium chloride, cadmium sulfide/sulfate, cadmium sulfate, and cadmium oxide fume and dust at low levels of

exposure for short durations. In several studies, single or multiple subcutaneous injections of cadmium chloride, cadmium sulfide, cadmium sulfate, and cadmium oxide caused local sarcomas in rats, as did cadmium powder, cadmium chloride, and cadmium sulfide after intramuscular administration. Excess zinc by inhalation, parenteral or oral routes, has been shown to reduce the carcinogenic potential of cadmium after exposure systemically or by inhalation.

After a report of the occurrence of prostate cancer in a small group of workers employed before 1965 in a nickel-cadmium battery plant in Britain, a series of cohort analyses did not confirm this excess, but increased lung cancer mortality was detected. Similar findings were reported in a small study in Sweden. A dose-response relationship was demonstrated between estimated cumulative cadmium exposure and lung cancer risk among workers in a U.S. cadmium recovery plant with excess lung cancer mortality. In the cohort of workers from 17 cadmium-processing plants in Britain, a decreased mortality from prostatic cancer was observed, whereas that for lung cancer was increased, with suggested trends with duration of employment and with intensity of exposure.

Although a number of early studies reported an increased risk for prostatic cancer, the results of later studies were not consistent, but both early and recent studies provide consistent evidence that the risk for lung cancer is increased in cadmium-exposed workers.

The IARC evaluation concluded there is sufficient evidence in humans and in experimental animals for the carcinogenicity of cadmium compounds, with limited evidence in experimental animals for the carcinogenicity of cadmium metal. The Working Group took into consideration the evidence that ionic cadmium causes genotoxic effects in a variety of types of eukaryotic cells, including human cells. Overall, cadmium and cadmium compounds are considered carcinogenic to humans (Group 1).

1.5 Beryllium

1.5.1 Epidemiology Observations

In an initial study, Mancuso (1970) found no overall evidence of an increased mortality in beryllium workers but encountered 6 cases of lung cancer in a group of 142 cases of beryllium-related bronchitis and pneumonitis (Mancuso, 1970). The age-adjusted lung cancer mortality rate was 284.3 per 100,000 compared with 77.7 for all white adult males employed in the same beryllium plant. Mancuso concluded that prior chemical pneumonitis influenced the subsequent development of lung cancer among beryllium workers. However, the lung cancer rate was higher in workers employed for a short duration, between 3 and 15 months, than in those employed for a longer period. Follow-up studies of subjects enrolled in the U.S. Beryllium Case Registry and in two primary beryllium-production works all showed excess lung cancer mortality. The Case Registry provided 7 lung cancer deaths against 3.3 expected (Infante *et al.*, 1980). However, 5 of these subjects had been exposed for less than 1 year, including 3 for less than 1 month. In a continuation of his earlier study, Mancuso (1980) again found evidence of excess lung cancer mortality in workers who had short but heavy exposures (Mancuso, 1980). A short exposure followed by a long latent interval before the development of lung cancer was confirmed by Wagoner *et al.* (1980), who also showed a significant excess, with 47 deaths observed and 34.3 expected. However, there is an overlap of the populations studied in these three investigations, as well as alleged statistical errors (Shapley, 1977), so that interpretation of the data presents some difficulties. The apparent lack of a dose-response effect was explained by the propensity for beryllium to be retained in the lung for long periods of time, thus demonstrating the inadequacy of length of employment as a measure of dose.

An extended analysis of mortality among those entered into the U.S. Beryllium Case Registry between July 1952 and the end of 1980 included 689 men of all races, as well as women. Mortality follow-up was extended through 1988. Excess mortality was found for all cancers, due primarily to an excess of lung cancer (SMR 2.00; 95% CI, 1.33–2.89) and also to nonmalignant respiratory disease (SMR 34.23; 95% CI, 29.1–40.0). The SMR for lung cancer was greater for those cohort members with acute beryllium pneumonitis. Taking account of the distribution of smoking habits, it was concluded that the study cohort smoked less than the U.S. reference population in 1965, and that if the 32% of the cohort members questioned were representative of the entire cohort, smoking was unlikely to be a confounder of the observed lung cancer excess (Steenland and Ward, 1991).

A cohort mortality study was carried out on 9225 male workers employed at seven beryllium plants in the United States (Ward *et al.*, 1992). A small, but significant, excess mortality from lung cancer was found in the total cohort, SMR 1.26 (95% C.1, 1.12–1.42). The risks for lung cancer were considerably higher in those plants in which there was also excess mortality from pneumoconiosis and other respiratory diseases, presumably indicative of higher exposure to beryllium. The risk from lung cancer increased with time since first exposure and was greater in workers first

hired in the period when exposures to beryllium in the workplace were relatively uncontrolled. Smoking was not considered to have been a confounding factor.

1.5.2 Animal Models

The carcinogenic activity of a number of beryllium compounds, in particular the oxide, sulfate, phosphate, and zinc beryllium silicate, has been confirmed in a number of investigations in rabbits, rats, mice, and monkeys. Intravenously administered beryllium oxide and zinc beryllium silicate have given rise to osteogenic sarcoma in mice and rabbits (Barnes and Denz, 1950). Inhalational exposure to beryllium oxide was followed by osteosarcoma in one of six rabbits (Dutra *et al.*, 1951).

Rats exposed to a beryllium sulfate aerosol at a mean concentration of 34 $\mu g/m^3$ for periods up to 56 weeks developed alveolar adenocarcinoma. All the 43 rats killed at the end of the exposure period had these tumors (Reeves *et al.*, 1967). Pulmonary tumors of various types also developed in rats, but not in monkeys or hamsters, after long-term exposure to beryl ore dust. After 17 months, 18 of 19 rats exposed to beryl ore at levels of 620 μg Be/m^3 had developed pulmonary tumors, but no control rats exposed to bertrandite dust did so (Wagner *et al.*, 1969).

Taking the various experimental observations together, a dose-response relationship for the production of malignant tumors in animal models becomes apparent, and the quantitative aspects of this are given in Chapter 21.

There are no reports of chromosome abnormalities in beryllium workers, but aberrations have been found in cultured mammalian cells. Beryllium has not been shown to be mutagenic in bacterial test systems (Simmon, 1979). However, beryllium sulfate induced morphological transformation of Syrian hamster cells and enhanced viral transformation of these cells (Casto *et al.*, 1979; DiPaolo and Casto, 1979). Beryllium chloride has been shown to decrease the fidelity of DNA synthesis in the cell-free system of Sirover and Loeb (1976a) (Sirover and Loeb, 1976b). Beryllium has been shown to block thymidine incorporation in hepatic DNA (Witschi, 1970) and of certain enzymes needed for DNA synthesis. It has been suggested that beryllium binding to nucleoproteins leads to specific inhibition of events leading to DNA replication (Sunderman *et al.*, 1979).

1.5.3 Evaluation

In summary, various beryllium compounds tested by inhalation in rats have produced lung tumors, mostly adenocarcinomas. Rabbits have developed osteosarcoma after intravenous injections. In the cohort mortality study of some 9000 workers involved in refining, machining, and producing beryllium metal and alloys, the significant excess in lung cancer mortality increased with time since first exposure, greater in workers first hired in the period when exposure to beryllium in the workplace was relatively uncontrolled. In the follow-up study of deaths among workers entered into the U.S. Beryllium Case Registry, the excess mortality from lung cancer was greater in those workers previously diagnosed with acute beryllium-induced pneumonitis. Potential confounding by smoking was addressed in several ways and did not seem to explain the increased risk for lung cancer.

In their evaluation, the IARC (1993) concluded there is sufficient evidence in humans and in experimental animals for the carcinogenicity of beryllium and beryllium compounds. Overall, beryllium and beryllium compounds are carcinogenic to humans (Group 1).

1.6 Lead

1.6.1 Epidemiological Observations

An early epidemiological study on lead workers showed no excess mortality from malignant neoplasms despite heavy exposure (Dingwall-Fordyce and Lane, 1963). In an update of this study, a small excess of malignant neoplasms of the digestive tract was found (observed 63, expected 48.6), but the excess mortality was not considered to be related to lead exposure (Malcolm and Barnett, 1982).

A case-control study of children with Wilms' tumor found an excess risk in children whose fathers had been employed in occupations classified as "lead related." However, the study could provide no evidence that actual lead exposure had occurred (Kantor *et al.*, 1979). A further case-control study found no evidence to support the hypothesis that paternal lead exposure is a risk factor for Wilms' tumor (Wilkins and Sinks, 1984).

An extensive cohort mortality study has been performed in the United States on a group of more than 7000 workers in lead-battery and lead-producing plants who had been exposed for a minimum period of 1 year (Cooper, 1976; Cooper and Gaffey, 1975). Lead absorption in many of these workers was greatly in excess of currently accepted standards, with a mean blood lead level of almost 80 $\mu g/100$ g in the production workers and 63 $\mu g/100$ g in the battery workers. In the initial study, a small excess mortality was found from cancer of the digestive organs and respiratory system (Cooper and Gaffey, 1975). In the succeeding 5-year period, however, the original mortality pattern was not maintained. In an update of this study, the mortality was examined

for the total 34-year period 1947–1980. Elevated standardized mortality ratios for malignant neoplasms have been found in both battery and production workers, the excess deaths being predominantly from gastrointestinal tract cancer and lung cancer. In the battery workers, there were 34 deaths from stomach cancer with 20.2 expected and 109 deaths from lung cancer with 87.8 expected, both standardized mortality ratios being significantly raised. A similar pattern was observed in the lead production workers. In interpreting these findings, account should be taken of the complex etiology of both lung and stomach cancer. The reference population used was U.S. white men, and smoking histories were not available. In the study, account could not be taken of the marked temporal and spatial variation of stomach cancer and of its close relationship to social class, and data were inadequate to seek a dose-response relationship. However, the possibility cannot be dismissed that heavy exposure to compounds of lead, perhaps in association with other chemical agents, has given rise to an excess of stomach and lung cancer; further epidemiological studies are required.

1.6.2 Animal Models and Short-Term Tests

Zollinger (1953) first observed renal adenoma and carcinoma in rats after the subcutaneous injection of lead phosphate (Zollinger, 1953). This observation has been confirmed, and several investigations have induced similar tumors after the administration in the diet of lead subacetate in rats and mice and lead acetate in rats (Boyland *et al.*, 1962; Van Esch and Kroes, 1969). Large doses of lead were used in these experiments, which caused gross morphological damage to the kidney, and which far exceeded doses tolerated by humans. Although tumors at other sites, including cerebral gliomas, have been reported, these have not been confirmed. Lead compounds have not given rise to mutagenic effects in bacterial test systems, but lead acetate has induced dose-related transformation in hamster embryo cells (DiPaolo and Casto, 1979), lead oxide enhanced transformation by simian virus (Casto *et al.*, 1979), and lead chloride has been shown to decrease the fidelity of DNA synthesis (Sirover and Loeb, 1976b). Epidemiological and experimental work from recent studies confirms that inorganic lead compounds are associated with increased risks of tumorigenesis (Silbergeld *et al.*, 2000). Several possible mechanisms by which lead compounds cause tumors have been shown that include direct DNA damage, clastogenicity, or inhibition of DNA synthesis or repair, and generation of reactive oxygen species that may cause oxidative damage to DNA. In addition, lead can also substitute for zinc in several proteins that function as transcriptional regulators and reduce the binding of these proteins to recognition elements in genomic DNA. This suggests that lead may alter gene expression through an epigenetic mechanism (Silbergeld *et al.*, 2000). Again the reader is referred to the mechanism chapter in this handbook as well as the chapter on lead for further information.

1.6.3 Evaluation

An IARC Working Group (2004) reevaluated the potential carcinogenic hazards to humans from exposure to inorganic and organic lead. The widespread occurrence of lead in the environment has been largely the result of anthropogenic activity since prehistoric times. Lead use has increased progressively with industrialization and rose dramatically with the use of lead auto batteries and leaded fuel. The predominant use of lead is currently in batteries, construction materials, and lead-based chemicals. It is being progressively phased out in pipes, paints, and gasoline. Recent human exposure has arisen predominantly from the widespread use of leaded gasoline and in areas near lead mines and smelters with high environmental concentrations of lead. Occupationally, the highest potential exposure to lead includes mining, primary and secondary smelting, production of lead acid batteries, pigment production, construction, and demolition.

To evaluate the epidemiological evidence of possible carcinogenic hazards, the Working Group considered six occupational cohort studies of highly exposed workers to be particularly informative, battery workers in the United States and the United Kingdom, and primary smelter workers in Italy, Sweden, and the United States. In their evaluation, the IARC concluded that inorganic lead compounds are probably carcinogenic to humans (group 2A) and organic lead compounds are not classifiable as to their carcinogenicity to humans (group 3). The Working Group noted that organic lead compounds are in part metabolized to ionic lead. To the extent that ionic lead generated from organic lead is present in the body, it will be expected to exert the toxicity associated with inorganic lead.

The remaining metals considered in this section have very little or no epidemiological evidence to incriminate them as carcinogens in human exposure situations. They have, however, been included here because of limited data in animal experimental studies. A more detailed review is given by Kazantzis (1981).

1.7 Cobalt

Finely divided cobalt metal powder, cobalt oxide, and cobalt sulfide have given rise to injection-site

fibrosarcoma after subcutaneous injection and to rhabdomyosarcoma after intramuscular injection in rats (Gilman, 1966). They were able to produce such neoplasms with fine particles from surgical prostheses made from a cobalt-chromium alloy. Cobalt chloride has been shown to decrease the fidelity of DNA synthesis *in vitro* (Sirover and Loeb, 1976a), to induce morphological transformation, and to enhance viral transformation of hamster embryo cells (Casto *et al.*, 1979; DiPaolo and Casto, 1979).

There have been few reports of cancer in cobalt workers despite past occupational heavy exposure. In certain nickel extraction plants in the U.S.S.R., an increased mortality from lung cancer was found in the cobalt-recovery shops and in the nickel-processing departments (Saknyn and Shabynina, 1973). However, exposure to arsenic-containing dust was heavy, and these workers may also have been exposed to nickel. There are no convincing reports of cancer having arisen in relation to surgical prostheses with cobalt-containing alloys, despite raised blood and urinary cobalt levels. IARC (1991) considered that cobalt and cobalt compounds are possibly carcinogenic to humans (group 2B) (IARC 1991). Again the reader is referred to the mechanism chapter in this handbook and the chapter on cobalt for further information.

1.8 Iron

Iron-dextran and certain other polysaccharide iron complexes have induced local sarcomas in mice, rats, rabbits, and hamsters after subcutaneous or intramuscular injection in large doses with evidence of a dose-response relationship (Haddow and Horning, 1960; Richmond, 1959; Roe and Carter, 1967). The significance of these observations arises in relation to iron therapy. Although many of these compounds have been administered parenterally in the treatment of anemia over the past 30 years or so, sarcoma at the injection site has been rarely reported. In a survey of all 72 soft tissue sarcomas found over a 2-year period in a defined area, no history of past parenteral iron therapy could be obtained (McIllmurray and Langman, 1978).

The repeated intratracheal installation, in hamsters, of ferric oxide suspended in normal saline did not give rise to lung tumors (Saffiotti *et al.*, 1968). However, given together with benzo(a)pyrene or with systemically administered diethylnitrosamine, an increased yield of lung tumors was obtained. Ferric oxide was thought to be a carcinogenic cofactor, possibly acting by retarding clearance of an inhaled carcinogen or by inducing cytopathological changes that make the cells of the respiratory tract more susceptible to carcinogens. Iron oxide did not produce morphological transformations in hamster embryo cells and only enhanced viral transformations in very high concentrations (Casto *et al.*, 1979). Iron did not decrease the fidelity of DNA synthesis in the cell-free system of Sirover and Loeb (1976) (DiPaolo and Casto, 1979).

There has been speculation on the role of iron oxide as a possible carcinogen common to hematite, asbestos, nickel, and chrome workers, but there is little evidence to support such a hypothesis. Boyd *et al.* (1970) observed a significantly increased mortality rate from lung cancer in hematite miners in Cumberland, England, but this excess risk could also be attributed to ionizing radiation from radon and radon daughters present in the atmosphere of the mine (Boyd *et al.*, 1970). Excess lung cancer mortality has also been observed in iron-ore miners from a number of other countries. Raised levels of ionizing radiation were found in the iron ore mines of Kiruna, Sweden, but measurements have not been made in all mines where a lung cancer hazard has been shown to exist. An increased mortality risk from lung cancer in iron and steel foundry workers has been attributed to exposure to polycyclic hydrocarbons. Exposure to high levels of iron oxide in the production of sulfuric acid from iron pyrites showed no excess mortality from cancer at any site (Axelson and Sjoberg, 1979).

On the basis of the experimental animal studies and on what they termed suggestible evidence in man, the IARC (1976) classified iron-dextran as "probably carcinogenic for humans." In regard to occupational exposure, the IARC concluded on the basis of epidemiological evidence that underground hematite mining does increase the risk of lung cancer in man, but that the evidence is inadequate to classify hematite as the carcinogen. A number of confounding factors have to be taken into account before the role of iron in human carcinogenesis can be adequately assessed. Again the reader is referred to the mechanism chapter in this handbook.

1.9 Manganese

In a single experiment, rats were given intramuscularly pure manganese powder, manganese dioxide, or manganous acetylacetonate suspended in trioctanoin in multiple treatments. Although no difference in tumor incidence between treated and control animals was found with manganese powder and manganese dioxide, a significant number of fibrosarcomas developed at the injection site in the rats given manganous acetylacetonate, with a mean latent interval of 17 months (Furst, 1978). Enhanced viral transformation of hamster embryo cells was obtained with manganese chloride (Casto *et al.*, 1979), and this compound also

decreased the fidelity of DNA synthesis *in vitro* (Sirover and Loeb, 1976b). When administered intranasally in rats, manganese is effectively taken up in the central nervous system (CNS) through the olfactory system (Henriksson and Tjalve, 2000). Studies have indicated that the astrocytes are the initial targets of manganese toxicity in the CNS and dysfunction of astrocytes possibly involved in neurotoxic action of manganese (Chen and Liao, 2002).

There are no clinical reports implicating manganese as a human carcinogen, and no epidemiological studies that have attempted to relate manganese exposure to cancer.

1.10 Platinum

The chance finding that certain coordination complexes of platinum have the property of inhibiting cell division in *E. coli* led to intense investigation of this group of platinum compounds. *cis*-Dichlorodiammine platinum(II) (*cis*-DDP) is a potent chemotherapeutic agent used in the management of, in particular, metastatic testicular and ovarian tumors. In a well-controlled study, DDP and analogues have been shown to significantly increase tumor frequency in rats and mice (Leopold *et al.*, 1979). Administered intraperitoneally in mice, DDP increased adenoma frequency, and together with topical applications of croton oil, produced skin papillomas and a few epitheliomas. Rats treated with *cis*-dichlorobiscycIopentylamine platinum (II) or *cis*-dichlorobispyrolidine platinum (II) developed a small number of injection-site and distant sarcomas. There were no tumors in the control animals. DDP and its analogues have been shown to be mutagenic in bacterial test systems without microsomal activation. DDP forms both intrastrand and interstrand cross-links with human DNA in cell culture (Roberts and Pascoe, 1972). The effects of DDP on chromosomes are described earlier in this chapter. Morphological transformation of hamster embryo cells and enhancement of viral transformation was produced with low concentrations of platinum, which together with antimony, arsenic, cadmium, and chromium, showed the highest activity in this respect (Casto *et al.*, 1979). Thus, these platinum complexes fit the model for electrophilic reactants binding to cellular nucleophiles, which are direct-acting mutagens and are also capable of cancer initiation. *Cis*-DDP is classified as probably carcinogenic to humans (group 2A) according to IARC (1987).

There are no reports of cancer related to occupational exposure to platinum compounds or of epidemiological studies of cancer mortality in platinum workers. However, because of the high risk of sensitization to soluble platinum compounds in the working environment, exposure has been consistently maintained at very low levels, making a cancer risk unlikely.

1.11 Titanium

In a long-term survival study, fibrosarcomas and lymphosarcomas were observed in a small number of rats injected intramuscularly with fine titanium metal powder suspended in trioctanoin. Tumors were observed with powdered nickel and powdered chromium metal but not with powdered copper or iron administered in a similar way. The organic compound titanocene, dichlorodicyclopentadienyl titanium, administered intramuscularly in rats and mice in a similar way also gave rise to injection-site fibrosarcoma, and a few animals developed hepatoma and malignant lymphoma, but details were not given (Furst and Haro, 1969).

Although titanium compounds such as titanium dioxide (TiO_2) are generally regarded as nontoxic mild pulmonary irritants, some studies have reported lung adenomas in rats exposed to high levels of TiO_2. As for human studies, a retrospective cohort mortality study was conducted among 4241 TiO_2 workers who were employed for at least 6 months, on or after January 1, 1960, at four TiO_2 plants in the United States. The result indicated that the exposures at these plants were not associated with increases in the risk of death from cancer or other diseases. Moreover, workers with likely higher levels of TiO_2 exposure had similar mortality patterns to those with less exposure, because internal analyses among workers revealed no increase in mortality by level of TiO_2 exposure (Fryzek *et al.*, 2003). A recent human study also did not suggest a carcinogenic effect of TiO_2 dust on the human lung (Boffetta *et al.*, 2004).

2 PRINCIPAL METALS SHOWING MUTAGENIC EFFECTS

Most of the toxic metals have very poor direct interactions with DNA and, in general, are weakly mutagenic. Even chromate, which can yield trivalent chromium DNA adducts, is not highly mutagenic in many systems. However, it is of interest that carcinogenic metals can interact with other environmental carcinogens. For example, metals can inhibit the repair of benzo(a)pyrene or UV-induced DNA adducts and potentiate the mutagenicity of benzo(a)pyrene or UV (Hartwig, 1998; Hu *et al.*, 2004a; 2004b). It is also of interest to note that there are poor animal models for metal-induced tumor. Many of the cancers that arise in humans occupationally exposed to carcinogenic

metals, such as nickel compounds and chromate, are associated with exposure to other environmental carcinogens such as cigarette smoking (Gibb *et al.*, 2000; Grimsrud *et al.*, 2002b; 2003). Recent success in inducing cancers with arsenite and chromate in mice was associated with the use of hairless mice exposed to both UV and these carcinogenic metals through their drinking water (Davidson *et al.*, 2004; Rossman *et al.*, 2001; 2004). Thus, in general, carcinogenic metals have strong interactions with carcinogens, such as PAH, UV, and the many carcinogens that are present in cigarette smoke. Some carcinogenic metals such as nickel compounds are able to induce cancers in animals exposed to these metals alone, although nickel also has a strong interaction with other organic carcinogens such as benzo(a)pyrene and UV (Schwerdtle *et al.*, 2002; Waalkes *et al.*, 2004; Wozniak and Blasiak, 2004).

2.1 Nickel

Nickel compounds are not very mutagenic in most of the tested assay systems (Coogan *et al.*, 1989; Costa, 1993b; 2002). However, some studies have shown that nickel compounds induce oxidative stress, genomic instability, and chromosome damage (Biggart and Costa, 1986; Conway and Costa, 1989; Costa, 2002; Kargacin *et al.*, 1993; Kasprzak *et al.*, 2003; Lin *et al.*, 1991; Sen and Costa, 1985). The Landolph laboratory has also shown that nickel compounds induce morphological cell transformation, but no mutation to ouabain resistance in C3H/10T1/2 cells (Miura *et al.*, 1989). Perhaps one of the most important effects of nickel in terms of effecting DNA is its ability to silence genes through DNA methylation and other epigenetic effects (Klein and Costa, 1997; Klein *et al.*, 1991). The epigenetic effects of nickel compounds are more potent with the water-insoluble forms of nickel compounds such as Ni_3S_2, but this effect is also evident when cells are exposed to soluble nickel compounds for long periods of time (Lee *et al.*, 1995). Nickel compounds can also induce oxidative stress *in vivo* (Coogan *et al.*, 1989; Doreswamy *et al.*, 2004; Kasprzak, 1995).

2.2 Chromium

Water-soluble chromate (chromium VI) compounds were tested for cell transformation, mutagenicity, and chromosomal damage and were found to be very active (Bianchi *et al.*, 1983). Analysis of the nature of mutations in a 104-base pair segment of the HPGRT gene exon 3 showed selectivity in substitutions for GC base pairs (Chen and Thilly, 1994). Treatment of a shuttle plasmid *in vitro* with a chromium (VI) reduction system with glutathione or cells containing the shuttle plasmid yielded mutations predominantly at GC sites (Liu *et al.*, 1999). Chromium (VI) is known to have a preference for binding to the phosphate backbone of DNA and with positively charged N7 of guanine (Huang *et al.*, 1995; Voitkun *et al.*, 1998; Zhitkovich, 2005). Chromium (VI) is also synergistic with other organic carcinogens, such as those present in cigarette smoke. One possible mechanism for these effects involves the inhibition of the repair of benzo(a)pyrene DNA adducts (Feng *et al.*, 2003; Hu *et al.*, 2004a). Chromate exposure has been shown to induce oxidative stress in cells, and these effects are greater with some insoluble chromium compounds (Leonard *et al.*, 2004; Martin *et al.*, 1998; Shi and Dalal, 1994). The oxidative stress, the reduction of chromium (VI) to chromium (III), and the binding of chromium (III) to DNA are thought to be involved in its mutagenesis and genotoxicity. The binding of chromium (III) to the DNA can yield a wide variety of DNA lesions, including ternary complexes of chromium (III) with its reducer (ascorbic acid or GSH), as well as DNA–DNA crosslinks, DNA–protein crosslinks, single-strand breaks, and formation of alkaline labile sites (Coogan *et al.*, 1991; Costa, 1993a; Huang *et al.*, 1995; Zhitkovich, 2005). It has been shown that lead chromate induced morphological and neoplastic transformation in C3H/10T1/2 Cl 8 mouse embryo cells, and chromium (VI) compounds induced mutation to 6-thioguanine resistance in cultured normal human diploid fibroblasts (Biedermann and Landolph, 1990; Patierno *et al.*, 1988).

2.3 Arsenic

In general, arsenic compounds show poor genotoxicity and mutagenicity. Some studies have found evidence of DNA damage by arsenite such as micronuclei formation (Liu and Huang, 1997; Schaumloffel and Gebel, 1998) and DNA protein crosslinks (Gebel, 1998), but others did not find DNA protein crosslink formation by arsenite (Costa *et al.*, 1997). Arsenic has been found not to be mutagenic in bacteria and cultured mammalian cells (Rossman *et al.*, 1980). However, a very consistent effect of arsenic compounds is being a comutagen, possibly by inhibiting the repair of DNA lesions produced by genotoxic agents such as UV (Rossman, 1981a; 1981b; Rossman *et al.*, 1977; 1986). Additional studies that support the comutagenic effects of arsenic are those studies showing that it is also a cocarcinogen (Rossman *et al.*, 2001; 2004). In addition, arsenic has been shown to inhibit the ligation step of DNA repair and thus can interact with many genotoxic insults (Hu *et al.*, 1998).

2.4 Cadmium

In general, cadmium compounds are weakly mutagenic in most assay systems (Filipic and Hei, 2004), but they have been shown to be genotoxic (Yang *et al.*, 2003). The mechanism by which cadmium may be genotoxic is by indirectly inducing oxidative stress in cells as a result of its inhibition of antioxidant enzymes and depletion of antioxidant molecules such as GSH (Stohs *et al.*, 2000). Cadmium has been reported to be very active in inducing apoptosis in a wide variety of cells, because of its induction of oxidative stress (Aydin *et al.*, 2003; Bagchi *et al.*, 2000; Jimi *et al.*, 2004; Poliandri *et al.*, 2003; Shin *et al.*, 2004; Tzirogiannis *et al.*, 2003; Watjen *et al.*, 2002). Cadmium has also been shown to inhibit DNA repair (Buchko *et al.*, 2000; Hartwig *et al.*, 2002a; 2002b; Waisberg *et al.*, 2003; Zharkov and Rosenquist, 2002).

CHAPTER

11

Immunotoxicology of Metals

PER HULTMAN

ABSTRACT

The present understanding of the effect of metals (including ions and their compounds) on the immune system has evolved recently. These effects include suppression, unspecific stimulation, hypersensitivity, and autoimmunity. Many metals show a paradoxical dose-response relationship with stimulation of certain immune functions at low doses and suppression at high doses. The global immune function is often preserved because of the redundancy and the reserve capacity of the immune system, and clinically relevant effects are uncommon. Clinically relevant hypersensitivity reactions caused by metals are dominated by T-cell–mediated allergic contact dermatitis, mainly in connection with exposure to beryllium, cobalt, chromium, gold, mercury, and nickel. Immediate (type I) hypersensitivity reactions with dominating symptoms from the airways occur infrequently, and then most often with platinum, and rarely with nickel and chromium. Induction of metal-induced autoimmunity with immune-complex deposits is well documented in humans, but the recognized numbers of cases are few. Studies in rodents that used mercury and gold have increased the knowledge of mechanisms in metal-induced autoimmunity. Of special importance is the unravelling of genetic factors as regulating susceptibility to mercury-induced autoimmunity both by interaction with the immune system and metal toxicokinetics. Recently, mercury, lead, and cadmium have been shown to accelerate and/or aggravate development of autoimmunity in spontaneous animal models. The importance of metal exposure for induction and/or acceleration of autoimmunity in humans remains to be studied, and a better understanding of genetic factors will be needed.

1 INTRODUCTION

1.1 Development of the Concept Metal Immunotoxicology

The potential of metals, or more accurately "metallic elements, their ions and their compounds" (Duffus, 2003), to cause widely divergent effects on the body because of an interaction with the immune system is a recently discovered path in the history of metal toxicity. Disease conditions like occupational asthma and dermatitis were associated with exposure to metals such as platinum, chromium, nickel, beryllium, and mercury during the first part of the 20th century or earlier. However, a clear recognition of these conditions as immune mediated had to await the rapidly expanding knowledge in immunology during the 1960s and 1970s. At the same time, animal studies linked metal exposure with immunosuppression, as well as nonspecific immune stimulation (Koller, 1973; Vos, 1977). Metals as a mean of inducing autoimmunity began to be explored in the late 1970s. The state of the art was summarized at the International Symposium on the Immunotoxicity of Metals and Immunotoxicology held in Hanover in 1989 (Dayan *et al.*, 1990). More recently a number of reviews on the effect of metals on the immune system have appeared (Enestrom and Hultman, 1995; Kimber and Selgrade, 1998; Martin, 2004; Schuppe *et al*., 1998; Templeton, 2004; Zelikoff and Thomas, 1998).

1.2 Overview of Mechanisms in Immunotoxicology

Like all xenobiotics, metals (and their metabolites) may have a direct or indirect action on the immune system. This might take the form of morphological damage to immunologically active tissues such as the thymus, lymph nodes, spleen, and myelopoiesis (bone marrow and peripheral blood), which might be grossly or microscopically evident. Further studies may show these morphological alterations to be due to abnormalities in cell proliferation, necrotic and/or apoptotic cell death, causing, for example, alterations in populations of immunocompetent cells such as T and B cells and dendritic cells. Subpopulations such as T-helper type 1 and type 2 cells may also be altered by metals, disturbing the balance in finely tuned immune reactions. The functional effect of these morphological alterations may be assessed by measuring a number of endpoints related to innate, humoral, or cell-mediated immunity *in vitro* and *in vivo* using experimental animals or in humans. This forms the basis for defining a major and a minor effect of metals (and other xenobiotics) on the immune system, *immunosuppression* (Section 2) and *unspecific immune stimulation* (Section 8), respectively. However, metals may also interact with the immune system by causing an immunologically based host response to the metal (and/or its metabolites), which is exaggerated and/or inappropriate in relation to the situation, and leads to structural and/or functional damage to the tissues. These reactions include specific T and/or B cells, confer a memory to the immune system, and are defined as *hypersensitivity reactions* (Section 4). When the immune reaction is directed against self-antigens, *autoimmunity* (Section 9) ensues. The mechanisms causing autoimmune reactions are, in general, not well known, but metals may alter self-proteins both directly and indirectly (Sections 6 and 7). A common, final pathway may be exposure of parts of self-proteins not previously presented to the immune system, cryptic epitopes, which are, therefore, identified as non-self and may elicit an autoimmune reaction.

1.3 Dose-Response Considerations in Metal Immunotoxicology

Dose-effect and dose-response relationships are fundamental principles in metal toxicology (Chapter 6). Non-immune mediated toxicity is normally characterized by an increasing proportion of the exposed showing a specific toxic effect with increasing dose and a threshold below which there is no dose-related response. Immune-mediated toxicity shows many exceptions from these basic rules. For example, a low dose may *enhance* a specific immune function, a middle-range dose may have no effect, whereas a high dose causes *immunosuppression*. This type of dose-response curve has been observed for arsenic (McCabe *et al.*, 1983), cadmium (Marth *et al.*, 2000), chromium (Borella *et al.*, 1990), lead (Descotes, 1999), and selenium (Descotes, 1999; Kiremidjian-Schumacher and Stotzky, 1987). Furthermore, a specific immunological endpoint assessed may often be substantially reduced without affecting the ability of the host to sustain an immunological challenge, which demonstrates the *reserve capacity* of the immune system. This might, in turn, be due to a reserve capacity of the specific immunological endpoint, or to *redundancy*. Redundancy means that additional immunological functions are either present or induced, compensating for the reduction in the single endpoint measured. These observations are all accountable for by the fact that the immune system is a dynamic, integrated, interdependent system that is capable of reacting to changing circumstances. Furthermore, the timing between exposure to a metal and the challenge to which the immune system is confronted, such as an antigen or an infection, may affect the outcome (Laschi-Loquerie *et al.*, 1987).

Dose-response relationships are even more complicated in hypersensitivity reactions, where an initial phase of sensitization is necessary for the elicitation (effector) reaction to take place later on. Sensitization will only occur above a certain threshold dose of the metal. The dose required for sensitization may depend on the route of exposure. Furthermore, the ability to be sensitized depends on genetic factors, as demonstrated by using different guinea pig strains for contact sensitization (Polak, 1983). More recent observations in humans relate to hypersensitivity reactions occurring after exposure to gold (Section 5.4) or beryllium (Section 5.1). Once sensitization has taken place, the elicitation of a hypersensitivity reaction on repeated exposure to the metal requires a higher dose than sensitization. The dose-response curve for hypersensitivity reactions is often bell shaped, which means that a threshold dose exists, but also that a high dose might inhibit the reaction.

Finally, experimental studies have with few exceptions dealt with exposure to a single metal, despite the fact that the common environmental human exposure to metals always involves many metals, and simultaneous exposure to a set of metals is also very common in occupational settings.

2 IMMUNOSUPPRESSION INDUCED BY METALS

2.1 General Considerations

Immunosuppression is a reduction in the normal immune function, irrespective of the magnitude. This is uncomplicated for xenobiotics such as cytotoxic drugs that cause a severe reduction in immune functions. However, many metals (and other xenobiotics) cause only a mild-to-moderate reduction of the immune function, and the direct consequences for the host are usually marginal and self-limited. *Immunodepression* has been proposed as a term for such mild-to-moderate suppression of the immune function (Descotes, 1999). This concept is potentially very useful for metals but would necessitate an agreement on how to define immunodepression and immunosuppression, including dose considerations. Because such an agreement is lacking, the term immunodepression will not be used in the following text, although the concept is acknowledged.

2.2 *In Vitro* Studies

A large number of *in vitro* studies have demonstrated that metals may suppress the function of all immune cells (Lawrence, 1981), including T (Colombo *et al.,* 2004; Mattingly *et al.,* 2001; Shen *et al.,* 2001; Shenker *et al.,* 1992) and B (Gallagher *et al.,* 1995; Shenker *et al.,* 1993) cells, as well as monocytes/macrophages (Sakurai *et al.,* 2004; Wataha *et al.,* 2000). *In vitro* observations are critically dependent on the metal concentration, the cell type(s), the duration, and exact conditions of the culture, including the oxygen pressure and the oxidative status, as well as the strain and species from which the cells are derived. As a consequence, contradictory results have often been reported, and *in vitro* studies should be treated cautiously and as an indication of possible *in vivo* effects only.

2.3 *In Vivo* Studies

In vivo studies using animal models have established the ability of metals to act as immunosuppressants on various functions on the immune system in the intact organism. This is especially true for organotins (Battafarano *et al.,* 1998; Smialowicz *et al.,* 1990; Vos *et al.,* 1984), arsenic (Burns *et al.,* 1991), cadmium (Borgman *et al.,* 1986; Fujimaki *et al.,* 1983; Koller *et al.,* 1975; Krzystyniak *et al.,* 1987), lead (Lawrence, 1981; McCabe *et al.,* 1999), inorganic as well as organic mercury (Abedi-Valugerdi *et al.*, 1997; Christensen *et al.,* 1996; Ellermann-Eriksen *et al.,* 1994), and nickel (Dogra *et al.,* 1999; Harkin *et al.,* 2003; Smialowicz *et al.,* 1987). A special effect of some metals is skewing of the T-helper cell response toward type 1 or type 2. This was first observed for zinc as an adverse effect on Th2 cells (Prasad, 2000). A skewing favoring a Th2 type of response has been observed during lead and mercury exposure (Heo *et al.,* 1997). The latter finding correlates with a decreased resistance to intracellular pathogens after exposure to mercury (Bagenstose *et al.,* 2001; Silbergeld *et al.,* 2000) and lead (Dyatlov and Lawrence, 2002), which concurs with the observation that a Th1 response is needed to efficiently handle intracellular pathogens (Igietseme *et al.,* 2004).

2.4 Experimental Host-Resistance Challenge Systems

The perceived genuine functions of the immune system are to protect the host from pathogenic agents such as microorganism (including bacteria, viruses, parasites, and fungi); to suppress development of neoplastic cells and eliminate such cells; and finally to eliminate or at least contain other non-self components, for example, crystalline material like silica. The mere observation of a significant effect of a metal on a certain immune parameter *in vivo* should, however, not be interpreted as a significant immunosuppression. The reason is the redundancy and the reserve capacity of the immune system (Section 1.3). Redundancy is the multiplication of crucial mechanisms in the immune system: if a specific function is affected, other mechanisms may carry out the jeopardized function. Reserve capacity means that the integrated immune system is capable of carrying out its genuine functions although certain immune parameters are suppressed.

To better assess the functional importance of the immunosuppressive effects observed for several metals *in vitro* and in *vivo*, a number of experimental infectivity and neoplastic models—host resistance challenge models—have been developed. Perhaps the best-examined metals in this respect is lead, which causes enhanced susceptibility whether the challenge is with virus (Gainer, 1974; Gupta *et al.,* 2002; Youssef *et al.,* 1996), bacteria (Cook *et al.,* 1975; Dyatlov and Lawrence, 2002; Hemphill *et al.,* 1971), or tumors (Kerkvliet and Baecher-Steppan, 1982; Kobayashi and Okamoto, 1974). Another example is mercury, which causes reduced resistance to viruses (Ilback *et al.,* 1996), bacteria (Koller, 1975), and parasites (Bagenstose *et al.,* 2001; Silbergeld *et al.,* 2000).

2.5 Clinical Immunosuppressive Effects

Despite the evidence that certain metals have a significant effect on the ability of the immune system

to carry out its genuine functions in animal models, reports showing a significant clinical effect of metal exposure on the immune function in humans are relatively uncommon and often of uncertain significance. One explanation might be that early animal studies often used high doses that may never or only very rarely be relevant for the human situation. Even when more realistic doses were used in the animal studies, the reserve capacity and redundancy of the human immune system compared with animals (Cunningham, 2002) might prevent any clinical consequence. However, concurrent conditions like malnutrition or chronic infections may theoretically narrow the reserve capacity, allowing metals to have a clinical immunosuppressive effect that would not have developed in otherwise healthy individuals. However, data on this subject are not available.

3 ESSENTIAL METALS AND THE IMMUNE SYSTEM

The elements zinc, iron, copper, selenium, chromium, and cobalt are essential metals for the human body and the immune system. There is ample evidence that Fe deficiency comprises humoral immunity in both humans (Feng *et al.,* 1994; MacDougall and Jacobs, 1978) and animals (Kochanowski and Sherman, 1985), possibly because of the need for iron in early events associated with cell activation, including generation of second messengers (Kuvibidila *et al.*, 1999). In contrast, excess iron suppresses innate and cell-mediated immunity (Bowlus, 2003). Zn deficiency and the following increased corticosteroid levels cause apoptotic loss of precursor B and T cells in mice, leading to thymic atrophy and lymphopenia (Fraker and King, 2004). Zn deficiency also seems to be of clinical relevance in humans (Black, 2003). Excess of Zn has resulted in divergent effects on the immune function, including some reports of immunostimulation in humans. Copper deficiency is immunosuppressive and reduces IL-2 and T-cell proliferation (Percival, 1998), whereas an excess of copper seems to be of little importance for the immune system. Selenium has a beneficial effect on the immune function, strengthening primarily the cell-mediated immunity by upregulating the expression of the T-cell high-affinity IL-2 receptor (Kiremidjian-Schumacher and Stotzky, 1987) and, as a consequence, also stimulating antibody production (Hawkes *et al.,* 2001). Chromium (Anderson, 2000) and cobalt (Barceloux, 1999) are essentials metals but may cause suppression of T cells (Faleiro *et al.*, 1996) and B cells (Wang *et al.,* 1997), as well as hypersensitivity (Sections 5.2 and 5.3).

4 HYPERSENSITIVITY INDUCED BY METALS

4.1 General Considerations

Several metals may interact with the immune system causing a specific immune activation that damages the tissues of the body; the response is exaggerated and/or inappropriate in relation to the situation. The mechanisms involved in these hypersensitivity reactions were classified as type I–IV by Coombs and Gell in 1968. Although this classification has been criticized for not taking into account recent progress in the understanding of the immune system and reactions to xenobiotica, especially drugs (Descotes and Choquet-Kastylevsky, 2001), it is still widely used. However, it does not indicate the involvement of T cells in the induction of hypersensitivity reactions described as antibody-mediated in the classification (type II and III). Furthermore, it does not take into account so-called pseudoallergic (anaphylactoid) reactions, where xenobiotics activate complement or release mediators such as histamine without involvement of antibodies. Finally, a xenobiotic may well cause hypersensitivity by more than one mechanism in the individual patient and over time (Descotes and Choquet-Kastylevsky, 2001). Keeping these important comments in mind, the following description will follow the traditional Coombs and Gell classification.

4.2 Type I Hypersensitivity (Anaphylactic or Immediate Hypersensitivity)

In IgE-mediated hypersensitivity, the immune system has become sensitized to certain substances—allergens—and will on renewed exposure to these substances elicit a release reaction from mast cells armed with the allergen-specific IgE antibodies. The release of vasoactive amines (histamines, leukotrienes, platelet-activating factor), together with eosinophilic and neutrophilic chemotactic factors, is responsible for the clinical manifestations such as hay fever with rhinitis and conjunctivitis, asthma, and the calamitous systemic anaphylactic reaction. Symptoms of this type have been recognized since the 19th century after exposure to platinum compounds, now recognized to be platinum salts containing reactive halogen ligands (Merget *et al.,* 1988). Induction of asthma by chromium and nickel compounds has also been described (Haines and Nieboer, 1988; Novey *et al.*, 1983).

4.3 Type II Hypersensitivity (Antibody-Mediated—IgG or IgM—Reactions Against Cells or Matrix)

These reactions give rise to cytotoxic depletion of mainly red blood cells, thrombocytes, and granulocytes by means of complement activation. The type II reaction is associated with hemolytic anemia and thrombocytopenia during exposure to gold (Panayi, 1990). Development of autoantibodies to basement membrane components in rats after Hg exposure (Sapin *et al.*, 1977) also belongs to this type of hypersensitivity.

4.4 Type III Hypersensitivity (Immune-Complex Mediated Reactions)

Combination of antigens and antibodies in the circulation with subsequent deposition of the immune complexes in the tissues leads to complement activation and inflammation. Alternately, the formation of the immune complexes may develop *in situ* in the tissues when either the antigen or the antibody is planted in the tissues separately. Type III reactions are important in all spontaneous, systemic autoimmune diseases (Jancar and Sanchez Crespo, 2005). In connection with metals, type III reactions have mostly been associated with Au (Gunnarsson *et al.*, 2001) and Hg (Oliveira *et al.*, 1987; Tubbs *et al.*, 1982).

4.5 Type IV Hypersensitivity (Cell-Mediated Reactions)

This is by far the most common type of hypersensitivity that has been associated with metals. The sensitization of T cells to metal-modified self-antigens involves antigen-presenting cells (APC), such as dermal dendritic cells and epidermal Langerhans cells, which migrate with the modified antigen to the local lymph nodes, where the antigen is presented to T cells leading to clonal proliferation and maturation with aquisition of skin-homing receptors, cutaneous lymphoid-associated antigen (CLA). This process takes 1–2 weeks. On reexposure to the antigen, the elicitation phase ensues in which antigen-specific effector cells are rapidly produced in the local lymph nodes, and these cells home through their CLA-expression back to the skin. Both $CD4^+$ (mainly type 1) cells and $CD8^+$ cells are now recognized as effector cells, whereas $CD4^+$ type 2, IL-10–producing cells may act as regulatory cells (Kupper and Fuhlbrigge, 2004). The effector cells cause a release of various cytokines, the most important effector cytokine being IFN-γ, but proinflammatory cytokines such as IL-1, GM-CSF, and TNF-α also play a role in initiating a nonspecific cutaneous inflammatory reaction (Watanabe *et al.*, 2002), allergic contact dermatitis. Metals that cause allergic contact dermatitis with some frequency are Be, Co, Cr, Au, Hg, and Ni.

4.6 Relation Between Atopy and Metal Hypersensitivity

The relation between atopy, a condition with inherited predisposition to develop IgE-mediated hypersensitivity to small quantities of inhaled or ingested environmental agents, and metal immunotoxicology was discussed at the workshop of Immunotoxicity of Metals and Immunotoxicology in 1989 (Cattaneo, 1990). Although case reports of type I hypersensitivity caused by sensitization to chromium (Section 5.2), cobalt (Section 5.3), nickel (Section 5.6), and platinum (Section 5.7) have been published, only platinum allergy is sufficiently frequent to be assessed for the influence of atopy. A recent review found no association between atopy and type I allergy to platinum salts (Merget *et al.*, 2003). With regard to metal-induced type IV allergy, allergic contact dermatitis, no increased predisposition was reported as a result of atopy at the workshop in 1989 (Cattaneo, 1990). No conclusive new information has been published since then. For example, with regard to the most frequent clinical relevant sensitizing metal in the population, nickel, a few studies have indicated an increased incidence of allergic contact dermatitis in atopics (Dotterud and Falk, 1994), whereas other studies have not (McDonagh *et al.*, 1992). Recent studies have tried to discern different immune responses to nickel in atopic and nonatopic patients using *in vitro* techniques; in one study there were no differences (Szepietowski *et al.*, 1997), but another study reported an impaired immune response to nickel in atopics (Buchvald and Lundeberg, 2004).

5 METALS CAUSING HYPERSENSITIVITY REACTIONS

5.1 Beryllium

Beryllium (Be) is a durable and light metal that is widely used in a number of different industries. It has been recognized since the 1940s that a minority (2–16%) of workers exposed to beryllium, the exact fraction depending on the chemical type of Be, the dose, and the genotype of the exposed population, will develop berylliosis, a chronic granulomatous lung disease (Fontenot and Kotzin, 2003). A mutation of the gene for the human leukocyte antigen (HLA)-DPB1, with the amino acid glutamine in position 69, is found in 80–90% of patients with berylliosis and is

known to be directly involved in the presentation of Be to T cells (Lombardi *et al.,* 2001). Therefore, the DNA sequence coding for the HLA-DPB1 amino acid residue Glu69 is not only a supratypic marker but also the actual immune response gene of berylliosis. Patients with berylliosis exhibit a positive blood T-cell proliferative test to soluble Be. However, many more workers exposed to Be exhibit a T-cell response to soluble Be compared with the number of workers affected with berylliosis, but T-cell test-negative individuals seem to be resistant to development of berylliosis on prolonged exposure (Barna *et al.,* 2003). Recent studies have linked markers such as HLA-DRArg74 (HLA-DR3) to sensitization to Be, but not to berylliosis. The marker might be linked to low IFN-γ production, and IFN-γ is of prime importance for development of granulomatous inflammations. In addition, both sensitization to Be and berylliosis is associated with a gene for the cytokine TNF-α, the TNF-α-308*2 marker (Saltini *et al.,* 2001). These observations are in agreement with the concept that berylliosis is a cell-mediated, type IV immune reaction, with activation of $CD4^+$ type 1 cells recognizing Be when presented by a mutated MHC class II allele, leading to clonal proliferation of T cells, followed by release of cytokines, which leads to a granulomatous, destructive inflammation in the lung tissue.

5.2 Chromium

Chromium (Cr) is a widely spread metal with diverse use ranging from steel manufacturing to cement and fabrication of paints. Cr is an essential nutrient, enhancing the effect of insulin (Anderson, 2000), but it is also carcinogenic (Rowbotham *et al.,* 2000) and may cause hypersensitivity reactions (Shrivastava *et al.,* 2002). Cr is the second most frequent sensitizer in man, being the most common among males because of work-related exposure. The chemical form of immunotoxicological interest is Cr(VI), which is rapidly absorbed through the skin and penetrates the cell membrane, quickly reduced to Cr(III) by sulfhydryl group containing cysteine or methionine moieties, and finally binds to proteins. The Cr(III)–protein antigen complex is presented by APC to T cells in the lymph nodes, and memory as well as effector T cells are formed, but only memory cells remain in the immune repertoire of the host. On renewed exposure to Cr, a secondary response consisting of activation of the T-memory cells and elicitation of the inflammatory reaction by lymphokines takes place, a typical type IV reaction (Thomas *et al.,* 2000) leading to allergic contact dermatitis. Experimental studies have shown that among two inbred guinea pig strains, $K_2Cr_2O_7$ caused sensitization in 83% of the animals in one of the strains and in none of the animals in the other strain (Polak, 1983), indicating the importance of the genotype for sensitization to Cr. However, no information on genetic susceptibility is available in humans. There are some reports of asthma in relation to Cr exposure, which may be type I (Novey *et al.,* 1983) and type IV (Moller *et al.,* 1986) reactions.

5.3 Cobalt

Cobalt (Co) is an essential element necessary for production of vitamin B_{12} (Barceloux, 1999). Two valence states exist: Co(II) and Co(III); the former is often used in the chemical industry, whereas metallic Co is used in the metal industry to produce alloys, especially "hard metals" (Barceloux, 1999). Immunological reactions to Co include sensitization, which is quite unusual in the common population (<1%) but may occur concomitantly with sensitization to Ni in women and Cr in men. The most common hypersensitivity reaction to Co is allergic contact dermatitis, a type IV reaction (Garner, 2004), although occupational asthma with increased serum IgE antibodies to Co indicative of a type I reaction has also been reported (Shirakawa and Morimoto, 1997).

5.4 Gold

Gold (Au) is the most frequent sensitizer in the common population (15%), although clinically relevant hypersensitivity reactions are uncommon (0.5%) (Bruze *et al.,* 1994). A positive patch test to Au is significantly more frequent in patients with gold in dental restorations. Although the main manifestations of Au hypersensitivity after skin sensitization is allergic contact dermatitis, oral lesions such as lichenoid reactions and "burning mouth syndrome" have also been reported. The oral and dermatological conditions may coexist. Treatment with Au salts, especially sodium aurothiomalate, for inflammatory arthritides has been used for at least 70 years and with substantial effect in many patients. However, side effects are common, causing 15–45% of the patients to stop treatment. The side effects usually develop during the first 6 months of treatment and include skin rash, blood dyscrasia, mouth ulcers, proteinuria, colitis, hepatitis, and pneumonitis (Panayi, 1990). Although a genotype causing slow sulfoxidation increases the risk for toxic side effects nine-fold (Matzubara and Ziff, 1987), the adverse effects are mediated by immune-mediated hypersensitivity reactions. Thrombocytopenia is caused by antiplatelet antibodies similar to those in spontaneous autoimmune thrombocytopenia (Greinacher *et al.,* 2001) and represents a type II hypersensitivity reaction. The

immune-complex–mediated (type III) membranous glomerulonephritis (GN) (Gunnarsson *et al.*, 2001) that develops after Au treatment is linked to HLA-DR3, like the thrombocytopenia. The gold-induced GN virtually always resolves or improves considerably when treatment with gold is stopped. Sodium aurothiomalate injections in mice with certain mouse MHC class II (H-2) haplotypes induces, like Hg and Ag, antinucleolar antibodies (Robinson *et al.*, 1986; Schuhmann *et al.*, 1990), but not the immune-complex GN seen after Hg treatment in the same strains (Hultman and Pollard, unpublished observations). The development of Au-induced autoantibodies is delayed for 2–3 weeks compared with mercury and silver (Robinson *et al.*, 1986), which has been attributed to the need for oxidation of Au(I) to Au(III), which is the immunological active Au ion (Schuhmann *et al.*, 1990).

5.5 Mercury

Hg is a well-known inductor of allergic contact dermatitis, which was first recognized at the end of the 19th century (Boyd *et al.*, 2000). Heavy proteinuria, usually a nephrotic syndrome, has been described during Hg exposure since the 19th century. In modern times, Kazantzis *et al*. (1962) described four cases of occupationally mercury-exposed workers with a nephrotic syndrome among a cohort of similarly exposed individuals. Stewart *et al*. (1977) described proteinuria in 9 of 21 technicians occupationally exposed to mercury after spillage of corrosive sublimate and with a wide excretion rate of Hg. In these case reports, the heavy proteinuria dominated by albumin suggests a glomerular damage in contrast to the more modest, low-molecular weight proteinuria associated with the tubulotoxic effect of Hg. A number of case reports have described an IC-mediated membranous GN after occupational exposure to Hg, after use of skin-lightening creams and laxatives containing Hg, as well as other routes of Hg exposure (Barr, 1990; Charpentier *et al.*, 1981; Kibukamusoke *et al.*, 1974; Lagrue *et al.*, 1979; Oliveira *et al.*, 1987; Pairon *et al.*, 1992; Stewart *et al.*, 1977; Tubbs *et al.*, 1982). Exposure to Hg in adults has also been associated with systemic illness, including antinuclear antibodies (Schrallhammer-Benkler *et al.*, 1992), fulfilling criteria for undifferentiated connective tissue disease (Röger *et al.*, 1992).

Acrodynia (pink disease), described already in the 19th century, is restricted to a subset of infants and young children exposed to inorganic or organic mercury compounds in different ways but for prolonged periods (Clarkson, 1990). The patients show anorexia, irritability, photophobia, and exhibit painful, puffy, pink hands and soles with hyperkinetic circulation (Boyd *et al.*, 2000; Weinstein and Bernstein, 2003). Orlowski and Mercer (1980) emphasized the marked individual susceptibility to mercury in acrodynia and suggested that the mucocutaneous lymph node syndrome (Kawasaki's disease) might also be caused by Hg, on the basis of the similar clinical picture and increased exposure to Hg, but this view has later been disputed (Aschner and Aschner, 1989).

5.6 Nickel

Nickel (Ni) has been associated with type IV and to some extent type I hypersensitivity reactions. Ni is the most common skin sensitizer in the population, and totally dominating among women. This might be due to the prevalence of Ni-containing material in the modern environment, including jewelry, buttons, clip, coins, and many alloys, although a number of measures have recently been instated in many countries to lower the exposure. Ni dermatitis is an allergic contact dermatitis (Section 4.5) with itching, papular erythema beginning at the site of contact with Ni, but may on repeated exposure also occur on other parts of the body. The reaction becomes chronic if exposure cannot be eliminated, which is often difficult and may necessitate not only change of work but also restrictions in everyday lifestyle (Hostynek, 2002). A few cases of Ni-induced asthma believed to be due to type I hypersensitivity have also been reported (van Kampen *et al.*, 2003).

5.7 Multiple Metal Exposure Related to Prosthetic Devices

Joint replacement arthroplasties have reduced morbidity and increased life quality for millions of patients. Metals have been the main material in these prostheses, and they were initially considered biologically inert. However, the development of sensitivity to metals after implantation of prostheses is now well documented in case and group studies (Merritt and Rodrigo, 1996), which is not surprising considering the corrosion of all metals in contact with biological material with subsequent release of soluble and particulate material (Jacobs *et al.*, 1994). The metals of most concern have been chromium, cobalt, and nickel. Patients with metal implants demonstrate 25–60% incidence of metal reactivity compared with 10% in the general population (Hallab *et al.*, 2001). An elevated immune response to metals such as Co and Cr (Hallab *et al.*, 2005), and polyethylene particles has been demonstrated (Toumbis *et al.*, 1997). The periprosthetic tissue in metal (Co, Cr, Ni) containing arthroplasties with early recurrence of pain, joint effusion, and osteolysis showed signs of an ongoing, lymphocyte-dominated immune response (Willert *et al.*, 2005). In conclusion, implantation of devices containing

Co, Cr, and Ni induce metal sensitivity in a large proportion of the patients, but only few develop clinical significant hypersensitivity, which may, however, be an etiological factor for prosthetic failure.

5.8 The Platinum Group of Elements (Palladium, Platinum, Rhodium)

The recent development of automobile catalysts has lead to an increased exposure in the environment and in the manufacturing industries not only to platinum (Pt) but also palladium (Pd) and rhodium (Rh).

Pt is a highly corrosive-resistant, catalytic, and strong metal, which has been used for a long time in various applications, mainly in the form of complex salts, for example, platinum chloride, platinum dichloride, platinum dioxide, and platinum sulfate. Platinum complexes, in the form of platinum (II) compounds, cisplatin and carboplatin, are among the most important chemotherapeutic drugs. Biological reactivity, especially hypersensitivity, is limited to charged compounds that contain reactive ligands, halogenated Pt salts, and the sensitizing potential increases with the number of chlorine atoms. The sodium and potassium salts of hexachlorplatinic (IV) acid and tetrachlorplatinite (II) are the most potent sensitizers (Ravindra *et al.*, 2004). Symptoms of allergic-like reactions such as lacrimation, sneezing, rhinorrhea, cough, dyspnea, and frank asthma in workers exposed to soluble complex platinum salts have been observed since the early 19th century and were called platinosis but have been renamed as "allergy to platinum compounds containing reactive halogen ligands" (Jacobs, 1987). This reaction is now believed to be mainly a type I reaction, although a type IV reaction has been indicated in some patients. A direct interaction with basophilic cells with release of histamine may occur (Parrot *et al.*, 1969), which varies with the coordination number of the salt. It is also possible that Pt compounds by inhibiting Th1 cells may cause a Th2-skewed $CD4^+$ response favoring type I hypersensitivity (Dearman *et al.*, 1997). Metallic palladium (Pd) is a skin sensitizer causing allergic contact dermatitis; more than 90% of subjects with Pd sensitization are also sensitized to Ni (Finch *et al.*, 1999). Other hypersensitivity reactions caused by Pd or Rh are rare (Ravindra *et al.*, 2004).

6 INTERACTION BETWEEN METALS AND PROTEINS

6.1 Introduction

The way metals induce hypersensitivity conditions is beginning to be recognized especially for type IV and type I reactions. The mechanisms involved in, for example, systemic autoimmune diseases are less clear, but T-helper cells (Th-$CD4^+$ cells) are likely to play an important, but probably not exclusive, role in all these reactions.

6.2 Mechanisms of Interaction Between T Cells and Metal Ions

Conceptually T cells, $CD4^+$ and $CD8^+$ cells, will only react with antigens in the form of small peptides presented in context of the groove formed by the major histocompatibility complex (MHC) molecules on the APC. Superficially, the interaction of metals with proteins/peptides has been compared with that of classical haptens such as trinitrophenyl, which are recognized by T cells when associated with peptides. However, the chemically highly reactive haptens interact easily with proteins by a covalent binding (Cavani *et al.*, 1995), whereas metals often require highly defined coordination complexes (Williams, 1990). Metal–peptide interactions have mainly been studied from an inhibitory point of view. The reaction between Ni-specific T-cell clones and peptides was inhibited when the peptide-pulsed APC was treated with Ni. Ni interacted specifically with a histidine residue of the peptide, because the T-cell response was restored by substituting lysine for histidine, and radioactively bound Ni was identified in complex with histidine but not lysine (Romagnoli *et al.*, 1991). Au (I) forms a complex with MHC-binding peptides containing two or more cysteine residues that inhibit subsequent T-cell receptor binding—substitution of the cysteines by serines eliminated the inhibitory effect of Au (I) (Griem *et al.*, 1995).

However, there are reasons to believe that interactions between the T-cell receptor and the peptide–MHC complex may also enhance T-cell recognition. This was studied by presenting Ni^{2+} to HLA-DR4–restricted Ni^{2+}-sensitive T cells, where some DR subtypes stimulated IL-4/IL-5 secreting $CD4^+$Th2 cells by binding to endogenous peptides in the antigen-presenting groove of APC (Emtestam and Olerup, 1996). Ni may also lead to Th2 skewing, because a low density of Ni^{2+}-binding ligands favors Th2 cell activation (Del Prete, 1991).

Binding to the α- or β-chain of the MHC molecule in the groove of the APC has been demonstrated for Au and Ni. Exposure of APC to Au before the peptide inhibited proliferation of MHC class-II–restricted T-cell clones, and radiolabeled Au bound to a panel of MHC class-II positive, but not class-II negative, cell lines (Sinigaglia, 1994). In a more recent study Lu *et al*. (2003) demonstrated the existence of T-cell clones being stimulated by a preformed HLA-DR/Ni complex, in which Ni was bound to His81 on top of the

HLA-DR52c β-chain and probably two other coordination sites on a limited selection of DR52c-associated peptides.

In some studies, the exact way the metal interacts with the peptide-MHC structure to inhibit the reaction has not been explained. For example, Pb inhibits presentation of ovalbumin to the T-cell hybridoma DO11.10, allowing for an effect on either the ovalbumin peptide or the class II molecule (Smith and Lawrence, 1988).

Although these observations have increased the understanding of interactions between T cells and peptides-MHC, they fail to explain why, for example, Ni hypersensitivity is not linked to certain HLA class I or class II alleles (Emtestam *et al.,* 1993). T-cell receptor (TCR) families have, therefore, been intensely studied. In Ni^{2+} sensitization, the phenotype TCRVβ17 dominates the T-cell response *in vitro* (Budinger *et al.,* 2001), and this TCR type is associated with the clinical severity of the Ni^{2+}-induced contact dermatitis (Vollmer *et al.,* 1997). It has been proposed that Ni might enhance short-lived, nonproductive contacts between the TCR and the MHC–peptide complex, sometimes resulting in a sufficiently high avidity for activation of the T cell, a process that may also be facilitated by carriers of Ni such as serum albumin (Thierse *et al.,* 2004). A similar observation has been made for Be, because Vβ3 seems to be required in combination with HLA-DPB1Glu69 to elicit Be-responding $CD4^+$ clones (Fontenot *et al.,* 2001).

7 OTHER INTERACTIONS BETWEEN METALS AND PROTEINS—IMPLICATIONS FOR AUTOIMMUNITY

Apart from the possibility of a direct, but chemically promiscuous, interaction between TCR and metal-peptide-MHC complexes, metals may interact with proteins in other ways to alter presentation of the peptide to T cells. First, metals that possess a high redox potential (oxidizing capacity), such as Au (III), Pd(IV), and Pt(IV), may oxidize and denaturate sulfur-containing amino acid side chains of proteins. Second, metals such as Hg(II), Pt(II), and Au(I) make strong bindings with side chains in proteins, forming stable metal–protein complexes that may alter the protein unfolding taking place in antigen-processing. Third, metals may induce a change in the specificity of the proteolytic profile of APC. The effect of one or more of these mechanisms might be to display a hitherto unrecognized part of peptides, so called cryptic epitopes, which are presented to the T cells instead of the usual immunodominant epitopes. Because the T cells have not been made tolerant to the cryptic epitopes, this might lead to self-reactivity (Griem *et al.,* 1998).

These mechanisms have been studied for Au and Hg. Murine T-cell hybridomas specific for bovine RNase A treated with Au(III) recognize cryptic epitopes of non-Au–treated RNase. These T-cell hybridomas also reacted with RNase A pretreated with Pd(II), Pd(IV), Pt(IV), or Ni(IV), whereas metal ions such as Cu(II), Fe(II), F(III), or Zn(II) failed to elicit any cross-reactivity. The sensitizing potential of Au(III), Pd (II), Pd(IV), Pt(IV), and Ni(IV) may, therefore, be due to their ability to induce presentation of cryptic self-peptides (Griem *et al.,* 1996).

Mercury has been shown to interact with the major autoantigen in Hg-induced experimental systemic autoimmunity, the nucleolar 34-kDa protein fibrillarin. First, by binding to sulfhydryl groups, fibrillarin is physically altered (Pollard *et al.,* 1997). Second, nonapoptotic (necrotic) cell death caused by Hg modifies the proteolytic cleavage pattern for fibrillarin, resulting in neopeptides of fibrillarin (Pollard *et al.,* 2000). Because exposure to Hg creates a 19-kDa immunogenic fragment of fibrillarin even without physical modification of fibrillarin, a new cleavage pattern of fibrillarin seems to be of prime importance for induction of autoimmunity development (Pollard *et al.,* 2000). In another experiment, T-cell clones obtained from genetically Hg-susceptible mice that had been given repeated injections of Hg for 1 week reacted with Hg-carrying self-proteins, including Hg(II)-complexed fibrillarin (Kubicka-Muranyi *et al.,* 1993; 1995). After 8 weeks Hg treatment, the T-cell clones preferentially reacted with untreated fibrillarin, suggesting a shift of the T-cell specificity from self-proteins modified by Hg to unaltered self-proteins. This process is known as a determinant spreading (McCluskey *et al.,* 1998) and makes tracing of the original insult-inducing autoimmunity difficult.

8 NONSPECIFIC IMMUNOSTIMULATION INDUCED BY METALS: THE EXAMPLES OF PB AND HG

Stimulation of cells in the immune system by metals that do not primarily induce antigen-specific reactions or generate metal-specific lymphocytes is considered nonspecific immunostimulation. An example of this is the lead-induced increase of plaque-forming (B-) (Stiller-Winkler *et al.,* 1988) cells and increased expression of class II molecules on B cells (McCabe *et al.,* 1991). Mercury stimulates proliferation of T cells in guinea pigs, rats, and rabbits (Pauly *et al.,* 1969); humans (Carron *et al.,* 1970); and mice (Jiang and Moller, 1995; Pollard and Landberg, 2001; Reardon and Lucas, 1987), although the stimulatory concentration range is very narrow in humans and mice. However, distinct

differences have been reported between the species with regard to the exact cells involved. For example, human (Nordlind and Henze, 1984) but not murine (Pollard and Landberg, 2001; Reardon and Lucas, 1987) thymocytes proliferate *in vitro* in response to mercury. Murine T cells show an absolute requirement for adherent cells (Jiang and Moller, 1995; Pollard and Landberg, 2001), whereas they are not needed (Caron *et al.*, 1970; Nordlind and Henze, 1984), or may even be dementrial (Shenker *et al.*, 1992), for the proliferative effect of Hg on human lymphocytes. Mercury caused after injection a significant proliferation of T cells in 22 of 23 mouse strains as assessed by the popliteal lymph node test (Stiller-Winkler *et al.*, 1988), demonstrating the ability of Hg to cause immune stimulation also *in vivo*. However, the dependency on MHC class II molecules (Hu *et al.*, 1997) and costimulatory molecules, especially IL-1 (Pollard and Landberg, 2001), in combination with the oligoclonal murine T-cell response *in vitro* (Jiang and Moller, 1996) as well as *in vivo* (Heo *et al.*, 1997) makes it possible that the Hg-induced T-cell response is antigen-dependent, although the antigen(s) is (are) unknown. Secondary effects of a polyclonal activation of T cells by mercury are B-cell activation and Ig isotype switching because of cytokines such as IL-4 and IFN-γ.

However, a number of nonantigen-specific proliferative effects of Hg have been reported *in vitro*: increase in intracellular calcium (Tan *et al.*, 1993), aggregation of transmembrane CD4, CD3, CD45, and Thy-1 receptors on T cells with increased tyrosine kinase $p56^{lck}$ (Nakashima *et al.*, 1994), and attenuation of lymphocyte apoptosis (Whitekus *et al.*, 1999) because of interference with the *Fas–Fas* ligand interaction *in vitro* (McCabe *et al.*, 2003).

9 METAL-INDUCED AUTOIMMUNITY

This is a seemingly paradoxical area of metal immunotoxicology. Ample evidence from experimental studies demonstrate that certain metals, most notably Hg and Au, may cause autoimmune diseases in several species (Fournie *et al.*, 2002; Hultman *et al.*, 1995; Pollard *et al.*, 2005; Schuhmann *et al.*, 1990), but there are relatively few reports of metal-induced autoimmunity in humans. Some authors (Descotes, 1999) have, therefore, questioned whether metal-induced autoimmunity is a relevant issue for humans. Some factors must, however, be taken into consideration when trying to assess the potential of metals for inducing autoimmunity.

First, induction of autoimmune diseases is heavily dependent on genetic susceptibility, and neither the susceptible genotype(s) in humans for metal-induced autoimmunity nor the number of humans that may carry such susceptibility is known. Because the genetic susceptibility to mercury-induced autoimmunity in rodents is, to a large extent, determined by MHC class II genes, which are also well known for their association with spontaneous autoimmune diseases in humans, there are strong theoretical reasons to assume the existence of humans genetically susceptible to mercury. Furthermore, genetic factors outside MHC determine the accumulation of Hg in mice given the same dose of Hg (Nielsen and Hultman, 1998), and non-MHC genes also determine the internal dose of Hg required to elicit an autoimmune response in mice with susceptible MHC genes (Hultman and Nielsen, 2001).

The largest cohort of humans exposed to inorganic mercury is dental amalgam bearers. Studies of dental amalgam implanted in the peritoneal cavity of mice (Hultman *et al.*, 1994) and inserted in the teeth of rats (Hultman *et al.*, 1998), have clearly demonstrated the potential of dental amalgam to cause systemic autoimmune diseases in genetically (MHC) susceptible rodents. However, it seems likely that the dose required for *de novo* induction of autoimmunity is not met in most humans with dental amalgam fillings. However, to what extent some dental amalgam bearers may develop *de novo* autoimmunity or acceleration of spontaneous autoimmune diseases because of a genotype causing high accumulation of Hg in the body and/or a low thresholds for induction of autoimmunity is unknown.

Historically, large cohorts have been exposed to mercury in environmental disasters (Bakir *et al.*, 1973; Harada, 1995), but autoimmune conditions have not been reported. This would indicate either that the frequency of such susceptibility genes is low or absent in the affected populations or that the dose was insufficient to elicit a reaction. However, in the Hg disasters, the main exposure was to organic mercury compounds, especially methylmercury but also ethyl mercury. Both these compounds are able to induce systemic autoimmunity in genetically susceptible mice (Havarinasab *et al.*, 2004; Hultman and Hansson-Georgiadis, 1999), although probably because of transformation of the organic compounds to inorganic mercury (Havarinasab and Hultman, 2005), which is, however, incomplete and, at least for MeHg, a rather slow process (Haggqvist *et al.*, 2005; Havarinasab *et al.*, 2004). Therefore, the exposure to autoimmunogenic inorganic Hg might have been too low in many cases to induce autoimmunity. Another explanation for the lack of reports on autoimmune diseases during the environmental Hg disasters might have been a limited attention to autoimmune diseases in those early years and not least that symptoms of autoim-

mune diseases might have been overlooked because of the drastic effects of organic mercury on the nervous system.

10 ACCELERATION AND AGGRAVATION OF AUTOIMMUNITY BY XENOBIOTICS

10.1 General Considerations

Environmental and other agents may induce various phenotypic expressions of autoimmune diseases because of interaction with different genotypes. This includes the possibility of not only *de novo* autoimmune disease but also an acceleration and aggravation of autoimmune conditions with other primary genetic or nongenetic etiologies. For example, in experimental models, the polyclonal B-cell activating agent lipopolysaccharide-lipid A portion (Hang *et al.,* 1983), UV radiation (Ansel *et al.,* 1985), halothane (Lewis *et al.,* 1982), and polyinosinic/polycytidylic acid (Carpenter *et al.,* 1970) accelerate spontaneous autoimmune disease manifestations. For metals, important observations on this subject have recently emerged from studies in rodents.

10.2 Acceleration of Spontaneous Autoimmune Diseases by Hg

Hg is a potent *de novo* inductor of a systemic autoimmune disease condition in rodents with certain MHC (H-2) class II genotypes (Fournie *et al.,* 2002; Pollard and Hultman, 1997). Although these rodent models continue to be very useful for explaining immunological mechanisms in systemic autoimmunity, dose-response studies applied to humans make it likely that *de novo* induction of autoimmunity by these agents will require exposure levels occurring only in specific hazardous work places or during accidental exposure or voluntary ingestion. However, uncertainty prevails regarding the existence and prevalence of especially susceptible genotypes (Chapter 33).

Recently, inorganic Hg was shown to accelerate the spontaneous autoimmune manifestations in the NZBWF1 mouse strain as evidenced by lymphoid hyperplasia (Pollard *et al.,* 1999), polyclonal B-cell activation (al-Balaghi *et al.,* 1996), hyperimmunoglobulinemia and antichromatin antibodies (Pollard *et al.,* 1999), as well as immune-complex deposits (Abedi-Valugerdi *et al.,* 1997; Arnett *et al.,* 1996; Pollard *et al.,* 1999). Hg treatment of the MRL-$^{+/+}$ strain and the autoimmune-prone, *Fas*-deficient MRL-$^{lpr/lpr}$ strain caused severely and slightly accelerated autoimmune manifestations, respectively (Pollard *et al.,* 1999). However, recent studies have shown that the autoimmunity may be severely aggravated also in the MRL-$^{lpr/lpr}$ strain, provided that a lower dose of Hg is administered (Pollard *et al.,* 2005). By use of the AKR strain, which is H-2 congenic with the MRL strains, aggravation of the autoimmune disease was linked to non-MHC genes (Pollard *et al.,* 1999). Studies in the autoimmune-prone BXSB and the nonautoimmune C57BL/6 strains, which share the H-2^{b} haplotype, showed that Hg triggers the *Yaa*-gene dependent lupus-like autoimmune disease in BXSB mice by aggravating lymphoid hyperplasia, antichromatin antibodies, and glomerulonephritis, whereas Hg had little effect on the MHC-congenic C57BL/6J strain, linking the genetic susceptibility for acceleration of autoimmunity by Hg to non-MHC genes also in this disease model (Pollard *et al.,* 2001). Interestingly, a short course of Hg to BXSB mice was sufficient to cause a lifelong increase in the autoimmune response. Furthermore, a dose of Hg that was comparatively lower than the dose accepted in the occupational setting accelerated the spontaneous autoimmune disease in the BXSB mice (Pollard *et al.,* 2001). Acceleration of spontaneous autoimmunity has also been observed in NZBWF1 mice after very low doses of organic Hg (Havarinasab and Hultman, 2006).

Although the preceding observations may give the impression that a sufficient dose of Hg will always accelerate spontaneous autoimmune diseases, we have found (Hultman *et al.,* 2006) that Hg treatment for more than a year in the spontaneous autoimmune (SWRxSJL)F1 mouse model (Vidal *et al.,* 1994) neither accelerated the onset nor increased the severity of the systemic autoimmune manifestations. The proposed explanation is that the SWR strain possesses non-MHC genes that can suppress Hg-induced exacerbation of autoimmunity. Therefore, the effects of autoimmune inductors such as Hg, Ag, and Au need to be examined in all available spontaneous models of autoimmune disease, because a specific interaction takes place between the genetic factors (especially non-MHC genes), the spontaneous autoimmune conditions, and the specific metal.

These studies on the accelerating effect of Hg exposure were all performed in models with a distinct and known genetic predisposition. Recently, Silbergeld *et al*. examined whether an autoimmune disease induced by a primarily nongenetic mechanism might also be accelerated by Hg (Via *et al.,* 2003). A lupus-like chronic graft-versus-host disease (GVHD) was induced using F1-hybrids of two strains resistant to Hg (C57BL/6 and DBA/2) and DBA/2 donor cells. A 2-week exposure to host and donor mice of low-dose Hg (20 μg/kg every other day) ending 1 week before GVHD induction, aggravated the lupus-like GVHD.

10.3 Acceleration of Spontaneous Autoimmune Diseases by Cadmium and Lead

Recent studies using Cd and Pb have expanded the results obtained by Hg. Cd in a high dose increased the ANA in autoimmune-prone NZBWF1 mice during the first months of treatment, whereas a lower dose increased the IgG2a serum level and the proteinuria, although without affecting the IC deposition (Leffel *et al.*, 2003). As mentioned previously, Pb enhances the autoimmune manifestations in autoimmune-prone NZBWF1 hybrid mice (Rudofsky and Lawrence, 1999). A recent study on lead in four New Zealand mixed strains revealed a complex relation between the spontaneous autoimmune disease, Pb exposure, genetics, and gender, leading to different phenotypic outcome: both acceleration and inhibition of the autoimmune condition were observed (Hudson *et al.*, 2003).

10.4 Comments on the Autoimmune Effects of Metals

The ability of metals to accelerate and aggravate genetically, as well as nongenetically, determined autoimmune disease processes in rodents is an important new observation in the immunotoxicology of metals. Although a few of these studies included some dose-response data, the potential importance of these findings for human conditions and the variation in phenotypic expression of the effect of metals warrant further dose-response studies in all autoimmune models. In addition, the mechanism(s) by which the metals are able to accelerate the autoimmune process should be examined, which will also improve the understanding of the general mechanisms in autoimmune diseases.

Therefore, new findings in rodents such as major genetic factors regulating susceptibility to induction of autoimmunity by mercury, silver, and gold; the existence of genetic factors determining uptake and retention of metals, as well as the threshold of metals for elicitation of autoimmunity; and the accelerating/aggravating effect of metals such as mercury, cadmium, and lead on spontaneous autoimmune conditions are all reasons why metals may be of importance for autoimmune conditions in humans. Although case reports in humans are evidence for the ability of metals like mercury and gold to induce autoimmune conditions, determining the importance of metal exposure for human autoimmune disease will require further studies.

Reproductive and Developmental Toxicity of Metals

PIETRO APOSTOLI, SPOMENKA TELIŠMAN, AND POLLY R. SAGER

ABSTRACT

Metals exert a wide variety of adverse effects on reproduction and development including influence on fertility, intrauterine growth retardation, abortions, malformations, birth defects, and developmental effects, mainly those on the nervous system. Metals may affect reproduction or development directly, at relatively low doses, or indirectly through systemic toxicity, generally at higher doses. More recent, important mechanisms of action are those related to endocrine disruption and oxidative stress. The effects produced by metals depend on several factors, such as the timing and duration of exposure, their distribution and accumulation in various organs (e.g., the nervous system), and on the ability to interfere with specific developmental processes. Interesting interactions between environmental and congenital factors have been documented; genetic polymorphisms can affect fetal susceptibility to teratogens or maternal ability to detoxify and excrete xenobiotics.

Male reproductive effects of high doses of many metals have been observed in animals, whereas there is still insufficient evidence to the human male concerning a quantitative dose-response relationship. This could be partly explained by considerable interspecies differences in susceptibility to reproductive toxicity and in the route, level, and duration of metal exposure. Human studies have provided substantial evidence of effects for only a few metals. These include lead-induced effects on male fertility and certain parameters of semen quality, even at moderate exposure levels, effects by cadmium on prostate impairment and serum testosterone, and less well-documented male reproductive effects of mercury, manganese, chromium, nickel, and arsenic at levels significantly lower than those that cause systemic toxicity.

The effects of metals on female reproduction may arise from their action on several stages beginning in fetal life, during early development or maturity, and include manifestations such as subfertility, infertility, intrauterine growth retardation, spontaneous abortions, malformations, birth defects, postnatal death, learning and behavior deficits, and premature aging; evidence is usually limited to animal data or studies on fertility and spontaneous abortions The clinical and epidemiological findings related to metal-induced effects on female reproduction are often difficult to interpret, because many other factors may influence the outcome such as age, ovarian reserve, hormonal imbalance, behavior, genetics, male fertility factors, and sexually transmitted diseases.

Exposure to metals during organogenesis may cause fetal anomalies, whereas exposure during other periods of development may result in embryo or fetal lethality or other developmental effects. Teratogenesis bioassays in rodents (hamsters, mice, or rats) have yielded positive results for the compounds of many metals (Al, As, Bo, Cd, Co, Cr, Cu, Ga, Hg, Li, Mn, Ni, Pb, Se, U, V, and Zn), producing fetal and early postnatal deaths, as well as malformations such as anencephaly, eye defects, cleft palate, and skeletal anomalies. The relevance of these findings to human exposure is, however, still unclear.

Neonatal and early postnatal periods are lifespan segments during which sensitivity to metals is high, and lead toxicity on the developing organism represents an illustrative example for related problems and questions. In the last decade, children's blood lead (PbB) levels have declined significantly in a number of countries, and current prevalent mean levels in developed countries are <50 μg/L. Despite this reduction, childhood lead poisoning continues to be a public health problem for certain high-risk groups. Recent studies have extended the association of blood lead and intellectual impairment to PbB levels <100 μg/L and now challenge the safety of this level that for more than a decade has served as a community alert level for preventive action. The recent studies cast doubt whether a toxicological threshold and no-effect value exists for lead-related developmental toxicity. This chapter focuses on the reproductive and developmental effects by metals of traditional interest for toxicologists, such as lead, mercury, and cadmium, but also provides information, where available, on chromium, arsenic, manganese, and nickel, and on metals of more recent interest such as aluminum, platinum, vanadium, lithium, and uranium.

1 INTRODUCTION

Adverse effects of metals on human reproduction and development continue to be a demanding challenge for researchers. It is often difficult to identify the metals involved, or their sources; a wide range of adverse events must be investigated; and there are limited data on the mechanisms of action and damage. For most metals, there is little information about quantitative dose-response relationships and no-adverse-effect exposure thresholds. Furthermore, most published studies have considered effects by a single metal, with few studies addressing combined exposure to toxic and/or essential metals—as is typical for human exposure. The possibility of synergistic or antagonistic interactions of metals and other factors (see also Chapters 6 and 7) should be given much more prominence in the future.

Metals can produce a wide variety of adverse effects on reproduction and development, influencing fertility, intrauterine growth retardation, abortions, malformations, birth defects, and developmental effects, including those on the nervous system. Although considered severe in general, the relevance of these outcomes is, however, differently perceived in various social, economic, and cultural contexts. Abortion or malformations are generally more easily identified, whereas subtle effects on fertility may be less obvious. There is also a worldwide tendency to delay parenthood, thus lengthening the preconception period for potential exposure, with possible effects on both male or female reproductive ability, as well as increasing prenatal and early postnatal cumulative exposure to toxic metals.

The long-term assessment of reproductive and developmental effects of metals is sometimes complicated by reduced exposure to certain metals, resulting from technological improvement and preventive measures, and by the presence of other occupational or environmental factors possibly affecting reproduction. The effective exposure to metals should be evaluated as close as possible to the "target time"—the period during which the metal may be toxicologically most active. The target time may be specific for each animal species, organ, or tissue, kind of effect, and route of exposure.

Metals may affect reproduction or development directly, at relatively low doses, or act indirectly through systemic toxicity, generally at higher doses. The direct toxicity can be identified as a "critical effect" on reproduction or development. With regard to occupational and environmental exposures, in contrast to experimental conditions, it is difficult to correlate specific exposures to specific effects because of the complexity of such exposures and the need to measure metals at very low levels in biological specimens.

In the last years, there has been increasing interest in two mechanisms of action on reproduction and development because of chemical hazards, including some metals, on endocrine disruption, and oxidative stress.

Endocrine disruptors (EDs) have been defined as "exogenous chemical substances or mixtures able to alter the structure or function of the endocrine system and to cause adverse effects on organisms or their progeny" (Medical Research Council, 1995). The importance of EDs is related to the biological hypothesis that low-level exposure to certain chemicals may contribute to endpoints such as lowering of age at menarche, impairment of semen quantity and quality, decreasing male-to-female sex ratio at birth, increasing rates of hypospadias and testicular cancer, infertility, spontaneous abortions, and structural and functional congenital malformations. However, linking specific exposures to effects is often difficult because of multiple exposures, the latency of effects, and the subtle nature of some outcomes (Davis *et al.*, 1998; Kaplowitz *et al.,* 2001; McKiernan *et al.*, 1999). Some effects of EDs may be receptor-mediated and may directly interact with cellular targets (Kavloc *et al.*, 1996). Cadmium, for example, may affect steroidogenesis by mimicking or inhibiting the actions of endogenous estrogens (Henson and Chedrese, 2004). The experimental and human investigations on EDs

were reviewed by Sharpe and Irvine (2004); they concluded that few definitive studies link reproductive disorders with exposure to environmental chemicals; this may either reflect the difficulty in obtaining such data or a genuine lack of effects.

The toxicity of several metals, including iron, copper, cobalt, and lead, may be mediated through oxidant-based and free-radical–based mechanisms, leading to oxidative stress. These metals increase the production of reactive oxygen species, decrease the levels of glutathione and other antioxidants (including selenium and zinc), affect the protective antioxidant enzymes by interfering with the metabolism of the specific metal(s) essential for the enzyme activity (such as Cu, Zn-dependent superoxide dismutase, Se-dependent glutathione peroxidase, Fe-dependent catalase), enhance cell membrane lipid peroxidation, cause apoptosis, and contribute to oxidative DNA damage.

Many factors including animal species and strains, gender, age, stress, inherited disorders, nutritional status, smoking, alcohol consumption, use of medications, and concomitant exposure to other chemicals or physical factors can influence both metabolism and effects, as well as dose-response relationships for reproductive and developmental toxicity of metals.

In risk assessment, the ideal situation combines adequate indicators of exposure with sensitive and specific effect indicators. Indicators of exposure are frequently based on blood concentrations or levels of metals in other body fluids, which may not adequately reflect body burden. New methods for assessing cumulative exposure, such as the application of X-ray fluorescence for measuring metals in bone, have the great potential of increasing the accuracy of risk assessment and evaluation of dose-response relationships. Examples of effect indicators for investigating reproductive damages include the time to pregnancy (TTP) and the sperm chromatin structure assay (SCSA).

TTP is defined as the number of months of unprotected intercourse that elapse before conception occurs. It is a composite measure that includes libido, ovulation, sperm or semen quality, and conceptus survival (Joffe, 1997). Regarding metals for which exposure may decline with time, TTP values could be causally associated with earlier, higher exposures; the resulting bias would overestimate the association of exposure and fertility (Weinberg *et al*., 1994).

The SCSA is a measure of the spermatozoal abnormal chromatin, defined as increased susceptibility to acid-induced denaturation *in situ* and quantified by flow cytometric measurement of denaturated DNA and native DNA (Spano *et al*., 1999). A higher proportion of single-stranded DNA occurs in altered cells. The metachromatic shift from normal to altered cells, expressed as alfaT, represents the ratio of altered to total fluorescence (Evenson *et al*., 2002).

The informative value for both effect and dose indicators is strictly related to the quality of the data. The main requirements of analytical quality assurance are related to the control of all the known sources of variations (Aitio and Apostoli, 1995) and compliance with international clinical and laboratory standards. Good laboratory practices, internal quality assurance, and participation in external quality control programs should be encouraged. In addition, to enhance interpretation of the results of effect indicators, validation studies and dose-response relationships are commonly required.

This chapter focuses on metals of traditional interest for toxicologists, such as lead, mercury, and cadmium, but also provides information, where available, on chromium, arsenic, manganese, and nickel, and on metals of more recent interest such as aluminum, platinum, vanadium, lithium, and uranium.

2 MALE REPRODUCTIVE EFFECTS

Mammalian male reproductive function can be affected through a direct effect on the testis, resulting in decreased or altered sperm production, through impairment of the accessory sex gland secretions, and/or indirectly through the neuroendocrine system, causing hormonal imbalance. Adverse effects on male fertility include altered genetic material of sperm, contributing to altered spermatogenesis, pregnancy loss, or genetic disease in offspring. Common endpoints for assessment of male reproductive function include size of testis, semen quality, secretory function of the prostate and seminal vesicles, reproductive endocrine function, impotence or reduced libido, and fertility. When evaluating reproductive effects of a certain metal on human males, one must take into account possible influences of concomitant exposures to other toxic and essential metals; these may act additively, synergistically, or antagonistically. Moreover, the influence of age and lifestyle factors particularly stress, smoking habits, and alcohol consumption must be considered. In addition, certain toxic metals such as lead and cadmium are pervasive in the human environment and accumulate in the human body over a lifetime; biomarkers of lead and cadmium exposure commonly correlate with age, smoking habits, and/or alcohol consumption. Quantitative assessment of the body status of certain essential elements, especially zinc and selenium, is relevant, because they can reduce or protect from the adverse male reproductive effects of several metals.

Recent evidence indicates that the human male reproductive capacity has deteriorated considerably during the past five decades. In industrialized countries, a substantial number of couples seek *in vitro* fertilization (IVF) or intracytoplasmic sperm injection (ICSI) because of poor semen quality.

Furthermore, large differences in mean sperm concentration between countries, and between different locations within a country, have been observed. The possible role of environmental and lifestyle factors in contributing to these trends and differences has been suggested and is widely debated, because consideration must be given to many potentially confounding factors. Because the underlying causes are likely to be multiple and complex, it is important to identify the factors contributing to the deterioration of human male fertility to prevent further decline in fertility potential.

The human male has a relatively low fertility potential compared with other mammals. For example, the number of sperm per human ejaculate is typically only twofold to fourfold higher than the number at which fertility is significantly reduced, whereas the number of sperm in rat, rabbit, or bull ejaculate is many times (up to 1400-fold) the number that will produce maximum fertility (Working, 1988). Human males have markedly smaller relative testis size and the lowest rate of daily sperm production per gram of testis, by a factor of more than 3, compared with mouse, rat, or monkey. The percentages of progressively motile sperm and morphologically normal sperm in human semen are also considerably lower than in experimental animals (Working, 1988). Certain rodent species and strains, commonly used in experimental studies, seem to be resistant to the male reproductive toxicity of lead (Apostoli *et al*., 1998) and cadmium (Gunn *et al*., 1965; Liu *et al.,* 2001). The human male may be more susceptible than the rat to metal toxicity, possibly because of poorer efficacy of the antioxidant defense system and greater vulnerability to oxidative damage to sperm DNA and sulfhydryl (–SH) groups required for the maintenance of sperm maturation and motility. Because of differences among species in reproductive endpoints and in the route, level, and duration of metal exposure, the experimental animal data may be useful for estimates of allowable human exposure.

Although experimental animal and *in vitro* studies have indicated adverse reproductive effects of high doses of many metals and beneficial or protective effects of some essential metals (particularly zinc, selenium, and magnesium), the internal metal dose was often not measured, and relatively few studies have evaluated the effects of long-term moderate oral exposure. For most metals, data relevant to humans are scanty and are usually limited by inadequate controls and adjustments for the influence of potentially confounding variables.

2.1 Lead

Since the mid-19th century, many studies have shown the toxicity of lead on male reproductive function in humans and experimental animals, although the impact of low to moderate levels of chronic lead exposure is still controversial. A recent comprehensive review presents the relevant literature (Apostoli *et al*., 1998), and, therefore, the subsequently published evidence is emphasized here.

Several studies of men occupationally exposed to lead have shown that blood lead levels equal to 400 μg/L were associated with significantly reduced semen quality, whereas reproductive endocrine function in the same subjects was either not affected or was only marginally affected (Alexander *et al*., 1996b; Assennato *et al*., 1986; Cullen *et al*., 1984; Lancranjan *et al*., 1975; Telišman *et al*., 2000). Other studies that measured only sex hormones have generally shown no relevant lead effect on male reproductive endocrine profile (Erfurth *et al.,* 2001; Gennart *et al.,* 1992a; Gustafson *et al.,* 1989; McGregor and Mason, 1990; Ng *et al*., 1991). For example, a Swedish study of 62 active and 15 retired lead workers and 26 control subjects (Erfurth *et al.,* 2001) showed no significant association between either blood lead, serum lead, or fing er bone lead levels and serum levels of follicle-stimulating hormone (FSH), luteinizing hormone (LH), testosterone, and sex-hormone binding globulin; the median and range blood lead values in the subgroups were 332 (83–932) μg/L, 186 (104–497) μg/L, and 41 (8–62) μg/L, respectively.

The following lead-related effects on human semen quality have been reported: a decrease in semen volume (Fisher-Fischbein *et al*., 1987; Lerda, 1992; Wildt *et al*., 1983), a decrease in sperm concentration and sperm count (Alexander *et al*., 1996a; Assennato *et al*., 1986; Braunstein *et al*., 1978; Cullen *et al*., 1984; Fisher-Fischbein *et al*., 1987; Lancranjan *et al*., 1975; Lerda, 1992), a decrease in sperm motility (Chia *et al*., 1992; Cullen *et al*., 1984; Lancranjan *et al*., 1975; Lerda, 1992; Viskum *et al*., 1999), and in the quality of motility (Fisher-Fischbein *et al*., 1987; Viskum *et al*., 1999), an increase in abnormal sperm morphology (Cullen *et al.,* 1984; Fisher-Fischbein *et al*., 1987; Lancranjan *et al*., 1975; Lerda, 1992; Wildt *et al*., 1983), particularly at the head of the sperm (Fisher-Fischbein *et al*., 1987; Lerda, 1992; Wildt *et al.,* 1983), and impairment of prostate secretory function as indicated by decreased seminal plasma zinc level (Wildt *et al*., 1983). Most of these

studies have one or more of the following shortcomings: a small number of subjects examined, no control group or an inadequate control group because of relatively high blood lead levels, the inclusion of subjects with current or recent urogenital tract infections, and/or a lack of control for other common factors capable of affecting reproductive parameters. The findings were mainly related to dose-response trend(s) on a group basis for different exposure categories, so that insufficient evidence was presented for establishing a quantitative dose-response curve and no-adverse-effect exposure threshold, particularly concerning the range of very low to moderate blood lead levels.

Some data suggest that the reproductive effects of lead in men are reversible; a trend toward normalization was found in subjects treated with a lead-chelating agent (Cullen *et al.*, 1984; Fisher-Fischbein *et al.*, 1987) or after cessation of occupational lead exposure (Viskum *et al.*, 1999).

A cross-sectional study of 149 industrial workers with low to moderate chronic lead exposure (Telišman *et al.*, 2000) showed significant lead-related reproductive effects even at blood lead levels <400 µg/L. The median (range) of current blood lead values were 103 (67–208) µg/L in 51 control subjects and 367 (119–659) µg/L in 98 lead workers; their long-term average blood lead values were <400 µg/L. Changes in reproductive parameters were more pronounced at relatively low-level lead exposure (<350 µg/L) compared with higher levels. For example, the dose-response relationship between sperm count and blood lead in the 149 subjects showed a decrease of approximately 65×10^6 sperm in the blood lead range 50–350 µg/L. A decrease in sperm count was significant even at blood lead levels of 240 µg/L compared with <100 µg/L. After adjusting for age, smoking, alcohol, blood cadmium, serum zinc, and serum copper, an increase in blood lead was significantly associated with decreasing sperm concentration, counts of total sperm and progressively motile sperm, seminal plasma levels of zinc, acid phosphatase and citric acid, and increasing percentage of pathological sperm with abnormal sperm head morphology. A better correlation of reproductive parameters was found with respect to delta-aminolevulinic acid dehydratase (ALAD) activity in blood, indicating that the reproductive effects were in part mediated through lead interference with zinc metabolism (Telišman *et al.*, 2000). In a similar study, Alexander and coworkers (1996a) showed that sperm concentration and sperm count in lead workers were inversely related to both current blood lead and long-term average blood lead, even at levels <400 µg/L.

In contrast, an international cross-sectional study of 362 lead workers and 141 control subjects from 10 companies in Belgium, Italy, and the United Kingdom (Bonde *et al.*, 2002) reported that, although median sperm concentration was reduced by 49% in men with blood lead >500 µg/L, a likely threshold as high as 440 µg/L was found for this parameter of semen quality. The mean (range) blood lead values were 44 (0–198) µg/L in the control subjects and 310 (46–645) µg/L in lead workers. Abnormal sperm chromatin structure was not significantly related to blood lead levels. However, it seems possible that differences in some lifestyle factors and the body burden of other relevant metals, not controlled for in this study, might have contributed to variations in reproductive parameters among the study population, thereby weakening or masking the relationship between blood lead and reproductive effects.

Recent data indicate that lead can adversely affect human semen quality even at blood lead levels <150 µg/L (Jurasovic *et al.*, 2004; Telišman *et al.*, 2003). In a study of 123 men who had never been occupationally exposed to metals, the median (range) blood lead values were 57 (range 25–149) µg/L. After adjusting for confounding variables (age, smoking, alcohol, blood cadmium, and serum copper, zinc, and selenium), an increase in blood lead was significantly associated with decreasing percentages of morphologically normal and subnormal sperm and with increasing percentages of slow sperm and overly wide sperm. A decrease in ALAD activity was significantly associated with decreasing size of testes and seminal plasma levels of the lactate dehydrogenase isoenzyme LDH-C_4. In another study (Benoff *et al.*, 2003), the seminal plasma lead levels of subjects not occupationally exposed to lead were found to inversely correlate with fertilizing capacity of sperm (sperm acrosome reaction) and the fertilization rate when using IVF technique, but also with seminal plasma zinc levels. Taken together, these studies suggest that lead may significantly reduce human semen quality even at low-level lead exposure that is common for general populations worldwide.

Several studies of lead workers have indicated that paternal blood lead levels of approximately 300–400 µg/L are a most likely threshold for increased rate of spontaneous abortions (Lindbohm *et al.*, 1991), reduced rate of live births (Gennart *et al.*, 1992b; Lin *et al.*, 1996), and prolonged TTP (Sallmén *et al.*, 2000; Shiau *et al.*, 2004), although inconsistent findings (Bonde and Kolstad, 1997; Coste *et al.*, 1991; Joffe *et al.*, 2003) or a minor incompatibility were also reported.

An Italian study (Apostoli *et al.*, 2000) reported that, although shorter TTP was found in lead workers compared with control subjects, within the group of lead

workers a longer TTP was associated with higher blood lead levels and significantly longer TTP was observed at blood lead levels equal to 400 µg/L.

A recent study from Taiwan (Shiau *et al.*, 2004) showed a clear dose-response trend of prolonged TTP with respect to increasing paternal blood lead levels; the fecundability ratios (inversely related to TTP) were 0.90, 0.72, 0.52, and 0.40 for blood lead categories <200, 200–290, 300–390, and equal to 400 µg/L, respectively, compared with unexposed men, indicating that even blood lead levels <300 µg/L may prolong TTP.

A significantly increased rate of congenital malformations was found in children of occupationally lead–exposed fathers at paternal blood lead levels of 200 µg/L (Sallmén *et al.*, 1992). A reduced sex ratio (reduced male proportion) among offspring of lead-exposed fathers has been observed in some studies (Dickinson *et al.*, 1994), but not in others (Min *et al.*, 1996).

Several experimental studies in rats, mice, rabbits, or monkeys have indicated that chronic lead exposure for at least 30 days, resulting in current blood lead levels equal to 400 µg/L, was associated with decreased intratesticular or epididymal sperm counts, sperm production rate, sperm motility, and serum testosterone levels, although mainly without significant effect on male fertility, whereas several other studies have shown no significant reproductive effect at comparable blood lead levels (Apostoli *et al.*, 1998). A recent experimental study in rabbits (Moorman *et al.*, 1998) showed an estimated threshold for reduced sperm count at a blood lead level of 240 µg/L and even lower for several other semen characteristics.

A study on the effect of combined exposure to lead and cadmium on the testes of rats (Saxena *et al.*, 1989) showed that animals orally exposed to the combination exhibited significantly more pronounced pathological testicular changes, with a reduction in sperm counts, compared with animals exposed to either of the metals alone. A protective effect of zinc against the lead-induced and cadmium-induced testicular injury in rats was reported (Batra *et al.*, 1998; Saxena *et al.*, 1989).

With regard to possible mechanisms for a male-related transgenerational effect of lead, an *in vitro* study (Quintanilla-Vega *et al.*, 2000) has shown that lead can compete with or replace zinc in human protamine P2 (HP2), a zinc-containing protein that protects sperm DNA by binding to it during spermatogenesis. Exposure of HP2 to lead resulted in a dose-dependent decrease in the extent of HP2-DNA binding, although lead effects on sperm DNA also contributed to this effect. This may affect sperm chromatin integrity, thereby reducing sperm fertilizing capacity and causing sperm DNA damage.

2.2 Mercury

Male reproductive toxicity of organic and inorganic mercury has been observed in animals mainly at dose levels that are otherwise toxic; evidence of a causal relationship in humans is limited because of a small number of studies performed and insufficient control for potentially confounding variables.

In workers exposed to mercury vapor (urinary mercury levels 71.2 µg/g creatinine), sex-hormone binding globulin level in serum inversely correlated with duration of exposure, whereas no correlation was observed with serum levels of FSH, LH, and testosterone neither with respect to duration of exposure nor mercury levels in blood and urine (McGregor and Mason, 1991). A significant positive correlation between serum total testosterone, but not free testosterone, and cumulative mercury exposure was found in workers exposed to mercury vapor for an average of 10 years (mean urinary mercury 27 µg/g creatinine and mean blood mercury 9.5 µg/L (Barregärd *et al.*, 1994).

No effect on fertility as assessed by the rate of live births was observed in male workers chronically exposed to mercury vapor (urinary mercury levels, 5.1–271.2 µg/g creatinine) (Lauwerys *et al.*, 1985). An increased rate of spontaneous abortions among wives of workers exposed to mercury vapor was, however, noted at paternal urinary mercury levels >4000 µg/L; the effect was not significant after controlling for previous miscarriage history (Alcser *et al.*, 1989). In another study of workers exposed to mercury vapor (Cordier *et al.*, 1991), a trend of increasing rate of spontaneous abortions was associated with paternal urinary mercury levels of 1–19 and 20–49, µg/L; however, the study did not address confounding factors such as smoking and alcohol consumption.

In studies of men with suspect infertility, compared with fertile men, nonsignificant association was found between parameters of semen quality and mercury levels in blood (Chia *et al.*, 1992; Leung *et al.*, 2001), urine, or ejaculate (Hanf *et al.*, 1996). In another study, an increased risk of subfertility was found to be associated, in a dose-dependent manner, with increasing levels of mercury in hair (Dickman *et al.*, 1999).

Both methylmercury and inorganic mercury can accumulate in animal testes, although the uptake and clearance of methylmercury were faster. Exposure of mice to methylmercury or inorganic mercury (a single intraperitoneal injection of 1 mg Hg/kg body weight) resulted in adverse effects on spermatogenesis, testicular morphology, and fertility, whereas DNA synthesis

in spermatogonia was depressed by methylmercury and, to a lesser extent, by inorganic mercury (Lee and Dixon, 1975). In monkeys dosed with methylmercury (25 μg/kg/day orally for 20 weeks), decreased sperm motility and increased abnormal sperm tail morphology were observed at subneurotoxic levels; there was no change in testicular morphology and serum testosterone (Mohamed *et al*., 1987). In rats exposed to methylmercury (0.8, 8.0, or 80 μg/kg twice weekly in the diet for 19 weeks), significantly decreased intratesticular testosterone and somewhat lowered epididymal sperm count were found in the high-dose group, whereas inverse correlation was observed between fertility and testicular mercury content (Friedmann *et al.*, 1998).

In rats, mice, guinea pigs, and hamsters exposed to inorganic mercury (mercuric chloride, intraperitoneally, 1, 2, or 5 mg/kg/day for 1 month), the highest dosage caused testicular degeneration and cellular deformation of the seminiferous tubules and the Leydig cells in all species, whereas the lowest dosage caused testicular degeneration only in the hamster; partial degeneration was observed in the rat and mouse, and no change was noted in the guinea pig (Chowdhury and Arora, 1982). In rats orally exposed to mercuric chloride (9 mg/kg/day, for 60–180 days), testicular morphological changes and decreased testosterone levels were found (Agrawal and Chansouria, 1989). In mice exposed to inorganic mercury through drinking water (4 ppm mercuric chloride, for 12 weeks), degenerative testicular changes, decreased absolute and relative testicular weight, and decreased epididymal sperm count were found; a protective effect of zinc was reported (Orisakwe *et al.*, 2001). Vitamin E, administered with mercuric chloride (1.25 mg/kg/day) by gavage for 45 days in mice, was protective against reduced epididymal sperm count, sperm motility and viability, and resulted in lower concentrations of mercury in the testis, epididymis, and vas deferens (Rao and Sharma, 2001).

2.3 Cadmium

Although various cadmium-associated effects on the male reproductive system have been described, there is little conclusive published evidence of cadmium-related effects on semen quality, sex hormones, or fertility in human males on which to base a reliable estimate of quantitative dose-response relationship(s) or no-adverse-effect exposure threshold(s). Most studies have failed to adjust for the influence of potentially confounding variables such as age, smoking habits, alcohol consumption, and the body status of the relevant metals, particularly lead, zinc, and selenium.

In men not occupationally exposed to cadmium, a significant increase in cadmium levels in blood and seminal plasma has been related to smoking habits (cigarette-years, or cigarettes/day) (Chia *et al*., 1994; Telišman *et al*., 1997, 2000). However, in addition to increasing individual exposure to cadmium, smoking itself may adversely affect male reproductive function by mechanisms of oxidative stress involving other compounds present in cigarette smoke. Published data on men with suspect infertility (including nonsmokers and smokers) showed a significant positive correlation between abnormal sperm morphology and blood cadmium levels (Chia *et al*., 1992, 1994; Telišman *et al*., 2000), but not with seminal plasma cadmium levels (Telišman *et al*., 2000).

An inverse correlation has been reported between testis size and blood cadmium (Jurasovi *et al*., 2004), between sperm motility and blood cadmium (Telišman *et al*., 2000), between semen volume and either blood cadmium (Chia *et al*., 1992) or seminal plasma cadmium (Chia *et al.*, 1994; Xu *et al*., 1993), and between sperm concentration and sperm count with respect to blood cadmium levels (Chia *et al*., 1994; Xu *et al.*, 1993). Several other studies reported no significant correlations between semen quality and cadmium levels in semen, seminal plasma, or blood. Nonsmoking patients with varicocele had significantly higher cadmium and lower zinc levels in the seminal plasma compared with fertile subjects (Benoff *et al*., 1997). In nonsmokers and nonconsumers of alcohol, a significant positive correlation was found between sperm DNA oxidative damage (8-OHdG level in sperm DNA) and the seminal plasma levels of both cadmium (range, 0.5–1.3 μg/L) and lead (range, 5–14 μg/L), whereas an inverse correlation was found with seminal plasma selenium levels, suggesting that cadmium may contribute to sperm DNA oxidative damage and thereby affect semen quality (Xu *et al*., 2003); however, the study did not evaluate the combined effect or interaction of cadmium, lead, and selenium concerning these endpoints.

A study of 297 Chinese men environmentally exposed to cadmium showed a significant dose-response trend of increasing urinary cadmium (range, 0.1–43.0 μg/g creatinine) and the prevalence of cases with abnormal levels of prostate specific antigen in serum. Furthermore, subjects with abnormal findings on digitorectal examination of the prostate had significantly higher blood cadmium (blood cadmium range, 0.1–44.7 μg/L), suggesting that increased chronic cadmium exposure can cause injury to the human prostate (Zeng *et al*., 2004a). In the same study population, a significant dose-response trend of increasing urinary cadmium and the prevalence of abnormally high serum testo-

sterone levels was found, although the relationship was not significant after adjusting for age, smoking, alcohol, and body mass index (Zeng *et al*., 2004b).

In a study of 123 men with no occupational exposure to metals, no significant relationship was found between parameters of semen quality and blood cadmium levels (range, 0.2–11.9 µg/L) after adjusting for age, smoking, alcohol, and biomarkers of lead, copper, zinc, and selenium by multiple regression, whereas significant relationships were found between increasing serum levels of estradiol, FSH, and testosterone with respect to blood cadmium (Jurasovic *et al*., 2004). Another study of men not occupationally exposed to cadmium also showed a significant relationship between increasing serum testosterone and blood cadmium levels (range 0.2–13.3 µg/L) after adjusting for similar confounding variables (Telišman *et al.*, 2000).

In a study of 161 men, including smelter workers exposed to cadmium and control subjects, significantly increased serum testosterone was found in men with urinary cadmium of 10–20 µg/g creatinine compared with 0–2 or 2–5 µg/g creatinine, no significant difference in serum testosterone was found for men with urinary cadmium levels >20 µg/g creatinine, but significantly increased serum LH was found in this group (Zeng *et al*., 2002). Other studies of cadmium-exposed male workers showed no significant effect of cadmium on reproductive endocrine function (Mason, 1990; McGregor and Mason, 1991).

No significant influence of occupational exposure to cadmium was found on the fertility of 83 male workers (mean urinary cadmium was 6.9 µg/g creatinine and mean duration of exposure 24 years) on the basis of the rate of live births compared with unexposed workers and in the cadmium-exposed workers before or after the onset of exposure (Gennart *et al*., 1992b).

Male reproductive toxicity after acute exposure to cadmium is well documented in experimental animals, but there is considerably less information on the effects of low to moderate levels of chronic oral cadmium exposure. In most experimental studies, a single, large dose of cadmium was administered by injection (intraperitoneally, subcutaneously, or intramuscularly); the acute effects seen in animals are not likely to occur in humans, because the exposure to cadmium is different in both industrial and environmental settings.

Many studies in experimental animals have shown that the mammalian testis is highly vulnerable to cadmium, which can cause germinal cell damage and testicular necrosis, possibly through a direct effect on the testicular vasculature, which may exert a secondary action by lowering testosterone production and thereby also affecting accessory genital organs, including the prostate. The following acute effects have been reported in experimental animals injected with soluble cadmium salts: decreased serum testosterone, a decreased size and weight of the testes, epididymis, vas deferens, prostate and seminal vesicles, decreased sperm production and motility, and suppressed libido and reproductive capacity (Laskey *et al*., 1984; Lau *et al*., 1978; Nordberg, 1971, 1975; Parizek, 1960; Saksena and Lau, 1979; Waalkes and Rehm, 1994). Testicular atrophy and necrosis and decreased fertility have been observed in animals at nearly fatal doses of cadmium (Bomhard *et al.*, 1987). In rats, long-term exposure to cadmium through the drinking water (10 mg/L for 52 weeks) led to pathological testicular changes, as well as liver and kidney damage, whereas reproductive capacity was reduced in 40% of animals (Saygi *et al*., 1991).

A synergistic effect of lead and cadmium on testicular injury in rats has been reported (Saxena *et al*., 1989). In contrast, a protective effect against male reproductive toxicity of cadmium was observed in animals treated with zinc (Gunn *et al*., 1966a; Niewenhuis, 1980; Parizek, 1960; Saxena *et al.*, 1989), selenium (Jones *et al*., 1997; Niewenhuis and Fende, 1978), or with sulfhydryl (–SH) containing compounds such as BAL, cysteine, glutathione, and metallothionein (Gunn *et al*., 1966b; Nordberg, 1971). Neither small chronic doses of cadmium, which induce metallothionein biosynthesis, nor injections of cadmium partially bound to metallothionein cause testicular necrosis (Nordberg, 1971).

Both the route and duration of cadmium administration is relevant for male reproductive effects. In rats exposed to 50, 100, or 200 ppm cadmium in drinking water for 3 or 6 months, significantly increased (rather than decreased) serum testosterone was found in all cadmium exposure groups after 3 months and in the 200 ppm group after 6 months (Zeng *et al*., 2003). Prostate zinc content decreased, and there was significant downregulation of the metallothionein gene. As previously mentioned, elevated concentrations of serum testosterone and its correlation with blood cadmium levels have been reported in chronically exposed men. In view of the fact that testosterone augments the progress of prostate cancer in its early stages, it is possible that cadmium-induced changes may contribute to initiation and development of prostate cancer in both rodents and humans.

2.4 Manganese

In men occupationally exposed to manganese dust, clinical signs of manganism were commonly accompanied with impotence or reduced libido (Emara *et al*., 1971; Mena *et al*., 1967; Rodier, 1955), indicating that manganese-related effects were in part neurological in

origin. A study of male workers moderately exposed to manganese dust (Lauwerys *et al*., 1985) showed a significantly reduced rate of live births compared with a control group (39 births observed vs. 70.5 expected); in a similar study, no effect of manganese was found (Gennart *et al*., 1992b). This may be due to higher levels of manganese in the former study (12.0 vs 8.2 µg/L mean blood levels; 1.50 vs. 0.84 µg/g creatinine in urine).

A high single dose of manganese (160 mg MnO_2/kg by intratracheal instillation) caused degenerative testicular changes and sterility in rabbits (Chandra *et al*., 1973; Seth *et al.,* 1973). Chronic dietary exposure of young rats to manganese Mn_3O_4 for 224 days resulted in no effect on male fertility at manganese doses <1100 ppm, whereas at a dose of 3500 ppm decreased testicular weight, sperm count, and serum levels of FSH and testosterone were noted together with general toxic effects (Laskey *et al*., 1982). In mice orally exposed to manganese acetate for 43 days, a significant decrease in sperm count and motility was observed at doses of 15.0 and 30.0 mg/kg/day, whereas there was no effect on fertility and testicular pathology (Ponnapakkam *et al*., 2003).

2.5 Chromium

In male workers exposed to chromium (VI) for 1–15 years in an electroplating factory, compared with unexposed workers (Li *et al*., 2001), significantly decreased sperm concentration (by 47%), sperm motility, and seminal plasma levels of zinc, lactate dehydrogenase, and the lactate dehydrogenase isoenzyme LDH-C_4 were found, whereas serum FSH was significantly increased; serum chromium levels in exposed workers were 1.40 ± 0.01 µmol/L. A study of male welders, whose chromium levels in postshift spot urine samples ranged from 0.17–4.74 nmol/mmol creatinine and those in blood ranged from 6.0–46.4 nmol/L, showed no significant difference in parameters of semen quality compared with nonwelding workers (Bonde and Ernst, 1992). Another study of male welders, whose blood chromium levels were 131.0 ± 52.6 µg/L, showed significantly decreased sperm concentration (by 67%) in exposed workers compared with controls and an inverse correlation between sperm concentration and blood chromium levels in the exposed workers (Dandevi *et al*., 2003).

Animal exposure to high doses of chromium (III or VI) has been shown to adversely affect spermatogenesis. Chromium (VI) is considerably more toxic (Ernst, 1990; Ernst and Bonde, 1992; Li *et al*., 2001) and may involve oxidative stress. This is evidenced by increased lipid peroxidation in the testes, decreased sperm count, and increased abnormal sperm morphology of mice exposed to chromium (VI), each of which was partially preventable by the supplementation with the antioxidants, vitamin E and especially vitamin C (Acharya *et al*., 2004).

2.6 Nickel

In a study of male welders, whose blood nickel levels were 123.3 ± 35.2 µg/L, a significant positive correlation was found between the percentage of morphologically abnormal sperm with sperm tail defects and the blood nickel levels (Dandevi *et al.,* 2003).

Experiments in animals have shown testicular toxicity involving oxidative stress after high doses of nickel. This is evidenced by increased lipid peroxidation, DNA damage, and apoptosis in the testes, morphological sperm head abnormalities, and decreased fertility in mice (Doreswamy *et al*., 2004); decreased DNA, RNA, and total protein in testes, and decreased sperm count and motility in rats (Das and Dasgupta, 2000); and decreased absolute and relative weights of testes, epididymides, seminal vesicles and prostate gland, decreased sperm count and motility, and increased abnormal sperm morphology in mice (Pandey *et al*., 1999). Other reports provide some evidence that nickel may be essential for male reproduction in rats (Nielsen *et al*., 2002; Yokoi *et al*., 2003).

2.7 Arsenic

No relevant evidence with regard to dose-response relationship for the human male is available because of a small number of studies performed and insufficient control for potentially confounding variables. Exposure of mice and rats to high doses of inorganic arsenic can adversely affect spermatogenesis and can decrease testicular and accessory sex organ weights and serum levels of LH, FSH, and testosterone (Pant *et al*., 2001; Sarkar *et al*., 2003). Long-term oral exposure of mice to sodium arsenite in drinking water at 4 ppm arsenic for 365 days, which is a dose level similar to human exposure through drinking water, resulted in significant accumulation of arsenic in the mouse testis, epididymis, seminal vesicles, and prostate gland, a decrease in the absolute and relative testicular weight but not of epididymal and accessory sex organ weights, a decrease in sperm count and motility, increase in abnormal sperm morphology, and changes in the activities of testicular enzymes (Pant *et al.,* 2004). Exposure of mice to the same dose of sodium arsenite in the drinking water (4 ppm arsenic) for only 35 days produced no significant effects (Pant *et al*., 2001).

3 FEMALE REPRODUCTIVE EFFECTS

Effects of metals on female reproduction may arise from their action on several stages beginning in fetal life, during early development or maturity, and include

manifestations such as subfertility, infertility, intrauterine growth retardation, spontaneous abortions, malformations, birth defects, postnatal death, learning and behavior deficits, and premature aging. Because it is difficult to obtain detailed information concerning effects on the reproductive system in humans, evidence is usually limited to animal data or studies on fertility and spontaneous abortions. Pregnancy loss is the endpoint most frequently used to monitor effects on female reproductive function, starting from early losses, which contain a large proportion of chromosomal abnormalities and may represent 35–40% of human pregnancies. The remaining 10–15% later abortions are clinically manifest, and some have been linked to environmental factors (Miller *et al*., 1980; Runnebaum *et al*., 1997). Thus, there seems to be a remarkably high background rate of fetal loss in humans.

The clinical and epidemiological findings related to metal-induced effects on female reproduction are often difficult to interpret, because many other factors may influence the outcome such as age, ovarian reserve, hormonal imbalance, behavior, genetics, male fertility factors, or sexually transmitted diseases. In addition, timing, duration, and intensity of exposure are important in assessing reproductive adverse effects. Ernhart (1992) pointed out some critical aspects in measuring the dose indicators, such as sampling time and the matrix (maternal or fetal blood, cord blood, or placenta) in which indicators of prenatal exposure should be determined. To better assess early exposure to metals and the trend of absorption through pregnancy, at least one sample should be taken during the first trimester and another during the last 6 weeks of the pregnancy. This will facilitate the assessment of effects on the various stages of development and organogenesis.

Knowledge about pathogenetic mechanisms of female reproductive damage is limited. Effects may be direct, when environmental or occupational metals interact with specific reproductive target organs, or indirect, when metals act on endocrine or other systems. The ovaries and ova are susceptible to direct damage by metals for an extended period of time, from meiosis through ovulation. Some experimental studies suggest an increased risk of miscarriage, fetal malformation, placental insufficiency, and premature birth because of metal exposure (Fagher *et al*., 1993; Laundanski *et al*., 1991). Metals such as lead may interfere with the hypothalamic-pituitary-ovarian axis at different levels by modifying the secretion of prolactin, adrenocortical steroids, or thyroid hormones; vascular effects on the placenta have also been suggested (Gerhard *et al*., 1998; Hertz-Picciotto and Croft, 1993; Piasek and Laskey, 1994).

Current evidence provides warning signals: the female reproductive system is vulnerable to toxic agents, and the number of working women potentially exposed to metals is increasing worldwide. It is estimated that most of working women are in reproductive age; about half of working women are used during pregnancy, and about 20% are exposed to chemicals of potential concern (Sharara *et al.,* 1998). Reviews on female reproductive effects include Gold and Tomich (1994), Gardella and Hill (2000), Foster (2003), and Kumar (2004).

3.1 Lead

The adverse effects of lead on both male and female reproduction have been known for as much as a century. Infertility, spontaneous abortions, and fetal and neonatal death have been reported after either male or female occupational exposure to lead (Mattison, 1983; Rom, 1976). In the early studies, such effects were usually associated with high exposure levels. The evidence for effects resulting from low to moderate exposure is less clear. In one investigation, 831 pregnant women living near a lead smelter in Port Pirie, Australia, were studied prospectively for lead exposure and absorption, assessed by blood lead and pregnancy outcome (McMichael *et al*., 1986). The exposed women had a mean blood lead concentration (PbB) of 100.6 µg/L, and control women 76 µg/L. Preterm delivery was significantly associated, in a dose-response manner, with maternal blood lead concentration. No association was detected for spontaneous abortion, low birth weight (for births at term), intrauterine growth retardation, premature rupture of the membranes, and congenital anomalies.

Falcon *et al*. (2003) assessed the relationship between placental lead concentration and outcomes of pregnancy. Higher placental lead levels were measured in premature rupture of membranes and preterm pregnancies (gestational age ≤37 weeks) compared with term pregnancies. The proportion of abnormal pregnancy outcome associated with placental lead concentrations above 120 ng/g was 40.6% versus 8.8% in placentas below this concentration. Higher placental lead levels were not generally related to reduced size at birth.

The literature on high lead exposure and abortion provides consistent evidence, starting with historical surveys carried out in Milan by Torelli (1930). In this study, spontaneous abortions were reported in 24% of women exposed to lead, with a relative risk of 5.3, and an infant mortality more than double the Italian national rate at that time.

In a survey carried out by a questionnaire in more than 500 women, who had worked at a smelter and

were born between 1930 and 1959, the spontaneous abortion rates were highest when the mother was employed during pregnancy (13.9%) or had been employed before and was living close to the smelter (17%). The frequency rate was higher (19.4%) when the father worked at the smelter. Because the smelter produced copper and lead in addition to other metallurgical and chemical products, the effects reported may not necessarily be attributable to lead alone (Nordstrom *et al*., 1978a). Other reports provide virtually no evidence that low-to-moderate lead exposure is associated with an increased risk of spontaneous abortion (Laundanski *et al*., 1991; Murphy *et al*., 1990).

Hu *et al*. (1991) provided interesting data on the pregnancies of women who experienced lead poisoning during their childhood between 1930 and 1944. Because lead is stored in bone for decades, it was hypothesized that demineralization of the skeleton might occur during pregnancy. The proportion of pregnancies ending in spontaneous abortion or stillbirth was approximately 30% among cases and 15% among controls. No increased risk of spontaneous abortion was seen for pregnancies fathered by lead-poisoned men.

Murphy *et al*., (1990) compared the rates of spontaneous abortion among 304 women living in the vicinity of a lead smelter with those of 335 nonexposed women. The geometric mean PbB concentrations in the sample were around 150 μg/L in exposed versus 50 μg/L in the not exposed group. The rates of spontaneous abortions in first pregnancies were similar, suggesting that the reported low levels of exposure from the general environment were not associated with increased risk of abortion.

The risk of spontaneous abortion of spouses of male occupationally exposed to lead seems less consistent. Anttila and Sallmén (1995) summarized the epidemiological studies on the possible impact of parental occupational exposure to lead or other metals on spontaneous abortion. They stated that no clear conclusion could be reached for maternal exposure. The investigation by Borja-Aburto *et al*. (1999) on pregnant women environmentally exposed in Mexico City concluded on the contrary that lead exposures in the range 100–250 μg/L could have adverse effects on pregnancy and that some of the effects were noted close to 100 μg/L. Other developmental effects, different from the neurodevelopmental, have been associated with very low maternal blood lead levels, as discussed in detail later.

In a review, Hertz-Picciotto (2000) examined studies conducted among populations with low-to-moderate exposures, most of which provided little evidence of an association with pregnancy loss or spontaneous abortions. However, these studies were hampered by small sample sizes, problems in definition or ascertainment of outcome, lack of controls for confounding variables, and/or deficiencies in the exposure assessment and evaluation of accumulated dose. The author concluded that exposures comparable to U.S. general population levels during the 1970s and to many populations worldwide today (i.e, far lower than many occupational exposures) may increase the risk for spontaneous abortion. Further research is needed to confirm the association, to delineate the role of maternal versus paternal exposures, and to assess increases in menstrual variability as an explanation for these findings.

In experimental animals, lead has been shown to reduce litter size, weight of offspring, survival rate, and to alter maturation of the female reproductive system or to interfere with function in the sexually mature animal (WHO, 1977).

Examination of 48-hour embryos of dams exposed to lead in their diet revealed delays in early cell divisions, with fewer embryos reaching the 8-cell stage. Although blastocyst formation seemed to be relatively resistant to lead, implantation of blastocysts was impaired. Lead-exposed blastocysts were able to implant when transferred to a lead-free environment, although neither estrogen nor progesterone levels in lead-treated mice were significantly altered; the maximum binding capacity of uterine cytosolic receptors for estradiol was increased in lead-treated animals. Coadministration of estrogens and progesterone with the lead treatment prevented implantation failure. The normally occurring increase in estrogen and progesterone after implantation was not observed in lead-treated mice. These data suggest that lead interferes with ovarian steroid stimulation of the endometrium (Jacquet, 1977; Wide, 1983; Wide and Nilsson, 1977; Wide and Wide, 1980).

The onset of puberty was delayed in female rats receiving lead in drinking water from the time of weaning. Delays in vaginal opening were also observed in their offspring exposed continuously from conception to doses of lead from 25–250 ppm. No other effects on fertility or reproductive performance were noted (Grant *et al*., 1980; Kimmel *et al.,* 1980).

Several studies have examined the importance of the exposure period. For example, Epstein *et al*. (1999) evaluated mice exposed at premating, prenatally, and postnatally. Compared with controls, prenatally and postnatally exposed mice had slowed brain weight development, lowered brain weight, and decreased DNA per brain, but there was no effect on proteins per brain. In contrast, premating lead exposure significantly increased brain weight and protein but significantly lowered DNA per brain. The latter effects could be due to action of lead on the developing maternal reproductive systems or on ovulation-fertilization. Time of exposure was also investigated by Ronis *et al*. (1996) when

rats were exposed to lead acetate in drinking water *in utero*, prepubertally or postpubertally. The most severe effects were observed in the "*in utero*" exposed group, with delayed vaginal opening and disrupted estrous cycling. These effects suggest lead actions on the hypothalamic pituitary axis and on gonadal steroid biosynthesis directly.

Mc Givern *et al*. (1991) administered lead acetate in drinking water to Sprague–Dawley rat dams. Female offspring from lead-treated dams had significantly delayed vaginal opening, and 50% of them exhibited prolonged and irregular periods of diestrous, accompanied by an absence of observable corpora lutea. The release of gonadotropins revealed irregular patterns of both FSH and LH. Alterations in pubertal progression and hypothalamic-pituitary-ovarian-uterus functions have been confirmed in female monkeys prenatally or postnatally exposed to lead. Blood levels of approximately 350 µg/L resulted in subclinical suppression of circulating LH and FSH and estradiol without producing overt effects on general health and menstruation (Foster and Younglai, 1991). The overall results of these investigations suggest that different levels of the hypothalamic-pituitary-gonad axis can be affected by exposure to lead, mainly when structures are undergoing rapid proliferation.

3.2 Mercury

Limited data are available from epidemiological studies showing that mercury disrupts female reproductive function. One recent study in girls examined the relationship of mercury and other toxicants to timing of menarche (Denham *et al*., 2005). No effects of mercury were found, although mercury levels in the study population of girls were at or below background levels observed in the general population. However, earlier studies had noted menstrual cycle changes in women who were exposed to higher levels of mercury vapor in the workplace (De Rosis *et al.*, 1985; Sikorski *et al*., 1987). Decreased fertility was noted in some dental health care workers with increased exposure to mercury vapor (Rowland *et al*., 1994). In contrast, a number of effects have been described in experimental animals exposed to mercury, including alterations in ovulation and estrous cycle. Mercury vapor exposure resulted in prolonged estrous cycles and alterations in progesterone and estradiol levels, but primarily in animals with weight loss; morphological changes in corpora lutea were also observed. However, no adverse pregnancy outcomes (rate or number of implantation sites) were observed (Davis *et al.*, 2001).

Exposure of nonhuman primates to 50 or 90 µg/kg/day methyl mercury did not alter menstrual cycles or menses length through four cycles. However, reproductive effects, including failure to conceive and resorptions were related to increased mercury blood levels (Burbacher *et al*., 1984). In female macaques, blood levels greater than 1 ppm were associated with decreased pregnancy rates and increased abortion rates (Mottet *et al.*, 1985).

Mercury was detected by photochemical techniques within ovarian follicles and in the corpora lutea of rats after chronic ingestion of mercuric chloride (1 mg /day) for 12 weeks. Estrous cycles were prolonged in these animals (Stadnicka, 1980). In golden hamsters, mercury was also localized to the corpora lutea after inorganic mercury administration (Lamperti and Printz, 1974). Decreased ovulation was observed at the third estrous cycle in these animals, which received 1 mg $HgCl_2$/kg on the four days of the estrous cycle. Progesterone levels in mercury-treated animals were also different from controls (Lamperti and Printz, 1973). Watanabe and coworkers (1982) reported similar decreases in ovulation in golden hamsters injected (subcutaneously) with 6.4 or 12.8 mg Hg/kg but found no alterations in ovulation in animals treated with the same amounts of methylmercury chloride. In a more recent study, reproductive performance was evaluated for mice, males and females, exposed to inorganic mercury premating, during mating and during gestation and lactation (females only). Fertility and offspring survival were significantly reduced, although litter size was not affected (Khan *et al*., 2004).

There are few mechanistic studies related to mercury effects on female reproduction. Morphological alterations in the actuate nucleus of the hypothalamus were associated with changes in pituitary levels of FSH and LH in hamsters treated with mercuric chloride by injection (Lamperti and Niewenhuis, 1976). The role of these alterations in regulation of ovulation is not clear.

Early development of mouse embryos was disrupted after exposure to methylmercury *in vitro* (Matsumoto and Spindle, 1982). Treatment of female mice with 0.5 or 1 mg Hg/kg of methylmercury chloride or mercuric chloride on day 0 of gestation did not result in increased abnormalities in embryos recovered on day 3.5 of pregnancy. Exposures to higher levels of mercury (up to 20 mg Hg/kg methylmercury and 2.5 mg Hg/kg inorganic mercury) resulted in some abnormalities. However, embryos exposed *in vivo* were less sensitive to damage than those exposed *in vitro* (Kajiwara and Inouye, 1986).

3.3 Cadmium

Few data are available on the effects of cadmium on human female reproductive function. Epidemiological

studies have not revealed reproductive effects in contrast to experimental evidence in animals. Studies are needed to determine whether cadmium at low doses may act as reproductive and developmental toxicant and whether the fetal toxicity is related to placental defects or to accumulation of cadmium in the fetus.

In vitro studies have shown effects on calcium and oxytocin activities in myometrial strips from term pregnant women (Sipowicz *et al*., 1995) and on steroid genesis in granulose cells obtained from ovarian follicular aspirates (Paksy *et al*., 1997). However, the lowest cadmium concentration that reduced progesterone production was about 3.5 times higher than levels reported in the ovary of a female smoker.

After acute and at high-dose administration in rats, cadmium has been shown to affect various female reproductive endpoints, resulting in hemorrhagic changes in the ovary and uterus or in persistent estrous and ovulation; these effects can be prevented by coadministration of selenium (Saksena, 1982; Watanabe *et al.,* 1979).

The effects of cadmium vary as to the sensitivity of early embryos, and studies on cadmium acetate exposure indicate no effects on fertilization, but only at the blastocyst stage or *in vitro* reduction of development to the morula stage (Schmid *et al*., 1983; Storeng and Jonsen, 1980).

Exposure of experimental animals to cadmium increased uterus weight accompanied by proliferation of the endometrium and induction of progesterone receptors, mimicking the effects of estrogens. Female offspring experienced an earlier onset of puberty and growth of the mammary gland. In rats, exposure to cadmium oxide dusts increased the duration of the estrous cycle, decreased the preovulatory luteinizing hormone levels in blood, and inhibited ovulation. These effects were generally observed after high-dose, acute exposures and, therefore, provide little information for current human exposures (Baranski and Sitarek, 1987).

Cadmium given before mating may lead to sterility in a dose-dependent fashion, because of anovulation resulting from reversible pituitary dysfunction. However, animals may develop tolerance and remain fertile despite cadmium treatment, with normal fetal outcome and postnatal development (Paksy *et al.*, 1996).

Piasek *et al*. (1999) evaluated the direct effects of *in vitro* cadmium exposure on steroidogenesis in Sprague–Dawley rat ovaries; production of progesterone and testosterone was affected in proestrous rats and pregnant dams, whereas estradiol was not affected. They concluded that cadmium interferes with the ovarian steroidogenic pathway at more than one site. These effects may be mediated by interference with DNA-binding zinc in steroidogenesis or by estrogen-like activity (Henson and Chedrese, 2004; Johnson *et al*., 2003).

3.4 Manganese

Reports in humans on the association between manganese exposure and adverse reproductive outcomes in females are limited. A survey carried out in Australian general population found more frequent stillbirths than expected in the group exposed to manganese (Tsuchiya *et al*., 1987).

In rats, manganese exposure reduced the number of ovarian follicles and induced persistent corpora lutea (Laskey *et al*., 1982). In mice, exposure during gestation led to fetal growth retardation and anencephaly (Sanchez *et al*., 1993).

3.5 Chromium

Few studies in human females have addressed potential adverse effects of chromium and chromium compounds. The effect of chromium (VI) on human pregnancy outcomes was examined in females working in manufacturing facilities in Russia (Shmitova, 1978; 1980). Complications during pregnancy and childbirth (not described further) were reported in women with higher levels of chromium in blood and urine than the control group. However, the quality of the data and reporting limits their interpretation regarding the potential ability by chromium to produce reproductive effects.

Bonde (1993) studied the spouses of stainless steel welders exposed to chromium (VI) for spontaneous abortions and congenital malformations. The author concluded that the weak indications of an increased risk of spontaneous abortion among partners of stainless steel welders (odds ratio [OR], 1.9; 95% confidence interval [CI], 1.1–3.2) needed to be corroborated. In a subsequent investigation of a similar population by Hjollund *et al*. (2000), information was collected on exposure and outcomes for 245 clinically recognized pregnancies. Male welding of stainless steel was associated with an increased risk of spontaneous abortion in spouses (adjusted relative risk, 3.5; 95% CI, 1.3–9.1). The mutagenic effect of chromium (VI) previously found in both somatic and germ cells could be responsible for the abortions, which in this case would be a male-mediated effect. In an earlier study, the same group (Hjollund *et al.,* 1995) examined outcomes in 2520 pregnancies of spouses of Danish metal workers exposed to chromium (VI) from 1977 to 1987. The number of spontaneous abortions was not higher for pregnant women whose spouses worked in the stainless steel welding industry compared with

controls (OR, 0.78; 95% CI, 0.55–1.1). At present, the effects of chromium on female reproductive function in humans remains unclear.

Reproductive effects have been observed in the offspring of mice exposed to chromium (III) after oral maternal exposure. Significant decreases in the relative weights of reproductive tissues (ovaries and uterus) were observed in the offspring of exposed BALB/c mice. A significant delay in timing of vaginal opening was also noted (Al-Hamood *et al*., 1998). Cultured mouse embryos were sensitive to chromium (VI) exposure *in vitro*; incubation of blastocysts with potassium dichromate inhibited edinner cell mass growth and differentiation, whereas hatching, attachment, and trophoblast outgrowth were not affected (Iijima *et al*., 1983).

Murthy *et al*. (1996) reported a number of reproductive effects (reduced number of follicles at different stages of maturation, reduced number of ova/mice, increased estrous cycle duration and histological alterations) in the ovaries of female mice exposed to potassium dichromate in drinking water for 20 days. The severity of the reproductive effects seemed to be dose related. Other experimental studies reported increased preimplantation losses and resorptions in rats and mice exposed to chromium (VI) (Kanojai *et al*., 1998; Trivedi *et al*., 1989). A decrease in the number of pregnant females was observed after the mating of unexposed females with male mice exposed to chromium chloride, whereas an increase in relative ovarian weight was observed in female mice exposed to potassium dichromate. Impaired fertility was observed in females exposed to chromium (III) mated with unexposed males. In females of different species fed with potassium dichromate (VI), microscopic examination of the ovaries revealed no treatment-related effects (Elbetieha and Al-Hamood, 1997).

Additional studies were carried out in rats to assess reproductive effects from exposure to potassium dichromate in drinking water. At the highest level of exposure, there were a decreased number of implantation sites, number of live fetuses, and fetal weight. There were also increases in the number of resorptions and the number of preimplantation and postimplantation losses. There was also a significant reduction in ossification of fetal bones (Junaid *et al*., 1996a). In a second study (Kanojia *et al*., 1996), female rats were exposed to potassium dichromate for 20 days before mating. Similar effects were observed on gestational weight, postimplantation loss, number of live fetuses, and fetal ossification (in fetal caudal bones). In a third study, female rats were exposed to potassium dichromate for 3 months premating (Kanojia *et al*., 1998). Reduced maternal gestational weight gain, increased preimplantation and postimplantation loss, reduced fetal weight, fetal subdermal hemorrhagic thoracic and abdominal patches, and increased incidences of reduced ossification in fetal caudal bones were observed in all treatment groups. In addition, the highest dose group exhibited increased resorptions, reduced numbers of corpora lutea and fetuses per litter, reduced implantations, reduced placental weight, and reduced fetal length. No treatment-related gross visceral abnormalities were seen in these studies.

3.6 Nickel

The effects of nickel exposure on female reproductive function remain unclear, and available information is sparse in both human and experimental studies. An investigation carried out in the arctic region of Russia, showed a spontaneous abortion rate of 15.9% in 356 women from a nickel refining plant compared with 8.5% in a control group of 352 females working in construction industry. Exposure concentrations were 0.08–0.196 mg Ni/m^3, primarily as nickel sulfate, and nickel concentrations in the urine ranged from 3.2–22.6 µg/L (Chashschin *et al*., 1994).

Nickel exposure is reported to affect early embryonic events in mice. Injection of nickel chloride on the first day of pregnancy led to decreased implantation frequency and reduced litter size, whereas the administration on days 2–6 significantly reduced litter sizes but did not modify implantation. *In vitro* incubation inhibited growth of two-cell-stage embryos and development to blastocysts (Storeng and Jonsen, 1980; 1981).

In more recent animal studies, no effect was demonstrated on the length of the estrous cycle or microscopic changes in the reproductive organs in mice or rats exposed to air concentrations of nickel sulfate, nickel oxide, or nickel subsulfide, ranging from 3–0.11 mg Ni/m^3, respectively (NTP, 1996a,b,c). Fertility was not adversely affected in female rats exposure to nickel chloride in drinking water (Kakela *et al.,* 1999). Other studies on histological alterations in reproductive tissues of rats exposed to nickel or to nickel sulfate in drinking water failed to show relevant effects (Obone *et al.,* 1999).

3.7 Arsenic

The effect of arsenic on female reproductive function has not been studied sufficiently and is not clear. The effect on human reproduction of arsenic was investigated in females exposed by means of air or drinking water. Tabacova *et al*. (1994) examined the relationship between arsenic exposure from a copper smelter area in Bulgaria and oxidative damage during pregnancy.

Placental levels of arsenic were highest in areas with the highest environmental contamination, and exposed pregnant women were at higher risk of oxidative damage during pregnancy. Aschengrau *et al*. (1989) investigated the relationship between community drinking water quality and spontaneous abortion. Type and concentration of trace elements were gathered from routine analyses of public tap water supplies of areas where the women resided during pregnancy. After adjustment for potential confounders, an increase in the frequency of spontaneous abortion was associated with high levels of arsenic.

In a case-control study of stillbirths, Ihrig *et al*. (1998) included the assessment of environmental arsenic exposures and analysis of confounders (race, ethnicity, maternal age, median income, and parity). There was a statistically significant increase in the risk of stillbirth in the group with highest exposure to arsenic. Further analysis showed that the increase was limited to Hispanic people, possibly because of a genetic impairment in folate metabolism. However, this study had a small number of cases in the high exposure group, lacked data on smoking, and did not consider potential confounding exposures to other chemicals. As a whole, the studies on arsenic reproductive effects have been criticized because they did not adequately measure exposure to arsenic and other metals and did not evaluate other potential confounding factors (Golub *et al*., 1998, NRC, 1999).

In the multigenerational experimental study by Schroeder and Mitchener (1971), female rats continuously exposed to arsenate in drinking water did not show decreased fertility. Two other studies demonstrated that reproductive functions (included precoital interval, mating index, and fertility index) were not affected in female rats orally exposed to trivalent arsenic by gavage from 14 days before mating through gestation (Holson *et al.*, 1999; 2000b). Some effects were demonstrated in female mice exposed to monomethyl arsonic acid before mating and during pregnancy with production of fewer litters than normal, but this effect was attributable mainly to decreased fertility of the males (Prukop and Savage, 1986). Also, rats treated with arsenic by daily gavage (before mating and continuing through gestation) had significantly reduced fetal body weights and significantly increased skeletal malformations that the researchers considered to be consequences of growth retardation.

In mice treated with arsenic acid, there was a significant increase in the number of resorptions per litter and significant decreases in the number of live pups per litter and mean fetal weight. However, overt maternal toxicity (including death) was found at the same or lower doses as those leading to developmental effects (Holson *et al*., 2000a; Nemec *et al*., 1998; Stump *et al*., 1999).

3.8 Platinum

After the introduction of automobile catalytic converters, platinum, palladium, and rhodium have been emitted with exhaust fumes, and increasing levels have been found in different environmental matrices such as road dusts, soils along heavily frequented roads, and sediments of urban rivers. Compared with other heavy metals, the biological availability of platinum, palladium, and rhodium in some experimental studies on road dusts ranged between that of cadmium and lead (Zimmerman and Sures, 2004). As stated by the same researchers, chronic effects on the biosphere cannot be excluded because of (1) their cumulative increase in the environment, (2) their unexpected high biological availability and bioaccumulation, and (3) their unknown toxicological and ecotoxicological potential.

Many clinical cases of pregnant patients affected by cancer treated by chemotherapy with platinum complexes have been reported in the obstetrical and gynecological scientific literature, with births at term and normal infants.

Male-mediated effects on Sprague–Dawley rats treated with a single intraperitoneal injection of cis-platinum were studied by Kinkead *et al*. (1992). Significant preimplantation loss was seen in the treated groups. The weights of the fetuses were also significantly lower than those of the control group. These results suggested that cis-platinum has a deleterious effect on the female reproductive system.

Morphological and functional effects on rat ovaries (Borovskaja *et al*., 2004), embryotoxic effects in rat (Chug *et al*., 1998), embryo lethality, and teratogenic effects (Ognio *et al*., 2003) have been demonstrated after exposure to platinum complexes.

3.9 Mixed Metal Exposure

For humans, there are few recent studies on mixed exposures to metals. Nordstrom and coworkers (1978a,b; 1979a) reported on the frequency of spontaneous abortions and birth weights of children born near a copper smelter in northern Sweden that emitted lead, arsenic compounds, and sulfur dioxide. The comparison of women working at the smelter with women not occupationally exposed suggested increased frequencies of abortions and depressed birth weights related to exposure. Because of the low levels of exposure in the nonoccupationally exposed population and the inclusion of smelter workers in the regional analysis, great care must be taken in interpreting the results. Similar results relating metal exposure to spontaneous abortions have been reported by Hemminki and coworkers (1980). Hospital records, union memberships,

and census data were used to identify groups with potential metal exposure. In women belonging to the union of metal workers, the rate of abortions was slightly higher (7.82%, number of abortions; $n = 195$) than the national average (7.34%; $n = 24{,}107$). The rate of abortions for women belonging to union branches with possible exposure to metals such as zinc, cobalt, and arsenic was compared for pregnancies during membership or for pregnancies before or after membership. The rate of abortions for conceptions during membership was again slightly higher than for nonmembership periods.

In a community study in which the major site of employment was a factory producing zinc and cobalt, increased abortions were noted for economically active women compared with all women in the community and for wives of men employed at the metallurgy factory compared with the wives of all industrial workers. The number of pregnancies among the female workers at the metallurgical factory was too low to be evaluated. However, data gathered from census and hospital records showed that the rate of abortions among welders (9.5%; $n = 28$) was higher than for all industrial workers (8.2%; $n = 2260$) (Hemminki *et al.,* 1983).

The effects of coexposure to metals on female reproductive function was demonstrated in a study carried out by Belles *et al*. (2002), focusing on the developmental toxicity in mice of lead nitrate (25 mg/kg, subcutaneously), methylmercury chloride (12.5 mg/kg, orally), and sodium arsenite (6 mg/kg, subcutaneously). Metals were administered on gestation day 10 separately or in their binary and ternary combinations. Maternal toxic effects were more remarkable in the group concurrently exposed to Pb, Hg, and As than in those given binary combinations of the elements and in those given the metals separately. With regard to developmental toxicity, the most relevant effects, namely decreased fetal weight and cleft palate, corresponded to the Hg-treated groups. These data suggest that at the current doses, the interactive effects of Pb and As on Hg-induced developmental toxicity were not greater than additive. In contrast, exposure of pregnant mice to Pb and As at doses that were practically nontoxic to dams, but administered concurrently with organic Hg at a toxic dose, caused supraadditive interactions in maternal toxicity.

4 DEVELOPMENTAL EFFECTS OF PRENATAL EXPOSURE

Exposure to metals during organogenesis may give rise to fetal anomalies, and exposure during other periods of development may result in embryo or fetal lethality or other developmental effects. Although methylmercury is clearly teratogenic for humans, other metals such as nickel, arsenic, and lead have less severe effects. Teratogenesis bioassays in rodents (hamsters, mice, or rats) have yielded positive results for the com pounds of many metals (Al, As, Bo, Cd, Co, Cr, Cu, Ga, Hg, Li, Mn, Ni, Pb, Se, U, V, and Zn), producing fetal and early postnatal deaths, as well as malformations such as anencephaly, eye defects, cleft palate, and skeletal anomalies (Sunderman, 1998). However, the relevance of these findings to human exposure is uncertain.

The effects produced by metals depend on the timing and duration of exposure, on their distribution and accumulation in various organs such as the nervous system, and on the ability to interfere with specific developmental processes. Effects may be enhanced by biochemical, physiological, and anatomical changes occurring during development, which may result in a modified metabolism of the metal itself (Rice and Barone, 2000). Interesting interactions between environmental and congenital factors have been documented; genetic polymorphisms can affect fetal susceptibility to teratogens or maternal ability to detoxify and excrete xenobiotics (Garcia, 2000).

Mechanisms of damage during development include proliferation (cell division), cell death, cellular differentiation, biosynthesis, cell–cell or tissue–tissue interactions, and cellular movements. Damage may be related to these kinds of epigenetic injury or to a direct genetic action on developing tissues (Mottet and Perm, 1983).

The primary etiological factors and pathogenetic mechanisms contributing to developmental effects caused by metal exposures are only partly known. Neurodevelopmental impairment may range from serious mental retardation and other overt clinical syndromes to subtle subclinical deficits as sensory, motor, and cognitive impairment that are difficult to identify. Subtle effects, although less severe at an individual level, may be important for public health policy. The damage may not become apparent until after some latency period; therefore, the critical periods of sensitivity and latent effects may complicate the interpretation of many experimental and epidemiological studies.

The symposium on Health Risks Associated with Prenatal Metal Exposure held in 1995 was designed to evaluate the health risks for mother and developing offspring associated with *in utero* exposure to metals commonly found in the workplace and/or ambient environment. Epidemiological and toxicological evidences of these effects were demonstrated, focusing on the mechanisms associated with exposure to arsenic, lead, and methylmercury (Zelikoff *et al*., 1995). Reviews by Carpenter (2001) and Mendola *et al*. (2002) may provide further background information.

4.1 Lead

Developmental effects of lead have been predominantly associated with postnatal exposure; however, evidence is emerging that both prenatal and postnatal exposures are important, and occur, for example, in areas where drinking water is contaminated by the metal.

Several studies have documented placental transfer of lead and lead levels in maternal blood, placenta, and cord blood. Environmental exposure in areas with water concentrations of lead >50 μg/L was associated with increased lead concentrations in cord blood and placenta, as well as in maternal blood. Lead levels in maternal blood were generally higher than in cord or neonatal blood, despite the higher affinity of fetal hemoglobin for lead (Alexander and Delves, 1981; Hubermont *et al*., 1978; Miller and Shaikh 1983; Ong and Lee, 1980; Roels *et al.,* 1978). Wibberley *et al*. (1977) studied placental lead levels in a series of Birmingham births classified as stillbirth, neonatal death, or survival beyond 1 week. Despite a wide range of lead levels even in normal births (15–356 μg/L) the results showed a pronounced excess of lead in those who failed to survive both birth and the neonatal period. There was no association of placental lead with impaired birth weight among survivors but, in agreement with other authors, seasonal variation was noted: with higher levels during the summer months. A study in Cassandra, Zambia, near a lead mine and smelting factory found mean blood lead (PbB) levels of 412 μg/L and 370 μg/L for mothers and infants, respectively, with a significant correlation ($r = 0.77$; $P < 0.001$) (Clark, 1977). The increased lead transfer, however, did not seem to have an adverse effect on the newborn's birth weight or red cell values.

The main current human data indicate that a direct association between moderate low-level lead exposure and malformations has not yet been proven, and there is a predominance of negative results. In particular, no evidence of association of low lead exposure with major congenital malformations has been reported.

However, Nordstrom *et al*. (1979a,b) investigated the frequencies of congenital malformations in the offspring of female employees at a smelter in northern Sweden and in the population living nearby. The frequency of single and multiple malformations was significantly higher (approximately twofold and fourfold, respectively) in the offspring of the women who had worked at the smelter during pregnancy. A significantly increased risk was found only in pregnancies where the mother had worked at the smelter. The numbers of malformations in the offspring of female employees were low; therefore, the results, although statistically significant, should be interpreted with caution. These results combined with those from studies carried out in seven different countries provide little evidence that low or moderate lead exposure is associated with an increased risk of major malformations. Effects of higher exposures are more equivocal. Needleman *et al*. (1984) examined 5183 consecutive deliveries of at least 20 weeks' gestation, correlating the congenital anomalies and lead concentration in umbilical cord blood. Lead was associated, in a dose-related fashion, with an increased risk of minor anomalies but not with the risk of malformations. However, an increased risk of neural tube defects was observed in an English study of mothers exposed to lead from the general environment (Bound *et al.*, 1997).

An effect on growth (stature about 2 cm shorter at 15 months of age) was noted for children whose mothers had a PbB concentration exceeding 77 μg/L, and the infant PbB increased to 100 μg/L during the first 3–15 months of life (Shukla *et al*., 1989). Bellinger *et al*. (1991) evaluated the relationship between prenatal low-level lead exposure and fetal growth in a sample of 4354 pregnancies. The authors concluded that the risk of adverse fetal growth is not increased at cord blood lead levels <150 μg/L but that modest increases in risk may be associated with levels ≥150 μg/L. Factor-Litvak *et al*. (1991) tested the hypothesis that exposure to lead during pregnancy from residence in a lead smelter town is associated with reduced intrauterine growth and an increase in preterm delivery. Mean PbB at midpregnancy was around 192 μg/L in the exposed women and 60 μg/L in the control group. After adjustment for the effects of potential confounders, no significant relationships were found between maternal PbB measured at midpregnancy, at delivery, or in the umbilical cord and birth weight or length of gestation or preterm delivery.

Dietrich *et al*. (1986; 1987) correlated prenatal, cord, and 10-day neonatal PbB levels and performance tests at 3 and 6 months. PbB levels during prenatal periods were inversely related to a series of sensorimotor developmental indices at 6 and 12 months of age, as well as lower birth weight. Further analyses by structural equation modeling showed that the effect of prenatal lead exposure, all less than 300 μg/L, was in part mediated through its effects on birth weight and gestational age.

Bellinger and coworkers (1994) investigated the association between prenatal and postnatal lead exposure and behavioral problems in 8-year-old Boston children. Prenatal and postnatal lead exposure was assessed by umbilical cord PbB (mean, 68μg/L) and dentin lead of a shed deciduous tooth (mean, 3.4μg/g).

The results showed that cord PbB level was not associated with the overall prevalence of problem behaviors. However, tooth lead was significantly associated with total problem behavior scores in both crude and adjusted analyses, suggesting that information about accumulated dose is important.

Some neurobehavioral effects, decreased ability to self-quiet and to be consoled, were associated with a rise in maternal blood lead levels from 36 weeks of gestation to birth (Rothenberg *et al.*, 1989). A longitudinal investigation of prenatal lead exposure and juvenile delinquency (Dietrich *et al.*, 2001) showed an increase in antisocial behavior with low-level lead exposure, even after adjusting for a variety of medical and social covariates. There is, however, still insufficient information on the role of potential confounding, as well as issues related to the transferability of experimental models, developmental periods of particular vulnerability, and dose-response relationships (Winneke, 1996).

A review (Bellinger, 2005) focused on the impacts of lead exposure on reproductive health and outcomes. Maternal blood lead levels of approximately 100 µg/L have been linked to increased risks of pregnancy hypertension, spontaneous abortion, and offspring neurobehavioral effects. Higher maternal lead levels have been linked to reduced fetal growth and congenital malformations, although considerable uncertainty remains regarding the specific malformations and the dose-response relationships. Of special concern is the likelihood that the fetus might be exposed to lead mobilized from bone stores as a result of pregnancy-related metabolic changes, making fetal lead exposure the result of exposure to a composite of exogenous lead during pregnancy and endogenous lead accumulated by the woman before pregnancy. Studies during recent years have confirmed that the risk to the fetus and long-term sequelae is discernible at progressively lower blood lead levels. In experimental animals, maternally administered lead is transferred to the conceptus. High concentrations of lead were found in fetal skeleton, liver, and blood but not in kidney (Dencker *et al.*, 1983).

Teratogenic effects may vary with the forms of lead and time of administration. Perm and Carpenter (1967) first observed specific tail and sacral vertebral anomalies in hamsters after administration of lead; these malformations persisted when lead was administered at different times during gestation; the histogenesis of these lesions is thought to involve localized edema, blisters, and hematomas (Carpenter and Perm, 1977; Perm and Perm, 1971). In mice, malformations occur in the anterior portion of the axial skeleton (Jacquet and Gerber, 1979); lead has also produced spina bifida and anencephaly in mice (Kruckenberg *et al.*, 1976). In rats, a single intravenous injection of lead nitrate (50–70 mg/kg) on day 9 of gestation caused urorectocaudal malformations; treatment on day 10–15 caused fetolethality, but administration after day 16 had little effect (McClain and Becker, 1975). Lead-chelator complexes were also found to be less teratogenic than free lead ions (McClain and Siekierka, 1975a,b).

Retarded fetal growth or fetal death is a consistent result of lead exposure during development. Resorptions and decreased fetal weights were noted in rats and mice after lead exposure (Kennedy *et al.*, 1975). Other effects have included depressed body length, brain, and body in neonatal pups (Carmichael *et al.*, 1981); increased resorptions in rats with no effects on fetal length or weight (Wardell *et al.*, 1982); and small (10%) decreases in the body weight of postpuberty pups (Ronis *et al.*, 1998).

Several behavioral parameters seem to be altered by prenatal exposure to lead. Discrimination learning is widely reported to be affected in animals at levels that did not alter growth (reviewed by Bornschein *et al.*, 1980); social behavior in mice was also altered (Cutler, 1977). By contrast, open-field activity, passive avoidance, and Rotorod performance were unaltered in surviving rats after maternal injection (intravenous) of 5 or 25 mg/kg lead nitrate on day 17 of pregnancy; the higher dose, however, produced increased mortality, hydrocephalus, and decreased weight in the pups (Minsker *et al.*, 1982). Grant *et al.* (1980) also reported no effect in most behavioral tests on rats after chronic exposure to lead.

4.2 Mercury

Several compounds of mercury are documented as affecting development in humans or experimental animals. Of these, methylmercury is the most thoroughly studied and best-documented example of a metal compound that disrupts normal development. Similar to lead, it exemplifies both the qualitative and quantitative differences in the response of adult and developing tissues. Reference reviews have been published by Castoldi *et al.* (2001), Clarkson (2002), Clarkson *et al.* (2003), and Davidson *et al.* (2004).

Methylmercury crosses the human placenta to the fetus. Mercury levels in the blood of prenatally exposed infants and in cord blood were higher than in maternal blood (Amin-Zaki *et al.*, 1974a; Miller and Shaikh, 1983). Although organic mercury bound preferentially to fetal erythrocytes, the highest concentrations of inorganic mercury were found in the placenta (Kuhnert *et al.*, 1981). The higher levels of mercury in cord and infant blood may reflect the

higher hematocrit of the fetus (White and Rothstein, 1973).

Prenatal exposure of humans to methylmercury can cause damage to the CNS, resulting in cerebral palsy and mental retardation in the infant. Engelson and Herner (1952) first described a human case of prenatal methylmercury poisoning, resulting from accidental contamination of food. An infant born to an exposed woman, with only minor signs of poisoning, suffered severe mental retardation. A similar case of family poisoning occurred in the United States in the late 1960s (Snyder, 1971).

Two major outbreaks of methylmercury poisoning, one in Japan in the mid-1950s and one in Iraq in the winter of 1971/72, included cases of prenatal poisoning. In Minamata, Japan, 21 cases of cerebral palsy in infants were associated with prenatal exposure (reviewed by Harada, 1968; 1977; 1995). The mothers generally experienced only mild, transient symptoms, whereas the effects on the children were severe and permanent. More subtle effects of prenatal exposure to methylmercury were described after a large outbreak of poisoning in Iraq in the winter of 1971/72 (Bakir *et al*., 1973). Families in rural Iraq consumed bread prepared from grain contaminated with a methylmercury fungicide. A number of children were severely affected (Amin-Zaki *et al*., 1974a). In a follow-up study, children with milder cases of psychomotor retardation were identified after prenatal exposure to methylmercury (Amin-Zaki *et al*., 1976; Marsh *et al*., 1977; 1980). The severity and frequency of effects in children correlated closely with maximum hair concentrations (marker of maternal exposure) in mothers during pregnancy (Clarkson *et al*., 1981; Marsh *et al*., 1980; 1981). Comparisons of dose-response relationships for the prenatally exposed children and nonpregnant adults in the Iraq outbreak indicated that the prenatal stage was roughly three to four times more sensitive to methylmercury damage than the adult (Clarkson *et al*., 1981). This dose-response relationship for prenatal effects was the first to be described for human exposure to any environmental chemical. Other studies have also used cord blood as an indicator of exposure to methylmercury (Grandjean *et al*., 1999a).

More recently, two large studies have examined the effects of low-level prenatal methylmercury exposure from consumption of fish or other seafood. The study based in the Faroe Islands examined neurodevelopmental outcomes in children whose mothers had consumed contaminated whale meat and fish (Grandjean *et al*., 1997; 1998; 1999b; Murata *et al*., 1999a). Subtle effects on brain function (motor function, visual spatial perception, language, attention, and memory) were found in children (age 7) exposed prenatally to low levels of mercury (mean 4.0 ppm mercury in maternal hair). In addition, prenatal methylmercury exposure was also associated with heart rate and blood pressure affects (Sorensen *et al*., 1999). The findings of delayed brainstem auditory evoked potential latency (Murata *et al*., 2004) and heart rate variability, but not blood pressure (Grandjean *et al*., 2004), have persisted in children now evaluated at 14 years of age. An additional study on infants in the same population associated methylmercury exposure with adverse neurological outcomes at 2 weeks of age (Steuerwald *et al*., 2000).

A second series of studies conducted in the Seychelles assessed global IQ in children with prenatal exposure because of maternal fish consumption (mean 6.0 ppm mercury in maternal hair); children were tested five times after birth up to age 9. In these studies, no detrimental effects of methylmercury exposure were found, except for one endpoint in boys only at 107 months (Davidson *et al*., 1995a,b; 1998; 2000; Myers *et al*., 1995). In fact, several endpoints were positively associated with mercury levels and fish consumption. A number of articles based on the Seychelles study, as well as Peru and Iraq, are found in a special issue of *Neurotoxicology* (Spyker Cranmer, 1995).

Possible explanations for the differing results include the patterns of exposure (episodic versus continuous), ethnic/genetic differences in responses to methyl mercury, types of neurodevelopmental measures, and possible confounders, such as diet other than fish and other chemicals found in seafood (Mahaffey, 1998; Nakai and Satoh, 2002).

Additional studies have examined children exposed prenatally to methylmercury in the Brazilian Amazon (Grandjean *et al*., 1999a), French Guiana (Cordier *et al*., 2002), Greenland (Weihe *et al*., 2002), Madeira (Murata *et al*., 1999b), New Zealand (Kjellstrom *et al*., 1986; 1989), Northern Quebec (McKeown-Eyssen *et al*., 1983), Peru (Marsh *et al*., 1995), and the Philippines (Ramierez *et al*., 2000; 2003). These studies reviewed by Castoldi *et al*. (2001) and Davidson *et al*. (2004) generally have small sample sizes, various designs and endpoints, and show differing results.

The effects of methylmercury on the developing and mature CNS are qualitatively different. In the adult, damage is selective in certain areas, whereas prenatal exposures produce more generalized damage. After prenatal exposure, the brain and skull may be abnormally small, and brain cytoarchitecture may be grossly disturbed (Huter and Russell, 1954). In two Iraqi children cell migration was disrupted, with Purkinje cells found in the white matter of the developing cerebellum (Choi *et al*., 1978).

Animal models provide additional information on the distribution of mercury compounds. As in humans,

methylmercury was readily distributed to fetal tissues in experimental animals (Berlin and Ullberg [1963c]; reviewed by Chang *et al*. [1980] and Stern *et al*. [2001]). Reported mercury concentrations in fetal brain were higher than in other fetal tissues and often exceeded maternal brain levels (Lee and Han, 1995; Matsumoto *et al*., 1967). Studies in nonhuman primates demonstrated greater movement of methylmercury from maternal to fetal circulation than back from fetus to mother, suggesting a mechanism for the accumulation of methylmercury in fetal tissues (Reynolds and Pitkin, 1975). Maternal mercury levels and infant blood kinetics were also described for a group of nonhuman primates that received between 0 and 90 μg methylmercury/kg/day orally during pregnancy (Stinson *et al*., 1989).

Developmental effects of methylmercury have been extensively studied in animals. Specific malformations have been induced by administration of a single dose of methylmercury during organogenesis. The sensitivity and types of malformations vary with time of treatment and strain or species of animals used. Examples include cleft palate (Gale and Ferm 1971; Olson and Massaro, 1977; Spyker and Smithberg, 1972; Su and Okita 1976a), limb malformations (Harris *et al*., 1972), and facial and brain defects (Inouye and Murakami, 1975; Spyker and Smithberg, 1972). Other developmental effects include increased fetal death and malformation (Nolens *et al*., 1972); decreased fetal weight, fetal death, and maternal toxicity (Mottet, 1974); and depressed birth weights (Curle *et al*., 1983).

Experimental models have been developed for neural damage caused by methylmercury. The original studies on experimentally caused Minamata disease were summarized in Murakami (1972). Cerebral damage has been reported in several types of animals (Fuyuta *et al*., 1978; Harada, 1977; Khera, 1973; Murakami, 1972). Cerebellar alterations have been detected in animals well after birth after *in utero* exposure (Chang *et al*., 1977a,b; Kakita *et al*., 2000a,b; Markowski *et al*., 1998; Reuhl *et al*., 1981a,b; Sakamoto *et al*., 2002).

Nonhuman primates have been used extensively to study the developmental toxicology of methylmercury. A series of studies have been conducted in a cohort of macaques exposed to relatively low levels of methylmercury *in utero* (0, 50, 90 μg/kg/day to the mother). Effects on birth weights and reproduction were seen in this group exposed to 90 μg/kg/day (Burbacher *et al*., 1984; 1988). Deficits in juvenile and adult macaques after methylmercury exposure *in utero* included visual recognition memory (Gunderson *et al*., 1986; 1988), social behavior (Burbacher *et al*., 1990), and growth (Grant-Webster *et al*., 1992). Tests of cognitive function yielded equivocal results; spatial memory was not affected (Gilbert *et al*., 1993), and only mild effects on fixed interval performance were noted in males after *in utero* exposure to methylmercury (Gilbert *et al*., 1996).

Behavioral changes have also been documented in other animal models exposed to methylmercury *in utero*. These include differences in motor coordination (Sakamoto *et al*., 2002), locomotor activity (Dorè *et al*., 2001; Geyer *et al*., 1985; Rossi *et al*., 1997; Spyker *et al*., 1972; Su and Okita 1976b), passive avoidance (Hughes and Annau, 1976; Kakita *et al*., 2000a; Sakamoto *et al*., 2002; Zanoli *et al*., 1994), operant conditioning (Musch *et al*., 1978), audiogenic seizure response (Meashi *et al*., 1982), and ultrasonic vocalizations (Adams *et al*., 1983). Studies have also documented sex-related differences on some behavioral measures (Goulet *et al*., 2003) and no effects on other behavioral measures (Colomina *et al*., 1997; Kakita *et al*., 2000b; Roegge *et al*., 2004; Rossi *et al*., 1997).

The mechanisms of damage that lead to the selective action of methylmercury on the developing nervous system are not well understood, although a number of cellular and molecular mechanisms have been proposed. See reviews by Castoldi *et al*. (2001, 2003), and Costa *et al*. (2004) for detailed discussions and references.

A few studies have documented effects on systems other than the nervous system, including impaired natural killer cell (NKK) function in (Ilback *et al*., 1991; Wilde *et al*., 1997); altered thymocyte development in mice (Thuvander *et al*., 1996); and structural changes in the kidney (Chang and Sprecher, 1976), although little persistent functional damage was noted (Smith *et al*., 1983); and ultrastructural changes in the liver (Ware *et al*., 1974; Fowler, 1983).

No human studies have documented adverse effects from prenatal exposure to elemental mercury or mercury vapor. In the general population, exposure of pregnant women to mercury vapor results primarily from mercury amalgam fillings in teeth. Mercury levels in autopsy tissues from infants and fetuses are reported to correlate with the number of mother's dental amalgams (Drasch *et al*., 1994). In another study, levels of inorganic mercury in blood and urine during early pregnancy correlated with amalgams, as did cord and maternal blood (Vahter *et al*., 2000). Removal of amalgam fillings during pregnancy may be an additional source of mercury vapor exposure, leading to potential fetal exposures (Molin *et al*., 1990). However, in a study that compared mercury levels in maternal and infant hair, no differences were found in woman who acquired amalgams during pregnancy as opposed to before pregnancy; both groups had higher levels of mercury in infant and maternal hair than those without amalgam fillings (Lindow *et al*., 2003). To date, the consequences of this prenatal exposure are not known.

Relatively few animal studies have been done with inorganic mercury or mercury vapor. After exposure

of pregnant rats to radiolabeled mercury vapor during late gestation, mercury accumulated in the placenta and the fetus in about equal ratios (Clarkson *et al*., 1972). There was substantial deposition of mercury in fetal tissues after exposure to mercury vapor in mice (Khayat and Dencker, 1982), guinea pigs (Yoshida *et al*., 1986), and squirrel monkeys (Warfvinge *et al*., 1994). High levels of mercury were found in fetal rat brain after prenatal exposure, but no adverse effects were noted except in the presence of maternal toxicity (Morgan *et al*., 2002). When pregnant rats were given dental amalgam restorations, mercury accumulated in fetal tissues, but was lower than in maternal tissues (Takahashi *et al.,* 2003). Combined mercury vapor and ethanol exposure increased mercury levels in fetal tissues (Dencker *et al*., 1983; Yoshida *et al*., 1997). In guinea pigs, mercury vapor was oxidized in the fetal liver and bound to metallothionein (Yoshida *et al*., 1987). Recent studies have identified a protective role for metallothionein in preventing transplacental transfer after mercury vapor exposure (Yoshida *et al*., 2002).

Some studies have demonstrated behavioral effects of prenatal exposure to mercury vapor (Danielsson *et al*., 1993; Fredriksson *et al*., 1992), whereas others in nonhuman primates showed no difference in various behavioral measures after prenatal exposure to fairly high levels of mercury vapor (Newland *et al.,* 1996).

Earlier studies using several species of animals showed little transport of inorganic mercury to the fetus (Berlin and Ullberg, 1963a–c; Clarkson *et al*., 1972; Suzuki *et al*., 1967). However, a more recent study using rats exposed to mercuric chloride during pregnancy and until weaning (postnatal day 20) reported measurable levels of mercury in fetal tissues, with the highest mercury levels in the kidney; levels of mercury were higher in fetal brains than maternal samples (Feng *et al*., 2004). Studies in BALB/c mice have also shown that prenatal exposure to mercuric chloride resulted in persistent alterations in immune function. Effects included inhibitory effects in females on cytokine projection by thymocytes, lymph node cells, and splenocytes; in contrast, stimulatory effects were observed in males (Silva *et al*., 2005). Distribution of mercury after administration of phenyl mercury exposure was similar to that of mercuric mercury (Berlin and Ullberg, 1963b; Garrett *et al*., 1972; Suzuki *et al*., 1967).

4.3 Cadmium

Data on the concentrations of cadmium in maternal blood and placental and fetal blood indicate that cadmium accumulates in the placenta, reaching the human fetus in detectable amounts (Lauwerys *et al*., 1978; Roels *et al*., 1978; Scanlon, 1972). Babies from smoking mothers, whose cadmium body burden is higher than in nonsmokers, have reduced weight at birth. It is difficult, however, to attribute the decreased birth weight exclusively to cadmium. Among nonsmoking women, cadmium levels in urine were higher in those with infants of below-normal birth weight. Data were not confirmed after adjusting urine cadmium levels by creatinine (Cresta *et al*., 1989). However, Nishijo *et al*. (2002) found an inverse correlation between maternal urinary cadmium excretion and gestational age after adjustment for maternal age.

Several studies in rats and mice indicate that cadmium may be fetotoxic from oral exposures before and during gestation. This fetotoxicity is most often manifested as reduced fetal weight and neurobehavioral toxicity (Baranski, 1987; Gupta *et al*.; 1993, Kostial *et al*., 1993; Sorell and Graziano, 1990; Whelton *et al*., 1988).

Nagymajtenyi *et al*. (1997) reported behavioral and neurotoxicological changes in rats treated with cadmium chloride during pregnancy, lactation, and 8 weeks after weaning (at doses ranging from 3, 5, to 14 mg/kg). Open-field behavior and spontaneous and evoked cortical activity were investigated at the age of 12 weeks. Vertical exploration and open-field center exploration were increased; spontaneous and evoked electrophysiological variables showed dose-dependent and generation-dependent changes, thus indicating that low-level exposure of rats to inorganic cadmium can affect some nervous system functions. Changes in some electrophysiological parameters and higher order nervous functions were confirmed by Desi *et al*. (1998) in rats at low-level prenatal and postnatal inorganic cadmium exposure during pregnancy.

4.4 Chromium

Little is known about the developmental effects of chromium in humans or animals. A descriptive geographical study on congenital malformations in communities around a site heavily polluted by chromium waste was carried out by Eizaguiree *et al*. (2000). A 10-km circle centered on the polluted site was subdivided into one circle of 2-km radius and eight 1-km wide rings. The relative risk of congenital malformations for the closest circle seemed to be markedly lower than that for the rest; the relative risk peaked in the rings 2–4 km away from the polluted site. The authors excluded a possible teratogenic effect of the chromium coming from waste with different distribution of the two forms of chromium. Chromium (VI), which accumulates in erythrocytes, was transferred readily to the fetal mouse on day 13 of gestation, whereas there was little transfer of chromium (III), which is bound mainly to plasma proteins. Later in gestation, both chromium (VI) and chromium (III) accumulated in calcified areas of fetal skeleton (Danielsson *et al*., 1982).

Chromium trioxide (at a dose that produced maternal toxicity) caused fetal death and increased the incidence of cleft palate and skeletal anomalies in hamsters on day 7, 8, or 9 of pregnancy; administration on day 10 or 11 had little effect (Gale, 1978; Gale and Bunch, 1979). Different rates of malformations were also observed in different strains of hamsters after chromium treatment (Gale, 1982). Similar results of fetal lethality and malformations in survivors were produced in mice after intraperitoneal injection of approximately 20 mg Cr(III)/kg (Matsumoto *et al*., 1976). However, no effects were noted in pregnant mice receiving chromium (VI) during organogenesis (Junaid *et al*., 1996b). Danielsson and coworkers (1982) investigated the relative toxic actions of chromium (III) and chromium (VI). Cartilage formation in differentiating chick fibroblast cultures was sensitive to damage by chromium (VI) but unaltered by chromium (III). These data suggest that the developmental effects of chromium (VI), which are greater than those of chromium (III), may result from increased uptake and greater direct toxicity.

4.5 Nickel

Nickel has not been shown to affect development in humans, and available data are based on animal experimental studies. In term infants, cord blood and maternal concentrations of nickel are nearly equal. However, detectable amounts of nickel have been identified in human fetal tissues and are somewhat higher than concentrations in full-term infants (Casey and Robinson, 1978).

In experimental animals, nickel was localized within embryos on day 8 of gestation after intramuscular or intraperitoneal injections of nickel (Sunderman *et al*., 1978) and in the visceral yolk sac, gastrointestinal tract, and kidney of the fetus on day 16 in the mouse (Olsen and Jonsen, 1979). Fetal tissue concentrations of nickel are generally higher than maternal levels in late gestation (Jacobsen *et al*., 1978).

The embryotoxicity and teratogenic effects of nickel have been reviewed by Sunderman *et al*. (1983). Malformations after the administration of soluble nickel salts have been reported in hamsters (Ferm, 1972; Sunderman *et al*., 1980), mice (Lu *et al*., 1979; Storeng and Jonsen, 1981), and rats (Sunderman *et al*., 1979); anomalies included ocular, skeletal, and neural defects and were generally observed after single parenteral administration. Nickel carbonyl seems to be the most teratogenic of the nickel salts even after exposure by inhalation (Sunderman *et al*., 1979; 1980). Neither $NiCl_2$ nor $Ni3S_2$ produced malformations in rats when injected on day 6 or 8 of gestation, although fetal weights were reduced (Sunderman *et al.,* 1978). Chronic and/or oral treatment is more likely to produce diminished growth without increased frequency of malformations (Ambrose *et al.,* 1976). Available animal data suggest that the developing fetus and neonates are sensitive targets of nickel toxicity, although effects were often reported at maternally toxic doses (Nieboer, 1988).

4.6 Arsenic

Human data about congenital malformations or developmental effects potentially caused by arsenic derive mainly from investigations of populations living near smelting factories or arsenic-processing plants (Nordstrom *et al*., 1978a,b; 1979a,b). In these studies, however, the analyses gave limited consideration to potential confounders (e.g., smoking), and there were no data specifically relating the apparent effects to arsenic exposure alone. After evaluating 13 studies of human populations and 43 laboratory animal or *in vitro* studies, DeSesso *et al*. (1998) concluded that neither the human nor the animal studies were of sufficient robustness to be conclusive.

Structural malformations in experimental animals were induced only when maternal arsenic blood concentrations were very high and depended on the route of administration under conditions not usual or relevant for human exposure (Holson *et al*., 2000b).

The inhalation of high amounts of arsenic, as As_2O_3, produced developmental effects in laboratory animals. Exposures lower than 2.2 mg As/m^3 caused modest decreases in fetal body weight, and those lower than 0.20 mg As/m^3 had no effects. However, it is unclear whether these effects occur only at doses that cause maternal toxicity (Nagymajtenyi *et al*., 1985).

In other experiments, no increases in fetal resorptions, fetal mortality, or malformations, and no decreases in fetal birth weight occurred when rats were exposed to 0.2–7 mg As/m^3 (as As_2O_3) before mating and during gestation. Around the 8 mg/m^3 exposure level, toxicity was observed in the dams (Holson *et al*., 1999).

4.7 Vanadium

Decreased fertility, embryolethality, fetotoxicity, and teratogenicity have been demonstrated in rats, mice, and hamsters after vanadium exposure, but it is not certainly established whether vanadate (V^{+5}) and vanadyl (V^{+4}) compounds are reproductive and developmental toxicants (Domingo, 1996). The same author (Domingo, 2002) reported reproductive, developmental, and behavioral toxicity, as well as mitogenic activity affecting the distribution of chromosomes during mitosis, inducing aneuploidy-related endpoints.

4.8 Uranium

Little is known about the potential toxic effects of uranium on reproduction and development in animals and humans.

A study of more than 13,329 Navajos born at the Indian Public Health Service Hospital was carried out to address the association between birth defects, stillbirths, and other adverse outcomes of pregnancy and exposure to uranium from mining and milling operations (Shields *et al*., 1992). The only statistically significant association between uranium pollution and unfavorable birth outcomes was identified with the mother living near tailings or mine dumps; these associations were weak and attributed to radiation, not to the chemical toxicity of uranium.

In vitro tests indicate that alloys with depleted uranium may be both genotoxic and mutagenic (Bosque *et al.*, 1992; 1993a,b). Exposure of pregnant rodent dams to uranium produced fetotoxicity and developmental effects. Various effects include reduced fetal weight, cleft palate, and dorsal and facial hematomas in animals dosed with uranyl acetate on gestational days 6–15 (Domingo *et al*., 1989); decreased fetal weight and incomplete bone (Bosque *et al*., 1993a); increased number of dead and reabsorbed fetuses, reduced fetal weight, and a higher incidence of skeletal variations occurred among surviving offspring (Bosque *et al.*, 1992); decreased fertility, teratogenicity, and reduced growth of the offspring was also observed (Domingo 2001).

4.9 Aluminum

As assessed by Domingo (1995), there is relatively little information regarding the embryotoxic and teratogenic activity of aluminum. The developmental toxicity of aluminum is dependent on the route of administration (Cranmer *et al*., 1986; Golub *et al*., 1987; Gomez *et al*., 1990; Paternain *et al*., 1988) and the solubility of aluminum compounds (Colomina *et al*., 1992; Gomez *et al*., 1991; Partridge *et al.*, 1989). Although there was no evidence of teratogenicity when high doses of aluminum hydroxide were administered to pregnant mice (Domingo, 1989) or rats (Gomez *et al*., 1990) during organogenesis, developmental effects were seen in rats and mice fed with aluminum chloride, lactate, or nitrate (Bernuzzi *et al*., 1989; Domingo *et al.*, 1987; Paternain *et al*., 1988). Neurotoxicity and behavioral changes have been reported in offspring at doses of aluminum that did not produce maternal toxicity in rabbits (Yokel, 1987), rats (Bernuzzi *et al*., 1989; Muller *et al*., 1990), and mice (Donald *et al*., 1989; Golub *et al*., 1987).

4.10 Lithium

Human data indicated that lithium, at doses resulting in serum levels typical of the therapeutic range, might cause developmental toxicity and an increased risk of major malformations (particularly cardiac). Because other information on teratogenic effects is contradictory, it is prudent to exercise caution in treating pregnant women with lithium (Leonard *et al.,* 1995). Effects seen in animals, such as nephrotoxicity or behavioral alterations in offspring, have not been confirmed in children of lithium-treated women (Moore *et al*., 1995)

5 DEVELOPMENTAL EFFECTS FROM NEONATAL EXPOSURE

Neonatal and early postnatal periods are lifespan segments during which sensitivity to toxic agents is high. The postnatal period is characterized by rapid growth and development, with higher caloric and nutritional requirements and with the activation of specific metabolic pathways.

Neonates differ from adults in metal absorption, distribution, metabolism, and excretion. For example, absorption from the gastrointestinal tract is influenced by higher neonatal gastric pH and the immaturity of the intestinal mucus; gastrointestinal absorption has been shown for certain metals to be higher in the developing organism than in adults. Higher respiratory rates may also put the developing child at increased risk for exposure to and absorption of airborne metals. Metal distribution may also differ, because of the different percentage of total body water (higher in infants and decreasing till 10–12 years), and the low level of plasma proteins, resulting in a higher amount of the diffusible fraction of metals. The weight and body ratio for each organ must be also considered. The brain/whole body ratio, for instance, is higher at delivery and decreases in subsequent years. Many enzymes such as those active in kidney for excretive function of metals are present at birth in lower concentrations and begin to increase during the first year of life.

Another factor of higher susceptibility during perineonatal periods is the relative immaturity of the different organs or tissues. For example, the blood–brain barrier is not fully developed until 6–9 months, and the toxic elements may be transferred to the brain more readily during the first months of life. High absorption of toxic elements may also be related to "normal" infant behaviors such as mouthing of objects or ingestion of nonfood materials that may be contaminated. Last, food intake may not only determine the amount of toxic metals but may also influence their absorption,

bioavailability, and toxicity. Differences in exposure and metabolic responses to metals have been reviewed by Sanstead *et al*. (1983) and Mahaffey (1983).

For breast-fed children, the main source of metals during the neonatal period is maternal milk. The nutritional habits of the mother and her current or past environmental or occupational exposure strongly influence the kind and level of xenobiotics excreted by the milk, caused, in part, by the redistribution of cumulative maternal bone stores. Ettinger *et al*. (2004) studied the relationship between maternal breast milk lead and infant blood lead levels among 255 mother–infant pairs exclusively or partially breast-feeding in Mexico City. Although the levels of lead in breast milk were low, they clearly influenced infant blood lead levels. These findings are balanced by the fact that human milk is an excellent source of nutrition for young infants, and environmental sources of lead contribute more to neonatal lead intake than do dietary sources (Lin-Fu, 1980) despite the more recent significant lowering of environmental lead pollution in many industrialized countries.

5.1 Lead

Lead is the most intensively studied metal to which neonates and infants have been exposed. Numerous studies in children and animal models have confirmed the adverse effects of lead exposure on cognition and other neurological functions, which constitute a serious public health problem in a global perspective.

The evidence for lowered cognitive ability in children exposed to lead has come largely from prospective epidemiological studies. In the past decade, children's blood lead levels have fallen significantly in a number of countries, and current mean levels in developed countries are typically below 50 μg/L. Despite this reduction, childhood lead poisoning continues to be a public health problem mainly for certain high-risk groups. The current World Health Organization (WHO)/Centers for Disease Control and Prevention (CDC) blood level of concern stands at 100 μg/L. However, recent studies have extended the association of blood lead and intellectual impairment to lower levels of lead exposure (Lanphear, 2005), and the 100 μg/L level should, therefore, not be interpreted as a toxicological threshold or no-effect value The recent studies cast doubt on whether a toxicological threshold and no-effect value exists for lead-related developmental toxicity as will be discussed in greater detail later.

The neonatal period is particularly sensitive to the effects of lead, because there is a higher amount of absorption from the gastrointestinal tract, a greater transfer of metals to the brain, and a higher vulnerability of the developing central nervous system (Cory-Slechta and Schaumburg, 2000; Leggett, 1993). The prevalent opinion is that there is an inverse relationship between IQ and blood lead level, but the magnitude of this effect has been the subject of some debate (Dietrich *et al.,* 1993; Tong *et al*., 1996; Winneke and Kramer, 1997). In children, severe, clinically overt neurobehavioral effects are usually associated with blood lead levels higher than 700 μg/L, but the current concern is focused on more subtle adverse effects caused by significantly lower levels. Great efforts have been directed to ascertain safe levels of blood lead (Adams and Victor, 1993; Cory-Slechta and Schaumburg, 2000; Moreira and Moreira, 2004). From a public health perspective, however, current lead exposure accounts for a small amount of variance in cognitive ability (1–4%), whereas social and parenting factors account for 40% or more.

Long-term follow-up studies carried out during the 1990s indicated that neuropsychological deficits persisted into adulthood and also involved social/emotional development (White *et al.,* 1993). Sciarillo *et al*. (1992) and Stokes *et al*. (1998) observed an increased incidence of depression, somatic complaints, and aggressive behavior in 4–5-year-old lead-exposed children.

To improve dose-response information on the neurobehavioral effects of environmental lead exposure in children, the WHO in collaboration with the Commission of the European Communities executed an international study between 1984 and 1989 in eight European countries (Winneke *et al*., 1990). Blood lead concentration (PbB) was the main marker of exposure. A number of tests evaluated psychometric intelligence, visual-motor integration, reaction performance, and behavior ratings; 1879 school-age children with PbB ranging from less than 50 to about 600 μg/L were examined. The strongest and most consistent effects occurred for the Bender Gestalt test (visual motor integration) and serial choice reaction performance. Psychometric intelligence was also negatively affected, although the association with PbB was only borderline.

The NHANES III, conducted from 1988 to 1994, assessed the relationship between blood lead concentration and performance among 4853 children in the United States aged 6–16 years (Lanphear *et al*., 2000). The mean blood lead concentration was 19 μg/L; 172 children (2.1%) had blood lead concentrations >100 μg/L. After adjustment for many covariates and confounders, the data showed an inverse relationship between blood lead concentration and scores on four measures of cognitive functioning. For every 10 μg/L increase in blood lead concentration, the following decrements in mean scores were noted: 0.7-point in

arithmetic, approximately 1-point in reading, 0.1-point in nonverbal reasoning, and 0.5-point in short-term memory. An inverse relationship between blood lead concentration and arithmetic and reading scores was observed for children with blood lead concentrations lower than 50 μg/L.

Other recent studies of neurobehavioral effects and cognitive function of children exposed postnatally to lead include one by Tong *et al*. (1996), who examined 375 children born near the lead smelting town of Port Pirie, Australia, for an association between environmental lead exposure and children's intelligence at age 11–13 years. Verbal, performance, and full-scale IQ were inversely related to PbB, with no apparent threshold. The expected mean full scale IQ declined by 3.0 points (95% CI, 0.07–5.93) for an increase in lifetime average blood lead concentration from 100–200 μg/L.

Walkowiak *et al*. (1998) investigated the effects of low-level lead exposure (mean, 43 μg/L; 95th percentile, 89 μg/L) on cognitive functioning in a cohort of 6–7-year-old German children. Impaired attention was demonstrated, whereas visual perception, visual memory, fingertapping, and reaction time were unaffected.

Wasserman *et al*. (1998) studied 379 3-year-old children born from mothers living near a lead smelter in Yugoslavia (geometric mean PbB of 409 μg/L in the exposed subjects versus 98 μg/L in controls). At age 3, small but significant decrements were found in destructive and withdrawn scores, somatic and sleep problems, and anxious-depressed subscale, after checking for confounders. Wasserman *et al*. (2000) conducted a subsequent investigation of 442 children from the same Yugoslavian lead-polluted area, comparing the relative contribution of prenatal blood lead with that of relative increases in PbB in either the early (0–2 years) or the later (from 2 years on) postnatal period to child intelligence measured at ages 3 and 4. This study confirmed that elevations in both prenatal and postnatal PbB were associated with small decrements in the children's intelligence.

Canfield *et al*. (2003) measured blood lead concentration in 172 children at 6, 12, 18, 24, 36, 48, and 60 months of age and compared it with the Stanford–Binet Intelligence Scale at the ages of 3 and 5 years. Blood lead concentration was inversely associated with IQ. Estimated by a linear model, each increase of 100 μg/L in the lifetime average blood lead concentration was associated with a 4.6-point decrease in IQ ($P = 0.004$). When estimated in a nonlinear model, IQ declined by 7.4 points as lifetime average blood lead concentrations increased from 10 to 100 μg/L.

Carta *et al*. (2003) assessed 64 adolescents living in a polluted area in Italy. By applying a linear model, it was found that the blood lead concentration was inversely associated with IQ, with an extrapolated decline of 1.29 points in total IQ for 10 μg/L increase in blood concentration.

Coscia *et al*. (2003) examined the effect of lead exposure on cognitive growth patterns in 196 children at ages 6.5, 11, and 15 years. Children with higher lead levels, measured at 15 years of age, showed lower verbal comprehension scores over time and greater decline in their rate of vocabulary development. Lead exposure was not significantly correlated with growth in perceptual organization test scores. Moreover, socioeconomic status and maternal intelligence were statistically significantly associated with growth patterns for both test scores, independently from the effects of lead.

Counter *et al*. (2005) assessed the effects of PbB concentration on nonverbal intelligence in Andean children working in glass manufacturing and chronically exposed to lead. A significant negative association ($r = -0.331$; $P < 0.0001$) was noted between PbB level and a non-language-based test of cognitive function—an approximate two-point decrease in IQ for each 100 μg/L increase in PbB.

Koller *et al*. (2004) reviewed the studies of Lanphear *et al*. (2000) and of Canfield *et al*. (2004) along with others in the field of low-level lead effects on children's cognitive development (Al-Saleh *et al*., 2001; Calderon *et al*., 2001; Garcia Vargas *et al*., 2001; Prpic-Majic *et al*., 2000; Rahbar *et al*., 2002; Wang *et al*., 2002) and concluded that these findings are scientifically important and that efforts to reduce childhood exposure to lead should continue.

Lanphear *et al*. (2005) carried out pooled analysis to examine the association of intelligence test scores and blood lead concentration, especially for children who had maximal measured blood lead levels <100 μg/L. They collected data from 1333 subjects from seven population-based longitudinal cohort studies, followed from birth or infancy until 5–10 years of age. The full-scale IQ score was the primary outcome measure. The geometric mean PbB peaked at 178 μg/L and declined to 94 μg/dL by 5–7 years of age. After adjustment for covariates, the estimated IQ point decrements associated with an increase in blood lead from 24–100 μg/L, 100–200 μg/L, and 200–300 μg/L were 3.9, 1.9, and 1.1, respectively. This suggests that the dose-response curve is steeper at the lower levels compared with the higher ones.

As alluded to previously, no clear and generally accepted threshold value has been identified. The current WHO/CDC blood level of concern stands at 100 μg/L but is being challenged by the recent studies showing adverse effects below this level. Meta-analysis on both cross-sectional and prospective studies

in lead-exposed children have concluded that a typical doubling of PbB from 100–200 μg/L is associated with an average IQ loss of 1–3 points. Proportional regular decrements of IQ (around 5–10 points) may be observed at levels of exposure up to 300 μg/L.

Lead toxicity and nutritional status may also be associated. Kordas *et al*. (2004) examined whether nutritional status variables account for part of the association between cognitive performance and lead exposure in 724 first-grade children aged 6–8 years. The mean blood lead concentration was 115 + 61 μg/L, and 50% of the children had concentrations >100 μg/L. Lead was negatively associated with four cognitive tests and was also inversely correlated with iron status, height-for-age Z scores, and head circumference. In multivariate models, the association between lead and cognitive performance was not strongly affected by nutritional variables, suggesting that the relation of lead to cognition was not explained by iron deficiency or growth retardation.

Chelation therapy has been considered as a possible means to decrease lead body burden and related effects, but it is unclear whether it can prevent or reverse the neurodevelopmental sequelae of lead toxicity. Liu *et al*. (2002) analyzed 741 children who had blood lead levels between 200 and 440 μg/L and were 13–33 months old at random assignment to chelation or placebo. By 6 months after randomization, blood lead levels had fallen by similar amounts in both chelated and placebo children, despite the immediate drops in the chelated group; there was no association between change in blood lead level and change in cognitive test score, and chelation therapy may not be indicated at this blood lead range. The improvement in scores in the placebo group implies that factors other than declining blood lead levels alone are responsible for cognitive effects. Chelation therapy lowered average blood lead levels for approximately 6 months but resulted in no benefit in cognitive or behavioral endpoints (Dietrich *et al*., 2004).

Several correlates to the observations made in humans and proposed mechanisms of action have been produced in experimental studies. In animals (rats and monkeys), observations on the basis of a broad spectrum of learning and retention models support the hypothesis that lead-induced neurobehavioral deficit extends long into adulthood, primarily after preweaning exposure; the evidence is less clear after postweaning lead exposure.

Lead administered to lactating experimental animals appears in their milk. This has been exploited as a model for postnatal exposure to lead. A significant fraction of maternally administered lead is transferred to rodent pups in milk (Keller and Doherty, 1980a,b; Momcilovic and Kostial, 1974). Although lead rapidly enters the brain from blood, its removal is slow (Goldstein and Diamond, 1974). The effect of several constituents of milk on lead absorption has been investigated in rodents. The addition of iron did not suppress uptake of lead in rats (Kostial, 1983); however, calcium and phosphorus reduced lead absorption (Mahaffey, 1981). Data from Barltrop and Khoo (1976) also suggest that the fat content of milk is responsible for increasing lead absorption. Neurological damage and neuropathology have been produced in rats and mice by exposing neonates to lead through milk (Bornschein *et al*., 1980). Effects include altered dendrite development and synapse formation (Alfano and Petit, 1982; Alfano *et al*., 1982; McCauley *et al*., 1982); changes in hippocampus structure and function (Alfano and Petit, 1981; Campbell *et al*., 1982); neurochemical alterations (Silbergeld and Hruska, 1980); and disruption of calcium homeostasis in the immature neonates (Winneke *et al*., 1996).

5.2 Mercury

Neonates may be exposed to methylmercury exposure through breast milk. In the Iraqi outbreak in 1971/72, mercury levels in milk were found to correlate with maternal blood levels (Bakir *et al*., 1973), with milk mercury approximately 5–8% of maternal blood levels (Amin-Zaki *et al.,* 1976). Infants born before the outbreak accumulated significant amounts of mercury through milk from mothers who ate contaminated bread (Amin-Zaki *et al.,* 1974b). Delays in motor development, speech development, and toilet training, as well as abnormal reflexes were noted in these children (Amin-Zaki *et al*., 1980). The half-life of mercury in blood was shorter in lactating women (about 42 days) compared with nonlactating women or men (about 75 days), but the difference could not be accounted for by secretion of mercury in milk (Greenwood *et al*., 1978).

In more recent studies in the Faroe Islands, children were examined during the first year of life for three developmental milestones (sitting, creeping, and standing). In this case, children who reached milestones early had significantly higher levels of mercury at 12 months of age. This could be due to the duration and advantages of breastfeeding, although this resulted in higher mercury levels in the children (Grandjean *et al.,* 1995).

Most animal studies of methylmercury have focused on prenatal exposure (see previous section of this chapter). Methylmercury was secreted into the milk of experimental animals (Mansour *et al.,* 1973; Yang *et al*., 1973) and was readily absorbed from the gut of neonates (Zepp *et al*., 1974). Neonatal rodents are reported to excrete only a small fraction of their body burden of methylmercury until weaning (Doherty and Gates, 1973; Thomas *et al*., 1982) with an abrupt change

in excretion rates taking place at weaning. Little is known about excretion patterns of methylmercury in human infants.

A number of effects have been noted in animals exposed postnatally to methylmercury. One group of nonhuman primates exposed to low levels of methylmercury (50 µg Hg/kg/day) from birth to 7 years, was followed for various types of behavioral changes more than 20 years. Mercury-related deficits were found in auditory, somatosensory, and visual function (Rice and Gilbert, 1982; 1990; 1992; 1995). Auditory impairment was found to increase with age between 11 and 19 years (Rice, 1998a). However, tests for cognitive impairment performed at age 20 years were negative (Rice, 1998b). This is consistent with other studies in which macaques were exposed to methylmercury *in utero* and postnatally; there was no reported mercury related impairment of discrimination reversal tasks when animals were tested as infants or juveniles (Rice, 1992). However, evidence of delayed toxicity has been suggested. Animals at 13 years of age (6 years after exposure stopped) began showing signs of clumsiness and impaired fine motor performance. Clinical neurological assessments revealed insensitivity to touch (Rice, 1989). Similar delayed signs of neurotoxicity were reported in animals exposed to methylmercury *in utero* and up to 4 years of age (Rice, 1996).

In rodent models, behavioral/locomotor alterations (passive avoidance response and Rotorod performance) were noted in rats exposed *in utero* and postnatally to moderate doses of methylmercury. Histopathology of the brains included focal cerebellar dysphasia (Sakamoto *et al.,* 2002). Exposure of rats exclusively during the postnatal period to methylmercury (5 mg/kg/day for 30 days) resulted in severe paralysis of the hind limbs and widespread neuronal degeneration in many areas of the brain (Sakamoto *et al.,* 1998). Earlier studies had documented changes in cerebellar structure and cell division (Choi *et al.,* 1981; Rodier *et al*., 1984; Sager, 1988; Sager *et al*., 1982; 1984). Other groups have noted neurochemical effects after postnatal exposure. Movement and postural disorders in rats correlated with altered metabolism of brain catecholamines and indoleamines (O'Kusky *et al*., 1988) and altered biogenic amines (Taylor and Di Stefano, 1976).

Recent attention has focused on another form of organic mercury, thimerosal (ethylmercury thiosalicylate, also known as thimerosal). Although thimerosal has been used as a preservative in vaccines and other medicinal products since the 1930s, there is relatively little information about the potential reproductive or developmental toxicity of the compound. Reports have suggested that the increased number of infant vaccines containing thimerosal correlated with the increasing rate of autism (reviewed by IOM, 2001). Many countries in Europe removed thimerosal from infant vaccines several years ago. In 1999, the United States took steps to remove thimerosal from routine vaccines for children under the age of 6. However, exposure of infants and children to thimerosal-containing vaccines still occurs in countries where multidose vials of vaccine are used (Knezdvic *et al*., 2002).

Mercury levels after exposure to routine vaccinations containing thimerosal have been evaluated in several studies. Stajich *et al*. (2000) measured total mercury levels in blood before and after administration of the birth dose of hepatitis B vaccine (12.5 µg mercury). Blood mercury levels in 15 preterm and 5 term neonates, measured at 48–72 hours after immunization, showed elevated levels of mercury. Postvaccination levels were about three times higher in preterm infants than term infants (mean, 7.36 µg/mL vs. 2.24 µg/mL). Pichichero *et al*. (2002) examined levels of mercury in blood, urine, and stool 3–28 days after 2- and 6-month-old infants were exposed to thimerosal through vaccination. They found that blood levels of mercury were lower than expected (means, 8.2 nmol/L in 2-month- olds; 5.15 nmol/L in 6-month-olds), on the basis of extrapolation from methylmercury. Significant amounts of mercury were excreted in stool (81.8 ng/g dry weight in 2-month-olds; 58.3 ng/g dry weight in 6-month-olds). In addition, the half-time in blood of mercury derived from thimerosal seemed to be shorter than that for methylmercury (about 7 days vs. 45 days). A follow-up study in neonates, 2-month, and 6- month-olds in Argentina, who received routine vaccinations containing thimerosal, confirms the earlier study (Pichichero *et al*., 2002).

An outbreak of ethyl mercury poisoning occurred in Iraq in 1960, resulting from the consumption of seed grain treated with a fungicide containing ethyl mercury toluene sulfonanilide (Damluji, 1962; Jalili and Abbasi, 1961). Although five children (age 4–8) were included in the Damluji study, there did not seem to be any differential toxicity. The children represented mild to moderately severe cases. In addition, elevated mercury levels in blood and tissue were reported in five infants with omphaloceles who were treated with thimerosal (Fagan *et al*., 1977). Other cases of mercury-related adverse events were also reported in infants and adults receiving this treatment (Stanley-Brown and Frank, 1971; reviewed by Magos, 2001).

Several studies have examined the correlation of thimerosal containing vaccines and autism. Controlled epidemiological studies in Denmark, Sweden, the United Kingdom, and the United States provide no evidence for an association between thimerosal exposure through vaccination and autism (Andrews *et al.,*

2004; Heron *et al*., 2004; Hviid *et al*., 2003; Parker *et al*., 2004; Verstrachen *et al.*, 2003). In these studies, rates of autism continued to rise despite removal of thimerosal from infant and childhood vaccines. Two uncontrolled studies led to the same conclusions (Madsen *et al.*, 2003; Stehr-Green *et al*., 2003). Although other studies reported correlations, these studies were cited by the IOM report as having serious methodological flaws or nontransparent analytic methods. Thus, the IOM concluded that the evidence favors rejection of a causal relationship between thimerosal-containing vaccine and autism (IOM, 2004).

Studies have been conducted in animal models to assess the distribution of mercury to tissues after exposure to thimerosal and/or ethylmercury compared with methylmercury. In studies in infant macaques exposed to injected thimerosal (with appropriate infant vaccines) or oral methylmercury, initial distribution of mercury from both exposures was similar (Burbacher *et al.*, 2005). However, total mercury was cleared from blood more than twice as fast after thimerosal exposure (T1/2 6.9 days vs. 19.1 days). In addition, the faster clearance from blood resulted in no significant accumulation in blood after repeated thimerosal exposure compared with methylmercury. Total mercury accumulation in brain was three to four times less after thimerosal exposure, although inorganic mercury levels were higher; inorganic mercury represented 71% of total brain mercury after thimerosal versus 10% for methylmercury. Blood to brain partitioning ratio for total mercury was slightly higher in the thimerosal group (3.5 vs. 2.5). This may indicate greater deethylation versus demethylation in brain. An additional study in neonatal mice confirmed that thimerosal exposure resulted in lower blood and brain levels of total mercury compared with methylmercury (Harry *et al*., 2004).

During the first half of the 20th century, mercuric oxide and mercuric chloride were administered to infants, frequently in teething powders. Acrodynia or pink disease, characterized by painful red hands and feet, affected only a small fraction of the children exposed (reviewed by Warkany, 1966). More recently, a few cases of acrodynia were identified in Argentina, where phenyl mercury had been used as a fungicide in diapers (Astolfi and Gotelli, 1981). In addition, transient effects on kidney function were noted for infants whose urinary mercury levels reached a "threshold" level (Gotelli *et al.*, 1985).

Little is known about exposure of infants to mercury vapor. One case of pink disease has been reported in an infant after contamination of the bedroom (Curtis *et al*., 1987). Mercury vapor levels near the floor where children are likely to spend time may be much higher because mercury vapor is heavier than air.

5.3 Cadmium

Few experimental animal studies have shown neurotoxic behavioral effects after neonatal cadmium exposure, and there are no published reports on early postnatal cadmium absorption or related developmental effects in humans.

Infants absorb up to 55% of the ingested dose compared with 10% absorption in adults (Alexander *et al*., 1974). Little maternally administered cadmium is secreted in milk in experimental animals (Kostial, 1983; Lucis *et al*., 1972). Factors affecting cadmium uptake include levels of dietary ascorbic acid, calcium, copper, iron, protein, selenium, vitamin D, and zinc (Fox, 1974).

Postnatal exposure to cadmium at high doses (6 mg/kg) was reported to induce synthesis of metallothionein; it did not, however, protect against the toxic effects of cadmium (Bell, 1979; 1980). Discrimination learning was not affected in rats exposed prenatally and postnatally to cadmium, although spontaneous activity decreased (Hastings *et al*., 1978).

5.4 Nickel

Information is solely based on experimental studies. Perinatal toxicity associated with nickel chloride exposure in drinking water was studied in female Long–Evans rats, which were exposed beginning 11 weeks before mating and through two successive gestation and lactation periods (Smith *et al.*, 1993). The frequency of perinatal death is the most significant toxicological finding of the study. The number of dead pups per litter was increased at each dose during lactation periods. Prolactin levels in pups were unchanged by treatment and were reduced in dams at the high dose.

5.5 Arsenic

Arsenic accidentally incorporated into a milk formula was responsible for the exposure of a large number of infants in Japan many years ago. Follow-up studies of these children revealed that arsenic trioxide, when ingested in amounts sufficient to produce clinical signs in infants, may cause permanent neurobehavioral deficits that are qualitatively different from arsenic poisoning seen in adults (Japanese Pediatrics Society, 1973).

Health risks caused by chronic exposure to arsenic-contaminated groundwater have been recognized in many Asian and Latin American countries. The health effects among adults have been well documented, but those among the younger generations, including children, infants, babies, and fetuses, have been rarely reported.

Calderon *et al*. (2001) examined the effects of chronic exposure to lead, arsenic, and undernutrition on the neuropsychological development of children. After checking for significant potential confounders, verbal IQ ($P < 0.01$) decreased with increasing concentrations of arsenic in urine (AsU). Higher levels of AsU were related to poorer performance on parameters such as long-term memory and linguistic abstraction; lower scores in tests measuring attention were obtained at increasing values of PbB.

Watanabe *et al*. (2003) reviewed data from an arsenic-contaminated area in Bangladesh. The authors concluded that although some human data suggest possible effects on developmental endpoints, the data are not sufficient to determine whether arsenic represents a serious developmental risk.

A cross-sectional study was carried out to investigate intellectual function in 201 children aged 10 in a contaminated area of Bangladesh (Wasserman *et al.*, 2004). Exposure to arsenic was associated with reduced intellectual function after adjustment for sociodemographic covariates. Water arsenic levels were associated with reduced intellectual function in a dose-response manner; children with water As levels >50 µg/L achieved significantly lower performance than did children with water As levels <5.5 µg/L. The association was generally stronger for water arsenic than for urinary arsenic.

Early postnatal administration of arsenic at sublethal doses produced little effect in experimental animals. Postnatal rats fed 1.5 mg/kg/day of arsenic trioxide from day 7–21 postpartum did not seem to differ from controls; 50% mortality occurred at 15 mg/kg/day (Tamura, 1978). Heywood and Sortwell (1979) reported high mortality among infant rhesus monkeys fed 3.75 or 7.5 mg/kg/day arsenic; no growth or developmental effects were noted among the survivors.

5.6 Aluminum

No evidences of human developmental effects of aluminum have been reported, but taking into account that gastrointestinal absorption of aluminum may be enhanced by certain dietary constituents, it may be advisable to avoid the consumption of high doses of aluminum during gestation and lactation (Domingo, 1995).

Although knowledge of aluminum toxicity has improved markedly in recent years, information concerning the developmental toxicity of this element is still limited. When high doses of aluminum were given concurrently with acids (citric or lactic), developmental and behavioral toxicities were shown in mice and rabbits (Domingo, 1995). A recent article by Colomina *et al*. (2005) assessed the potential combined influence of maternal-restraint stress and aluminum exposure on postnatal development and behavior. The only effect noted was an increase in the platform quadrant swim time in treated rats.

5.7 Mixed Metal and Multichemical Exposure

In addition to an article by Calderon *et al*. (2001) on neurodevelopmental effects quoted in the preceding section (5.5 Arsenic), timing of menarche has been investigated in relation to several ubiquitous environmental pollutants to which children are commonly exposed at low levels (i.e., dichlorodiphenyl dichloroethylene [p,p′-DDE], hexachlorobenzene (HCB), polychlorinated biphenyls (PCBs), mirex, lead, and mercury (Denham *et al.*, 2005). The study was conducted on 138 girls, 10–16.9 years of age, and residents in an industrialized area. Metals and organic compounds were measured in blood. Mercury levels were at or below background levels, whereas all lead levels were well below 100 µg/L, the CDC action limit, and PCB levels were consistent with a cumulative, continuing exposure pattern. The median age at menarche for the total sample was 12.2 years compared with a predicted age in a control group of 10.5 months later. The analysis of multichemical exposure among adolescent girls suggests that the attainment of menarche may be sensitive to relatively low levels of lead and of certain PCB cogeners.

CHAPTER

13

Ecotoxicology of Metals—Sources, Transport, and Effects in the Ecosystem

POUL BJERREGAARD AND OLE ANDERSEN

ABSTRACT

Metal smelting and combustion processes are the major anthropogenic sources for emission of metals into the atmosphere. Metals emitted this way are generally bound in small particles with a potential for atmospheric long-range transport and contamination. Sediments are the ultimate sink for metals emitted to the aquatic environment, most evident in coastal and estuarine sediments. Besides direct emissions, man-made environmental changes such as acidification, oxygen depletion, and draining of water-logged areas may mobilize metals not otherwise available to organisms. The speciation of metals is an important determinant for the bioavailability, uptake, and toxicity of metals in the environment. Organisms have developed a wide range of mechanisms for internal handling and storage of essential and/or toxic metals. No other metal than mercury is consistently biomagnified along food chains. In the environment, the most adverse impacts (on populations) from metals have been caused by organic tin compounds used in antifouling paints and alumina mobilized by acid rain. High concentrations of organic mercury and cadmium in certain organisms may cause concern for human health in populations relying heavily on these types of organisms as food items.

1 SOURCES FOR METAL EMISSION

Human activities may augment the concentrations of metals naturally present in various compartments of the environment, leading to metal contamination or pollution in the environment. These anthropogenic activities may cause direct mobilization and emission of metals into the environment, but in some cases, human activities may indirectly cause changes in the environment that mobilize metals that were otherwise bound in stable forms. Several ways of assessing the anthropogenic impact on metal fluxes have been used (Salomons and Förstner, 1984), and one of them is calculation of the "anthropogenic mobilization factor," which is the ratio between anthropogenic and natural emissions to the atmosphere (Lantzy and Mackenzie, 1979). Because lake, coastal, and oceanic sediments are the ultimate sinks for a considerable fraction of the metals emitted as a result of human activities (see Section 2), the so-called sediment enrichment factor can be used to assess contamination of aquatic environments with metals. The sediment enrichment factor is the ratio between metal concentrations in anthropogenically affected sediments and the natural background concentrations (Salomons and Förstner, 1984).

In certain geological areas, naturally high toxic metal concentrations occur. Examples are acidic tropical Al-Fe soils; ultramafic soils with high concentrations of Ni, Cr, and Mg; and soils covering or close to ores containing one or more of the metals and metalloids Cd, Zn, Fe, Ni, Co, Pb, Cu, Cr, Hg, Mn, Se, and As. In volcanic areas, ground waters may contain high concentrations of As compounds.

1.1 Direct Emissions of Metals into Nature

1.1.1 Emissions to the Atmosphere

Combustion of fossil fuels, incineration of garbage, and metal smelting have been some of the major

sources leading to metal contamination of the atmosphere.

1.1.2 Emissions into Water

Mining activities and a number of industrial processes involving metals (e.g., catalysts in chloroalkali processes, anticorrosive surface treatment) are some of the major point sources from which metals are released into the aquatic environment, but metals from more diffuse sources such as atmospheric deposition, storm water (erosion of gutters, wearing of tires, etc.), and ordinary household waste water may end up in the aquatic environment. Deliberate emission of metals into the aquatic environment has taken place when copper has been used as an herbicide to prevent algal growth or used in fish farms to treat parasite infections in the gills of the fish.

1.1.3 Emissions to Soil

On a general scale, atmospheric deposition has constituted one of the major inputs of metals into soil, especially in areas affected by deposition from metal smelting activities. In certain areas, specific sources for metal contamination may, however, be important. Phosphate fertilizers have been important sources for contamination of agricultural soils with cadmium and likewise sludge from sewage treatment plants has added metals (especially cadmium has caused concern) to farmland when used as soil amendment. The addition of copper to, for example, the feed of pigs may lead to copper concentrations in the pig manure that are high enough to exceed the soil quality criterion for copper if the manure is used as soil amendment over several years.

Some metals and metalloids (e.g., copper and arsenic compounds) have been used as pesticides and thus spread deliberately in the terrestrial environment.

1.2 Indirect Mobilization of Metals

1.2.1 Acid Rain

When acidic precipitation falls on soils in which the buffer capacity has been exceeded, cations bound to the negative charges on the surfaces of soil particles are exchanged with hydrogen ions, and the concentration of metals in the pore water of the soil increases. As rainwater percolates, the metal ions will be transported either toward the groundwater or toward streams and lakes. The acidification of lakes is often associated with increases in metal (i.e., alumina, cadmium, lead, mercury) concentrations (Nelson and Campbell, 1991) in both lake water and biota, and it is especially the elevated concentrations of alumina and mercury that cause concern from an ecotoxicological and toxicological point of view (Scheuhammer, 1991).

1.2.2 Oxygen Depletion

Eutrophication of coastal marine areas has led to an increasing number of incidences of oxygen depletion in the bottom layers of the water column during recent decades. In bottom waters with full oxygen saturation, the upper few millimeters of the sediment are normally oxidized, and manganese and iron are found in their oxidized forms (MnO_2 and Fe^{3+}). If the oxygen tension decreases below approximately 16% of full saturation, MnO_2 is reduced to Mn^{2+} that may leak out of the sediment into the water column. The manganese concentrations in anoxic or oxygen-depleted waters may increase from approximately 1 µg/L to up to 1 mg/L (Kremling, 1983). The reduced manganese in the water column is oxidized fairly slowly (Section 8) on reintroduction of conditions of full oxygen saturation, and benthic organisms may be exposed to increased manganese concentrations for extended periods of time. This leads to accumulation of manganese in benthic organisms, and the use of the manganese content of lobsters has been suggested in monitoring programs for oxygen depletion (Baden and Neil, 2003; Baden *et al.*, 1994; Eriksson and Baden, 1998).

1.2.3 Pyrite Oxidation

If waterlogged, anaerobic terrestrial areas are drained, oxygen typically penetrates deeper into the soil, and this leads to oxidation of pyrite (FeS_2) in the soil, and the oxidized iron compounds (a complex mixture of iron oxides and hydroxides) will leach toward the streams together with the sulfuric acid from the oxidation of the reduced sulfur. The iron contamination in streams of such areas may have severe consequences for both invertebrates and fish in the streams.

2 THE BIOGEOCHEMICAL TRANSPORT OF METALS

2.1 Atmospheric Transport

Metals undergo—as the other elements in the Earth's crust—natural, biogeochemical cycles in which they are transported between lithosphere, hydrosphere, and atmosphere. For a number of metals, human activity has increased the mobilization from the lithosphere to a degree where the addition of metal to the hydrosphere—especially via the atmosphere—from anthropogenic sources far exceeds the addition from natural sources.

Metals are naturally added to the atmosphere with windblown dust, volcanic eruptions, sea spray, forest fires, and directly from the vegetation (Nriagu, 1989). The anthropogenic addition of most metals to the atmosphere takes place primarily by combustion of fossil fuels, metal smelting, garbage incineration, and, in the case of lead, also previously by the combustion of leaded petrol. Except for metals for which important gas phase releases take place (such as mercury), most of the metal emission to the atmosphere is in the form of particle-bound metal. The industrial emissions have exceeded (Nriagu, 1979) and still exceed (Nriagu, 1988; 1989; 1996; Nriagu and Pacyna, 1988) the natural background flux for several metals. In the 1970s, the anthropogenic mobilization factors were as high as 100 for lead, 83 for silver, 45 for molybdenum, 39 for antimony, 23 for zinc, 19 for cadmium, and 13 for copper (Salomons and Förstner, 1984). The anthropogenic sources to pollution of the atmosphere with metals are all caused by combustion processes, and some of the particles created have such a long residence time (days to months) in the atmosphere that the metals discharged may be dispersed over large distances. The particles formed by natural processes (also transporting metals from the lithosphere to the atmosphere) are, on the other hand, typically in the size range of 2–100 µm that precipitate fairly quickly—typically within 10 km of the emission site.

The small particles dispersing globally in the atmosphere are primarily brought back to the sea or earth surface with precipitation, either because the drop or crystal formation takes place with the particles or because the particles are scavenged by the falling precipitation.

2.2 Metal Speciation in Water

Metal ions dissolved in pure water are hydrated by an inner hydration shell, where water is tightly bound by the Coulombic field, and an outer hydrations shell, where water is more loosely and randomly bound. ^{18}O-water exchange studies indicate extensive differences in exchange rate between different ions, Rh(III), Cr(III), and Al(III) ions being particularly slow exchangers, whereas most ions have very rapid, almost instantaneous, hydration water exchange. The half-times of inner shell water exchange reactions of ions vary within about 15 orders of magnitude (Raspor, 2004). This has important for other complexation reactions, such as during complexation of metals with various inorganic and organic ligands; the overall exchange rate is often determined by the very first dehydration reaction (Morgan and Stumm, 1991). Most often the inertness or lability of other complexes of the ion follows the stability of the inner hydration shell. The stability of complexes is generally considered to increase with increasing formation constant, but thermodynamically unstable, but highly inert, complexes because of very slow ligand exchange rate may exist for extended time periods. Also, phase transfer reactions, including sediment binding and biological uptake of metals, are highly dependent on both ΔG and kinetic factors. In general, soft (class B) ions form complexes with monodentate and multidentate ligands that are both more stable and kinetically more inert than hard (class A) ions, with borderline ions in between, both with hard and soft ligands (Andersen, 1999).

In the aquatic environment, metals exist in a chemical equilibrium between free, dissolved ions, organic and inorganic complexes, and metal bound to organic and inorganic particles (see Figure 1). The surface of both inorganic particles (e.g., clay particles, iron, and manganese oxides) and organic particles (e.g., unicellular algae) is dominated by O^-groups. Depending on the affinity of the individual metal for O^--dominated surfaces, the equilibrium between free, dissolved cations and particle-bound metal may be shifted toward particle-bound metal. Metals are present as various aquo- and mixed aquo complexes with amines, humic, OH^-, CO_3^{--}, in seawater Cl^-, or bound to organic and inorganic compounds, which may be dissolved or associated to sediment. In estuarine waters, speciation is changed as salinity increases. For some metals (e.g., cadmium) this may result in solubilization from particulate matter because of formation of chlorine complexes, but often,

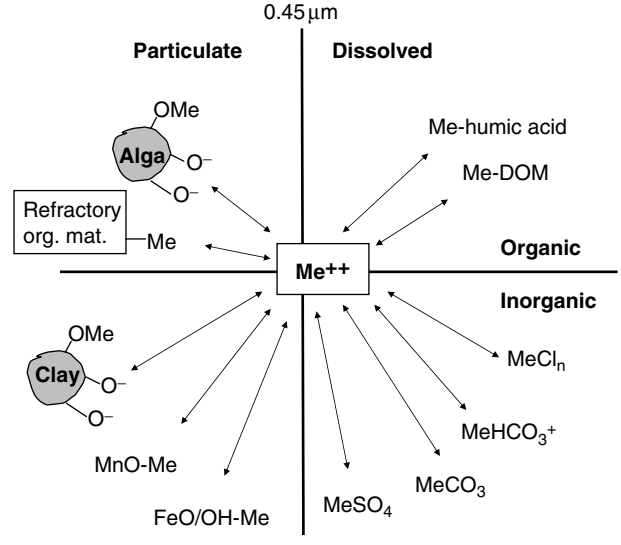

FIGURE 1 Schematic presentation of equilibria between free metal ions and various organic and inorganic chelators (including both particulate and dissolved ligands). Dissolved material is operationally defined as any material that will pass a filter with a pore size of 0.45 µm. Not all potential ligands are included, and stoichiometric adjustment is not made.

most metals transported to estuaries are precipitated because of flocculation of dissolved and suspended organic matter. Also, the fraction of hydrated metal ions, which is often the most bioavailable, is reduced. To ease speciation calculation, computer software have been developed, which on the basis of experimentally determined stability constants and chemical description of natural waters (concentrations of Cl^-, CO_3^{--}, PO_4^{---}, SO_4^{--}, Na^+, Ca^{++}, etc.), calculate metal speciation. Examples are CHESS (Santore and Driscoll, 1995), MINEQL+ (Schecher and McAvoy, 1995), and MINTEQA2 (Brown and Allison, 1987). Also, interactions between metals and natural organic matter (NOM) have been integrated in speciation modeling programs as WHAM (Tipping, 1994) and NICA (Benedetti *et al*., 1995), the latter model incorporating multiple binding sites and competition between cations. Because of the extensive heterogeneity of NOM, this kind of modeling represents an extensive task. Also, all such programs assume equilibrium and cannot predict speciation in dynamic systems.

2.3 Metal Transport in the Ocean

When metal-carrying particles hit the surface of the oceans, the metals may—depending on the character of their binding to the particles and the chemical properties of the individual metals—stay bound to the particles or dissolve in the seawater.

The upper hundreds of meters of the oceans are the habitat of filter-feeding zooplankton organisms that obtain their food by filtering particles (mainly unicellular algae) from the water. Because only a minor fraction of the metal content of the food is taken up into the organisms during the passage of the gut (for many metals considerably less than 10%), the main fraction of the original metal content of the unicellular algae is excreted in the fecal pellets of the zooplankton organisms. A considerable part of the pelagic filter feeders are crustaceans (copepods, euphausiids, etc.), and the fecal pellets of these organisms are lined by a thin chitin membrane. Whereas unicellular algae and fine clay particles sink very slowly down through the water column (~2 m per day), crustacean fecal pellets have much higher sinking rates, approximately 400 m/day (Fowler and Small, 1972; Komar *et al*., 1981; Small *et al*., 1979). This means that the activity of the filter feeders transfers the particle-bound metal in the upper layers of the water column to a form in which it is transported downward in the ocean. On their way down through the water column, the fecal pellets may be eaten several times, and the original content of organic material, nutrients, and metals is gradually liberated to the water masses, but some of the content reaches the ocean bed.

For a number of surface-active metals, these processes result in low concentrations in the upper part of the water column, because the metals are being bound to particle surfaces and transported downward. It is characteristic for these metals (e.g., cadmium, copper, nickel, zinc) that their depth profile is similar to the depth profile of the major nutrients (Bruland, 1980; Bruland *et al*., 1978).

The metals are removed from the upper layers of the water column by a biologically mediated, downwards transport process (Fowler *et al*., 1987). The higher the affinity of a specific metal for binding to biological material is (e.g., reflected in concentration factors for the metals in zooplankton fecal pellets), the faster the metal is removed from the water column, leading to short residence time for the metal in the ocean (Cherry *et al*., 1978; Higgo *et al*., 1977). Concentrations in the seawater and residence times for metals (and also nonmetallic elements) in the ocean show a positive correlation (Whitfield, 1981).

The partitioning coefficient (K_y) for a metal (Y) is defined as the concentration of the metal in seawater and the average concentration in the crust of the earth ($K_y = [Y]_{seawater}/[Y]_{crust}$). Metals with a high K_y do thus occur at a high concentration in the seawater relative to the average concentration in the Earth's crust. For elements, an electronegativity function, Q_{yo}, can be defined, such that $Q_{oy} = (x_y - x_o)^2$ and x_o and x_y are the electronegativities of oxygen and the element Y, respectively. For elements whose concentration in the seawater is controlled by solid-phase chemistry, there is a negative correlation between the partitioning coefficient (K_y) and the electronegativity function, Q_{yo}, illustrating that metals with a high affinity for binding to O^--dominated surfaces are removed faster from the ocean water than metals with a low affinity for binding (Whitfield, 1982).

2.4 Transport of Metals in Freshwater and Estuaries

Metals are continuously added to freshwater systems because of the erosion caused by rainwater. The erosion in the drainage areas of river systems typically is in the order of 5 cm/1000 years, and the rivers of the world each year transport approximately 24 billion tons of material to the oceans. Human activities such as ploughing, forest destruction, etc. are estimated to have increased the amount of material transported by the rivers by a factor 2–3 (Salomons and Förstner, 1984).

The metal contents and chemical composition of freshwater in different river systems vary strongly with the geological characteristics of the drainage areas. Whereas the chemical composition of seawater (regarding inorganic content) shows little variation,

freshwater is characterized by large differences in pH value, alkalinity, hardness, and ion content. The variability in the content of particles and dissolved organic material is generally also larger in freshwater than in seawater. Also in freshwater, metals exist in equilibrium between free and bound forms (Figure 1), but the variability in the character of freshwater makes it more difficult to generalize concerning the speciation of the metals in freshwater than it is in seawater.

Most trace metals in river systems are transported in a particulate form; this is particularly true for the metals that constitute an important part of the mineral structure of the inorganic particles (Fe, Al). Most of the particle-bound metal is transported in the river water by suspended particles with a diameter less than 100 μm; the highest metal concentrations are generally found in/on the smallest particles, because the surface to volume ratio increases with decreasing diameter.

A fraction of the particle-bound metal sediments in the river system itself, the sedimentation depends on the flow and the velocity of the water and the variation in these (potential resuspension of sedimented material) and on the physical shape of the river system.

The metal remaining in the river water is transported toward the sea. In the zone in which river water is mixed with seawater, the concentration and speciation of the metals are affected—often in a fairly dramatic way. On the metals' way out through the mixing zone or the estuary, the processes taking place are influenced by these changes:

1. The ionic strength increases
2. The velocity of the water decreases
3. The pH value increases
4. The freshwater is "diluted" by seawater
5. The particle content (the *turbidity*) increases

The physical shape of the estuary plays an important role in the changes in the composition of the water. The following description is based on a slightly idealized situation in which the salinity increases gradually from the river mouth to full seawater strength, and the effect of tides and sea currents is ignored.

In estuaries, a maximum in the amount of suspended material is often seen where the river water first meets the seawater (Meade, 1972). Part of the increased particle load is explained by the fact that dissolved organic material in the freshwater flocculates under the influence of the increasing ionic strength and the increasing pH value, leading to particle formation. The particles may also be of marine origin (marine sediments resuspended by wave action, sea currents, etc.). At the same time as particle formation takes place in the estuary, there will also be a tendency for particles to precipitate because of the lower flow velocity.

When considering the fate of the river-borne metals in the passage of the estuary, it is important to note that even if the largest fraction of the metal content of the river water is bound to particles, the concentration of dissolved metal is most often higher in the river water than in the seawater.

If the chemical speciation for a specific metal were totally unchanged during the passage from river water to seawater, the concentration of dissolved metal would merely decrease along the estuary; the metal is then said to behave conservatively. Metals may also, however, under influence from the increasing ionic strength in the estuary, be liberated from particles because of, for example, ion exchange and potential complex binding to, for example, chloride. This may result in an increase (when the dilution is taken into account) in the concentration of dissolved metal out through the estuary. As a third possibility, metals with a sufficiently high affinity for binding to particles may be removed from solution (by a shift in the equilibrium between free and particle-bound metal, see Figure 1), so that the dissolved concentration decreases faster than predicted by the dilution alone. The fate of metals in estuaries may vary tremendously—party depending on the chemical properties of individual metals. Also, a particular metal may behave very differently in different estuaries.

When particles precipitate in estuaries, the metal contained by the particles is removed from the water column. In considerations concerning the overall biogeochemical transport of metals, it is, therefore, interesting to know which fraction of the metal content of the rivers that precipitate during the transport from river systems to seawater. Investigations in the St. Lawrence River and its estuary have shown that more than 90% of the river's iron and manganese precipitate in the estuary, whereas the values for nickel, cadmium, copper, and zinc vary between 25 and 60% (Yeats and Bewers, 1982). It is true for a number of metals that a major proportion of the content transported in the river water precipitates in the estuaries of the rivers. For strongly surface reactive metals like the transuranic elements americium and plutonium, it has been found that up to 99% precipitate in the coastal areas after discharge from the nuclear reprocessing plant for nuclear fuel at the Irish Sea.

The fact that a considerable amount of the metal content of the rivers precipitates in the estuaries has the effect that the anthropogenic pollution of the rivers with metals leads to an increase in the metal concentrations in the sediments of many estuaries and coastal areas.

The downward transport of metals will also take place in lakes and in polluted areas; elevated metal concentrations in lake sediments have been demonstrated.

2.5 Metals in Sediments

Sediments are important sinks for pollutants, including metals. Metals bind both to the organic content of sediment, to clay minerals, and form mixed complexes with available oxyanions. Even at high sediment concentrations of, for example, cadmium, the binding capacity of sediment is not saturated. Compared with organic chemicals, metal transfer between sediment and water depends on highly complex processes. Although organic pollutants, in principle, partition between the water phase, the sediment phase, and biota in aquatic systems mainly on the basis of their lipophilic character (i.e., affinity for the organic fraction in sediment and lipid fractions in biota), the partitioning of metals depends much more on water chemistry and sediment chemistry, mainly relative amounts of sulfur and iron compounds, organic content, and redox status, and also on metal characteristics, mainly hard and soft character. Metals interact with particles by means of physical-chemical sorption (i.e., nonspecific attraction [van der Waals forces]) acting between surface charges on particles and the charges of metals/metal compounds. Chemical processes include precipitation and coprecipitation, ion exchange, isomorphous substitution, and solid-state diffusion.

Sediments are most often already anoxic a few millimeters below surface, and in this reducing environment, alternative terminal electron acceptors include sulfate, nitrate, iron, and, in some cases, other metals, and organic matter (methanogenesis). The redox status of sediments extensively affects the speciation and solubility and thereby toxicity of sediment associated metals. The toxicity of metals associated with sediments depends on the bioavailability of the metals, mainly governed by the water concentration (pore water and overlying water) and speciation (see later). For sediment eating and suspension feeding invertebrates as, for example, polychaetes and mussels, direct exposure to metals during digestion of sediment and suspended matter is an important exposure route.

Four chemical processes are considered to increase the transfer of metals from sediment to water: elevation of salinity, changes in sediment redox status, reduced pH, and the presence of organic complexing compounds. The first three processes release "free" metal in the form of mixed complexes with small inorganic ions and water, the fourth releases organically bound metal with another bioavailability than that of the inorganic metal complexes.

Metal ions form highly insoluble hydroxides and sulfides, and for some metals, also phosphates, whereas chlorides, carbonates, and sulfates are more soluble. Also, metals are bound strongly to various oxygen-containing iron compounds. Iron oxide hydroxide (FeOOH) and other iron oxides form a lattice where phosphate ions can exchange with OH, thereby locally increased pH may occur from liberated OH–, and also, a range of metal ions can bind to FeOOH. The metal sequestering capacity of FeOOH is especially high when some of the hydroxy groups are exchanged by phosphate. For transition metals, the ions with the lowest oxidation step typically form more stable complexes, leading to metal mobilization in case of sediment oxidation. The pool of sulfide available for metal binding (acid volatile sulfide) is an important determinant of the toxicity of sediment-associated metals. This pool is smaller in oxidized sediment, leading to metal release. On the other hand, FeOOH is formed only at oxic conditions. Accordingly, the effect of changing the redox status of sediment on the bioavailability of sediment-associated metals depends on the chemical composition of the sediment.

3 UPTAKE AND ACCUMULATION OF METALS

3.1 Bioavailability, Uptake, Accumulation, and Elimination

The term bioavailable refers to the fraction of total metal that can be taken up into an organism (Sanders and Riedel, 1998).

Terrestrial animals absorb metals in their food over their digestive epithelium, volatile metal compounds through the lungs, and for the smaller invertebrates, over the body surface. Aquatic organisms absorb toxic metals from water over the gill epithelium and over the entire body surface, besides from food and imbibed water over digestive epithelium.

The bioavailability of metals varies extensively among metals and organisms and also depends on the speciation of the metals. Accordingly, changes in the physicochemical characteristics of exposure media, especially water, influence the proportions of metal species that can be absorbed.

In principle, only lipophilic metal complexes (e.g., with carbamate pesticides) or organometals (e.g., mercury and tin compounds) can diffuse over biological membranes, whereas hydrophilic metal complexes including free hydrated ions must pass cell membranes by other mechanisms than free diffusion.

Metals can be taken up by endocytosis (e.g., $FeOH_3$), by diffusion (e.g., $Hg(CH_3)_2$), by facilitated diffusion (mainly soft class B ions with affinity for S- or N- containing ligands in membrane carrier proteins), or by active ATP-dependent uptake via cation pumps

(mainly hard class A ions that do not bind to carriers and are transported against concentration gradients) (Philips and Rainbow, 1993; Simkiss and Taylor, 1989). In biological fluids, ligand exchange to form thermodynamically stable complexes with multidentate biological molecules (chelation) prevents back diffusion. Apparently, the soft class B metals can be transported against a concentration gradient transferring the ion along a series of ligands with increasing affinity along a thermodynamic gradient, the metals finally being intracellularly sequestered by the ligand with the highest affinity. This can lead to storage or subsequent transport, as, for example, seen for metallothionein.

Some metals are absorbed from solution as hydrated ions, explaining the increasing bioavailability and toxicity of, for example, Cu and Cd, at decreasing salinity (Mclusky *et al*., 1986). Besides the uptake of hydrated metal species, inorganic and organic neutral metal complexes with increased lipophilicity (e.g., $CdCl_2$, $HgCl_2$, $Hg(CH_3)_2$) may be absorbed by direct diffusion (Sanders and Riedel, 1998)).

Metals with hydrated ionic diameters similar to those of essential metals can be taken up by the ATP-driven pumps and calcium channels, thus Pb, Cd, Mn, and Co can be absorbed as metabolic analogs by means of the Ca pumps (Markich and Jeffree, 1994). The relevance of this mechanism depends on the organism, for molluscs and malacostracan crustaceans with extensive calcium uptake for shell and exoskeleton formation (Bondgaard and Bjerregaard, 2005; Norum *et al*., 2005), this route may determine total uptake.

3.2 Metal Transport in Aquatic Food Chains

Aquatic organisms may take up metals either directly from solution or from ingested food. Phytoplankton organisms do, of course, accumulate metals directly from solution (Whitfield, 2001), but for most pelagic filter-feeding herbivores (such as, e.g., copepods) metals in the ingested food seem to be the major source (Mason *et al*., 1996; Reinfelder and Fisher, 1991); differences between metals and species do, however, occur (Wang, 2002). It has been shown that metals taken up into the cytosol of the unicellular algae and subsequently becoming associated with proteins (Reinfelder and Fisher, 1991) are assimilated to a higher degree in copepods than metal bound to structural elements in the algae (i.e., cell walls). Recent investigations (Ng *et al*., 2005), however, show that this phenomenon cannot be generalized across all species (phytoplankton as well as herbivores) and metals. In some benthic filter feeders such as the blue mussel *Myrtillus edulis,* uptake from water seems to be the dominant route for accumulation of cadmium for example (Fischer, 1988; Riisgard *et al*., 1987).

For most predators, food seems to be the dominant source for metal uptake (Luoma and Rainbow, 2005), that is, for cadmium in fish (Pentreath, 1977) and crabs (Bjerregaard *et al*., 2005).

Except for mercury (Section 7.10), there is no consistent tendency that metal concentrations increase along aquatic food chains.

4 DEFENSE AGAINST AND STORAGE OF METALS

Various mechanisms protecting against metal toxicity exist among different species, several acting by accumulating metals in inert granules that either are excreted or deposited for the lifetime of the organism. Other strategies involve heat-stable metal chelating proteins like metallothioneins (MTs) and metallothionein-like proteins that occur in eucaryotes (invertebrates, vertebrates, and plants) and have been characterized in a variety of species (Vijver *et al*., 2004).

Speciation of metals, homeostatic strategies for essential metals, and protective strategies for toxic metals at the cellular level in organisms may be as follows:

1. Free or complexed ionic species: Mixed aquo, chloride, phosphate, or carbonate complexes. Complexes with metabolic compounds (amino acids, carbohydrate, metabolites, etc.).
2. Bound in active centers of LMW peptides or functional proteins: Hemoglobin, hemocyanin, zinc finger proteins, cytochromes, carbonic anhydrase, superoxide dismutase.
3. Bound to transport or sequestration proteins: Metallothionein, ferritin, transferrin.
4. Bound in lysosomal vesicles as metal granules: Precipitated in extracellular deposits. Hair, feathers, exoskeleton, mineral deposits, residual bodies.
5. Bound to cellular constituents potentially causing harm: Enzyme poisoning, binding to DNA, or ion channels.

There is high sequence homology between MTs from different species, and they apparently all have similar functions as mammalian metallothioneins (i.e., storage, transport, and compartmentalization of essential metals and detoxification of toxic metals). Also, their metal-binding profiles and gene expression regulation are similar to that of mammalian metallothionein (i.e., binding Zn, Cu, Cd, Hg, and induction by these and

a few other metals). In mammalian species, the regulation of MT gene expression has been explained and shown to involve a nuclear receptor, metal-responsive transcription factor (MTF1) (Selvaraj *et al*., 2005). After binding of metals to the MTF1, it binds to metal response elements (MRE) upstream structural genes for MT (Andrews, 2000). This mechanism has been demonstrated in a few nonmammalian species including *Drosophila melanogaster*. Sequencing of MTF1 genes demonstrates high structural conservation from *Drosophila* to mouse, rat, and humans, strongly indicating that this regulation mechanism is general in all higher eucaryotes.

Some terrestrial invertebrates have adapted to a life in areas polluted by high levels of toxic metals. One such example is the wood louse *Porcellio scaber* (isopod, crustacean), which is capable of concentrating extensive amounts of metals in intestinal cells as various types of precipitates (metal granules). This protective system comprises three types of granules: type A mainly binds Ca, Mg, Zn, and Pb by precipitation as phosphates; type B granules contain Cu and Cd bound to MT; and type C binds excess Fe in the form of hemosiderin. Mixed-type granules can form by precipitation of phosphates around existing type B or C granules, depending on the pattern of metal exposure. All granule types are scavenged by lysosomes forming excretory vacuoles.

The intestinal mucosa is composed of both digestive cells sloughed at regular time intervals so the metal content is disposed of, and storage cells, whose metal content remains in the animal's digestive system (Hames and Hopkin, 1991). *Porcellio scaber* also deposits toxic metal in granules in hepatopancreas, a digestive organ in invertebrates combining hepatic and digestive functions.

Porcellio scaber is predated by the spider *Dysdera crocata*, which can ingest extensive amounts of toxic metals with its prey and has a slightly different protective system than *Porcellio scaber*, also involving digestive epithelium sloughing.

Based on numerous studies, formation of metal granules seems to be a widespread protection mechanism in invertebrate species. In marine prosobranch gastropods (snails), one study of more than 40 different species reported the formation of various types of phosphate granules in digestive gland containing mainly essential metals (Gibbs *et al.,* 1998). Other species with described metal granules include bivalves, collembolans, crustaceans, and oligochaetes (Vijver *et al*., 2004).

4.1 Metal Toxicity and Defense Systems in Plants

Plants have an extensive capability for adapting to metal stress. Two major situations have been described. In numerous situations, plants have during geological time scales adapted to growth on soils with very high metal or metalloid levels by invading areas where ore deposits are close to the soil surface. A gradual selection has created new endemic plant species, metallophytes, with an absolute, genetically determined metal tolerance to even extreme metal concentrations.

In other situations, plants (especially grasses) have rapidly (within few decades) developed tolerance to elevated soil levels of metals in areas polluted with metals because of human mining and other industrial activities. This tolerance is most likely because of selection of certain alleles of preexisting genetic polymorphisms and creates what has been called races, subspecies, ecotypes, and physiotypes, with varying degrees of metal tolerance (Peterson, 1993). In some taxa with a high degree of genetic plasticity, different ecotypes have evolved that are resistant to several metals. Especially in species within the genus *Silene* (*Caryophyllaceae*), a large number of metal-tolerant subspecies have developed. In *Silene vulgaris* (bladder campion), several alleles of a few loci have been identified to encode for resistance to high levels of metals (Schat *et al*., 1996). Cut1 and Cut2 alleles cause tolerance to Cu and possibly Mn; Znt1 and Znt2 alleles cause tolerance to Zn and possibly Cd. In plants carrying a combination of Cut and Znt alleles, Co tolerance has been described. Whether specific (now unknown) genes are needed to confer tolerance for each metal or group of closely related metals is presently not known, but this mechanism is likely as the target of metal toxicity can be various metal transporters in the cell membrane, metalloenzymes involved in metabolic functions, as well as other specific functions (Larcher, 2003). In a more general sense, five different mechanisms have been described to cause increased metal tolerance (Ernst, 1996; Larcher, 2003):

1. Formation of intracellular chelates by metal-binding proteins and polypeptides (phytochelatins).
2. Chelation by molecules from internal metabolism followed by compartmentalization into vacuoles.
3. Active export.
4. Impeded transport over the cell membrane.
5. Immobilization in the cell wall especially by pectins.

Cell vacuole–based protection mechanisms have been observed to dominate in leaves of metallophytes, whereas cell wall–based mechanisms dominate in roots, which makes sense in relation to the kinetics of metals in plants. Metals are taken up in roots and transported in cell sap.

Metallophytes can absorb extensive amounts of metals, especially in hyperaccumulators, who have been reported to concentrate metals by factors of 10 to almost 4000, thereby reaching extreme concentrations of tens of grams per kilogram (various metals in various plant species). This is used for phytoremediation of metal polluted soils or waters. In special cases, hyperaccumulator plants can be harvested for use as fuel and the ashes used for metal refining (phytomining).

5 TOXICITY OF METALS IN ECOSYSTEMS

Despite the fact that some of the first observations on the ecotoxicology of metals came from terrestrial studies on, for example, the toxicity of organomercurials used in farming, today, by far most experimentation, data, and mechanistic understanding in ecotoxicology relates to the aquatic environment, both in general and specifically for metals. Research indicates that the primary site for toxic actions of most metals in aquatic organisms is the gill, especially in acute exposures of freshwater organisms.

The functions of the gill are much more complicated than those of terrestrial lung. Besides gas transport and acid-base regulation, some kidney functions (e.g., N-metabolism, water, salt, and metal homeostasis) are in part regulated by the gill. These functions are executed by an array of negatively charged gill membrane proteins that bind cations. This is likely the reason for the high sensitivity of the gill to toxic metals. During acute exposure to toxic metals, extensive histological damage is rapidly induced in gills, leading to reduced gas exchange and efflux of essential ions and eventually mortality.

At lower level chronic exposures, metals, including Cd, Cu, Ag, Zn, and others, tend to bind to specific gill structures involved in metal homeostasis: Monovalent cations (e.g., Ag^+ and Cu^+) affect Na^+ transport, whereas divalent cations (e.g., Cd^{++} and Zn^{++}) affect Ca^{++} transport. Some metals cross the gill membrane and exert a toxic effect after systemic distribution (e.g., Hg^{++} and Pb^{++}). Although Cu in aquatic environments predominantly exists as the divalent Cu^{++} ion, it is most likely reduced to Cu^+ before or during interaction with the gill.

Early in the development of ecotoxicology as a science providing data for risk assessment and risk regulation, it became clear that in aquatic environments metal toxicity was poorly correlated to total metal concentrations, stimulating intense research in speciation, to identify determinants of toxicity (i.e., relations between water chemistry, dominant metal species, and toxicity). Selective analytic procedures have been developed to try to quantify labile (bioavailable) fractions of total metal. These methods include voltammetry, ligand competition, and resin equilibration. At present, the only technique allowing reliable measurement of free metal concentrations is the use of ion selective electrodes and only at relatively high (toxicologically relevant) concentrations.

Accumulating evidence on disproportionality between concentration and effect led to formulation of the free ion activity model (FIAM) (Campbell, 1995), which has been further developed into the biotic ligand–modeling concept (BLM) (Paquin *et al*., 2002), which incorporates metal speciation in description of toxicity. Like the pure speciation models, various BLMs assume equilibrium.

A BLM is a conceptual framework, describing that the acute toxicity of metals is associated with binding of "active" forms of metals (labile complexes or "free" hydrated metals) to biological structures (biotic ligands) as proteins, organelles, etc. Accordingly, the BLM predicts that water chemistry extensively affects metal toxicity, either through binding the metal (e.g., dissolved organic carbon, complexing compounds) or competing for sites at the biotic ligand (e.g., calcium).

Various authors have developed formal BLM descriptions allowing calculation of metal toxicity from metal speciation data acquired from chemical analysis of water and the speciation models described previously, in combination with conditional stability constants for metal–gill tissue complex formation measured experimentally. In this sense, the BLMs are extensions of the previous speciation models including further compartments, the biotic ligands. The presently final modeling approach to predict metal toxicity is the development of a sediment biotic ligand model based on measurement of sediment concentrations of acid-soluble metals (simultaneously extracted metals, SEM) and acid-volatile sulfide (AVS), modeling metal partition using the WHAM, and toxicity modeling using a BLM for metals (Di Toro *et al*., 2005).

The applicability of the various models for predicting metal toxicity is limited by the fact that a central assumption of all BLMs is that metal uptake is under

thermodynamic, not kinetic, control, meaning that the uptake is slow compared with the rate of binding to gill tissue. This may, however, not always be true, especially at low external metal concentration and for metals with slow reaction kinetics (e.g., Ni^{++}, Al^{+++}, Co^{++}, Cr^{+++}) for which metals, even the reaction with gill tissue, may never approach equilibrium.

6 RISK ASSESSMENT OF METALS

6.1 The Aim of Ecotoxicological Risk Assessment

The aim of ecotoxicological risk assessment is to protect ecosystems from damage because of human activities. Accordingly, the aim of ecotoxicological studies is to predict how natural populations respond to contaminant exposure. During this effort, ecotoxicological risk assessment contributes, however, often to protect human health by generating both exposure data and effects data. Because of the widely differing endpoints in human health risk assessment (individual health with emphasis on the most sensitive individuals) and ecological risk assessment (ecosystem health extrapolated from effects at the population and individual levels), the present use of human risk assessment–based methods in ecotoxicological risk assessment is problematic unless relevant extrapolation methods are used to assess effects at population, community, and ecosystem levels from effects at the individual or suborganismal levels, including molecular effects at the subcellular level.

6.2 Integrated Risk Assessment

Historically, risk assessment and risk management have focused on human health, using mainly human-focused toxicological data obtained in rodent and other mammalian test systems. When ecological risk assessment started to come into use only about four decades ago, methods previously developed in data generation for human risk assessment were adopted in a rapidly developing process; however, the assessment was conducted independently on human health risk assessment. The present trend is to perform integrated risk assessment and let the two processes support each other. The contribution of ecotoxicology to support human health risk assessment is mainly related to generation of exposure data. There are, however, important examples that effects observed in ecotoxicology have a major impact on estimating effects in humans, the best examples are within endocrine disruption. Extensive studies have investigated relationships between ecosystem composition (water, sediment/soil, biota), bioavailability, bioaccumulation, trophic transfer, and toxicodynamics of contaminants, including metals. With regard to metals, those compounds with a strong potential for bioaccumulation are most important for top predators like marine mammals and also in relation to human health (i.e., cadmium and methylmercury).

Scope of human health risk assessment:

- Protecting single individuals, ideally the most sensitive (children, pregnant, elderly, diseased, vulnerable genotypes).
- Thereby also protecting cohorts and populations.
- The critical effect is on the single individual.
- And biomarkers can be valuable risk indicators.

Scope of ecotoxicologic risk assessment:

- Protecting ecosystem health = optimal functioning of a biota assemblage.
- Not protecting single individuals—even massive killings are acceptable if fecundity can reestablish original population size.
- Critical effect is on (a) key species (not necessarily the most sensitive).
- (In many cases we do not know which species is/are key species).

6.3 Methods of Ecotoxicology

Classical dose-response assessment of acute toxicity adopted from human-oriented toxicology has been widely used in ecotoxicology to estimate the potency of ecotoxicologically relevant compounds. This method has, however, shortcomings, which can be illustrated from studies of the toxicity of metals (salts of Cd, Cu, Zn) toward one of the most widely used test organisms, the fresh water Cladoceran *Daphnia magna*, which can reproduce both sexually and asexually, the parthenogenic reproduction mode offering the possibility of generating a large number of genetically differing but stable clones in the laboratory. In early toxicity testing, the calculated acute LC_{50} of Cd^{++} in *D. magna* varied several orders of magnitude between different laboratories. Intensive method development under the auspices of OECD, EEC, and ASTM (ASTM, 1987; EEC, 1992; OECD, 2004) led to development of standard tests reducing extensively the interlaboratory variation. Identified error sources for estimating cadmium toxicity included medium composition, including, among other factors, the presence or not of EDTA and water hardness (Barata *et al*., 1998; Guilhermino *et al*., 1997), test temperature (Lewis and Horning, 1991), the *D. magna* clone used (Barata *et al*., 1998), the endpoint of effect (Suedel *et al*., 1997), and the mode of feeding

before testing. By standardizing all aspects of test conditions including the endpoint (24- and 48-hour immobilization test), the interlaboratory variation has been extensively reduced, thus the 48-hour EC_{50} for immobilization varied a factor 4.2, from 0.033–0.14 mg Cd/L among 13 tests in different laboratories (Mark and Solbe, 1998). This is still a rather large variation, but considerably less than earlier observed.

It is an important principle in human risk management to set exposure standards protecting the most vulnerable individuals, elderly, sick, children, or fetuses, or specific genotypes, thereby protecting the entire exposed cohort. Similarly, ecotoxicological risk management should set standards protecting the most vulnerable species, thereby protecting the entire community exposed. The next step in ecotoxicology was development of specific life-stage tests and full life-cycle chronic tests, because reproduction and larval development are especially important life cycle events. In *D. magna*, a 21-day lethality and reproduction test was standardized and validated. This led to further development of mathematical modeling of population composition with regard to the various life stages in response to exposure, and endpoints were transformed to be NOEC instead of LC_{50}. Recently, benchmark modeling has been introduced to further increase the credibility and reproducibility of test results.

The sensitivity of different species to toxins varies extensively, often by several orders of magnitude. Therefore, to protect the most sensitive species, $LC_{50,}$ NOEC, or (e.g., $BMD_{5\%}$) is determined for a number of species in a community, and the concentration protecting 95% of species calculated by modeling. For acute toxicity, this value is called final acute value (FAV).

Still, the relevance of toxicity data obtained under strict laboratory conditions for effects during *in situ* exposure in ecosystems is not straightforward. Toxicity and ensuing effects are modified by, for example, water composition, in freshwater, hardness and organic compounds as, for example, humic and fulvic acid affect the toxicity of metals. Also genetic variability in populations *in situ* as opposed to the use of genetically homogeneous clones in laboratory work will lead to different toxicities. For cadmium, NOEC will be lower and EC_{95} for a natural heterogenous *D. magna* population containing a wide variety of genotypes with regard to sensitivity compared with the sensitivity of a laboratory clone of average sensitivity.

6.4 Practical Risk Management

In the United States, the Toxic Substances Control Act (TSCA) of 1976 resulted in the 1979 TSCA inventory of approximately 60,000 chemicals then in use; today more than 75,000 compounds are enlisted. According to the TSCA, all producers or importers of chemicals not in the TSCA inventory must submit a premanufacture notice (PMN) to the Office of Pollution Prevention and Toxics (OPPT) 90 days before start. The PMN requires chemical, physical, and technical data for the new compound, as well as existing environmental and toxicity data. On the basis of the PMN, risk assessment is performed and risk management implemented. The risk assessment initially follows two avenues:

- Environmental emission and exposure evaluation, resulting in estimation of predicted environmental concentrations (PECs) in relevant scenarios.
- Hazard profile development preferentially using existing toxicity data. Because such data seldom are available, surrogate data are generated using (quantitative) structure-activity relationship (QSAR) analysis by the "ECOSAR" software (ECOSAR, 1998). In most cases either a predicted LC_{50} or a predicted no effect level (PNEC) is calculated.

Based on these exposure and effects assessments, risk characterization is performed to estimate the nature and likelihood of effects. Thus, a risk ratio can be calculated as RR = PEC/PNEC. If RR is around 1 or larger, there are reasons for concern.

For the risk management process, assessment factors are used to correct for uncertainties associated with the quality of data available. The best type of ecotoxicity data are those from field tests, but in most risk assessment cases, only limited toxicity data are available. The RR is a realistic calculation of risk on the basis of often-limited knowledge and not suited for risk management. To take into consideration the quality of data and thereby the uncertainty associated with the RR, assessment factors are used to generate environmental exposure criteria (EEC):

$$EEC = RR/AF$$

Assessment factors used by OPPT for setting concern levels for new chemicals:

Available toxicity data:	Assessment factor:
Limited (e.g., one acute LC_{50} via (Q)SAR	1000
Base set acute toxicity (algae, fish, and daphnia)	100
Chronic toxicity	10
Field test data	1

6.5 Biomarkers as Hazard Indicators in Ecotoxicological Risk Assessment

Biomarkers are important both in human health and in ecotoxicological risk assessment and would *a priori* be expected to play an important role in integrated

risk assessment. This role is not fully achieved, mainly because of limitations in possibilities of extrapolation from biomarkers to likely effect.

Development and use of biomarkers in ecotoxicology and environmental risk assessment:

- Adoption of clinical chemistry methods from human toxicology.
- Adoption of classical markers from ecophysiology and population ecology.

The value of the use of biomarkers in human health risk assessment is restricted by the fact that many biomarkers are hazard indicators rather than risk indicators. Also, because a strong causal link between bioindicator signal and ensuing risk of disease is not always demonstrated, even for many molecular biomarkers, they often function as exposure markers rather than as effect markers. Accordingly, the research needs are related to establishing quantitative relations between biomarker signal and endpoint (risk of adverse effect). Another promising research area involves development of biomarkers for genetic (polymorphisms) or acquired susceptibility to general or specific exposures or diseases.

The value of biomarkers in ecotoxicology is limited by two factors:

1. Problems with extrapolation from biomarker signal typically measured at the individual level or below.
2. Lack of knowledge of the specific ecological significance of the biomarker. Therefore, development and use of markers at higher organizational level (e.g., life cycle traits, reproduction) have high priority.

Because of lack of solid knowledge on long-term ecological consequences of increased mutation load, biomarkers of mutagenic/carcinogenic environmental exposures including metabolic markers are presently most relevant in relation to human risk assessment.

In the case of endocrine disruption, biomarkers have a potential of becoming developed to a stage of very high relevance in integrated risk assessment. Here, a suite of biomarkers is available at the molecular (function and metabolism), histological, and functional levels. Together, these markers are likely capable of forecasting risks of chemicals to both humans and ecosystems because of impaired reproductive functions.

Molecular techniques as genomics, proteomics, and metabolomics are being rapidly used to develop potential biomarkers in human risk assessment with extensive future perspectives. This development is highly accelerated by the human genome project allowing allocation of differential effects at various molecular levels to specific genes. A similar development in ecological risk assessment is impeded by the low degree of sequencing in many key species.

7 MONITORING METAL POLLUTION—BIOMONITORING

The degree of contamination of an ecosystem with metals (and other contaminants) may, of course, be assessed by determining concentrations of metals in air, water, soil, or sediments in the system, but for several reasons, many monitoring programs around the world use selected organisms—so-called monitoring organisms—for monitoring purposes.

The most important advantages in determining metal concentrations in biomonitoring organisms rather than in the abiotic environment are the following:

1. The organisms concentrate chemicals to measurable concentrations.
2. The organisms reflect the average degree of pollution over time.
3. The concentration in the organisms reflects the *bioavailable* fraction of the polluting metal, or, in other words, the fraction that is available for uptake in organisms.

7.1 Mussel Watch

One of the best-known examples of a monitoring organism is the widespread use of the blue mussel *Mytilus edulis* for monitoring the contamination of coastal marine areas (Farrington *et al*., 1983; Goldberg, 1986; Goldberg *et al*., 1978; 1983). The blue mussel has several advantages for this purpose (Bayne, 1989; Widdows and Donkin, 1992):

1. It is distributed all over the world.
2. It is steadfast.
3. It is easily sampled and handled.
4. It is easy to perform experiments with.
5. Its physiology and way of life are well established.
6. It is a dominating species in many coastal areas.
7. It tolerates fairly high concentrations of contaminants in its tissues.
8. It has a relatively low and noninducible MFO-activity (not relevant for metals).
9. It is consumed by humans, so its content of pollutants is relevant for considerations concerning food safety.
10. Mussels can easily be translocated from clean to polluted locations.
11. Mussel populations are relatively stable and the development of contamination can be followed over time.

For correct interpretation of monitoring data on metals—which occur naturally in seawater—it is necessary to have an adequate knowledge about biotic and abiotic factors influencing metal uptake and accumulation in the mussels (Widdows and Donkin, 1992).

7.2 Other Monitoring Organisms

Atmospheric contamination with metals has been assessed by means of moss analyses in a number of countries (Herpin *et al*., 1996; Hertz *et al*., 1984; Hynninen, 1986; Markert *et al*., 1996; Miljøstyrelsen and Statens Naturvårdsverk, 1983; Wolterbeek, 2002).

Macroalgae such as *Fucus* species have been used to assess metal contamination in coastal areas (i.e., contamination with radioactive elements) (Dahlgaard and Boelskifte, 1992; Holm, 1995; Kershaw *et al*., 1999).

Metal contamination in the freshwater environment has been monitored by means of freshwater mussels (Kraak *et al*., 1991; Mersch and Pihan, 1993) and aquatic mosses (Mersch and Pihan, 1993; Say *et al*., 1981).

For information on further uses of biomonitoring organisms, the reader is referred to Philips and Rainbow (1993).

8 ECOTOXICOLOGY OF INDIVIDUAL METALS

8.1 Alumina

Alumina concentrations in the deeper waters of the oceans typically range between 10 and 20 nmol/L (Measures, 1995), whereas the concentrations in the surface waters are strongly affected by inputs from the terrestrial environment and may range between 0.2 and almost 100 nmol/L.

Alumina exists in soils mainly bound in silicates, hydroxides, and oxides, and on acidification of the soil, ionic alumina is released from the silicates. At pH values above 5 the ionic alumina exists as polymeric hydroxy cations that are strongly bound to the surface of the silicate minerals (Savory and Wills, 1991), and pore water concentrations and leaching from the soil are negligible (Savory and Wills, 1991). In the silicate-buffering region, primary silicates are transformed to secondary silicates, transforming lime feldspar to kaolinite, where the Ca^{++} ion is exchangeable:

$$CaAl_2Si_2O_8 + H_2O - >[Al_2Si_2O_5(OH)_2O_2]^{2-}Ca^{2+}$$

In the aluminium hydroxide–buffering region, aluminium hydroxides close to the surface of clay minerals can be released from the solid particles. Combining weathering with low pH can thus liberate extensive, ecotoxicologically effective Al concentrations to soil and surface waters (Kloppel *et al*., 1997). If soil pH decreases below 4.5, increasing amounts of alumina attains a soluble form, and alumina concentrations in the soil water may reach tens of milligrams per liter.

Alumina mobilized from the soil leaches to groundwater, rivers, and lakes, and alumina concentrations in freshwater generally increase with decreasing pH values, typically from concentrations below 100 µg/L at pH values above 6 to 500–700 µg/L at pH 4 (Dillon *et al*., 1983).

The exact mechanism by which alumina exerts its toxic effect toward fish is not known, but it has been proposed (Poleo, 1995) that negatively charged sites on the gill surface act as nuclei for polymerization of $Al(OH)_2(H_2O)_4^+$, which is the dominating species of alumina at pH values between 5 and 6 where toxicity is highest (Lydersen, 1990; Lydersen *et al*., 1990a; 1990b; 1991; Rosseland *et al*., 1992).

Acidification and subsequent mobilization of alumina have profound impacts in aquatic ecosystems (Dillon *et al*., 1983).

The main cause for fish death in acidified lakes and rivers is believed to be impacts on the functions of the gills imposed by toxic Al species with subsequent loss of salts from the blood and disturbances in the gas exchange.

Exposure to alumina at pH around 5–5.5 results in structural changes in the gills (fusion of the secondary gill lamella, increased thickness of the mucus layer), so the diffusion distance between blood and water increases. The increased distance of diffusion means that the uptake of oxygen and the release of carbon dioxide are rendered less efficient. By acute poisoning in acidic water and alumina, the fish die from disturbances in the gas exchange (Malte and Weber, 1988), whereas the cause of death after chronic exposure is less clear.

The concentration of salts (especially Na^+ and Cl^-) in the blood of freshwater fish is higher than in the surrounding water. This means that salts have a tendency passively to diffuse from the blood out into the water. Freshwater fish lose some salts through the urine, but the largest loss takes place from the gills. The loss of salts is replaced by a continuous active uptake of salts over the gills. By uptake of salts in the gills, Na^+ is exchanged with H^+ or NH_4^+ and Cl^- with HCO_3^- or OH^-. At instances of fish death in acidified freshwater areas, it has been found that the concentrations of salts in the blood of the fish decrease in the most heavily affected areas (Leivestad and Muniz, 1976). When fish are transferred from moderately to strongly acidified surroundings, the salt concentration in the blood decreases likewise.

The resistance of the fish toward the combination of acidic water and alumina increases when the salt content of the water increases. This is a natural consequence of the fact that the difference between the salt concentrations of the water and the blood—and thereby at the loss of salts—decreases if the salt concentration increases in the water. Likewise, the fish are far more resistant in hard (calcium containing) water (Wood *et al*., 1988). It is known that calcium under normal conditions participates in the regulation of the gill's permeability to Na^+ and Cl^-, and a high concentration of calcium in the water reduces the salt loss from the gills of the fish.

In freshwater environments affected by acidification (e.g., Norway, Sweden, Scotland, Canada), fish populations have shown marked declines. In the beginning of the 20th century, declines were observed in fish populations in certain Norwegian lakes and rivers. Thus, the sea trout disappeared from approximately 1500 acidified lakes in southern Norway between 1940 and 1980, and the roach started to disappear from lakes in western Sweden around 1930.

Seawater has a fairly high buffering capacity, and acid precipitation does not generally generate problems with decreases in pH and mobilization of alumina in marine areas.

8.2 Antimony

Antimony exists in seawater mainly (>95%) as antimonate (oxidation state V) and minor amounts of Sb(III) and monomethyl antimony (Cutter and Cutter, 1995; 1998; Cutter *et al*., 2001). Antimony concentrations typically range between 0.5 and 2 nmol/L, and the antimony concentration does not show typical nutrient-type profile because the highest concentrations tend to appear in the surface layers (Cutter *et al*., 2001).

Antimony may be released from metal smelters and from combustion of fossil fuels, and the anthropogenic emission of antimony has been estimated to be 38,000 tons annually (Lantzy and Mackenzie, 1979). The mobilization factor for antimony has been estimated to be 39.

EC_{50} values for the aquatic toxicity of antimony of 8 mg/L for daphnia and approximately 50 mg/L for green algae have been reported (Hammel *et al*., 1998).

8.3 Arsenic

The metalloid arsenic appears in nature in the oxidation states −3, 3, and 5 and in a multitude of different chemical compounds (the structures of some of the forms mentioned here are shown in Figure 2).

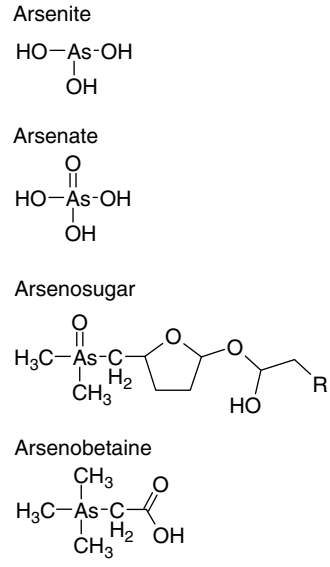

FIGURE 2 Various arsenic forms mentioned in the chapter.

In seawater arsenic is mainly found as arsenate (AsO_4^{3-}; >80%) and arsenite (AsO_3^{3-}; <20%) forms for which the degree of protonation depends on the pH value of the water. Concentrations typically range between 15 and 25 nmol/L (Cutter *et al*., 2001; Santosa *et al*., 1994). In the anoxic pore water of the sediments, the reduced form arsenite dominates. In the photic zone of the oceans, algal methylation of arsenic may lead to concentrations of monomethyl- and dimethyl arsenic of approximately 0.1 and 0.5 nmol/L, respectively (Cutter *et al*., 2001).

Arsenic is emitted into the environment through metal smelting, combustion of fossil fuels, use in pesticides, and from volcanoes. Anthropogenic emissions are far higher than the natural releases of approximately 8000 tons annually (Matschullat, 2000), and a mobilization factor of 3.3 was estimated in the 1970s (Lantzy and Mackenzie, 1979).

Arsenate is taken up from the water by algal cells—possibly via the same route as phosphate. Phytoplankton organisms transform the inorganic arsenic taken up to organic arsenic compounds in the form of arsenosugars (Francesconi and Edmonds, 1997; Francesconi and Kuehnelt, 2004).

In marine animals, most of the arsenic content is likewise present in the form of organic arsenic compounds—mainly in the form of arsenobetain. Whereas the pathways for the algal synthesis of arsenosugars are known, the pathways for the synthesis of the arsenobetain are not explained. The formation of the organic arsenocompounds is considered to be a mechanism for detoxification of the toxic, inorganic arsenic compounds (Francesconi and Edmonds, 1997; Francesconi and Kuehnelt, 2004).

Acute and chronic toxicity of inorganic arsenic to fish and aquatic invertebrates typically occur at concentrations of 1 mg/L (Mance *et al*., 1984c).

In some parts of the world, the soil naturally contains such high concentrations of arsenic that mobilization of inorganic arsenic constitutes a human health problem when groundwater is used to supply drinking water.

8.3 Cadmium

8.3.1 Background Levels and Emissions

Cadmium has been called "the dissipated element," because its uses are most often as minor components (surface treatment, pigments, plastics, solders, fertilizers), and recycling is, therefore, difficult. Coal burning, scrap smelting, and garbage incineration are sources for air pollution with Cd. The anthropogenic mobilization index for cadmium is high. Because of potential toxicological consequences of high anthropogenic emission of cadmium, this element has become substituted from many uses.

Cadmium is a natural component of rocks, soils, and sediments. Average concentrations in the earth's crust and in the upper lithosphere have been estimated to 0.11 mg/kg (Bowen, 1979) and 0.5 mg/kg[1] (Goldsmith, 1958), respectively. Cadmium concentrations in igneous rocks are normally well below 1 mg/kg, whereas sedimentary rocks as bituminous and carbonaceous shales can contain very high Cd concentrations, up to more than 200 mg/kg (Thornton, 1992) and thereby provide extensive exposure of plants and animals because of weathering. A survey of Cd concentrations in surface soils from many parts of the world reported average concentrations between 0.07 and 1.1 mg/kg, and the authors concluded that concentrations >0.5 mg/kg reflect anthropogenic input (Kataba-Pendias and Pendias, 1984).

In the open areas of the oceans, the concentration of total cadmium ranges between 5 and 25 ng/L in the surface water, whereas the concentration in the deep sea typically is approximately 50–100 ng/L (Bruland, 1980; Bruland *et al*., 1978; Yeats *et al*., 1995), somewhat higher in the Pacific and South Atlantic than in the North Atlantic. The relatively low surface concentrations are likely because of scavenging of Cd by microplankton where it may replace zinc (Price and Morel, 1990). In Arctic and Antarctic waters, with much lower organic concentrations, the difference in concentration between surface and deep waters is much smaller (Macdonald and Sprague, 1988). This may explain the very high cadmium body burdens reported in Arctic and Antarctic vertebrates (see later).

Because of the erosion from rainwater in the upper layers of the soil, small amounts of cadmium are constantly transported to freshwater systems. Because of the differences in the cadmium concentration in different types of soils, the natural background concentration of cadmium in freshwater may vary from one place to another; cadmium concentrations in uncontaminated freshwater range between 10 and 100 ng/L. Much higher concentrations may occur in freshwater systems because of emissions with surface runoff, drainage, and sewage (spillover or incomplete treatment) from industrial and municipal areas, especially high concentrations occur near mines with polymetallic sulfide deposits, up to 1 mg/L (Boyle and Jonasson, 1979).

It is estimated that 69% of the cadmium transported in the rivers of the world precipitate in estuaries (Salomons and Förstner, 1984), and an average sediment enrichment factor of 5.3 in coastal areas and lakes has been reported (Salomons and Förstner, 1984).

The biogeochemical cycle of Cd in freshwater follows nutrients like phosphate, silicates, and nitrates. In freshwater, the bioavailability and toxicity Cd has been demonstrated to decrease with lower pH (Andersson and Borg, 1988; Lawrence *et al*., 1989; Yan *et al*., 1990) and with increasing hardness. In general, suspended organic material scavenges Cd and makes Cd less bioavailable and transfers Cd to the sediment. Cadmium is easily bound to clay and organic particles in the freshwater, and the fraction of the total cadmium in freshwater that is found in the particulate form increases with the particle content of the water. The dissolved cadmium will to a smaller or larger degree—depending on the pH value and the hardness of the water—form a $CdCO_3$ complex, and some of the dissolved cadmium will also be bound to organic material dissolved in the water. This means that the free cadmium ions (Cd^{++}) in many instances only will constitute a small percentage of the total amount of cadmium present in the freshwater.

In full-strength seawater, dissolved cadmium is mainly present as chloride complexes ($CdCl_2^0$, $CdCl^+$, $CdCl_3^-$), and Cd^{++} constitutes only between 2 and 3% of the total dissolved cadmium (Mantoura *et al*., 1978; Sunda *et al*., 1978). At reduced salinities in estuaries and coastal areas, Cd^{++} constitutes a higher proportion of the dissolved cadmium.

8.3.2 Uptake in Organisms

The unicellular algae that are the first link in the food chain of the open ocean take up cadmium directly from the seawater so that the concentration in the algae may be up to 1000 times higher than in the surrounding water.

The filter feeders among the zooplankton retain only a minor fraction of the cadmium ingested with the food; the rest is excreted with the feces of the animals. Zooplankton organisms also take up cadmium directly from the seawater—as well as through the gills as on the external surface. The sum of these routes of uptake gives zooplankton organisms (both on 2nd, 3rd, and maybe the 4th level in the food chain) cadmium concentrations that are generally 500–2000 times higher than the cadmium concentrations in the surrounding seawater. The bioaccumulation of cadmium does thus not lead to biomagnification.

Cadmium is taken up by aquatic plants and may reach extensive levels in polluted lakes. In macrophytes from Lago Maggiore (Guillizoni *et al*., 1989) measured 1.6 mg/kg as mean of means, whereas some plants had higher levels: 6.7 mg/kg in *Egeria densa* and 9.6 mg/kg in *Ceratophyllum demersum*, an effective accumulator species for several metals. One of the most efficient Cd accumulators, the water hyacinth *Eichhornia crassipes* that produces MT-like proteins in root tissue has been suggested for remediation of Cd-polluted waste water and freshwater systems because of rapid growth and high biomass production (Nir *et al*., 1990). Several experimental studies with this and other metal hyperaccumulators for remediation of, for example, water ponds in old mining areas are under way with cadmium and other metals.

Both in mammals and birds, cadmium is deposited mainly in the kidneys. In penguins from the Antarctic, an area not polluted by cadmium because of human activities, kidney concentrations between 50 and 80 mg/kg wet weight have been reported in several studies, leading to renal tubular necrotic changes (Elinder, 1992). Also Arctic and Antarctic whales and seals have very high renal cadmium levels; Greenland harbour seals have much higher Cd levels than seals from the North Sea, which receives cadmium discharges because of human activities. The explanation is likely because of extensive uptake of Cd by Arctic and Antarctic amphipods (including krill), oysters, mussels, and squid, which are important food resources for many marine vertebrate species.

It has been found for a number of different marine species that the cadmium concentration in the tissues increases throughout the lifespan of the organism, so that old organisms contain higher cadmium concentrations than young organisms.

8.3.3 Contamination with Cadmium

Cadmium is emitted into the atmosphere by metal smelting and incineration of coal, oil, and different types of garbage. Runoff from gutters and discharge from galvanization industries and other types of chemical industries emit cadmium to the aquatic environment, and cadmium is spread with phosphate fertilizers over agricultural areas. The largest input of anthropogenic cadmium to marine areas comes from atmospheric cadmium. The atmospheric input is, however, distributed over so large an area that it probably only has a minor impact on the cadmium concentrations in the marine organisms.

8.3.4 Cadmium's Toxicity in Water

Cadmium bound in a complex form is apparently not available for uptake in organisms and thereby not toxic. The free, dissolved cadmium ions (Cd^{++}), on the contrary, are toxic. Because a large amount of the cadmium present in seawater forms chloro complexes, cadmium (in the same dissolved concentration) will be far more toxic in freshwater than in seawater, because the concentration of Cd^{++} is higher in the freshwater. Experiments have shown that the lowest concentration of cadmium that has adverse effects on the marine flora and fauna is in the range of 5000 ng Cd/L. There are no well-documented examples that contamination of the sea with cadmium has led to adverse effects in marine ecosystems. On the other hand, contamination of the sea with cadmium can give rise to considerations concerning the use of seafood for human consumption, because blue mussels even from uncontaminated areas contain relatively high amounts of cadmium.

Because calcium reduces the uptake, as well as the toxicity, of dissolved cadmium, the calcium content of the water (hardness) plays an important role for cadmium's toxicity in freshwater. Daphnia are very sensitive to cadmium and in soft water; the reproduction in our most common species of daphnia is affected at 340 ng Cd/L, and the species composition in the zooplankton community is changed at exposure to 200 ng Cd/L (Marshall and Mellinger, 1980).

8.3.5. Cadmium in Agricultural Soil and Uptake of Cadmium into Plants

The uptake of cadmium in a specific plant species is proportional to the cadmium content of the soil. The uptake is, however, somewhat dependent on the pH value of the soil and the content of organic material, clay content, and agricultural practices. The variability in the cadmium uptake between different plant species may be very large. Because most humans have their most important exposure to cadmium from the plant material in our basic food (especially potatoes, cereal products, and rice), the increase in the cadmium concentration of the agricultural soil and thereby in the cadmium content of the crops has caused considerable concern in many countries.

Some species of mushrooms have an extraordinary ability to accumulate cadmium from the soil (Seeger, 1978), also in areas not especially contaminated with the metal. Because some of these mushroom species (e.g., *Agaricus* species) are commonly collected for human consumption, the high cadmium content causes some concern regarding the potential human health aspects.

Cadmium has been added to agricultural soil especially from four sources: atmospheric deposition, phosphate fertilizers, lime, and manure.

In the 1970s, approximately 8000 tons of cadmium were emitted to the atmosphere each year; 7200 tons were the result of human activity, whereas only 800 tons came from natural sources (Nriagu, 1989). Around heavy industry (i.e., metal smelters), the atmospheric deposition of cadmium may be very high—up to 170 g Cd per hectare per year.

The total European emission of cadmium into the atmosphere decreased from around 3000 tons in the 1960s and 1970s to approximately 400 tons in 1999 (EEA, 2003), and as a consequence of this decrease in the emission, the yearly deposition of cadmium in, for example, Denmark declined from approximately 2–3 g Cd per hectare around 1978 to approximately 0.4 g Cd per hectare now.

Phosphate fertilizers contain cadmium. Phosphate fertilizers are manufactured from raw phosphates that are either minerals like apatite (mainly calcium phosphate) with a low cadmium content or former seabed sediments with a high cadmium content. Around 1978, the Danish agricultural areas had approximately 3 g cadmium added per hectare per year with phosphate fertilizers. After introduction of limits for cadmium in phosphate fertilizers, the cadmium addition to the Danish soil from this source has decreased to below 0.1 g hectare per year. The application of lime contributes with approximately 0.4 g Cd per hectare per year; this number has not been changed much since 1978.

In 1978, the total addition of cadmium into the Danish agricultural soil constituted 6 g cadmium per hectare. It is assumed that slightly less than 1 g cadmium disappears from each hectare with draining water, seeping to groundwater and removal of crops. Because the ploughing layer on average contains 510 g Cd per hectare, the cadmium concentration increased by approximately 1% per year in 1978. The increase in the cadmium content of agricultural soil and herbage has been documented in English soil and herbage samples taken between 1860 and 1980 (Jones *et al*., 1987; 1992; Nicholson *et al*., 1994).

The measures taken to reduce the main sources of pollution of the agricultural soil with cadmium should now have lowered the rate of increase in the cadmium concentration in the soil.

8.3.6 Implication for Human Health

Humans in the general population receive most of their exposure to cadmium through basic plant material (rice, potatoes, grain products) in their diet, and the cadmium content in plants generally increases linearly with the cadmium content in the soil in which the plants are grown. Because the margin between the average daily cadmium intake and the intake expected to cause adverse effects in the most sensitive part of the population is very narrow—and in some areas nonexistent—the increase in cadmium concentrations in agricultural soils has caused some concern worldwide.

Mussels and other marine species (e.g., marine mammals) may accumulate cadmium to concentrations that pose a problem to humans whose diet is composed of a large fraction of these organisms.

A detailed description of human exposure to cadmium and the toxicological effects of chronic exposure is given in Chapter 23.

8.4 Cobalt

Dissolved cobalt concentrations in ocean water around 20–40 pmol/L have been reported with no clear vertical profile (Jickells and Burton, 1988; Landing *et al*., 1995). $CoCO_3^0$ dominates in seawater, with Co^{++} as the second most important species (Mantoura *et al*., 1978). Cobalt coprecipitates with other metal hydroxides.

Cobalt is emitted to the aquatic environment mainly in connection with mining activities, and concentrations up to 4.5 mg/L have been recorded (Schrautzer, 1991).

Anthropogenic emissions to the atmosphere are smaller than natural fluxes, and a mobilization factor of 0.71 has been estimated (Lantzy and Mackenzie, 1979). Seventy-nine percent of the cobalt transported by rivers globally is precipitated in the estuaries, and an average sediment enrichment factor of 1.4 in coastal areas and lakes has been found.

8.5 Chromium

Chromium exists in the aquatic environment in an equilibrium between Cr(VI) and Cr(III), which is strongly influenced by redox conditions. In seawater, chromate dominates (3–4 nmol/L reported for Mediterranean water), whereas Cr(III) concentrations were typically around or below 1 nmol/L (Vandenberg *et al*., 1994).

Chromium is emitted to the aquatic environment from galvanizing industries, tanning industries, and

from more diverse sources originating from the use of chromium in dyes, wood impregnation, etc., and an average sediment enrichment factor of 2.2 in coastal areas and lakes has been found. The anthropogenic mobilization factor for chromium is 1.6.

Acute toxicity of chromium toward fish is exerted at concentrations generally above 10 mg/L, whereas sublethal effects (such as reduction in growth) toward various aquatic organisms (e.g., phytoplankton and fish) are exerted from about 10 µg/L (Mance *et al.*, 1984a).

8.6 Copper

Copper is an essential element, and more than 30 copper-containing enzymes are known. In, for example, crustaceans, copper is an integral component of the respiratory pigment, hemocyanin.

Copper concentrations in the oceans show a gradual increase from approximately 1 nmol/L in the surface layers to 3–5 nmol/L in the bottom layers (Bruland, 1980; Yeats *et al.*, 1995). $Cu(OH)_2^0$ is the dominating inorganic Cu species in seawater ~90%), whereas Cu constitutes less than 1% (Mantoura *et al.*, 1978). Uncontaminated freshwater systems show large variability in copper contents (0.2–30 µg/L), with a world median concentration of 3 µg/L (Bowen, 1985). However, copper has a high affinity for binding to organic chelators such as humic and fulvic substances, algal exudates, etc., so the content of dissolved organic material will strongly influence the speciation of copper at a given site. In most aquatic systems, the free copper ions constitute less than 1% of the total amount of copper present.

In the global flux, 19,000 tons of copper are emitted to the atmosphere by natural routes, whereas anthropogenic sources contributed between 56,000 and 260,000 tons during the 1970s (Lantzy and Mackenzie, 1979). The total annual addition of copper to marine areas with rivers is estimated to 2.5 million tons, of which approximately two thirds are retained in the sediments of the estuaries and coastal areas. An average sediment enrichment factor of 2.1 has been reported in lakes and coastal areas. In estuarine areas affected by discharges from mining activities, copper concentrations in the sediments may reach several thousands of µg/g(Salomons and Förstner, 1984). In oxic marine sediments, copper is especially bound to iron oxides and in the organic fraction of the sediments.

Copper has a relatively high toxicity toward aquatic organisms. In the open oceans where the concentrations of organic chelators are low, relatively small increases in the natural background level of copper may inhibit the photosynthetic activity in surface waters (Nielsen and Wium-Andersen, 1970). Copper shows sublethal and lethal effects toward various groups of aquatic invertebrates from approximately 5 µg/L[1] (Mance *et al.*, 1984b). Fish may show mortality at exposure from approximately 30 µg/L (Mance *et al.*, 1984b).

Copper sulfate has been used as an algaecide in aquatic systems, and it is also used in aquaculture systems to treat gill parasites in fish; both of these applications have led to toxic manifestations in the freshwater environment.

Among the mammals, ruminants are relatively sensitive to copper; for example, sheep may develop signs of copper poisoning (liver damage and anaemia) if their food contains 8–10 µg Cu/g. Nonruminants are far less sensitive to the effects of copper, and copper is used as a growth promoter in pig production (up to 250 µg Cu/g). This addition of copper to the pig's feed may lead to elevated copper concentrations in the agricultural soil if the same areas are amended with pig manure for several years, and soil quality criteria may be exceeded.

8.7 Iron

Iron exists in oxic environments as Fe(III) and in anoxic environments as Fe(II). Iron is an essential metal, acting as a cofactor in a number of enzymes and being a constituent of hemoglobin.

Average iron concentrations in surface and deep seawater are 70 and 760 pmol/L, respectively (Johnson *et al.*, 1997). Iron may be rate limiting for phytoplankton growth on the oceans (Whitfield, 2001). In anoxic deep water, iron concentrations may reach 1 µmol/L (Bruland, 1983).

Ninety-nine point eight percent of the iron transported in the rivers of the world is precipitated in the estuaries, and an average sediment enrichment factor of 1.2 in lakes and coastal areas has been found.

Some of the major problems with iron contamination of the aquatic environment are seen in connection with draining of waterlogged areas from which Fe(III) may be released to the streams (Section 1.2.3). For most freshwater invertebrates, sublethal and lethal toxicities are exerted by total iron concentrations in the mg/L range, but larvae of insects such as mayflies show LC_{50} values at a couple of hundred µg/L (Mance and Campbell, 1988).

8.8 Lead

Lead occurs naturally in the earth's crust with an average concentration around 13 mg/kg, and the anthropogenic contamination with lead—mainly because of the use of leaded petrol—has exceeded that of any other metal. During the 1970s, the anthropogenic emissions

of lead to the atmosphere were estimated as between 400,000 and 500,000 tons (Lantzy and Mackenzie, 1979; Nriagu, 1989), a value exceeding the natural cycling of lead by approximately 100 times. An average sediment enrichment factor for lead in lake and coastal sediments of 4.1 has been reported (Salomons and Förstner, 1984).

Tetramethyl and tetraethyl lead are added to petrol as antiknocking agents. During combustion in an engine, the organic lead compounds will be split to methyl and ethyl radicals (that prevent unwanted chain reactions—knocking) and elementary lead. The elementary lead is oxidized to PbO, which will react with HBr and HCl under the formation of PbBrCl and salts of lead, ammonium, chloride, and bromide. Dibromo and dichloroethylene are added to the gasoline with the purpose of removing the lead from the engine (combustion of the ethylene compounds yields HBr and HCl). The lead salts formed are found in the exhaust gas as particles, of which 95% have a diameter less than 0.5 µm. During the decades when leaded petrol was used, lead concentrations in urban air could easily exceed 1 µg Pb/m^{-3}; the effects on human health from this exposure are described in Chapter 31.

The particulate lead will—depending on the size of the particles—be transported for shorter or longer distances before it is deposited again. A minor fraction of the emitted lead (bound in the largest particles) hits the soil quickly and gives rise to lead contamination along the roads. Particles with a diameter <0.5 µm may remain in the atmosphere for long a time, and the lead emitted subsequent to the use of leaded petrol gave rise to global lead contamination.

This emission of lead can be traced in different compartments in the environment, for example, in the Greenland ice cap and in the oceans. The prehistoric lead concentrations in the Greenland ice cap were only a few pg/g. From approximately 1750, lead concentrations increased linearly, reaching approximately 60 pg/g in 1940. After leaded petrol was taken into use in the 1940s, lead concentrations increased very rapidly, reaching levels as high as 400–500 pg/g in the 1970s. When the use of leaded petrol was gradually phased out between the 1970s and the late 1990s in North America and Europe, the lead concentrations in the ice layers decreased correspondingly (Murozumi *et al.*, 1969).

Lead concentrations in the oceans show a peak in the upper 500–1000 m because of the atmospheric deposition. In the Pacific Ocean, peak values of approximately 10 ng Pb/L are found (Schaule and Patterson, 1981), whereas levels in the Northern Atlantic (influenced by emissions from both the North American and the European continents) reach 40 ng Pb/L. Below 2000 m, lead concentrations typically range between 1 and 2 ng Pb/L.

8.8.1 Lead in Ammunition

The use of lead in ammunition has resulted in the dispersal of major quantities of this metal in the environment. In Denmark alone, approximately 800–1000 tons of lead was used for this purpose each year (until around 1990). Approximately 200 tons of these ended up in shallow, coastal areas. Occurrences of up to 10 lead shots/m^2 are not unusual, and in some fiords in Western Jutland, several hundred lead shots/m^2 have been found (Danish EPA, 1989). Extreme values of more than 2 kg/m^2 have been found in shallow waters in the vicinity of shooting ranges. The problem with the dispersal of lead ammunition in the environment through hunting has been attempted by exchanging lead shots with steel shot, and the use of lead shot is now forbidden in many countries. However, the degradation of the lead shots that are already in the environment proceeds fairly slowly, because the surface of the lead shot in the anaerobic zone of the sediments are covered with lead sulfides that have low solubility and prevent further degradation. In terrestrial soil, it is assumed that half of the lead shots will be degraded in 40–70 years, and that all of the lead shots have been degraded in 100–300 years (Danish EPA, 1989).

8.8.2 Effects in Birds and Mammals

Studies of rats (Mouw *et al.*, 1975), pigeons (Hutton, 1980), starlings (Grue *et al.*, 1986), and swallows (Grue *et al.*, 1984) living near trafficked roads while the use of leaded petrol was at its highest showed increased concentrations of lead in the investigated animals and lower ALAD activity than was seen in animals from more rural areas. The reduction in ALAD activity in the swallows did not lead to reductions in the concentrations of hemoglobin, and the breeding success of the animals was not affected (Grue *et al.*, 1984).

Ducks and swans normally ingest sand, gravel, and small stones that in the gizzard participate in grinding the food. If the birds instead ingest lead shot, the lead shots will dissolve in the gizzard and digestive system. The lead taken up causes lead poisoning, and for swans in Western Jutland, lead poisoning used to be the most common cause of death. Lead-poisoned birds initially have paralysis in the esophagus and digestive system, and at later stages in the legs, neck, and wings; concurrently, the sense of equilibrium is lost. One to two lead shots may be a lethal dose.

8.9 Manganese

Under oxidized conditions, manganese exists in a multitude of oxy- and hydroxide forms (e.g., vernadite -MnO_2, hausmannite Mn_3O_4, feitknechtite -MnOOH)

mainly a mixture of oxidation states III and IV (Burdige, 1993); the oxidized form of manganese is often referred to as MnO_2. Mn^{++} dominates under reduced conditions in the environment. Mn^{++} is the dominating species and $MnCl^+$, $MnSO_4^0$, and $MnCO_3^0$ also play a role (Mantoura *et al*., 1978).

Concentrations of dissolved manganese in the oceans are typically higher (~1 nmol/L) in the upper part of the water column than in the deep waters (0.25 nmol/L) (Landing *et al*., 1995), probably because of the impact of atmospheric deposition of manganese transported from the terrestrial environment (Statham *et al*., 1998). Manganese concentrations in coastal waters are generally higher (~one order of magnitude) than concentrations in the surface waters of the oceans (Hydes and Kremling, 1993). Sixty-nine percent of the manganese transported in the rivets of the world are precipitated in the estuaries (Salomons and Förstner, 1984).

Anthropogenic emission of manganese into the atmosphere is lower than the natural flux with a mobilization factor of 0.53 (Lantzy and Mackenzie, 1979).

Manganese plays an important role in oxidation-reduction processes in marine sediments (Burdige, 1993). Under oxic conditions, the manganese present in the upper few millimeters of the sediment is present in the oxidized form, but if the bottom waters (e.g., below thermo- or haloklines) are depleted in oxygen because of eutrophication, manganese is reduced and Mn^{++} leaks out of the sediment to the bottom waters where concentrations approaching 1 mg/L may be reached (Kremling, 1983). Mn^{++} dominates below an oxygen saturation of approximately 16% (Gerringa, 1991), and the reoxidation of Mn^{++} after an incident of oxygen depletion occurs fairly slowly (in the order of weeks) (Dehairs *et al*., 1989).

Increased concentrations of manganese have been found in benthic, marine organisms in areas affected by oxygen depletion (Baden *et al*., 1994; Baden and Neil, 2003; Eriksson and Baden, 1998), but the highest concentrations (approximately 1 mg/L) reached in the seawater are hardly toxic to marine organisms.

8.10 Mercury

8.10.1 Background Concentrations, Uses, and Emissions

Mercury concentrations in the oceans range between 0.7 and 1.1 pmol/L with no apparent concentration gradients between surface and deeper waters (Dalziel, 1995).

In modern times, mercury has been used for many different purposes (chloroalkali industry, seed dressers, antimicrobial agent in the paper industry, etc.), and until the early 1970s, approximately three quarters of the global use of approximately 10,000 tons use was released to nature.

Ecotoxicological and toxicological problems with the uses and releases of mercury were revealed both in the terrestrial and the aquatic environment during the 1960s—mainly in Swedish and Japanese investigations. The use of alkylmercury compounds as seed dressers resulted in elevated levels of mercury in terrestrial wildlife in agricultural areas—especially avian top predators such as hawks, owls, and harriers were affected (Berg *et al*., 1966; Johnels *et al*., 1979). Releases from industrial uses in the chloroalkali and paper industries led to contamination of the aquatic environment, the top predators again showing the highest degree of contamination (Johnels *et al*., 1967). Discharges to the Minamata Bay in Japan caused severe mercury poisoning in the local population after consumption of fish and shellfish from the bay (further described in Chapter 33).

Today, the discharge of mercury from industry has been considerably reduced, but the human mobilization of mercury during the last century has increased the emission of mercury to the atmosphere with approximately a factor of 3 (UNEP, 2002). An average sediment enrichment factor of 8.7 has been reported for lakes and coastal areas (Salomons and Förstner, 1984).

8.10.2 The Transformation of Mercury in Nature

In nature, mercury may be transformed between elemental mercury, divalent mercury, and methylmercury, and these transformations play a vital role both in the global cycling of mercury and for the accumulation and adverse effects of mercury in organisms.

8.10.2.1 Methylation

Inorganic mercury may in nature be transformed to methylmercury by both abiotic and biotic processes, and the biological transformation is believed to be the more important. Most of the knowledge on methylation processes has been obtained from studies in freshwater systems.

Several different types of microorganisms are capable of methylating Hg(II), and the methylation takes place especially at the interface between oxic and anoxic zones in nature—typically in the upper parts of sediments where the oxygen gradient is sharp. Sulfate reducing and methanogenic bacteria are capable of methylating inorganic mercury, and in some environments the quantitatively most important methylation is carried out by these organisms.

The degree of methylation in aquatic ecosystems depends on a number of different factors:

1. Temperature

   The higher temperature, the higher methylation.

2. Dissolved organic material
   a. If the dissolved organic material can be used as an energy source by the microorganisms, the rate of metabolism in these may be increased, which also leads to an increase in the methylation rate.
   b. If the dissolved organic material binds Hg(II)—which is the substrate in the methylation process—the rate of methylation may decrease with increasing concentration of organic material.
3. pH

   The net methylation rate generally increases when the pH value decreases. The rate of both methylation and demethylation may increase with decreasing pH, but because the rate of methylation most often increases more than the rate of demethylation, the net methylation rate will increase.

4. The concentration of bioavailable Hg^{++}:

   The larger the Hg^{++} concentration, the higher rate of methylation.

5. Complex binding ligands (both organic and inorganic, see Figure 1):

The higher amount of ligands, the lower rate of methylation.

Either methylmercury (CH_3–Hg^+) or dimethylmercury (CH_3–Hg–CH_3) is formed in the methylation process. At neutral and low pH, methylmercury (as CH_3–Hg^+Cl^-) is the most stable of the two compounds, whereas dimethylmercury is most stable in an alkaline environment. The pH value in seawater is approximately 8.2 (and thereby higher than in most freshwater systems), and in seawater, the formation of dimethylmercury plays a role, although it is of less importance than the formation of methylmercury in most freshwater systems. Dimethylmercury is fairly volatile, and it may evaporate to the atmosphere. Dimethylmercury is generally found at lower concentrations in the upper layers of the oceans than in the deeper, and this may be because of the evaporation to the atmosphere.

8.10.2.2 Demethylation

Certain types of bacteria are capable of demethylating methylmercury. The demethylation may take place in both aerobic and anaerobic bacteria, but the most quantitatively important demethylation seems to take place in the aerobic environment. The demethylation has been demonstrated both in the sediment and water phase of lakes and it has, likewise, been shown that freshwater algae are capable of degrading methylmercury.

8.10.2.3 Net Methylation

The amount of methylmercury present in a specific ecosystem will, therefore, not only depend on the rate by which methylmercury is synthesized, but rather the equilibrium between methylation and demethylation processes.

The total concentration of mercury in seawater is typically ranging from 1–5 ng/L. The fraction that methylmercury constitutes of the total mercury content in the seawater may vary somewhat, but it is generally in the order of 1%; in freshwater, the fraction of methylmercury is typically somewhat higher.

8.10.2.4 Reduction of Mercury

In the aquatic environment, Hg^{++} may be reduced to elemental mercury that can evaporate to the atmosphere. The reduction of Hg^{++} proceeds both abiotically and biotically—the latter probably predominantly in connection with enzymatic activity on the surfaces of unicellular algae (Poulain *et al*., 2004).

8.10.2.5 Oxidation of Elemental Mercury

Elemental mercury is relatively volatile, and it evaporates from both soil surfaces and the aquatic environment to the atmosphere, where the mercury has a residence time of approximately 1 year. The elemental mercury may be oxidized to Hg^{++} in the atmosphere with the participation of ozone, and the divalent mercury is predominantly bound to particles in the atmosphere (Morel *et al*., 1998).

8.10.3 The Global Mercury Flux

Mercury exists in nature in equilibrium between the elemental mercury, Hg(II) salts, and organic mercury compounds, especially methylmercury, and the overall flux of mercury between soil, atmosphere, and oceans is especially related to mercury's shift in oxidation state between elemental and divalent mercury.

The evaporation of mercury to the atmosphere is larger from soil than from the oceans, and because the fraction of land as well as industrial activity is largest in the northern hemisphere, higher mercury concentrations are generally found in the atmosphere of the northern hemisphere than in the atmosphere of the southern hemisphere (Fitzgerald and Mason, 1997; Mason *et al*., 1994).

The emissions of mercury from industrialized areas are decreasing in Europe and North America but increasing in South East Asia (UNEP, 2002).

Even if the Arctic comprises only 1–2% of the earth's total surface, it is estimated that 6–10% of the total anthropogenic emission of mercury to the atmosphere is deposited there. In the months of spring and summer, the combination of ultraviolet light, ozone, bromine, and low temperature results in a more efficient transformation of the elemental mercury of the atmosphere to reactive mercury species (that are deposited) than at other locations on the earth (AMAP, 2002).

8.10.4 Uptake of Mercury in Organisms and Transport in Food Webs

As a general rule, organisms take up and retain methylmercury far more efficiently than inorganic mercury, and the relatively high content of mercury at the highest trophic levels of aquatic food chains is due to incorporation of organic mercury into the organisms at the lower trophic levels and subsequent transport in the food chains (Kraepiel *et al*., 2003; Morel *et al*., 1998).

The uptake of inorganic mercury in unicellular algae typically takes place by Hg^{++} absorbing to the surface of the algal cell without penetrating the surface. Methylmercury, on the other hand, penetrates the surface of the algae and is thereby taken up into the intracellular parts of the cell (Watras and Bloom, 1992; Watras *et al*., 1998). Mercury concentrations in phytoplankton organisms are typically 10^5–10^6 times higher than the concentrations in the surrounding water, the bioconcentration factor for methylmercury generally is higher than that for inorganic mercury (Watras *et al*., 1998).

Invertebrates generally take up and retain organic mercury more efficiently than inorganic mercury. Shrimps, *Crangon crangon*, exposed to the two mercury species in food for 3 weeks assimilated approximately 75% of the ingested organic mercury and only 4% of the inorganic mercury, and uptake of organic mercury from water was far more efficient than uptake of inorganic mercury (Riisgard and Famme, 1986).

Fish generally assimilate organic mercury efficiently from the food, and retention times for organic mercury may be very long as illustrated in experimental studies with rainbow trout in which half-lives of more than 200 days were found (Giblin and Massaro, 1973; Ruohtula and Miettinen, 1975). In piscivorus fish in the top of food chain, methylmercury typically constitutes more than 90–95% of the total mercury content of the fish.

In aquatic food chains, the methylmercury concentration that the top predators attain will depend on the amount of methylmercury that enters the food chain at the lower levels, because the food (also in predatory fish) is the main source for uptake of mercury. This underlines that the rate by which inorganic mercury in a specific ecosystem is methylated, participates in determining which total mercury concentrations will be attained by the top predators in the system.

The fact that the mercury concentration in fish typically increases with increasing size (and age) of the fish is, of course, partly a result of the efficient uptake and retention of methylmercury, but the fact that the food preferences of an individual fish (and thereby its trophic level in the food chain) changes with size, also play a role. As an example, small perches will feed mainly on plant material (with a low mercury content), whereas larger perches feed on zooplankton with a somewhat higher mercury content. As adults, the perch feed on other fish (with an even higher mercury content), and this means that the mercury dose that the perches ingest with the food increases with the size and age of the fish (Meili, 1997).

It is known from investigations in lakes that the main fraction of the total methylmercury burden in such ecosystems is bound in the biota—especially at the upper levels of the food chains. Generally, the fish in lakes with a low pH and/or alkalinity show the highest concentrations of methylmercury (Gilmour and Henry, 1991; Spry and Wiener, 1991). Contrary to that, the largest pool of inorganic mercury is bound in the sediments of the lakes (Meili, 1997).

Specific problems are associated with metal contamination of the tropical zones, where regulations concerning prevention of environmental pollution are not always followed. Unregulated gold mining has resulted in extensive freshwater mercury pollution, resulting in contamination of fish and birds. Biomagnification has been demonstrated from gastropod molluscs (*Ampullaria* sp) to accipiters (*Rostrhamus sociabilis*) and from invertebrates to fish, birds, and humans (Alho and Vieira, 1997; Pfeiffer *et al*., 1993).

8.10.5 Effects of Mercury in Wildlife

Fish may reach relatively high concentrations of methylmercury in their tissues (easily ~1 μg Hg/g wet weight in low-alkalinity freshwater systems), so high that adverse effects might be predicted in some circumstances. Sublethal adverse effects may be seen in the most sensitive species at body burdens of methylmercury exceeding 1.4 μg Hg/g wet weight, whereas lethal effects are observed in some species at whole body concentrations of 5–10 μg Hg/g wet weight (Spry and Wiener, 1991).

Canadian investigations have shown that the reproduction in fish eating birds—especially the effects on the common loon *Gavia immer*—are affected negatively

in lakes in which the contamination of the fish with methylmercury is high (Chan *et al.*, 2003; Scheuhammer and Blancher, 1994). The adverse effects are related to effects on the nervous system, and the breeding behavior is affected. The effects begin to appear when the mercury concentration in the food of the birds exceeds 0.3 µg Hg/g wet weight (Scheuhammer, 1991); more than this value is widely occurring in Canada, as well as in other countries.

Exposure to methylmercury in the laboratory is capable of reducing shell thickness in the eggs of domestic fowls (Lundholm, 1987; 1995) by affecting the overall calcium metabolism of the bird (a mechanism somewhat different from the one exerted by DDE). Earlier studies, however, showed no such effect of organic mercury in mallards (Haegele *et al.*, 1974) and methylmercury in ring doves and American kestrels (Peakall and Lincer, 1972), and it is questionable whether exposure to methylmercury was a participating agent in the widespread eggshell thinning observed among predatory and fish-eating birds during the 1960s.

8.10.6 Implications for Human Health

Predatory fish—both in the marine and freshwater environment—accumulate methylmercury to fairly high levels and mammals—such as seals, dolphins, and some whales—that feed on predatory fish accumulate methylmercury to even higher levels. Polar bears that feed on seals again attain even higher levels.

Humans who rely on fish or predatory mammals at the top of aquatic food chains as their main food source may be exposed to high levels of methylmercury in their diet—levels that easily exceed the limits recommended by WHO.

It is beyond the scope of this chapter to cover the details of human exposure to and the effects of mercury that are described in Chapter 33.

8.11 Molybdenum

Molybdenum is an essential element with special importance for plants. It exists in seawater in the hexavalent state (as molybdate); surface concentrations of 0.1 µmol/L (Collier, 1985).

Molybdenum is emitted to the environment through combustion of fossil fuels (up to 300 mg/kg in lignite), and fly ash may contain up to 60 mg/kg (Davis, 1991). The mobilization factor for molybdenum is as high as 45 (Lantzy and Mackenzie, 1979).

Ecotoxicological problems with emitted molybdenum have especially been associated with effects on grazing livestock (Davis, 1991).

8.12 Nickel

Nickel concentrations in the ocean vary from 2–3 nmol/L in the surface waters to 5–10 nmol/L in the deeper waters (Bruland, 1980; Yeats *et al.*, 1995). $NiCO_3^0$ is the dominating species in seawater, followed by Ni^{++} and $NiCl^+$ (Mantoura *et al.*, 1978).

Nickel is emitted into the atmosphere, and a mobilization factor of 3.5 has been estimated (Lantzy and Mackenzie, 1979). Ninety-two percent of the nickel transported in the rivers of the world is precipitated in the estuaries, and an average sediment enrichment factor in lakes and coastal areas of 1.3 has been found (Salomons and Förstner, 1984).

8.13 Selenium

Concentrations of total dissolved selenium in ocean water typically vary from 0.5 nmol/L in the surface layers to 1.0–1.5 nmol/L in the deeper layers (Cutter and Cutter, 1995). In the photic zone of the upper few hundred meters, organic selenium compounds (Se(-II) dominate, whereas selenite and selenate exist in equilibrium at depths below approximately 300 m at a ratio of approximately 0.65 (Se(IV)/Se(VI)) (Cutter and Cutter, 1995).

Selenium concentrations in soils show large variability, leading to deficiency symptoms in terrestrial organisms in some parts of the world and toxic symptoms in others.

Selenium is emitted to the environment especially through combustion of fossil fuels, and the anthropogenic emission to the atmosphere was estimated to 14,000 tons (Lantzy and Mackenzie, 1979). The natural emission was estimated to approximately 3400 tons, with only 410 tons bound in particles (Lantzy and Mackenzie, 1979).

Mobilization of naturally occurring selenium as a result of human activity may be seen under special circumstances. In an interaction between fairly complicated geological, chemical, and hydrographical conditions, intensive irrigation in California led to mobilization of soil selenium that ended up in surface waters in the Kesterson Reservoir (Hamilton, 2004); teratogenic effects were seen among the water birds of the reservoir, and reproduction among the fish was affected.

8.14 Silver

In the oceans, the depth profile for silver shows typical nutrient-like characteristics (Flegal *et al.*, 1995; Ndung'u *et al.*, 2001; Zhang *et al.*, 2001), with low concentrations (0.7 pmol/L) in the surface water and

higher concentrations (7 and 20 pmol/L in the Atlantic and Pacific, respectively) in the deeper waters. The concentrations of silver are closely correlated to silicate concentrations (Flegal *et al*., 1995).

Silver is emitted into the aquatic environment from photographic industries and mining activities and into the atmosphere by combustion of fossil fuels, leading to a relatively high mobilization factor of 83 (Lantzy and Mackenzie, 1979).

The accumulation and toxicity of silver has been reviewed by (Ratte, 1999).

8.15 Tin

8.15.1 Inorganic Tin

Tin exists in seawater as Sn(II) and Sn(IV). Surface and deep seawater concentrations of 0.5–5 and 0.2 ng/L, respectively, have been reported (Bruland, 1983).

Tin has been discharged into the environment from tin mining, and elevated concentrations of tin have been registered in sediment dwelling organisms in coastal areas affected by drainage from operating and abandoned tin mines (Bryan *et al*., 1980). The anthropogenic mobilization factor for tin is 8.3 (Lantzy and Mackenzie, 1979).

However, the largest ecotoxicological problems caused by tin compounds are associated with the use of organic tin compounds and especially the use of tributyltin in antifouling paints.

8.15.2 Tributyltin (TBT)

8.15.2.1 TBT as Antifouling Agent

Since man began to use ships as means of transportation, seafarers have had to fight fouling of the water-covered parts of the ships. The fouling with algae and barnacles may affect speed and stability, whereas attacks by shipworm (which is a mussel species) and other boring animals might destroy the woodwork of the ships. As far back as 300 years BC, there were descriptions of ships that had the water-covered parts protected against fouling with plates of lead. In the 17th and 18th century, copper plates were used for the same purpose, and around 1830, painting of ships with copper oxide–containing paints was initiated.

Many different toxic compounds (organic mercury compounds, arsenic compounds, etc.) have been used besides copper oxide, and in the 1960s, the use of organic tin compounds—especially tributyltin oxide—in ship painting was initiated.

Because of their broad versatility and high efficiency, the organic tin compounds have been the most widespread components to protect ships against fouling during the 1970s and 1980s in many countries, and they have, likewise, been used to prevent fouling of equipment in marine aquaculture.

However, tributyltin (TBT) is a highly toxic chemical, and the adverse effects of the chemical reaches far outside the ship hulls in the aquatic ecosystems.

8.15.2.2 Use and Dispersal of TBT

Organic tin compounds are used for many purposes, but of the approximately 35,000 tons that were used globally in the middle of the 1980s, 9% (in the form of TBT) was used as antifouling chemical in paints for ships. Approximately two thirds were used (mainly in the form of dibutyltin) as additive in PVC (Fent, 1996).

The TBT is formulated in the ship's paint in a way such that a gradual liberation to the water phase takes place. In areas with intense leisure time boating, a marked seasonal variation in the TBT concentrations of the water and sediments is observed; the concentration increases during summer when the leisure time boats are in the water (Blanck and Dahl, 1996). The TBT concentrations are highest around harbors and major shipping routes.

8.15.2.3 Uptake and Metabolization of TBT

The chemical character of TBT is dominantly nonpolar (the *n*-octanol/water partitioning coefficient is approximately 5600), and the chemical is accumulated in aquatic organisms to concentrations which for fish typically are approximately 200 times higher than the concentration in the ambient seawater, whereas molluscs such as snails and mussels may concentrate the compound to concentration factors as high as 50,000–100,000. Equilibrium between TBT in the seawater and the tissues is reached after 2–3 months (Bryan *et al*., 1987). Snails and mussels have a low capacity to metabolize TBT, and it is lost from dog whelks *Nucella lapillus* with a half-life of 50–100 days.

Higher organisms may metabolize TBT by hydroxylating and subsequently eliminating the butyl groups one by one such that the TBT is metabolized to dibutyltin and further to monobutyltin and inorganic tin, which are all less toxic than TBT (Lee, 1991).

In seawater, TBT is relatively quickly degraded by bacteria and algae to mono- and dibutyltin (Lee *et al*., 1989). The half-life for TBT in seawater is in the range of days to weeks, whereas the half-life in sediments may be up to 6 months or longer (Seligman *et al*., 1986).

8.15.2.4 Adverse Effects of TBT in the Marine Environment

Of the species investigated so far, molluscs (gastropods, mussels) seem to be the most sensitive toward TBT.

8.15.2.4.1 Effects on Mussels and Oysters During the 1970s, it was observed in French (Alzieu, 1991) and English (Thain *et al*., 1986) oyster aquacultures that oysters with an abnormally thick shell occurred increasingly frequently. Oysters with an abnormal shell development had poor growth, and the soft part portion became so poor that these oysters could not be sold for human consumption. Because the mortality among the oyster spat in the years 1977–1979 was very high and because the frequency of abnormal shell development and larvae mortality was highest in the vicinity of harbors and yachting harbors, TBT was suspected of causing this damage.

Investigations in the laboratory showed that TBT—besides the effect on shell formation in adults—has an extremely adverse effect on the reproduction in oysters and different species of mussels. When the oyster larvae after their free-swimming stage attach to the substratum to develop to oysters, they are very sensitive to TBT. Twenty nanograms TB/L inhibit the growth of the smallest oyster spat (Thain *et al*., 1986), whereas the larger spat are slightly more resistant.

8.15.2.4.2 TBT's Effect on Sexual Development in Snails Snails belonging to the families *Buccinidae* (i.e., the dog whelk *Nucella lapillus*) and *Nassidae* are normally gonochoristic (each individual is either male or female throughout life). In the late 1960s, female dog whelks were found around the Marine Biological Laboratory in Plymouth, which had developed obvious male sexual characters (i.e., penis and vas deferens) (Blaber, 1970). At the same time, an analogous phenomenon was found in the American snail species *Nassa obsoletus* (Smith, 1971; 1980; 1981), and here it was established that the cause for the development of the imposed male sexual characters was exposure to TBT. In these families of snails, the formation of imposed male sexual characters in the females is termed *imposex* (Smith, 1971). Imposex has now been registered in many species of snails worldwide; the number is approaching 200.

The development of imposex in females is divided into seven stages (Gibbs *et al*., 1987): Stage 0, normal female; Stage 1, formation of vas deferens initiated; Stage 2, penis development initiated; Stage 3, vas deferens 50% developed; Stage 4, vas deferens fully formed; Stage 5 vas deferens/prostate tissue begin to block the vaginal opening; Stage 6, the capsule gland contains aborted egg capsules.

Although the development of imposed male sexual characters does not seem to affect the ability to reproduce in *Nassa obsoletus* (Smith, 1980; 1981), the female dog whelks may end up sterile in severe cases, because prostate-like tissue around the vas deferens blocks the vaginal opening of the female. It is assumed that sterile females may die because they abort the eggs (that cannot be liberated via the blocked vaginal opening) in the body cavity (Gibbs *et al*., 1987).

Dog whelks are very sensitive to TBT, and in adult females concentrations as low as 5 ng TBT/L may induce growth of penis. Young and not yet sexually mature females of dog whelks are even more sensitive than the adult individuals and exposure to less than 1 ng TBT/L in nature seems to induce growth of penis and vas deferens tissue in females (Gibbs *et al*., 1987).

Imposex occurs not only in coastal areas but also in open marine areas with major shipping routes (Ten Hallers-Tjabbes *et al*., 1994; 2003) (i.e., in the Danish Belt Area and Kattegat no normal females of the whelk *Neptúnea ántiqua* were found in a recent survey) (Strand and Jacobsen, 2002).

In periwinkles (e.g., *Littorina littorea*) and mud snails (*Hydrobia* sp.) the masculinizing effects of TBT are exerted in a slightly different manner than in the whelks, and in these species the condition is termed *intersex* (Bauer *et al*., 1995). Intersex in the periwinkles is divided into four stages. A penis is developed in the female only in Stage 4 (which is very rarely observed). The periwinkles are far less sensitive to TBT than the whelks.

8.15.2.4.3 Effects in Populations Many of the English populations of dog whelks declined in numbers during the 1970s and 1980s, and it is assumed that population sizes start to be affected when between 20 and 40% of the females have become sterile (Gibbs *et al*., 1991; Langston *et al*., 1990; Spence *et al*., 1990).

8.15.2.4.4 The Mechanism of Action for TBT Several mechanisms of action—that do not mutually exclude each other—have been suggested for TBT's interference with sexual development in gastropods.

It has been proposed that the mechanism of action for TBT is related to the aromatase inhibiting effect of the chemical (Bettin *et al*., 1996). There are also indications that exposure to TBT (albeit at fairly high exposure concentrations) reduces the excretion of testosterone by inhibiting the sulfate conjugation of the testosterone (Ronis and Mason, 1996). Regulation of free testosterone levels may, in certain invertebrates, be associated with the formation of testosterone fatty acid esters (Gooding and LeBlanc, 2001), and TBT affects the equilibrium between free and bound testosterone (Janer *et al*., 2005; Santos *et al*., 2005). TBT accumulates in gastropods in especially high concentrations in the nervous system (Bryan *et al*., 1993), and it has been proposed that TBT exerts its effect through interaction with the formation of neuropeptides involved in

regulation of steroid synthesis (Oberdorster *et al*., 1998; 2005; Oberdorster and Clellan-Green, 2000; 2002).

Besides the effect on hormonal regulation, TBT has other toxicological properties (TBT uncouples the production of ATP in the mitochondria and affects the immune system).

8.16 Vanadium

Vanadium exists in seawater mainly as vanadates. Vanadium is emitted to the environment especially from combustion of fossil fuels, and the mobilization factor is 3.2 (Lantzy and Mackenzie, 1979).

8.17 Zinc

In the oceans, zinc concentrations show the typical nutrient-type profile with concentrations below 0.5 nmol/L in the surface waters and concentrations between 2 and 10 nmol/L in the deeper waters (Bruland, 1980; Landing *et al*., 1995), the Pacific generally showing higher concentrations than the Atlantic. $Zn(OH)_2^0$ and Zn^{++} are the dominating species in seawater (Long and Angino, 1977; Zirino and Yamamoto, 1972).

Zinc is emitted into the atmosphere through combustion processes and metal smelting, with an anthropogenic mobilization factor of 23. Zinc is discharged into the aquatic environment from mining activities and a variety of industrial processes (i.e., galvanizing). Slightly more than half of the zinc transported by the rivers of the world is precipitated in the estuaries (Yeats and Bewers, 1982), and an average sediment enrichment factor of 3.5 in lakes and coastal areas has been reported (Salomons and Förstner, 1984).

8.18 Radioactive Metals

Radioactive metals are produced in various nuclear processes, and they have been released into the environment during nuclear weapons testing, accidents at nuclear power plants, and from nuclear fuel reprocessing plants.

8.18.1 Cesium

^{134}Cs and ^{137}Cs are major fission products in nuclear processes, and with their half-lives of 2.1 and 30 years, respectively, they constitute an important source of contamination of the environment with radioactivity. Major releases have come from nuclear weapons testing, from the nuclear fuel reprocessing plant at Windscale, UK, and from the Chernobyl accident at which 85 and 46×10^{15} Bq of ^{137}Cs and ^{134}Cs, respectively, were emitted (EEA, 2003).

Cesium has a low tendency to adsorb to particles in water, and discharges of ^{137}Cs from Windscale could be traced in seawater in the Irish Sea, north of Scotland, along the Norwegian coast around Svalbard, not reaching "background concentrations" (originating from global fallout from nuclear weapons testing) until the current after 6–8 years and 5000–7000 km reached Northeast Greenland (Hallstadius *et al*., 1986).

Atmospheric transport of ^{137}Cs and fallout may create problems in especially sensitive ecosystems far away from the sites of emission. Oligotrophic freshwater systems are among such sensitive ecosystems. ^{137}Cs is taken up into organisms through the same routes as potassium, and the ability of cells to transport potassium against concentration gradients to high intercellular concentrations also leads to a fairly high bioconcentration of radioactive caesium. After the Chernobyl accident in 1986, a considerable amount of ^{137}Cs was deposited in the northern and central parts of Scandinavia and in a large number of Swedish lakes, the ^{137}Cs content of the fish exceeded the limits (1500 Bq/kg) for human consumption (Hakanson *et al*., 1992).

On deposition from the atmosphere, ^{137}Cs is concentrated in lichens that constitute an important fraction of the food of reindeers during the autumn and winter seasons. Fallout from nuclear weapons testing, and especially the Chernobyl accident, resulted in ^{137}Cs activities in reindeer in certain Scandinavian areas that vastly exceeded the limits for human consumption (Ahman and Ahman, 1994). Fungal mycelia assimilate ^{137}Cs very efficiently from the soil, and mushrooms may be an important source for ^{137}Cs uptake in ruminants such as roe deers (Zibold *et al*., 2001) and goats (Hove *et al*., 1990). Predators with roe deer and reindeer as their main prey, such as lynx, also accumulated ^{137}Cs to high activities after the Chernobyl accident (Ahman *et al*., 2004).

8.18.2 Polonium

Polonium has no stable isotopes, but ^{210}Po is one of the decay products in the decay series of the naturally occurring, radioactive isotope ^{238}U. ^{210}Po has a half-life of 138.4 days, and it is an α-emitter. In the marine environment, some organisms are naturally exposed to very high doses of radiation from ^{210}Po. Polonium is concentrated in phytoplankton to bioconcentration factors of $3–7 \times 10^4$ (Fisher *et al*., 1983c), and the isotope is taken up especially from food in crustaceans; it is accumulated in the midgut gland or hepatopancreas of the animals (Cherry and Heyraud, 1982). In some crustaceans, this results in very high radiation doses. The highest recorded doses have been identified in pelagic

penaeid shrimps receiving yearly doses as high as 3.1 sievert for the entire animal and 26 sievert in the midgut gland (Heyraud *et al*., 1988). These values represent the highest doses of naturally occurring radioactivity received by any organism.

8.18.3 Strontium

^{90}Sr is a major fission product in nuclear processes and with a half-life of 28 years, ^{90}Sr was a constituent of the global radioactive fallout after the intense nuclear weapons testing in the 1960s. Because of its similarity with calcium, ^{90}Sr accumulated in milk and in bone (Bartlett *et al*., 1972).

8.18.4 Transuranic Metals

Transuranic elements such as plutonium, americium, and curium are produced by neutron activation in nuclear processes. Some of these isotopes have long half-lives, and they are α- emitters with a high toxicity.

Emission from nuclear weapons testing and nuclear fuel reprocessing plants has led to contamination of, for example, the marine environment. The aquatic chemistry of plutonium is very complicated, but both plutonium and the trivalent americium are taken up into marine organisms to high bioconcentration factors; this is true for both phytoplankton (Fisher *et al*., 1983a; 1983c), zooplankton (Fisher *et al*., 1983b), and benthic bivalves (Bjerregaard *et al*., 1985).

Contamination with plutonium from the previous emissions from Windscale could be traced in water and seaweeds in the currents north of Scotland and up along the Norwegian coast (Hallstadius *et al*., 1986).

CHAPTER

14

Risk Assessment*

GUNNAR F. NORDBERG AND BRUCE A. FOWLER

ABSTRACT

Risk assessment for metallic substances usually follows the generally accepted framework format for risk assessment for all toxic substances, which involves (1) exposure assessment, (2) hazard identification, (3) assessment of dose-response relationships, and (4) risk characterization. The importance of risk communication is also addressed. Risk assessment/risk communication is of particular relevance for metals and metalloids, because all living organisms are exposed to these elements, and metals such as lead, cadmium, and mercury and the metalloid arsenic have been responsible for many human poisonings and even deaths. It is, hence, imperative that readers of this handbook have a firm perspective on the exposure levels of metallic substances that produce adverse health effects and the various risk assessment approaches that have been used and are evolving to protect the health and well-being of living organisms. Biomonitoring approaches, identification of toxic metallic species for hazard identification, dose–effect relationships, construction of dose-response curves, and the development of benchmark doses for various metallic species are discussed in relation to protecting sensitive subpopulations, because not all individuals within a general population are at equal risk for toxicity. Risk characterization using modern biomarkers that are capable of detecting early cellular effects to low-dose exposures to metallic substances will play an increasingly important role in assessing risk from exposure to this class of toxic substances on an individual or mixture basis. The issue of metal/metalloid-induced carcinogenesis is of ever increasing importance, because many of the elements associated with this cellular outcome produce a number of early cellular effects, including formation of reactive oxygen species (ROS) and apoptosis. Finally, the issue of risk communication/risk management is of great importance, because these issues are critical to addressing the health concerns of exposed populations and the practical, ethical, and financial issues related to reducing hazardous exposures to metallic substances.

1 INTRODUCTION

Risk is a basic and important concept in toxicology and environmental health. The use of scientific information to identify and quantitatively estimate human health risk (i.e., the probability of occurrence of adverse effects that may be caused by exposure to metals) is fundamental to risk assessment in this field.

During the last decades, principles for the assessment of risks to human health from exposure to chemicals have been generally agreed, and four components of a risk assessment are usually included (WHO/IPCS, 1999). The USEPA has also recently published a Framework for Inorganic Metals Risk Assessment (2006a), which addresses a number of cross-cutting issues, such as variability in susceptibility including age, gender, current damage or disease, genetic polymorphisms, and metal mixtures.

The four steps in risk assessment are exposure assessment, hazard identification, assessment of dose-response relationships, and risk characterization. These

*Partly based on the chapter "Risk Assessment" by the late Dr. Lars T. Friberg in the 2nd edition of this Handbook.

four components will be described in this chapter, with a focus on how they can be applied to metals and their compounds. Risk assessment documents for several metals, metalloids, and metal compounds have been published by the World Health Organization in its International Program on Chemical Safety (e.g., WHO/IPCS, 2001). Weight-of-evidence evaluations of carcinogenicity of metals and compounds are published by the International Agency for Research on Cancer (e.g., IARC, 2006a). There are also Union and National criteria documents.

As a result of risk assessment, further steps are often required in terms of risk control and risk management. Risk communication is an increasingly important component of these processes. It comprises the interaction between risk assessors and those concerned (i.e., industrial workers for occupational exposures and the general public for environmentally distributed substances). Risk assessment of widespread substances such as metals often requires careful consideration and judgment of available scientific information to reach widely accepted recommendations.

To perform in-depth risk assessments of a large number of chemical substances is a time-consuming process. It has recently been suggested that simplified approaches may be used, but they are very uncertain and cannot be recommended as a replacement for actual risk assessments. A valuable step for substances with limited quantitative data is to perform the hazard identification step, which may be sufficient for labeling of substances for hazards such as flammability, acute toxicity, irritation, sensitization, carcinogenicity, and reproductive toxicity. Readers of this handbook will see that the information available on the toxicology of metals and their compounds varies widely among metals. Only for a limited number of the metals is there adequate information to make reliable dose-response assessments for humans. In some regions of the world, legislation is being advanced requiring producers and importers of chemical substances, including metals and their compounds, to provide specific data relevant for risk assessment, and we hope that such information provided by this and other mechanisms will give us a basis for improved safety in the use of metals that are presently incompletely investigated.

To perform an adequate risk assessment, there is a need for the responsible scientists, as well as for administrators, to consider certain conceptual and other issues. Some of the major issues of importance for exposure and dose assessment, hazard identification, dose-response estimation, and risk characterization are discussed in the following. The reader is referred to Chapter 9 for a discussion of additional considerations in risk assessment of essential metals.

2 EXPOSURE AND DOSE ASSESSMENT

A description of exposure to the metal compound being considered is a very important component of risk assessment. In combination with results of dose-response analysis, it forms the basis for risk characterization (Section 5).

2.1 Exposure and Dose Terminology

Although efforts have been made to distinguish the terms "exposure" and "dose," there is still no general recognition of such special usage, and the terms usually describe similar conditions as also discussed in Chapter 4. The term "exposure" means that a person or group of persons is exposed to one or more chemical agents such as a metal, and sometimes this term is reserved for the external contact between the human being and the environment. This is the main focus of the WHO/IPCS document 214, where it is said that human exposure assessment is to identify and to define the exposures that occur, or are anticipated to occur, in human populations. This can be a complex endeavor requiring analysis of many different aspects of the contact between people and hazardous substances (WHO/IPCS, 2000). However, in cell biology, the term exposure is also used to describe exposure of cells and subcellular organelles *in vitro* to solutions of metal compounds. The term "dose" originates from pharmacology and means the amount of drug given to a patient. A proportion of the dose is absorbed systemically; this is the absorbed dose, also named internal dose (see also Chapter 3). A fraction of the internal dose is transferred to the organ in the body suffering damage at relatively low exposures (i.e., the critical organ). The concentration of a metal compound in the critical organ is of considerable interest in risk assessment of metal exposures as discussed further in Sections 2.4, 2.5, and 4.1.2. The assessment of metal exposure and dose, thus encompasses primarily the contact between human beings and metals in surrounding media such as air, drinking water, food, and media in contact with the skin but may also include estimation of internal dose and accumulation in critical organs. This section will deal with exposure and dose assessment in this broader scope.

2.2 Exposure, Applied/Inhaled Dose, Daily Intake

Exposure assessment will provide a description of the exposure, often taken as external exposure, by exposure route and its distribution in time and space.

Exposure in terms of concentration of metal/metalloid or its compounds in inhaled air, in drinking water, in food, or in media contacting the skin can be measured or estimated from mathematical models describing concentrations in exposure media from emissions of pollutants into air or water. Such models are often available as computer software for application in risk assessment (e.g., EUSIS, the European Union system for the evaluation of substances) (Vermeire *et al*., 2005). Actual measurements of concentrations of metals and their compounds in air are also performed both in the general environment and particularly in workroom air. Concentrations of metals in drinking water and recreational waters are recorded in environmental monitoring programs.

Emission to air or water can be measured or estimated from the inherent chemical properties of the metal compound in question, patterns of usage, natural occurrence, and waste disposal. Often industrial emissions and other point sources releasing metals into the environment are regularly monitored.

The daily oral exposure dose (or orally applied dose; cf WHO/IPCS, 1999) or daily oral intake of a metal is the amount of metal taken into the gastrointestinal tract. The gastrointestinal intake can be measured by determinations of the amount of metal in portions of food of the same composition as those consumed, the so-called double portion method. It can also be estimated from records of consumption and determinations of metal concentration in various foodstuffs and for metals with limited uptake in the gastrointestinal tract by determinations of the amount of metal in feces, successfully used, for example, for cadmium (cf Chapter 23). When there is exposure through inhalation, the inhaled dose can be estimated from measurements of the metal or its compound in air in combination with estimations of lung ventilation volume based on time of exposure and work load. The use of different types of sampling procedures for estimating air levels of chemical substances such as area sampling and personal sampling should be guided by the purpose of the study to be performed. If source identification is important, stationary sampling may be preferred, whereas personal sampling will be chosen if an estimate of inhaled doses of individuals is desired (WHO/IPCS, 2000). The importance of quality control in sampling and chemical analysis is dealt with in Berglund *et al*. (2001) and in Chapters 2 and 4.

2.3 Absorbed Dose, Internal Dose

As mentioned in the foregoing text, the absorbed dose or internal dose is the amount of metal taken up into the body. When available, data on the internal dose, and particularly the dose in the critical organ, are very useful when describing dose-response relationships (see Section 4). Internal dose can be calculated based on information about absorption. Gastrointestinal absorption of various metal compounds varies widely from almost no absorption to almost 100% absorption as discussed in Chapter 3. In that chapter uptake of metal compounds through inhalation is also described. The great importance of water solubility for uptake of gaseous metals and metal compounds is pointed out, as well as the importance of solubility in tissue fluids and particle size for metals occurring in aerosol form in air.

Internal dose can be estimated from concentrations of metals in blood, plasma, whole blood, or urine based on knowledge about the toxicokinetics of the metal compound considered. For compounds with short biological half-times and excretion through urine, there is a peak concentration in plasma concentration and a subsequent peak in urinary concentration. Other excretion patterns give rise to other relationships between plasma, whole blood, and urine concentrations. Other media used for biological monitoring are saliva, hair, nails, and *in vivo* determinations of metals in bone, kidney, liver, and other body organs as described in more detail in Chapter 4.

2.4 Dose/Concentration in Critical Organ and Critical Target

The best dose estimate is the concentration of metal at the target molecule that determines the expression of adverse effect. It is seldom possible to measure this concentration. Second best is to estimate the concentration in the organ or tissue where an adverse effect is expressed at relatively low exposures (i.e., the critical organ for the critical effect). For certain metals, for example, cadmium, whose critical effect is exerted on the kidney, *in vivo* determinations of levels of cadmium in this organ can be performed by *in vivo* neutron activation analysis (cf Chapter 23). Such measurements provide an extremely good dose estimate for risk assessment. However, because of the high cost and limited precision in such analyses, they are not used routinely in occupational and environmental health. Indeed, risk estimates are in many studies based on other biomarkers as described in the sections to follow.

2.5 Use of Biomarkers in Estimating Concentration in Critical Organ and Critical Target Dose

A possibility to study the accumulation of chemical substances in exposed people is by the use of blood

and urine samples as an indicator of exposure and for risk estimations. Such biological monitoring takes into consideration interindividual and intraindividual variations in uptake because of variations in, for example, metabolism and physical activity. Biological monitoring measures *total* exposure and not only exposure through, for example, inhalation. Much information of importance for occupational health criteria and standards comes, for example, from studies in which humans have been exposed to metals through contaminated food, even though occupational exposure limit values mostly are set for air concentration. Biological monitoring approaches and practices for a number of substances, including metals, have been recently reviewed by the NRC (2006).

For metals, such as lead and cadmium, exposure through food usually constitutes the major exposure route for the general population. For cadmium, smoking is an additional important source, giving rise to considerable increases in blood cadmium. When exposure through food is low, smoking may contribute to approximately half the body burden of cadmium. Exposure within industry may not necessarily be through inhalation only. Secondary contamination of hands, clothing, and of cigarettes, snuff, and pipe tobacco carried in pockets may be an important exposure source (Chen *et al*., 2006; Piscator *et al*., 1976). For a few metals it is possible to determine the concentration in the critical organ by direct *in vivo* measurements. An example is *in vivo* cadmium measurements of the amount of cadmium in the kidney (Chapter 23).

The rationale for the use of biological monitoring to estimate internal dose and critical concentration in critical organ as a proxy to critical target dose is discussed in Chapter 4. Emphasis is given to the importance of adequate use of chemical speciation, quality assurance of sampling, and chemical determinations. A prerequisite for successful use of concentrations in indicator media for estimation of exposure, accumulation of the metal in critical organs, and risks of adverse effects is knowledge of the toxicokinetics and metabolism of the metal, including data on the relationship between external exposure, internal dose, concentration in critical organ, and concentrations in indicator media. For risk estimation, data are also required on mechanism for elicitation of adverse effects and relationships between critical organ concentration (a proxy of critical target dose) and the appearance of adverse effects.

3 HAZARD IDENTIFICATION

On the basis of all available evidence in humans, experimental animals, and *in vitro*, possible adverse effects of the metal or metal compound are evaluated. The weight of evidence is considered whether specific adverse effects can be caused under exposure conditions existing for humans. The primary consideration is what specific chemical species of the metal humans are exposed to. Subsequently, hazard assessment is performed based on information concerning relationships between such exposures and adverse health effects.

3.1 Speciation

The fundamental importance of speciation in risk assessment has recently been highlighted in "Elemental Speciation in Human Health Risk Assessment" (WHO/IPCS, 2007).

The need to consider different metal compounds (species) separately when evaluating metabolism and effects is well recognized for some metals and has recently been reviewed by Yokel *et al*. (2006) (see also Chapters 18, 19, 24, 31, 33, and 38). Mercury is a classic example. Not only is it necessary to separate organic from inorganic mercury compounds, but also metallic mercury has a different metabolism from both its organic and inorganic compounds, and, for example, methylmercury is much more toxic than phenyl mercury. Arsenic occurs as inorganic, as well as organic, compounds. Man is exposed primarily to certain stable organic arsenic compounds in fish and crustaceans. The toxicity of such compounds is considered to be low, although detailed data on possible long-term effects are lacking. Usually, trivalent inorganic arsenic compounds are considered more toxic than pentavalent ones. Evidence for carcinogenicity is mostly available for the trivalent form or a mixture of trivalent and pentavalent forms, because they occur in groundwater used as drinking water (IARC, 2004). Arsenic concentrations in urine are used as an indicator of exposure and risk, but it may be that a small, poorly soluble fraction of arsenic is of importance in the causation of lung cancer in inhalation exposures, and the relationship between lung cancer risk and urinary arsenic may be different than the one for oral exposures.

In all risk assessment, it is fundamentally important to recognize the different kinetics, metabolism, and toxicity of different species of metals. It, therefore, becomes more and more important to analyze not only the metals as such but also the different forms they occur in. Reliable methods are available (e.g., for analysis of different compounds of arsenic and mercury) (see WHO/IPCS, 2007, and Chapters 2, 19, and 33). The issue of speciation has not been a part of hazard and risk assessment of metals except for mercury. The role of elemental speciation and speciation analysis in human health hazard and risk assessment is also

important for several metals and should be considered by risk assessors and regulators in their daily work (WHO/IPCS, 2007).

3.2 Human Data

When performing risk assessment for human exposures, data from humans are of special importance. In addition to general medical knowledge about human diseases, pathology, physiology, and biochemistry, specific knowledge about adverse effects observed in humans as a result of exposure to the toxicant under consideration is of great value. Case reports may be available and detailed studies of a small number of exposed persons with a specific disease who have all been exposed to the same metal compound. Collection of such data is sometimes named "toxicovigilance," a concept encompassing the active detection, validation, and follow-up of clinical adverse events related to toxic exposures in humans (Descotes and Tesud, 2005). Case studies can generate hypotheses for further studies but can seldom establish causality, except when there are unique features such as an association with a rare disease (e.g., Minamata disease) from methylmercury exposures.

Experimental studies in human volunteers can be performed if ethical considerations according to the Helsinki declaration are observed. Kinetics of metal compounds at low doses can be performed, and mild, reversible effects of low doses can be studied. Only few such studies have been reported in the field of metal toxicology.

Studies on the occurrence of diseases in groups of exposed and unexposed persons (i.e., cohort-type epidemiological studies) often provide useful information if well performed. For uncommon diseases, case-control studies may be more feasible (cf Chapter 8). These so-called analytical epidemiological studies can contribute to the establishment of causal connections between exposure and effect; however, the weaknesses inherent in any epidemiological study should be considered (Rothman and Greenland, 1998). Descriptive and correlation studies (also named ecological studies) are mainly hypothesis generating and can seldom establish causality by themselves. They may, however, be valuable as a complement to other observations.

When establishing causality, several of the classical "Hill's criteria" (Hill, 1965) are still valid:

1. Strength of association, meaning that it is more likely that an association with a large relative risk is causal.
2. Consistency, meaning that if association can be found in several studies by different investigations, causality is supported.
3. Temporality, meaning that exposure must precede effects.
4. Biological gradient, meaning that an association for which a dose-response relationship has been demonstrated is likely to be causal unless there is confounding.
5. Specificity, meaning that the effect is specific to the exposure. In metal toxicology, this is rarely the case. Although the presence of specificity implies causality (e.g., for asbestos exposure and mesothelioma), its absence does not exclude it.
6. Biological plausibility. If the mechanism of injury is known from animal experiments, this supports causality. However, if the mechanism is not known, or if there are no animal experiments reproducing the same effect of a specific exposure that, in itself, is not sufficient reason to reject causality.

In the evaluations of causality for cancer published by the International Agency for Research on Cancer–IARC (cf preamble in IARC, 2006) as result of meetings of expert task group discussions, criteria for causality have been selected and developed. To classify an agent as carcinogenic to humans (**IARC Group 1**), it is usually required that there is sufficient evidence of carcinogenicity in humans. Such evidence is based on epidemiological studies of good quality showing a statistically significant association between exposure to the agent and the occurrence of cancer; in addition, the IARC working group should be convinced that bias and confounding could be ruled out with reasonable confidence. During the last decade, classification in Group 1 can also be supported by a combination of limited evidence for carcinogenicity in humans and sufficient evidence of carcinogenicity in experimental animals and strong evidence in exposed humans that the agent acts through a relevant mechanism of carcinogenicity.

The IARC thus uses their own combination of criteria in their evaluation, some of which are similar to those advanced by Hill, for example, consistency and biological plausibility. Similar criteria are used by other organizations classifying chemical substances and other exposures as human carcinogens (see Sections 3.4, 3.5, and 3.6).

3.3 Data from Studies on Acute and Chronic Toxicity in Animals, Cells, and Molecular Systems *In Vitro*

Although human data are available for several metals and their compounds, there is a lack of such data for most metals not yet used extensively in society (see the respective chapters on individual metals

in this handbook). Data on acute and chronic toxicity in experimental animals provide useful information on potential effects in humans. To provide such useful information, animal studies have to be well performed. Test guidelines are available for the various specific animal bioassays for short-term, subchronic, and chronic toxicity, for developmental and reproductive toxicity, immunotoxicity, and carcinogenicity (see *www.oecd*). Available human and animal data for metals on some of these specific effects are provided in separate chapters of this handbook, for immunotoxicity in Chapter 11, for reproductive and developmental effects in Chapter 12, and for carcinogenicity in Chapters 5 and 10. Animal studies published in recent years often fulfil the OECD requirements or similar guidelines, but older data may not. Positive findings may still be useful even if the size of groups do not meet the requirements of the guidelines. The absence of observed effects, however, cannot be assessed from such incomplete data.

In addition to the categories of bioassays mentioned, specific tests may be required for effects like skin and eye irritation. Traditionally, such irritation effects have been assayed in whole animals, but recent achievements concerning alternatives to animal testing have made it possible to test some of these irritation effects in alternative systems (see *http://ecvam.jrc.it*). Particularly for effects like irritation, implying some degree of animal suffering, it is important from an ethical point of view to use nonanimal assays as much as possible if such systems can provide the same degree of safety for humans in the final risk assessment.

When human data are entirely or almost entirely lacking, hazard identification is based on animal and *in vitro* data.

Only when the nonhuman data are of good quality, can a reasonable degree of safety for humans be achieved. Even limited human data complementing good nonhuman data improves the risk assessment considerably both from a qualitative (hazard identification) and a quantitative (dose-response analysis) point of view (see Section 4).

In vitro data on cells and molecular systems provide very useful information when mechanism of action for toxic metals can be described. In situations in which such mechanisms can be shown to be valid at dose levels occurring in human tissues to realistic exposure levels for humans and animals, such *in vitro* data are very valuable for extrapolation of observations in animals to humans (see Chapter 6).

The role of metals in carcinogenesis was discussed in an international meeting in 1980 (Belman and Nordberg, 1981). No firm conclusions in regard to the use of so-called short-term tests were reached at that time, although lifetime studies on animals were considered predictive of probable carcinogenicity in man, especially when the routes of exposure and the sites of the tumors are the same. These are the same evaluation principles as used by IARC in their documents on carcinogenic risks to humans (IARC, 2006a,b). There are several examples of metals/metalloids (arsenic, beryllium, cadmium, chromium, and nickel) that have proven carcinogenic in both humans and animals. At the international meeting referred to previously (Belman and Nordberg, 1981), some chronological observations were made on the carcinogenicity of metallic compounds as judged by case reports, animal experiments, and epidemiological studies. This evaluation has been updated by us, including all metal compounds classified by IARC as human carcinogens or possible human carcinogens (IARC, 2006a,b) and is shown in Figure 1.

The reason that caution should be exercised when extrapolating data from animals to humans is not only because of the possible differences in metabolism related to species differences. Exposure situations will also differ. Often exposure in animal experiments is higher and more acute than exposure in real life. On the other hand, if only single substance exposures occur, this situation excludes several possibilities for interactions. Furthermore, the number of animals exposed is usually small compared with the number of people that may be exposed and does not include the very young or very old and other risk groups, such as people with deficient or suboptimal nutritional intakes and people who already suffer from diseases.

As mentioned (Section 3.2), the IARC classification system for carcinogenicity in humans uses these principles for classification into Group 1. Experimental data in animals and *in vitro* systems are the main basis for classification of exposures into Group 2, although epidemiological data are also required for classification in Group 2A. As stated in the preamble of the IARC monographs (IARC, 2006b).

3.3.1 IARC Group 2

This category includes agents for which, at one extreme, the degree of evidence of carcinogenicity in humans is almost *sufficient*, as well as those for which, at the other extreme, there are no human data but for which there is evidence of carcinogenicity in experimental animals. Agents are assigned to either Group 2A (*probably carcinogenic to humans*) or Group 2B (*possibly carcinogenic to humans*) on the basis of epidemiological and experimental evidence of carcinogenicity and mechanistic and other relevant data. The terms *probably*

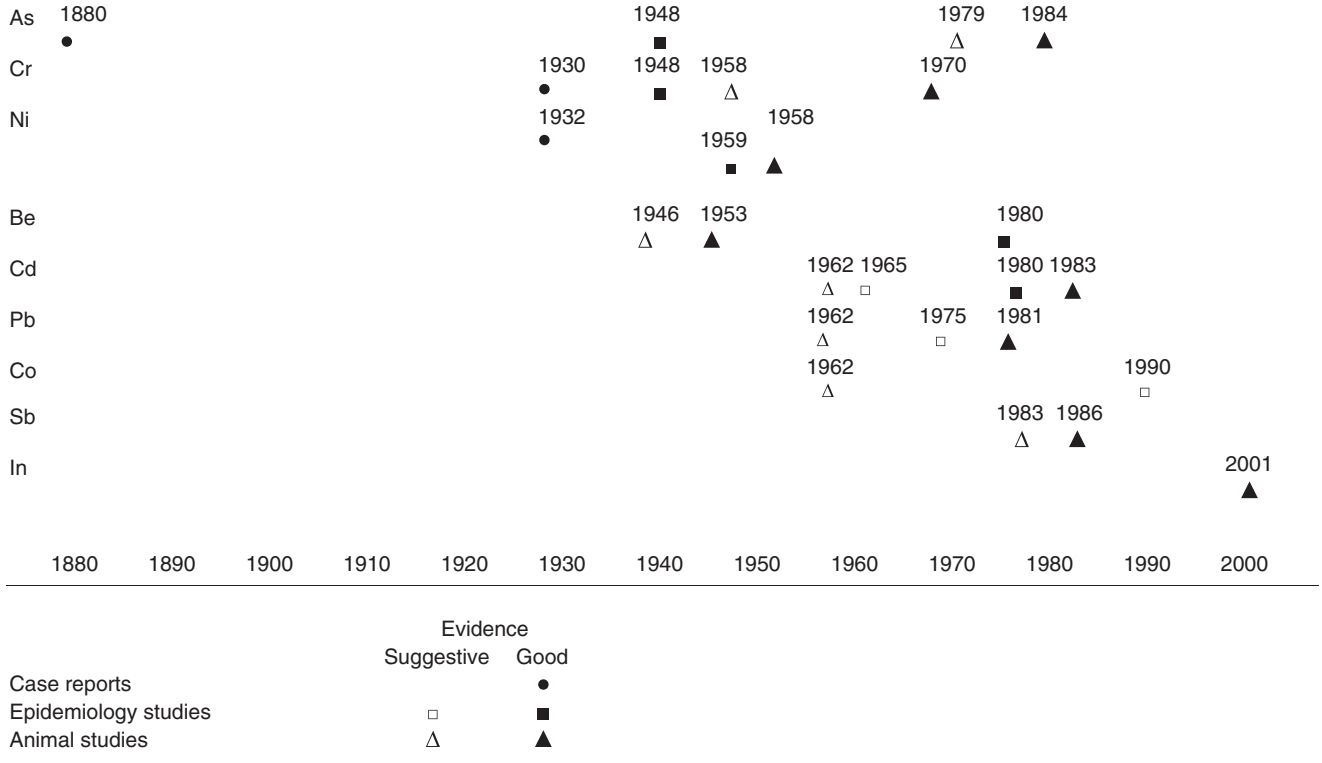

FIGURE 1 Chronology of observation on carcinogenicity of metallic compounds. At an international meeting in 1980 (Belman and Nordberg, 1981), the first five elements listed in the figure were judged as contributing to human cancer. The suspected metallic compounds are not listed in the figure, but as pointed out in the review, specific metallic compounds usually constitute the carcinogenic entity. Data by Takenaka *et al*., (1983), Pershagen *et al*. (1984) have been added as well as data on Pb, Co, Sb as Sb_2O_3, In as InP (review IARC [2006a] IARC [2006b]). The last four metallic compounds are considered by IARC as probable human carcinogens (group 2A). IARC has classified vanadium pentoxide and iron–dextran complex as possible human carcinogens, but they are not listed in the figure.

carcinogenic and *possibly carcinogenic* have no quantitative significance and are used simply as descriptors of different levels of evidence of human carcinogenicity, with *probably carcinogenic* signifying a higher level of evidence than *possibly carcinogenic*.

3.3.2 IARC Group 2A: The Agent is Probably Carcinogenic to Humans

This category is used when there is *limited evidence of carcinogenicity* in humans and *sufficient evidence of carcinogenicity* in experimental animals. In some cases, an agent may be classified in this category when there is *inadequate evidence of carcinogenicity* in humans and *sufficient evidence of carcinogenicity* in experimental animals and strong evidence that the carcinogenesis is mediated by a mechanism that also operates in humans. Exceptionally, an agent may be classified in this category solely on the basis of *limited evidence of carcinogenicity* in humans. An agent may be assigned to this category if it clearly belongs, based on mechanistic considerations, to a class of agents for which one or more members have been classified in Group 1 or Group 2A.

3.3.3 IARC Group 2B: The Agent is Possibly Carcinogenic to Humans

This category is used for agents for which there is *limited evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals. It may also be used when there is *inadequate evidence of carcinogenicity* in humans but there is *sufficient evidence of carcinogenicity* in experimental animals. In some instances, an agent for which there is *inadequate evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals together with supporting evidence from mechanistic and other relevant data may be placed in this group. An agent may be classified in this category solely on the basis of strong evidence from mechanistic and other relevant data.

Other frequently cited classifications of carcinogenicity are those made by EU, USEPA, and ACGIH, and they will, therefore, be described in the following text.

3.4 Classification According to the European Union (HSE 1999; Nordberg *et al.*, 2004)

For the purpose of classification and labeling and having regard to the current state of knowledge, substances are divided into three categories:

Category 1: Substances Known to be Carcinogenic to Man

There is sufficient evidence to establish a casual association between human exposure to a substance and the development of cancer.

Category 2: Substances that Should be Regarded as if they are Carcinogenic to Man

There is sufficient evidence to provide a strong presumption that human exposure to a substance may result in the development of cancer, generally on the basis of appropriate long-term animal studies and other relevant information.

Category 3: Substances, Which Cause Concern for Man Owing to Possible Carcinogenic Effects but in Respect of Which the Available Information is not Adequate for Making a Satisfactory Assessment.

There is some evidence from appropriate animal studies, but this is insufficient to place the substance in Category 2.

3.5 Classification According to the USEPA (USEPA 1986, 2005)

Group A: "Human Carcinogen"

"This group is used only when there is sufficient evidence from epidemiologic studies to support a causal association between exposure to the agents and cancer."

Group B (1 and 2): "Probable Human Carcinogen"

"This group includes agents for which the weight of evidence of human carcinogenicity based on epidemiologic studies is 'limited' and also includes agents for which the weight of evidence of carcinogenicity based on animal studies is 'sufficient.' The group is divided into two subgroups. Usually, Group B1 is reserved for agents for which there is limited evidence of carcinogenicity from epidemiological studies. It is reasonable, for practical purposes, to regard an agent for which there is 'sufficient evidence of carcinogenicity' in animals as if it presented a carcinogenic risk to humans. Therefore, agents for which there is 'sufficient' evidence from animal studies and for which there is 'inadequate evidence' or 'no data' from epidemiologic studies would usually be categorized under Group B2."

Group C: "Possible Human Carcinogen"

"This group is used for agents with limited evidence of carcinogenicity in animals in the absence of human data. It includes a wide variety of evidence, e.g., (a) a malignant tumor response in a single well-conducted experiment that does not meet conditions for sufficient evidence, (b) tumor responses of marginal statistical significance in studies having inadequate design or reporting, (c) benign but not malignant tumors with an agent showing no response in a variety of short-term tests for mutagenicity, and (d) responses of marginal statistical significance in a tissue known to have a high or variable background rate."

Group D: "Not Classifiable as to Human Carcinogenicity"

"This group is generally used for agents with inadequate human and animal evidence of carcinogenicity or for which no data are available."

Group E: "Evidence of Non-Carcinogenicity for Humans"

"This group is used for agents that show no evidence for carcinogenicity in at least two adequate animal tests in different species or in both adequate epidemiologic and animal studies. The designation of an agent as being in Group E is based on the available evidence and should not be interpreted as a definitive conclusion that the agent will not be a carcinogen under any circumstances."

3.6 Classification According to the American Conference of Governmental Industrial Hygienists, Inc. (ACGIH 2006)

A1: Confirmed human carcinogen
A2: Suspected human carcinogen
A3: Confirmed animal carcinogen with unknown relevance to humans
A4: Not classifiable as human carcinogen. Agents cause concern that they could be carcinogenic for humans, but there is not enough data to classify the agent into any of the other categories.
A5: Not suspected as a human carcinogen.

A number of *in vitro* systems have been suggested as alternatives to animal testing, and extensive research and validation activities are ongoing (see *http://ecvam.jrc.it*). A limited number of tests regarding irritation effects have been found to be useful, and it is hoped that further research and validation will identify useful tests that can be applied in risk assessment for other adverse effects.

Based on so-called structure activity relationships (SAR), rough estimates of the toxicological properties of chemical compounds with similar chemical structure as compounds with known toxicity can sometimes be made. When quantitative estimates are made based on structure similarities, the term "Quantitative Structure-activity relationships"— QSAR has been used. These estimates usually are less precise than estimated based on even limited animal experiments.

At present, epidemiological studies, when available, and animal tests in combination with human data and complemented by information about toxicokinetics and mechanism of action in animals and humans, are the dominant information sources for risk assessment of metal compounds.

4 DOSE-EFFECT AND DOSE-RESPONSE ASSESSMENT

4.1 Concepts in Quantitative Toxicological Analysis

4.1.1 Dose Effect and Dose Response

Terms used when establishing dose-response and dose-effect relationships must be defined and understood. The terms "dose" and "exposure" have been described in Section 1 of this chapter, and their similar meaning has been pointed out. In quantitative toxicological analysis, it is useful to make a distinction between "dose-response" and "dose-effect" relationships (see also Chapter 6). IUPAC (Nordberg *et al.*, 2004) has recommended the following:

Dose-effect relationship: Association between dose and the resulting magnitude of a continuously graded change, either in an individual or in a population.

Dose-response relationship: Association between dose and the incidence of a defined biological effect in an exposed population, usually expressed as percentage.

This terminology has been used for a long time in metal toxicology (see Task Group on Metal Interactions, 1978; Task Group on Metal Toxicity, 1976;) and in previous editions of this handbook. It will be used in this chapter and in other chapters of this edition. There is, however, no general agreement among toxicologists on this usage, because the words "effect" and "response" are synonyms in common language. There may be advantages in replacing the term "dose-response" by more precise terms like "dose-prevalence" and "dose-incidence" (see Chapter 8 for explanation of terms), but up to the present, such terms have not been much used outside of the field of epidemiology; they are seldom used in toxicology. Therefore, the definitions of "dose-effect" and "dose-response," as traditionally used in metal toxicology and listed above according to IUPAC, will be used in this handbook, because they facilitate distinction between these two dimensions of relationships. The dose-effect concept describes the relationship with the severity of effect, and the dose-response concept describes the distribution of a specific effect in the population. Further considerations concerning the relationship between dose-effect, dose-response and variation in sensitivity among individuals in a population has been given in Chapter 6. The use of these concepts supports clear descriptions and discussions on these relationships that are of great importance in risk assessment.

4.1.2 Critical Concentration, Critical Organ, Critical Effect, and No-Observed-Effect Level

In health effects evaluations, one major issue is to identify adverse effects and to establish exposures or doses at which these adverse effects occur. Severe effects, even death of the exposed individual, occur at high doses, and low doses give rise to less severe effects. Sometimes effects can be detected by laboratory methods at exposure levels without evident symptoms or signs of disease. Such subclinical effects, nevertheless, can be adverse effects if they impair the function of organs or other physiological systems. This type of effect is of great importance in occupational and environmental health, because these professions deal with the prevention of adverse effects and promotion of health for the population. If early adverse effects can be prevented, more severe effects, which are pathophysiological consequences of the early effect, will automatically be prevented. A focus on early adverse effects is thus fundamental in the mentioned professions and guides the related risk assessments.

The effect that is used as a basis for setting exposure recommendations and for risk management is named the *critical effect*. This effect is often a subclinical effect.

The related organ, suffering functional impairment, is named the *critical organ*. In some instances, the tissue concentration of a toxicant in an organ can be related to the appearance of effects. The lowest tissue concentration giving rise to an effect in an organ of a particular

individual is the *critical concentration* in that individual. The concept of a critical concentration is only applicable to effects that occur as a result of a specific threshold concentration being reached, so-called deterministic effects or threshold effects.

When a group or population is exposed to a toxic agent and several effects are studied, a set of dose-response curves are achieved as displayed in Figure 2. At high doses, severe and lethal effects occur (curve D in Figure 2). A well-known concept in this context is the median lethal dose LD-50. Experiments in animals determining the dose-response curve for lethality are of very limited value in environmental and occupational health. Such experiments should also be limited based on ethical considerations. At doses lower than those causing lethality, there will be toxic effects leading to disease (curve C, Figure 2). The median toxic dose (TD-50) for a specific toxic effect that may represent a clinical disease not leading to death is shown in Figure 2 (curve C). At slightly lower doses *TD-05, the toxic dose for 5% of the exposed group* may be identified. At even lower doses, adverse functional changes without clinical effects may be identified by biomonitoring (curve B, Figure 2). Such subclinical changes, which can be shown to have a relationship as a precursor to clinical disease, are often taken as critical effect. The part of this curve representing relatively low doses and low response levels (e.g., the level when 5% of the exposed group displays this effect, i.e., the effect dose for 5% (ED-05), is of interest in occupational and environmental health. When a practical threshold is reached, when no adverse (critical) effect can be observed, the *"No-observed-adverse-effect-level" (NOAEL)* is reached (Figure 2). Because

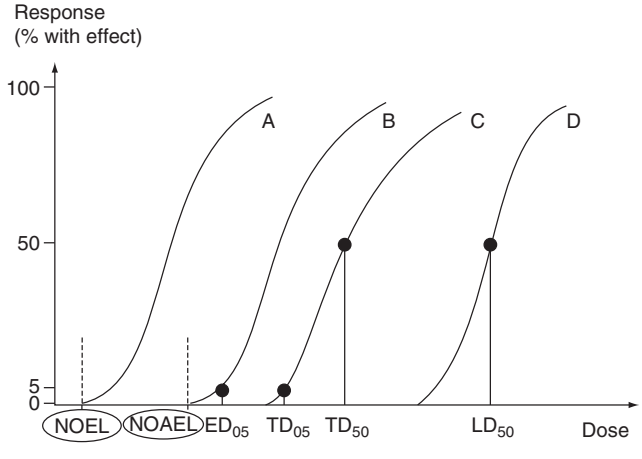

FIGURE 2 Spectrum of dose-response curves for deterministic (threshold-type) effects of a metal compound. No-observed-effect level (NOEL), no-observed-adverse-effect level (NOAEL), effect dose 5% (ED-05), toxic dose 5% (TD-05), toxic dose 50% (TD-50), and lethal dose 50% (LD-50) are indicated.

observations are made in specific dose groups, NOAEL is the highest dose level at which a group of individuals have been exposed without any statistically significant adverse effects being demonstrated. At even lower doses, there may be a dose-response curve describing (curve A in Figure 2) slight, but statistically significant, changes in enzymes for which there is a high reserve capacity, and a small decrease does not imply any decrease in organ function. Such effects are named subcritical effects. Doses below this curve, at which no effects whatsoever occur, represent the *no-observed-effect-level (NOEL)*, which is the highest dose at which no effects at all can be observed (Figure 2).

The S-shaped dose-response curves for threshold-type effects are explained by a Gaussian distribution in sensitivity among persons making up the group studied. This has been further discussed and explained in Chapter 6).

As pointed out in the foregoing text, in preventive medicine, it is of particular importance to identify early effects. If these can be prevented, then later, perhaps more severe, effects can be avoided. Against this background, the terms critical concentration, critical organ, and critical effect have been established for some metals (Nordberg, 1992; Task Group on Metal Accumulation, 1973; Task Group on Metal Interaction, 1978; Task Group on Metal Toxicity, 1976). These concepts are mainly applicable to deterministic/threshold-type effect, but the critical effect concept may also be used when stochastic/nonthreshold effects are considered. Further description and discussion of these concepts and examples of their use can be found in Friberg and Kjellstrom (1981), Kjellstrom *et al*. (1984), Nordberg (1992), WHO/IPCS (1992), and Jarup *et al*. (1998).

Effects that occur as a result of a random interaction of the metal compound with DNA or when they depend on a series of events such as in multistage carcinogenesis are named *stochastic effects or nonthreshold effects*. They are often assumed to display a linear component of the dose-response curve at low doses (curve C in Figure 3). Cancer and some reproductive effects are considered to belong to this category of effects (see also Section 4.2.2).

4.1.3 Benchmark Dose

The concept of benchmark dose (BMD_{Cr}) was introduced into toxicology and risk assessment by Crump (1984) as the statistical lower confidence limit on the dose producing a predetermined level of change in adverse response (the benchmark response, or BMR) compared with the response in untreated animals. There are several advantages in using this concept instead of NOAEL in risk assessment, as discussed in Chapter 6, because the variance in the observation

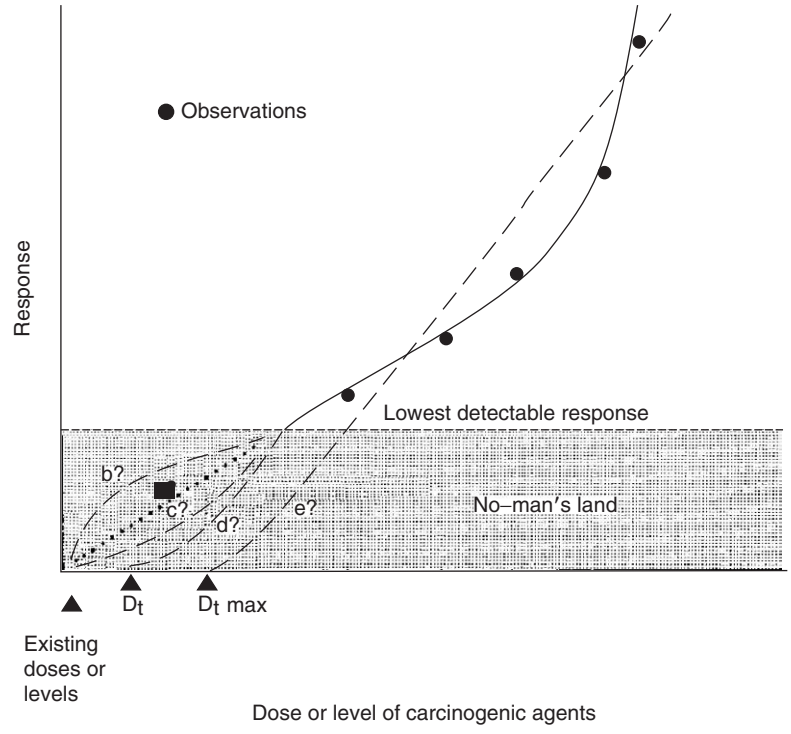

FIGURE 3 Illustration of detection limit for epidemiological and experimental observations of cancer incidence (mortality) as a function of dose (exposure level) of a carcinogenic agent. By response is meant the response caused by the agent, (i.e., the difference between incidence in exposed groups and incidence in the control group). D_t is the threshold dose (Modified from the Swedish Governmental Cancer Committee, 1984).

is considered in a more systematic way. Data with more observations and less variance generate BMD_{Cr} values that are higher, and data with more variance generate lower BMD_{Cr} values for the same BMR. The BMD approach thus uses more of the data and provides more safety. Gaylor *et al*. (1998) redefined the Benchmark dose (BMD_{Ga}) as the point estimate of the dose corresponding to a specified low level or risk, for example, the dose giving rise to a 10% increase in adverse response BMD-10 is the same point in the dose-response curve as ED-10 or TD-10 (see Section 4.1.2) or PCC-10 (Section 4.1.4). Gaylor *et al*. suggested that the lower confidence limit (LBMD) of the BMD_{Ga} be used instead of NOAEL in risk assessments. LBMD as defined by Gaylor is the same concept as BMDL used by USEPA (2006b) and is the same dose as the original BMD_{Cr}. Methods and software for calculating BMD and BMDL are available from USEPA (2006b), and these methods are often used in publications calculating BMD and BMDL; this terminology will be used in this chapter. It is also used in Chapter 8 and in some of the chapters on specific metals, for example, Chapter 23, in this handbook. The software available from USEPA provides various mathematical models, some of which are similar to those used by Crump (1984). These models are in some details different from those used by Gaylor *et al*. (1998). When reporting BMD and BMDL values, the mathematical models and methods used should always be specified, because they do influence the values obtained. The BMD concept was initially developed for use with dose-response data in experimental animals. One important consideration when calculating BMD/BMDL is the background response and how well it is studied. A small "control" group with a large variance will cause difficulties in calculating LBMD regardless of whether experimental data in animals or epidemiological data are considered. In animal experiments, the issue of causality and confounding (see Section 3 and Chapter 8) are not as important considerations as in epidemiology. When calculating BMD and BMDL based on epidemiological data, these considerations must be addressed. Confounding and effect-modifying factors can have considerable influence on BMD values. It was shown, for example, for renal dysfunction in population groups exposed to cadmium in China, that BMDL for Cd was considerably lower in the presence of concomitant exposure to arsenic than in the absence of such exposure (Jin *et al*. [2004]; Hong *et al*. [2004]; Nordberg *et al*. [2005]).

The use of probabilistic risk assessment approaches to take into account variability within exposed populations is a further refinement to these statistical methods.

The BMD, as discussed in the foregoing text, is a point on the dose scale in a dose-response relationship (using so-called quantal data), and the concept has been most frequently used for such data. The advantages of converting dose-effect data (continuous data) to dose-response data have been discussed in Chapter 6. The advantage can be that the occurrence of values considered "abnormal" from a clinical chemistry point of view can be used—usually deviating by more than two times the standard deviation from the mean among healthy persons. When such specific values are known to be related to adverse long-term health outcomes, as for low mol proteinuria in population groups exposed to cadmium (see Chapter 23), the BMD and BMDL are meaningful points in the dose scale that can be used for risk assessment.

The benchmark approach has been extended so that it can be used with dose-effect data (continuous data), also those obtained in epidemiological studies, where confounder adjustment is needed (Budtz-Jorgensen *et al*., 2001; Crump, 1995; Kalliomaa *et al*., 1998). Such benchmark dose calculations may be useful in risk assessments, but their implications in terms of health risk usually have not been defined or discussed. The influence of statistical variance in such calculations has been considered by Sand *et al*. (2003).

When using BMD values in risk assessments, it is important to specify whether dose-response (quantal or dichotomous) data or dose-effect data (continuous data) are used. The BMR should always be specified for dose-response data. It is also important to describe what methods are used to define the magnitude of effect that is under consideration when using dose-effect data. In line with the terminology of this book, the term BME (benchmark effect) is recommended for dose-effect data but has not yet been used as far as known by us.

Measurement imprecision in the dose scale (e.g., in epidemiological studies) will also affect the BMD and should be dealt with as discussed in Chapter 8.

If the considerations discussed in this section are taken into account, BMD/LBMD calculations provide very useful numbers for risk assessment and are recommended when adequate data allowing such calculations are available.

4.1.4 The Critical Concentration on a Population Basis

The critical concentration is established on an individual basis and varies among individuals (Task Group on Metal Toxicity, 1976). The dose-response relationship expressing the response of a particular effect as a function of metal concentration in the critical organ thus displays the frequency distribution of individual critical concentrations.

It is not possible to speak of one single critical concentration even for a specified effect. Because this had sometimes been done, Friberg and Kjellstrom (1981) suggested the introduction of a "population critical concentration" (PCC) instead of a "critical concentration" when assessing data based on a population. To the PCC should be appended a number indicating the response rate expected at this PCC. PCC-50 would be the concentration in the critical organ at which 50% of a population has the critical effect, PCC-20 the concentration at which 20% has the critical effect, and thus has exceeded their individual critical concentrations. The PCC would bring together a number of previously used terms, such as "earliest effect level," "no-observed-adverse effect level" (NOAEL), "critical concentration," without further specification. The use of the PCC concept would be similar to the use of LD50 and ED50 in toxicology and is similar to the benchmark dose concept (see Section 4.1.3).

In risk assessment and risk control of chemicals with specific responses, it is a separate decision to decide on a maximum acceptable response rate for a given effect based on a risk estimation. If 5% is the maximum, then the PCC-5 has to be established. If 0.1% is the maximum, then a PCC-0.l must be established. Standards refer to exposure, however, and it is, therefore, necessary to define the exposure that gives rise to 5% response. To arrive at this exposure, interindividual parameters have to be taken into consideration. Variations in metabolism and sensitivity to a toxic substance will be parameters of importance for the individual. For example, it should be established whether high absorption, unfavorable interactions with other substances, high retention, and low excretion together with high tissue sensitivity within the critical organ may favor an effect even at low exposure levels.

To predict the proportion of a population that has concentrations in the critical organ above the individuals' critical concentrations, knowledge of the distribution of the concentrations of the substance in the critical organ on a population basis is needed together with data on the PCCs. This will give, on the one hand, data on the combined effect of the exposure and metabolism on tissue concentrations, and, on the other hand, information on PCCs. The proportion of a population with concentrations above the critical concentration is then equal to the probability of any individual in the population having an actual concentration in the critical organ above his or her critical con-

centration and the response rate. This proportion has been estimated for cadmium by Kjellstrom (1985) and Jarup (1998); see also Chapter 23. The PCC in terms of urinary cadmium—UCd (biomarker of Cd level in kidney cortex) related to adverse kidney effects has been reported as, for example, PCCUCd-05 (Population critical concentration of urinary cadmium for 5% of the studied group—Jin *et al*. [2004]). These authors also reported the lower confidence limit of this value (i.e., LPCCUCd-05), which is identical to LBMD-05 in the "benchmark dose" terminology (see Section 4.1.3).

Different aspects of the combined effect of distributions of exposure, toxicokinetics, metabolism, and effects have been discussed in Chapter 3 and in papers by Nordberg and Strangert (1978, 1985), Kjellstrom (1977, 1985), Sakurai *et al*. (1982), Jarup *et al*. (1998), Diamond *et al*. (2003), and Chapters 23 and 33.

4.2 Based on Short-Term and Long-Term Studies in Animals

There are relatively good data from epidemiological studies in humans for a limited number of metals and their compounds (see Section 4.3). For other metals and their compounds, mainly data from studies in animals and *in vitro* systems are available. This section will describe how data from animal experiments and combined studies in humans and animals can be used in quantitative risk analysis to arrive at recommended safe exposures for humans.

4.2.1. Threshold-Type Critical Effects

The following considerations are applicable to chemical substances giving rise to threshold-type (deterministic) critical effects but not to genotoxic-type carcinogenic or other nonthreshold effects.

In food toxicology, animal data have been used for a long time as a basis for recommended acceptable daily human intakes (ADIs) of food additives. Traditionally, these recommendations by FAO/WHO have been based on long-term and chronic toxicity studies in animals from which NOAEL has been estimated. To arrive at an ADI, the NOAEL in animals was divided by a safety factor of 100. This method has been widely used in the past but has recently been developed to take into account additional data, when available (see later). Although the method should have been applicable also for metals and their compounds, there are only few metals that have been used as food additives, the most common one is iron. Because human data have been available for iron, an ADI or RDA (recommended daily allowance) entirely based on animal data has not been recommended. Instead, human data have been an important basis for such recommendations (see Chapter 9). For metals and metal compounds occurring as natural components of the environment or as contaminants in food, WHO/FAO sets a provisional tolerable weekly intake (PTWI); this can also be per day PTDI. The same evaluation principles are used as for ADI. The method, dividing NOAEL in animals with 100, to arrive at an ADI (PTWI) is only applicable for substances that are not carcinogenic. For carcinogenesis and other nonthreshold (or stochastic) effects, linear extrapolation is recommended (see later).

The safety factor (or uncertainty factor) of 100 has been explained by a factor of 10 to account for extrapolation from animals to man and another factor of 10 for variability in the human population. The disadvantage with these safety factors is that they do not allow the incorporation of actual data on toxicokinetics and toxicodynamics even if such data are available in animals and in humans. Based on suggestions by Renwick (1993), WHO/IPCS (1999) suggested that (in the absence of actual data) the safety factor (uncertainty factor) of 10 for interspecies differences can be subdivided into two factors: one for interspecies differences in toxicokinetics of 4 and another factor of 2.5 representing interspecies differences in toxicodynamics. The factor of 10 for variability in the human population can be subdivided in a factor of 3.2 for variability in toxicokinetics and another factor of 3.2 for variability in toxicokinetics (Table 1).

The default factors recommended are based on the experience that animals may react quite differently to toxic metals than humans, partly because of a different sensitivity to a particular substance (i.e., a toxicodynamic difference) and partly because of differences in toxicokinetics and metabolism. It may also be difficult to detect certain types of toxic effects in animals, such as neuropsychiatric effects, unless specific tests are performed. It is, therefore, important to look for adequate animal models. The models may differ for different substances and exposure routes. A few examples may illustrate this.

Methylmercury is a very toxic form of mercury to humans. It is highly stable and is accumulated in the body as methylmercury. In rats, this compound is much more readily transformed into inorganic mercury, and the effects are less severe (Chapter 33). In man, as well as in most animal species, arsenic is methylated to a considerable degree as a possible detoxification mechanism, but recent studies have implicated the trivalent monomethyl arsenic acid (MMA-III) as a highly toxic metabolite species that may play a role in arsenic-induced carcinogenesis. In the marmoset monkey, however, there seems to be no methylation at all (Chapter 19). Another monkey, the rhesus monkey, seems to be more resistant to cadmium-induced kidney dysfunc-

TABLE 1 Default Factors in Risk Assessment

Interspecies = 10	Interindividual = 10
TK = 4 TD = 2.5	TK = 3.2 TD = 3.2

TK, Toxicokinetics; TD, toxicodynamics.

tion than man and several other animal species (Tertiary Monkey Experiment Team, 1981; Friberg *et al*., 1985).

When differences between humans and animals have been identified and an adequate animal model for extrapolation to humans can be used, it is, of course, important to use such a model to obtain data relevant for humans. When extrapolating data from animals to humans, the specific observed differences in toxicokinetics could be used in the extrapolation. However, in most instances, such differences are not known, and extrapolation has to be done relying on the default factors listed in Table 1.

It can be seen from the various chapters on individual metals in this handbook that the method that uses the factors in Table 1 in deriving recommended safe levels of exposure for humans has not yet been much used for metals. It may, however, be a feasible option for the future. On the basis of metals on which human epidemiological data are available, the adequacy of the method can be evaluated against actual human dose-response data.

An alternative to the estimation of safety factors (uncertainty factors) are actual estimates of variability in toxicokinetics and toxicodynamics in humans. Probabilistic approaches, calculating risks for adverse effects based on such actual data and estimates of variability in toxicokinetic and toxicodynamic parameters are described in Section 4.3.

4.2.2 Carcinogenesis and Other Nonthreshold Effects

In the evaluations by IARC (Section 3, IARC [2006a,b]), only the weight of evidence for carcinogenicity is considered, and no quantitative estimation of risk is presented. However, quantitative estimations of cancer risks to humans based on combined animal and (limited) human data have been presented by other scientific bodies. The longest history of successful estimations of importance for health protection are those in the field of radiation protection.

In developing rules for protection against carcinogenic effects of ionizing radiation, the assumption has been made that thresholds do not exist and that any exposure involves an increased risk. This philosophy has also been adopted in many quarters for carcinogenic effects of chemical substances, including metals. The form of the dose-response curve for carcinogenic substances has been discussed at an international symposium (Task Group on Air Pollution and Cancer, 1978), and it has been concluded that "in considering protection of human populations, and in the absence of firm evidence to the contrary, it is not justified to assume a 'threshold', i.e. that there is a dose below which no response is obtained." It has also been concluded that "in the absence of relevant dose-response data the most appropriate way to estimate the risk of lung cancer is to assume that it will be directly proportional to the increase in dose.

For small added doses, a simple linear dose-response curve, as used in radiation carcinogenesis, is appropriate." These conclusions imply that basically the same philosophy was adopted as that long used in radiation protection, namely that thresholds do not exist and that any exposure may involve some risk. Similarities with ionizing radiation were considered as best founded in regard to (ultimate) carcinogens (not requiring metabolic activation) acting on directly exposed tissues.

A number of mathematical models have been proposed for extrapolation from high to low doses. They are commented on in Chapter 6 and have also been discussed by an Interdisciplinary Panel on Carcinogenicity (1984) and by WHO/IPCS (1999). It has been pointed out that the dose-response models are quantitatively similar to one another in statistically detectable response rates of 10–100%, but yield substantially different estimates at lower response rates, where estimates may differ by orders of magnitude.

Evidence from epidemiological and experimental data, including certain genetic data, leads to the conclusion that—although knowledge is still incomplete—a linear extrapolation to the low doses in "no-man's land" will be closest to the knowledge concerning mechanistic dose-response relationships for initiators.

Experimental observations, as well as epidemiological data, are almost always based on doses that are considerably higher than those that can be considered as an acceptable exposure. A rationale for extrapolation to low-dose areas and low-exposure levels is, therefore, needed. The levels are within an area where statistically valid conclusions concerning dose-response relationships cannot be drawn from epidemiological or experimental studies. The situation is illustrated in Figure 3. A linear extrapolation according to curve "a" would lead to an underestimation or overestimation of the risk if curve "b" or "c," respectively, was true. Exposures within the dose interval that occur in practice would wrongly be considered "dangerous" if the true relationship showed a threshold dose (D_t) according to curve "d" or "e."

Promoters act basically through nongenetic (nonstochastic) mechanisms, and there is reason to believe that usually a certain exposure (dose in target organs) is necessary for an effect to develop at all. Under such

circumstances, a linear extrapolation from high to low doses may lead to overestimation of risks. Various models have been developed on the basis of initiation, promotion, and, when available, also toxicokinetics (WHO/IPCS, 1999). Such models are used to a variable extent by regulatory agencies in countries around the world for extrapolation of observed relationships to specific response levels like the 10% or 1% level. For further extrapolation into the low-dose range to establish regulations or recommendations of acceptable exposures, linear dose-response relationship is often used.

The linear dose-response relationship means that one may apply the concept of collective dose in risk assessment relative to carcinogenic substances that are persistent in the environment and that—as may be the case for metals—are ultimate carcinogens. The collective dose can be defined as the product of the average dose given to an individual in a defined exposed group and the number of individuals in that group (ICRP, 1977).

The unit risk concept developed by the USEPA (USEPA/IRIS, 2006b,c) is defined as the upper bound lifetime cancer risk estimated to result from an agent at a concentration of 1 μg/L in water or 1 μg/m^3 in air. It is based on a linear extrapolation of observational data (see also Section 6).

4.3 Probabilistic Estimation of Dose-Response Relationships by Toxicokinetic (TK) and Toxicodynamic (TD) Modeling

Probabilistic approaches for characterization of uncertainty have been advanced as an alternative to the "safety factor" approach (Price *et al*., 1997; WHO/IPCS, 1999). Methods using estimated variability in toxicokinetics and toxicodynamics as a basis for risk estimation and estimation of uncertainty in the risk estimates was advanced by Nordberg and Strangert (1978) and has later been developed by inclusion of Monte Carlo simulation as will be described in the following text.

Toxicokinetics (metabolism) describes the movements of a toxicant through the body. It describes to what extent the toxicant is taken up from air, skin, diet, and drinking water. It describes transformation at the site of uptake; transport by blood to various organs; transformation, accumulation, and biological half-life in organs and its excretion in urine, feces, and through skin, hair, and sweat. A detailed description of general principles and mechanism of these events is given in Chapter 3, and this description will not be repeated here except for a few salient points. On the basis of knowledge about particle size and solubility of metals or metal compounds that occur as air pollutants in particle form, their deposition in the lungs can be predicted and their uptake modeled. For metals taken up through the gastrointestinal tract general knowledge about mechanisms are not as much developed, and observational data from animals or humans are required to estimate uptake into blood. The same is true for transport and distribution to various organs in the body and for excretion. Specific transporters and binding proteins are often of great importance for uptake and distribution. Good examples are the DMT1 (divalent metal transporter) carrying Cd and other metals through the gastrointestinal mucosa and metallothionein (MT), a small protein binding Cd in the gastrointestinal mucosa, blood plasma, and in tissues like liver and kidney (cf Chapters 3 and 23). Transformation of metal ions into a bound state (e.g., DMT 1, MT for Cd) or oxidation/reduction reactions (e.g., Cr, Hg) influences distribution and toxicity and needs to be considered in toxicokinetics.

On the basis of an understanding of the toxicokinetics of a metal compound (species) and quantitative measurements in humans and animals, a quantitative toxicokinetic model can be established. Concentrations in critical organs and tissues can be calculated for various exposure scenarios as described in Chapter 3. For example, the accumulation of Cd in the kidney cortex can be calculated as an input into a TK/TD model.

Toxicodynamics (TD) describe mechanisms of action of toxicants, how they can cause tissue damage, and under what conditions in terms of tissue concentrations and time of tissue exposure/dose that adverse effects on tissue structure and function will occur.

4.3.1 Deterministic or Threshold-Type Effects

Some metal compounds (species) elicit tissue damage/adverse changes in organ function when a sufficiently high concentration is reached in the cells of the critical organ. Such effects occurring at a critical concentration that is determined by the sensitivity of the target molecules and the status of defense systems in a particular individual are *deterministic effects* also named *threshold effects*. Organ sensitivity varies among individuals in a population. For example, adverse effects caused by cadmium in the kidney cortex is determined by sensitivity and binding of Cd to target molecules in the renal cell membranes on one hand and the binding of Cd to intracellular MT and other antioxidant defense systems (cf Chapter 23). A relationship can be established by simultaneous measurements of metal concentration in a critical organ directly or indirectly through biomarkers (cf Chapter 4) on one hand and on the other hand measurements of the occurrence of the adverse effects in a large number of individuals in a population.

When there are limited data on humans, but an understanding of threshold-type relationships from animal data, rough estimates of relationships between tissue concentrations and occurrence of effects can be estimated. In such situations, data are often limited to a small number of persons (e.g., workers), who have suffered the adverse effect as a result of high exposure. Experience from such calculations, performed more than 10 years ago for cadmium (cf Chapters 3 and 23) can now be evaluated in relation to epidemiological data from exposed groups in the general population (Chapter 23). Variance of critical concentration in the kidney cortex, estimated from studies carried out in the 1970s and 1980s based on data from small groups of exposed workers has turned out to be somewhat smaller than the variation observed later in epidemiological studies of the general population, because workers are a more homogenous group than the general population. Estimated population critical concentration (PCC) (e.g., PCC_{10}) was adequate for workers but somewhat higher than the actual value for the general population.

In recent calculations using the same basic model, but complemented by Monte-Carlo simulated variation (Diamond *et al*., 2003) adequate estimations of dose response for renal dysfunction in human general populations exposed to background levels of cadmium have been presented.

4.3.2 Stochastic or Nonthreshold Effects

TK/TD modeling is also useful for modeling of dose-response relationships in carcinogenesis. Such models should be combined with an understanding of the mechanisms and quantitative relationships between tissue levels of carcinogenic metals and appearance of tumors. For metals there are not good examples where such calculations have been used in risk assessment, but they have been used for other classes of chemical compounds (WHO/IPCS, 1999).

4.4 Based on Epidemiological Studies

As a result of long-term interest and gradually increased recognition of adverse effects of lead, cadmium, mercury, and their compounds, a considerable amount of epidemiological data are available on human health effects. The considerations of causality in epidemiological studies have been discussed in Section 3.2. It is always important to be reasonably sure that the relationships are causal before a quantitative assessment is made. Often epidemiological data are based on a limited number of exposed persons, for example, in some occupational studies, and it may not be possible to make a calculation of benchmark dose. In such cases, NOAEL can be estimated and used in risk assessment. Sometimes limited data in humans can be combined with TK/TD modeling in calculating risk levels, and NOAEL can be estimated. Such calculations were done in the past to estimate acceptable exposures before epidemiological data were available (Berglund *et al.,* 1971; see also Chapter 33). In recent epidemiological studies, several authors have presented benchmark dose calculations for exposures to cadmium and methylmercury (see Chapters 23 and 33). When using the reported numbers, consideration of possible confounding is important. When confounding and effect modification by other factors can be ruled out, such benchmark doses and their lower confidence levels are of great value in risk assessment and risk management.

4.4.1 Sensitive Groups

The dose-response analysis should focus on the critical effect in the most sensitive subsection of the population (e.g., the fetus of the pregnant mother when adverse effects on the fetus are the critical effect).

4.4.2 Carcinogenic Effects

It was pointed out in Section 4.2.2, that estimation of a safe level of exposure to a carcinogenic metal compound usually involves extrapolation to lower exposures because it is not possible in epidemiological studies to demonstrate low response levels considered acceptable in general environmental exposures (i.e., 1:100 000 in a lifetime). Epidemiological observations on cancer outcome in exposed groups still are of great value in quantitative risk assessment as a starting point for such extrapolations. The best example of a metal/metalloid is inorganic arsenic occurring in drinking water (see Chapter 19; IARC [2004]). There is an increasing body of epidemiological observations on skin, lung, bladder, kidney, and other cancers among population groups in a number of countries exposed to elevated levels of arsenic in drinking water, and dose-response relationships for these effects are also available. Because of the widespread arsenic exposures in drinking water in some parts of the world and number of people exposed, it may be difficult on a practical basis to achieve full population protection at the levels considered desirable for carcinogens in general (see earlier), but this is an ongoing and important discussion.

4.5 Simplified Approach as an Alternative to Risk Assessment

It has recently been suggested that a simplified approach may be used, the so-called threshold of

toxicological concern (TTC) assessment (Kroes *et al.*, 2005). This method is based on classifying chemicals according to their chemical structure and estimating their toxicity, when unknown, from the toxicity of other chemicals with similar chemical structure. Obviously, such a procedure is very uncertain and cannot be used as a replacement for actual risk assessments. It will not be considered further in this text.

5 RISK CHARACTERIZATION

There are both qualitative and quantitative dimensions of risks, and the risk characterization should address both aspects. Some critical effects are severe, like cancer, and a defined numerical risk of such an effect needs to be considered in a different way than the same risk for a critical effect implying an increased urinary excretion of an enzyme or protein without immediate consequences for development of disease. As mentioned in Section 4.1.2, it is desirable to focus dose-response analysis on the critical effect (i.e., the earliest, often subclinical, adverse effect). However, in some cases, particularly when carcinogenesis is involved, such early biomarkers may not be available, and the cancer risks in themselves are the basis for the risk characterization.

The combination of exposure assessment and dose-response analysis generates quantitative estimates of how many persons exceed safe levels derived from NOAEL or benchmark doses and thus are at risk of displaying the critical effect. A concept frequently used in evaluations by expert committees convened by EU is the "margin of safety" (MOS). This is the ratio between NOAEL in animals and the human exposure levels in exposure assessment. Usually MOS of 100 is considered acceptable for noncarcinogenic effects. The considerations as to whether safe levels are exceeded should focus on defined sections of the population (i.e., those most exposed and those most sensitive). Particular attention should be given to estimates of exposure in sensitive groups like pregnant women and children. These sections of the population are particularly sensitive to neurotoxic metals like methylmercury and lead. Risks calculated for such groups often are of crucial importance for risk management.

The risk characterization should also provide information to the risk manager about the quality of the data that has been used in the risk assessment for the manager to be able to judge whether it is reasonably good for decisions about regulatory action. If there are obvious data gaps in the scientific evidence, these problems must be pointed out for the risk managers to be prepared to answer possible questions relating to the risk assessment and risk control measures (for further discussion see WHO/IPCS, 1999).

6 RISK MANAGEMENT AND RISK COMMUNICATION

The scientific database available for the various steps in risk assessment varies considerably among metals as is evident when reading the 31 chapters on individual metals in this handbook. For many of the metals, WHO/IPCS Environmental health criteria documents are available, as well as national documents from various countries (e.g., ATSDR Tox profiles) cited it the various chapters of this book. However, there are a substantial number of metals for which documentation is limited, making it difficult to make a reliable hazard identification and quantitative dose-response analysis. This consideration that is included in the risk characterization is important in risk management.

6.1 Managing Human Exposures by Emission Control, Substitution, Labeling, or Restrictions in Use

Regardless of the risk assessment, exposures are sometimes limited by control of emissions. These considerations are often taken when constructing new manufacturing plants with new production technology and increased automation and encapsulation of productions processes, resulting in considerable reduction in exposure to workers (see also Chapter 16). The "best-practical-means" or "best-available-technology" approach is also used for emissions to the general environment and implies that an industry must use the best available technology to reduce emission of hazardous substances, taking into consideration, however, economic aspects.

The best-practical-means approach, if properly used, carries with it the advantage that resulting concentrations in different media (e.g., in ambient air and soil) around a point source will be as low as possible using the available cleaning techniques. Under certain circumstances, this might mean that, for example, concentrations in the environment may be lower than the levels permissible from the toxicological point of view. Large safety margins may thus sometimes be achieved. The resulting ambient concentrations should, however, be checked against health criteria and other general considerations relating to ecology. The "best-available-technology approach" has been implemented in Swedish environmental legislation since the 1970s and has been effective in limiting exposures of population groups living in the vicinity of point sources of

industrial metal emissions. However, this is not always sufficient to control human exposures that are related to global or regional spread of metals. Despite the successful control of point sources of mercury, high levels still occur in Swedish lake fish as a result of global mercury cycling and the acidification and sulfur pollution of Swedish lakes from European regional sources. Restrictions in intake of certain species of Swedish lake fish, particularly in pregnant women, thus still are recommended by the Swedish Food Agency.

One way to limit human exposures to chemical substances is by labeling. In the EU, as a result of systematic hazard identification efforts, a large number of substances have been classified for hazardous properties. Classification includes acute toxicity (aquatic and terrestrial), irritation, sensitization, carcinogenicity, and reproductive toxicity, and related labeling is implemented (cf European Chemicals Bureau: www.ecb.jrc.it).

If the risk characterization indicates that there are substantial problems with certain uses of a metal, authorities may suggest voluntary substitution of such uses for less toxic substances. If control cannot be achieved by voluntary measures, a ban of such uses of highly toxic metal compounds may be considered. For most metals and uses, this is not possible, but it may be feasible to restrict the use of the most toxic metals. Metals are indispensable in a technological society. All metals are elements that, owing to geological conditions, will be present in varying concentrations in the earth's crust even in nonindustrialized environments. Highly toxic metals often occur in nature together with less toxic metals. Cadmium, for example, is found in ores together with zinc.

In certain instances, the use of some metal compounds has been successfully prohibited. Several governments have, for example, forbidden the use of methylmercury as a fungicide and the use of tetraethyllead as an additive to motor gasoline. Cadmium and lead compounds have been widely used as color pigments. Severe restrictions on this practice are now being enforced in the EU, where many uses of mercury are also being discouraged. For example, many chlor alkali plants are being converted to nonmercury-based technology.

6.2 Controlling Human Exposures by Guidelines and Legislated Permissible Exposure Levels

Exposure guidelines and standards are necessary for toxic metals, often more so than for other substances. Metals are not disintegrated in nature and may be transported over great distances. Furthermore, they have a tendency toward accumulation in nature, as well as in the human organism. We have to live with a certain amount of exposure to metals both in industry and in the general environment. A major problem is to determine what levels of exposure can be accepted with only a minor, defined risk. This discussion focuses on the effects on humans only. Basically, the same principles apply when evaluating effects on the environment. For certain metals, such risks may be the dominating ones, implying that they should receive priority from the standpoint of prevention and control.

Standards for chemicals may be formulated either in terms of concentrations in environmental media (examples are air quality standards, threshold limit values, and drinking water standards) or in terms of amounts of substances that may be ingested into the body within a given unit of time (e.g., acceptable daily intake). These concentrations and amounts should be sufficiently low so that the threshold dose (if one exists and can be determined) will not be reached, or so that the population of concern will not be subjected to "unacceptable risk" even after a lifetime or a working lifetime of exposure.

If a significant exposure takes place via different media, which is often the case for metals, a standard for one media cannot be considered separately (i.e., without looking into possible exposure by means of other media). Take lead as an example. In some places, even the exposure by ambient air, food, and/or water may give rise to concentrations in blood close to or above effect levels. In such situations, occupational exposures must be limited to a very minimum, whereas at other places where ambient levels are low, a higher occupational exposure can be permitted without causing adverse health effects.

Depending on whether the risk characterization indicates that some persons in the population or the work force (for occupational exposures) are at risk of adverse health effects, risk reduction measures are recommended or legislated. Recommendations are issued by international organizations, and various countries or unions may issue legislation about permissible exposure values.

Health-based exposure guidelines are issued by international organizations such as World Health Organization (WHO) in collaboration with Food and Agricultural Organization (FAO). These organizations issue acceptable daily intakes (ADIs) for food additives, tolerable daily intakes (TDIs) or provisional tolerable weekly intakes (PTWIs) for food contaminants. Air pollution guidelines and drinking water guidelines are also recommended by WHO. Recommendations for essential metals have been discussed in Chapter 9.

These recommendations and guidelines are set based on risk assessments using predetermined safety (or uncertainty) factors, and they are thus considered health based, not considering other factors that may be of importance when setting standards in national legislation (see later).

Sometimes the precautionary principle is used when issuing exposure recommendations (cf Hayes, 2005). This principle may imply recommendation of voluntary limiting action against exposures to levels lower that those otherwise recommended based on generally agreed principles of risk assessment. Such lowering of exposures is performed when it can be achieved without any major costs. The precautionary principle is a part of environmental legislation in Sweden and several other European countries. This principle is related to ethical considerations like the paragon of virtue practiced by the ancient authorities in medicine like Hippocrates.

Nongovernmental organizations like the International Commission on Occupational Health (ICOH) sometimes issue policy documents of a precautionary nature. For example, the ICOH Scientific Committee on the Toxicology of Metals in collaboration with the Scientific Committee on Neurotoxicology recently launched the "Declaration of Brescia," recommending lowering of limit values of lead manganese and mercury and other preventive measures (Landrigan *et al*., 2006 and Chapter 16).

Standards (national legislation) for occupational exposures in the United States of America are set by the Occupational Safety and Health Administration (OSHA) and the National Institute for Occupational Safety and Health (NIOSH). There are also drinking water standards and air pollution standards in the United States, which are set by the U.S. Environmental Protection Agency (USEPA) for a number of metals such as lead and metalloids such as arsenic.

For cancer, the USEPA (USEPA/IRIS, 2006a,b) has developed the unit risk concept, which is defined as the upper bound lifetime cancer risk estimated to result from an agent at a concentration of 1 μg/L in water or 1 μg/m^3 in air. The upper bound confidence limit (UCL) is defined as the upper bound of a confidence interval around any calculated statistic that is most commonly an average. The interpretation of unit risk would be as follows: unit risk $= 2 \times 10^{-6}$/μg/L would indicate two excess cancer cases (upper bound estimate) to be expected per 1 million persons if exposed daily over a lifetime to 1 μg of the agent per liter of water or cubic meter of air. For cadmium, which the USEPA considers to be a class B1 carcinogen, the inhalation unit risk estimate is $1.8 \times 10^{-3}(\mu g/m^3)^{-1}$. The USEPA uses mathematical models, based on animal studies, to estimate the probability of a person developing cancer from such exposures.

The EU has issued a limited number of permissible occupational limits (PEL) that are either indicative or binding for member states. They are based on criteria documents issued by the Scientific Committee on Occupational Exposure Limits (SCOEL). Member states like Germany and Sweden have issued a larger number of such limits that are implemented on a national level in harmony with the PELs issued by EU. Other countries like Japan, Russia, and China have their own lists of permissible occupational exposure limits. In the past, there were considerable differences in such limits among countries like the Soviet Union and China on the one hand and the United States and western European countries on the other hand. As a result of the International Program on Chemical Safety, and its predecessors, starting in the 1970s, these differences have gradually decreased (see also discussion by L Friberg in Chapter 1 of this handbook).

The European Union has regulated maximum levels of contaminants, including lead, cadmium, and mercury in foodstuffs (EG466/2001). The EU (1998) has (98/83/EC) adopted drinking water standards for a number of substances including some metals, and these standards are implemented in member states that report values to the European commission.

Biological exposure levels for metals/metalloids in media such as blood for metals such as lead and urine for arsenic are used in both occupational and environmental exposure situations to assess the degree of actual uptake into exposed individuals or populations. These data have been used as screening levels for determining the need for medical interventions or clean up activities. Blood lead measures for occupational and childhood exposures would be the most well-documented and extensively used example. In the United States, the CDC has recommended a blood lead level of concern for lead of 100 μg/L; this level should be used for screening of children.

In Sweden, biological exposure levels in terms of blood concentrations allowed among industrial workers are issued by the Swedish Work Environment Authority (concerning levels for lead see Chapter 31 and for cadmium see Chapter 23).

When national or union authorities issue recommendations and limits, a number of factors are taken into consideration in addition to the risk characterization such as socioeconomic, political, risk/benefit, and cost/benefit factors (cf IPCS/WHO, 1999).

Readers of this handbook will see that the information available on the toxicology of metals and their compounds vary widely among metals. Only for a limited number of the metals is there adequate information to

make a reliable dose-response assessment for humans. An ongoing discussion in Europe is about the new component of chemicals control REACH (Registration and Evaluation of Chemicals; see *http://ecb.jrc.*it), requiring manufacturers and importers of chemical substances, including metals, to furnish a specified amount of toxicological data for the substance to be used in the EU. Some consider that the requirements for toxicological information are too limited (Rudén and Hansson, 2006). It is hoped that this new legislation will provide additional data relevant for risk assessment for some of the metals and metal compounds that are presently incompletely investigated.

6.3 Risk Communication

Risk communication is the process of communication between professionals performing risk assessments and risk managing on the one hand and on the other hand workers in the case of occupational exposures or the general public for general environmental exposures.

In a democratic society, risk communication is of great importance. In the case of occupational risks communication, it may be direct between risk assessors/risk managers in central agencies and workers by means of workers' unions and safety organizations in companies. Such risk communication may sometimes involve considerations like those used when communication involves factors of outrage (see later), but in other cases, such communications are characterized by mutual understanding and acceptance of risks and risk reduction measures suggested by risk assessors.

When communicating with the public, the behavior of the risk assessor is crucial for acceptance.

The following principles are listed by US ATSDR concerning risk communication:

1. Accept and involve the public as a partner. Your goal is to produce an informed public, not to defuse public concerns or replace actions.
2. Plan carefully and evaluate your efforts. Different goals, audiences, and media require different actions.
3. Listen to the public's specific concerns. People often care more about trust, credibility, competence, fairness, and empathy than about statistics and details.
4. Be honest, frank, and open. Trust and credibility are difficult to obtain; once lost, they are almost impossible to regain.
5. Work with other credible sources. Conflicts and disagreements among organizations make communication with the public much more difficult.
6. Meet the needs of the media. The media are usually more interested in politics than risk, simplicity than complexity, danger than safety.
7. Speak clearly and with compassion. Never let your efforts prevent your acknowledging the tragedy of an illness, injury, or death. People can understand risk information, but they may still not agree with you; some people will not be satisfied.
8. Communicate important information to societal decision makers such as legislators, who must frequently make decisions about the need to use public resources for regulatory actions or clean up activities. One mechanism is to use the World Wide Web or Internet for this purpose, because this is a common source of information *(*cf *www.atsdr.cdc.gov/cabs).*

Depending on the situation and the risk under consideration, risk perception by the public may be different than that perceived by the risk assessor. A number of factors, for example, how familiar, widespread, and dreaded the risks are and whether risks are controllable or not determine the degree of outrage by the public (WHO/IPCS, 1999). Increased interaction with the public may be useful in such situations. Communication with the public sometimes is described as a converging process. On the basis of the risk characterization, information about the risk in question is communicated to the group of the public with the highest exposure at a public meeting, and feedback is requested. It is important for the risk assessor, presenting risks to the public, to find out about reasons for possible discrepancies in risk perception. Depending on comments received, answers to questions and new information adapted to the needs of the public are prepared and presented at a new meeting, for example, comparisons between the risks from exposures to the agent under consideration and other risks in society. This procedure may be repeated. Often, a convergence of opinions will occur between risk assessors and the public.

Diagnosis and Treatment of Metal Poisoning—General Aspects

GEORGE KAZANTZIS

ABSTRACT

Metal poisoning may or may not be apparent from the clinical features induced. The exposure pattern in terms of time, concentration, and route of exposure is a determinant of clinical effect. Short-term high- and long-term low-level exposure by ingestion is seen more often in the domestic environment and by inhalation more often occupational in origin. Acute and chronic clinical effects of metal toxicity may involve the gastrointestinal, respiratory, cardiovascular, renal, hemopoietic, and central nervous systems.

In the diagnosis of metal poisoning, the presenting features may be nonspecific, the clinical examination giving no lead on the cause of illness. A full occupational history is required, with a knowledge of the work processes involved and a detailed history where poisoning may occur in the domestic environment, in particular where poisoning results from the long-term absorption of cumulative metals. However, metal accumulation and poisoning may occur in the absence of environmental exposure, as, for example, transfusional siderosis in the thalassanemias, iron overload in idiopathic hemochromatosis, and copper accumulation in Wilson's disease. In addition to history and clinical examination, trace metal analysis in body fluids, tissues, and environmental samples is required, together with biochemical and physiological investigation.

In the treatment of metal poisoning, prevention of further absorption by removal from exposure; minimizing absorption from the gastrointestinal tract; and general supportive therapy that requires maintenance of respiration and circulation, water, and electrolyte balance; and control of nervous system effects is a priority. Elimination of the absorbed poison may be promoted by diuresis, biliary excretion, or by hemodialysis or exchange transfusion. A number of therapeutic agents counteract the effects of an absorbed toxic metal by combining to form a less toxic compound that may be excreted more effectively by displacing it from its receptor site or into a tissue where it cannot exert its toxic effects. Toxic metal antagonists, chelating agents, compete for toxic metals with ligands essential for physiological function by forming a stable complex with the metal in the form of a heterocyclic ring. Chelating agents possess electron donor groups showing a high affinity for the metal to be removed, releasing it from complexes with proteins or other endogenous ligands in a form in which it can be readily excreted. Chelation is indicated in the treatment of metal poisoning, metal storage diseases, blood transfusion in iron overload, and to aid the elimination of metallic nuclides. However, chelation may result in depletion of essential metals or the distribution of toxic metals to other tissues such as the brain. Chelators may also have toxic effects.

Dimercaprol, now a classic chelator with high toxicity, competes with protein sulfhydryl groups for arsenic, forming a stable chelate, and is effective for inorganic mercury, antimony, bismuth, and gold. Unithiol, DMPS, an analog of dimercaprol, is effective in accelerating metal excretion without severe adverse effects in acute and chronic intoxication by inorganic and organic mercury, bismuth, arsenic, and chronic lead poisoning.

Succimer, DMSA, less toxic than DMPS, has been the preferred antidote for lead poisoning, particularly in children, although adverse effects have also been reported. Calcium EDTA, given intravenously, will bind lead with the displacement of calcium. However, it has marked toxic effects and may redistribute lead to the brain after acute or chronic lead poisoning. Penicillamine, an effective chelating agent for copper, iron, lead, mercury, and zinc, is, in particular, effective in the management of Wilson's disease and in which it may be given indefinitely to maintain a negative copper balance. Trien, TETA, is effective in the treatment of Wilson's disease, where intolerance to penicillamine has developed. Desferrioxamine, DFOA, given parenterally, has an affinity for iron and is the treatment of choice in acute iron poisoning, in particular in children. It is indicated in the treatment of transfusional siderosis as in thalassemias and has been effective for the removal of aluminium in dialysis encephalopathy. Deferiprone, L1, is effective orally for the long-term chelation therapy of transfusional siderosis. Lipophilic derivatives of DTPA have been administered as an aerosol to diminish the lung concentration of inhaled insoluble plutonium oxide particles. DEDTC has been effective in the treatment of acute nickel carbonyl poisoning.

A combination of the two chelating agents has been shown to be effective in some cases of poisoning. Combined treatment with EDTA and dimercaprol is effective in acute lead poisoning in children with encephalopathy or blood lead levels greater than 100 μg/L.

Other therapeutic measures in metal poisoning are a modification of tissue response to the poison or an alteration of biochemical or metabolic state of the subject. Thus, the inflammatory process in chronic beryllium disease may be arrested by corticosteroid therapy. In chronic manganese poisoning that closely resembles Parkinson's disease, L-dopa has been effective in reducing symptoms and neurological signs without evidence of a reduced body burden of manganese.

1 CLINICAL EFFECTS

1.1 General Considerations

Metal poisoning may be acute, resulting in death or followed by partial or complete recovery. It may be subacute in onset, or there may be a latent interval between absorption and its development, which may then follow the same course as previously mentioned or give rise to chronic poisoning. However, toxic metals produce other important clinical effects not usually included under this term. These effects are (1) hypersensitivity reactions that may involve the skin, kidney, lung, hemopoietic system, and possibly the nervous system; (2) the induction of cancer after an appropriate latent interval; and (3) teratogenic malformations. Furthermore, an increasing number of metals are being shown to give rise to genetic damage in test systems, and the question arises as to whether mutations may also occur in man, with a consequent increase in abnormal individuals in later generations. These other effects, because of their importance and magnitude, are considered elsewhere.

Adverse effects, which may become manifest by biochemical or physiological tests or by abnormal clinical signs, may occur in the absence of symptoms or in the presence of vague, ill-defined complaints of ill health that do not make up a recognizable syndrome. Common examples are anemia after exposure to lead compounds and renal tubular dysfunction after long-term exposure to cadmium.

The clinical effects described previously imply that an adverse biological change has been produced in the organism with some impairment of cellular function resulting from exposure. The model on which this adverse effect is based assumes that a critical concentration of the toxic metal has been attained in the critical organ to give rise to a critical effect. This critical effect may or may not be of immediate importance to the health of the organism as a whole (Nordberg, 1976). It may be argued that such a critical effect cannot be considered to be synonymous with a clinical effect. Here it is useful to distinguish between critical and subcritical effects. Effects may also occur below the critical concentration in the critical organ that do not impair or seem to impair cellular function (Nordberg, 1976; see also Chapter 12). Although the biological significance of such a subcritical effect may be unknown, it would be reasonable, given the present state of knowledge, to exclude such a subcritical effect from clinical consideration.

1.2 Exposure Pattern and Clinical Effect

Various factors act as determinants of a clinical effect after exposure to a toxic metal. Such factors include dose; route of absorption; the chemical and physical form of the metal concerned; genetic variation manifested through racial, familial, and individual susceptibility; dietary pattern and nutritional status; immunological status; presence of intercurrent disease; and interaction with other chemical compounds in the environment. Some of these determinants are considered in Chapter 7 and in those chapters dealing with the specific metals. The exposure pattern, in terms of concentration, time, and route of exposure, is an important determinant of clinical effects that requires further consideration here.

A short-term exposure may produce a clinical effect very different from that produced by an exposure similar in terms of total dose over a longer period of time. The effects of ingestion of a toxic metal are more often seen in the domestic or general environment than in an industrial setting. Short-term, high-level exposure by ingestion may follow the accidental, suicidal, or homicidal ingestion of a toxic metal compound, giving rise to well-recognized acute syndromes, usually involving the gastrointestinal tract and possibly involving secondarily the renal, cardiovascular, nervous, and hemopoietic systems. Long-term, low-level exposure by ingestion is seen increasingly in the general environment as a result of the contamination of food and drink by metals that have cumulative properties in the organism. Clinical effects may involve any organ system in the body, but the gastrointestinal tract is not primarily involved.

By contrast, short-term, high-level inhalation exposure is most often occupational in origin. It may not only give rise to acute respiratory effects but may also involve the cardiovascular, central nervous, renal, and hemopoietic systems. Again, long-term, low-level inhalation exposure is usually occupational in origin, and its control forms a large part of industrial hygiene practice. However, long-term, low-level inhalation exposure to certain toxic metals may also occur in the general environment and from smoking cigarettes. The effects may involve any organ system in the body and may spare the respiratory system.

Mercury forms a good example of the extreme variation in clinical effect that may be produced, depending on the pattern of exposure and the chemical form of the metal (Kazantzis, 1980). The lung is the critical organ after short-term, high-level inhalation exposure to mercury vapor, resulting in pneumonitis and respiratory failure, whereas the CNS is the critical organ after long-term exposure to mercury vapor. After the ingestion of an inorganic soluble mercuric compound, the kidney becomes the critical organ, manifesting with anuria because of tubular necrosis. As a result of the long-term ingestion of methylmercury as a food contaminant, nervous system effects may develop but with a clinical syndrome different from that seen after the long-term inhalation of inorganic mercury vapor. The variability in clinical effect produced by the toxic metals is further illustrated in the following section. The adverse effects that result after exposure to the individual metals are described in detail in succeeding chapters of this handbook.

1.3 Acute Clinical Effects of Metals

1.3.1 Gastrointestinal Effects

Acute gastroenteritis follows the ingestion of a toxic quantity of most metals in the form of soluble salts. A not uncommon occurrence is the contamination of food or drink, especially if acidic, by dissolution of metal from food containers. Symptoms develop a short time after ingestion, often involve a number of people, and may be labeled as "food poisoning." Vomiting and diarrhea may be followed by circulatory collapse and involvement of other systems, depending on the poison absorbed. Poisoning with soluble compounds of antimony, cadmium, copper, lead, tin, and zinc has occurred in this way. Acute gastroenteritis with collapse may be the predominant feature after the ingestion of rodenticides containing arsenic, barium or thallium, yellow phosphorus, or zinc phosphide. Similar symptoms may follow the ingestion of soluble compounds of bismuth, chromium, iron, silver, and vanadium. The ingestion of a soluble mercuric salt gives rise to gastroenteritis with a bloody diarrhea that may resemble fulminating ulcerative colitis. Lead colic, which may occur as an acute effect after prolonged exposure to lead, has on many occasions simulated an acute surgical emergency.

1.3.2 Respiratory Effects

Acute chemical pneumonitis, which may be accompanied by pulmonary edema, follows the inhalation of a number of freshly formed metal fumes. Particularly toxic in this respect is the inhalation of freshly formed cadmium oxide fume, with acute symptoms developing some hours after an apparently innocuous exposure (Beton *et al*., 1966). The inhalation of antimony pentachloride, arsine, beryllium fume, iron pentacarbonyl, lithium hydride, nickel carbonyl, titanium tetrachloride, selenium dioxide, hydrogen selenide, vanadium pentoxide, or zinc chloride can give rise to a similarly acute picture with pulmonary edema. The inhalation of high concentrations of mercury vapor or dust or inorganic mercury compounds can also give rise to pneumonitis before other symptoms of mercurialism develop. Respiratory symptoms with rigors and fever resembling an acute respiratory infection may follow the inhalation of freshly formed zinc fume, brass fume, or other metallic oxides, giving rise to metal-fume fever (Hunter, 1975). Pneumonic consolidation has followed the inhalation of manganese dust. The inhalation of complex salts of platinum can give rise to acute and severe asthma. Decomposition products or other contaminants of industrial air may be responsible for some of these effects.

1.3.3 Cardiovascular Effects

A number of metallic ions interfere with the normal function of myocardial cells, giving rise to arrhythmias, including ventricular fibrillation. Ventricular

fibrillation may be responsible for a fatal outcome in cases of poisoning by antimony, barium, or lithium salts. Cobalt can give rise to cardiomyopathy (Alexander, 1972). Some metals have been shown to have a hypotensive effect. These include antimony, cadmium, cobalt, copper, iron, and vanadium, a state of shock being a common presenting feature in poisoning with these metals.

1.3.4 Effects on the Central Nervous System

Metal poisoning may present with an acute illness involving the CNS. Most important, because unfortunately still not uncommon in children, are convulsive attacks that may terminate in coma or lead to death as a result of acute lead poisoning. A successful therapeutic outcome in such cases depends on early diagnosis and treatment. Convulsions may also follow the absorption of iron, barium, lithium, thallium, and organic tin compounds. Acute psychosis may also be the presenting feature in metal poisoning. After heavy exposure to tetraethyl lead, a patient may present with delusions, hallucinations, and hyperactivity that may precede coma and death (Beattie *et al*., 1972).

1.3.5 Renal Effects

Renal damage, manifesting as oliguria or anuria caused by acute tubular necrosis, is another way in which metal poisoning may present, although this feature often follows an initial presentation with acute gastrointestinal, circulatory, or respiratory effects. Oliguria and anuria caused by tubular necrosis are common occurrences, especially in children, after the ingestion of soluble mercuric or iron salts. The condition may also follow pneumonitis resulting from cadmium fume inhalation. Renal failure has been a sequel to the absorption of a number of soluble metal compounds, including antimony, arsine, bismuth, copper, uranium, and vanadium salts.

1.3.6 Hemopoietic Effects

Acute hemolytic anemia often accompanied by renal failure may be the presenting feature after the inhalation of arsine or stibine gas (Jenkins *et al*., 1965). Acute hemolysis has also followed the ingestion of large doses of soluble copper salts.

1.4 Chronic Clinical Effects of Metal Toxicity

The term chronic effect is a relative one, signifying that the clinical effect may develop gradually and may persist for a longer interval than an acute effect. Chronic effects are associated with longer-term exposure at lower levels than acute effects. Only examples of chronic effects are given here, the great variety of these being described in the individual metal chapters.

1.4.1 Gastrointestinal Effects

Some chronic gastrointestinal effects may, in fact, be examples of mild acute poisoning after the repeated ingestion of the toxic metal over a period of time. Chronic gastrointestinal symptoms have occurred in people drinking canned juice contaminated with high concentrations of tin or zinc or ingesting drinking water contaminated with copper. However, intestinal colic has been observed in industrial workers and in children with relatively low-level lead exposure, and this can be considered a true example of chronic lead poisoning (Beritic, 1971). Anorexia, nausea, and vomiting in industrial workers may be seen with selenium and tellurium poisoning, when the characteristic garlic odor of the breath may also be elicited. Anorexia, and often digestive disturbances, has also been reported in people living in seleniferous regions and with a high dietary intake of selenium. Anorexia, nausea, vomiting, and diarrhea followed by constipation accompanied by a burning sensation of the tongue and stomatitis have resulted from occupational exposure to thallium compounds.

1.4.2 Hepatic Effects

Several metals are hepatotoxins, giving rise to effects ranging from abnormalities in hepatic enzyme levels to clinical jaundice. Such effects have been reported after exposure to antimony, arsenic, bismuth, copper, chromium, iron, and selenium.

1.4.3 Respiratory Effects

Chronic pulmonary disorders giving rise to dyspnea may result from absorption of metal dust or fume. An inflammatory response consisting of noncaseating granuloma formation followed by pulmonary fibrosis may result from exposure to beryllium after a latent interval of many years (Stoeckle *et al*., 1969). Progressive dyspnea with the clinical, radiological, and functional changes associated with emphysema is seen in workers exposed to cadmium oxide fume or dust. The respiratory abnormality is usually, but not invariably, associated with renal tubular dysfunction. Pulmonary fibrosis has followed occupational exposure to finely powdered aluminium metal dust. Dyspnea, wheeze, and productive cough giving rise to an illness resembling asthmatic bronchitis have followed occupational exposure to vanadium pentoxide dust. Progressive breathlessness associated with pulmonary fibrosis has

occurred in hard-metal workers exposed to the dusts of tungsten and titanium carbides with cobalt used as a binder. Chronic asthma can occur in workers sensitized to chromium after the inhalation of chromate dust or chromic acid fume and also to organic platinum compounds. Once sensitization to platinum has occurred, the reaction can be triggered by exposure to minute quantities of the salts of chloroplatinic acid.

1.4.4 Effects on the Nervous System

Peripheral neuropathy may develop in the recovery stage of acute arsenic intoxication, about 1–3 weeks after exposure. It is a mixed motor and sensory neuropathy, with a "glove and stocking" distribution. Neuropathy develops in those who survive the acute gastrointestinal effects of thallium poisoning, and it may lead to a later fatal termination. With both these metals, skin changes occur at a later stage, with the former metal, arsenical pigmentation results, and with the latter, hair loss. A motor neuropathy involving predominantly the upper limbs with wrist drop and extensor weakness of the fingers is seen in chronic lead poisoning. By contrast, antimony salts of organic acids give rise to a sensory neuropathy that may involve the trigeminal nerve. Bismuth and copper have also given rise to peripheral neuropathy.

Permanent brain damage with cerebral cortical atrophy or hydrocephalus may be the sequel to acute lead encephalopathy. Convulsions may recur over a long period, and idiocy may develop.

The use of lead paints and leaded gasoline has given rise to the widespread occurrence of lead in the environment. Elevated blood lead levels after long-term exposure to house dust with decaying fragments of leaded paint has been shown in epidemiological studies to affect cognitive development in children (Bellinger *et al*., 1992; Needleman *et al*., 1990; Chapter 31).

Degenerative changes in the nerve cells of the basal ganglia giving rise to a parkinsonian syndrome were considered to result from the absorption of manganese after long-term occupational exposure (Mena *et al*., 1970). Parkinson's disease, a not uncommon disorder, is characterized by muscular rigidity, akinesia, tremor, and postural deformities. In a case-control study to determine whether welding-related parkinsonism differs from idiopathic Parkinson's disease in welders exposed to manganese welders had a significantly younger age of onset of parkinsonism, suggesting welding as a risk factor for this condition (Racette *et al*., 2001).

Degenerative changes affecting in particular the granular cells in the cerebellum and neurons in the calcarine, precentral, and postcentral cortex, follow the absorption of alkylmercury compounds and present with a characteristic neurological syndrome whose principal features are paresthesia of extremities and face, ataxia, dysarthria, and concentric constriction of the fields of vision. Pyramidal signs may also occur. Another characteristic neurological disorder consisting principally of intention tremor of the hands, tremor of the eyelids and tongue, and a combination of behavioral and personality changes known as erethism develops after chronic exposure to mercury vapor.

1.4.5 Renal Effects

Certain chronic renal disorders may also follow exposure to toxic metals. Proximal renal tubular dysfunction consisting mainly of tubular proteinuria, glucosuria, aminoaciduria, and phosphaturia may develop after cumulative exposure to cadmium, lead, and uranium compounds. Hypercalciuria has also occurred in chronic cadmium poisoning as a further manifestation of renal tubular dysfunction, and this has led to renal stone formation and to osteomalacia in a few cases after industrial exposure (Kazantzis, 1979).

Osteomalacia has been observed in a population environmentally exposed to cadmium in Japan. Although the skeletal disorder (Itai-Itai disease) only occurred in postmenopausal women, evidence of renal tubular dysfunction was found in the population as a whole (Friberg *et al*., 1974; 1985).

Progressive impairment in renal function terminating in uremia and indistinguishable clinically from chronic nephritis has been observed after childhood lead poisoning. The wide range of abnormal responses of the kidney to absorbed metals can be further illustrated by reference to the nephrotic syndrome. Heavy proteinuria, with hypoproteinemia and edema, has followed exposure to inorganic mercury, organic gold, and bismuth preparations.

1.4.6 Hemopoietic Effects

Chronic arsenic poisoning is associated with an anemia caused by decreased red blood cell formation with increased destruction. The anemia of chronic lead poisoning also results from decreased hemopoiesis combined with increased red cell destruction (Goyer and Rhyne, 1973). By contrast, cobalt has an increased hemopoietic effect and has given rise to polycythemia, but not to increased production of other cellular elements in the blood.

2 DIAGNOSIS OF METAL POISONING

As can be seen from the preceding, metal poisoning may involve any of the organ systems of the body and

give rise to a variety of effects. The presenting features may be entirely nonspecific, the clinical examination giving no lead on the cause of the illness. The principal features that should be considered in arriving at a correct diagnosis are elaborated in the following.

2.1 History of Exposure

In most cases, a history of exposure to a toxic metal will give the necessary clue. In an industrial situation, there may be a clear history of exposure that may be obtained from the patient, a relative, or a coworker. The clinician should not fail to take a full and accurate occupational history when a poisoning of occupational origin is suspected. It may be necessary to seek additional information from the employer or his agent, from an occupational hygienist, or from a health and safety representative. Exposure to a toxic metal may, however, occur without this being suspected by any of the persons questioned, and this can only be inferred by an adequate knowledge of the work processes involved. A good example may be given with exposure to arsine gas, which usually presents as an acute medical emergency. Arsenic may be a contaminant in scrap metals, flue dusts, etc., and arsine may be formed in any reducing situation, or when a metallic dross containing arsenic comes into contact with water. The condition should, therefore, be suspected in a scrap-metal worker presenting with the appropriate clinical features.

In the domestic environment, an appropriate history may give an exposure inferred from medicaments such as iron pills or household chemicals. Unlabeled pills or chemicals should, of course, be kept for analysis. In a homicidal instance, a psychotic factory worker succeeded in poisoning three fellow workers in succession by adding a thallium salt to tea, causing the deaths of two men before the poisoning was suspected (Cavanagh *et al.*, 1974). In the general environment, diagnosis of metal poisoning, especially if caused by long-term absorption of cumulative metals in the body, can be very difficult. Methylmercury poisoning after the eating of contaminated bread in Iraq was diagnosed at the beginning of the outbreak, because the medical officers had previous experience of the condition.

Metal accumulation may also occur in the absence of environmental exposure. The thalassemias are a heterogenous group of genetic disorders of hemoglobin synthesis. Symptomatic treatment of anemia requires regular blood transfusion from childhood. For the prevention and treatment of resulting iron overload, transfusional siderosis, a chelating agent is required, desferrioxamine being the best choice. However, repeated intravenous or subcutaneous injection with possible side effects is stressful to patients, and an orally effective iron chelator, deferiprone, is suited for long-term in-home treatment. This can be combined with desferrioxamine and be effective at lower doses (Kontogiorghes *et al.*, 2000).

Primary or idiopathic hemochromatosis is an autosomal-recessive disorder caused by excessive absorption and storage of iron. Deposition of iron in organs and tissues causes fibrotic changes and functional impairment, in particular arthropathy, cirrhosis with hepatomegaly, diabetic mellitus, hypogonadism, cardiac arrhythmias, heart failure, and skin pigmentation caused by melanin and hemosiderin deposition (Bacon, 2001; Niederau *et al.*, 1994). Repeated phlebotomus has been effective in reducing serum ferritin, and in cases with excessive iron deposits, this has been combined with an iron-chelating agent, in particular desferrioxamine. Because early diagnosis is essential for the successful treatment of this condition, relatives of patients with primary hemochromatosis are candidates for genetic screening (Tavill, 1999).

In Wilson's disease, hepatolenticular degeneration, a recessively inherited metabolic disorder, there is a failure to excrete copper into bile, resulting in copper accumulation first in the liver, then in the brain, cornea, and kidneys (Walshe, 1984). The age of onset may be as early as 5 years up to the fifth decade. Hepatic necrosis releases copper into the circulation, causing damage to erythrocyte membranes leading to hemolytic anaemia. Copper accumulation results in widespread neurological disturbances with tremor, slurred speech, muscular rigidity, mental deterioration, and pigmented rings at the corneal rims of the eye, this being a diagnostic marker. Diagnosis depends on an accurate estimation of copper in an uncontaminated 24-hour urine sample, in Wilson's disease usually more than 100 μg/24 hours. Treatment to produce a negative copper balance is effective with the chelating agents penicillamine, triethylene tetramine, and with zinc, which inhibits copper absorption from food and increases fecal copper excretion. In particular, treatment is more effective in those diagnosed in the presymptomatic phases of the disease (Sarkar, 1999).

2.2 Clinical Features

The presenting clinical features, especially in acute poisoning, may be entirely nonspecific. Lead colic has been mistaken for the acute surgical abdomen, and craniotomy has been performed after encephalopathy caused by lead. Such mistakes would not have been made if a careful history had been taken. Certain clinical sequences should alert the physician to the possibility of metal poisoning. Gastroenteritis followed by

peripheral neuropathy that is, in turn, followed by hair loss is a classical presentation for thallium poisoning. Gastroenteritis followed by oliguria or anuria follows the ingestion of inorganic mercuric and other soluble metal compounds as mentioned in the previous section. Hemorrhagic gastroenteritis, especially if accompanied by collapse and hypotension, should alert the clinician to an acute metal poisoning by ingestion. Similarly, acute pulmonary edema in a subject free of heart disease should raise the suspicion of a toxic inhalation exposure. Acute cadmium fume poisoning should be suspected, especially if soldering or welding had been performed, for iron and steel may be plated with cadmium. Metal poisoning should also be considered in the differential diagnosis of oliguria or anuria of unknown etiology. Several metals give rise to renal tubular dysfunction, in particular cadmium, uranium, and lead. With lead, this condition is seen more often in children, so that lead poisoning should be considered in every case of glycosuria presenting in childhood. The causes of peripheral neuropathy are often obscure, and many cases remain undiagnosed. Metal poisoning should be considered in the differential diagnosis of peripheral neuropathy.

Few of the signs described in this chapter are specific to metal poisoning. There are, however, certain specific signs indicative of metal absorption, although not necessarily of poisoning. Among these, the following should be mentioned: the characteristic garlic smell in the breath of selenium and tellurium workers, the green tongue of the vanadium worker, and the pigmented alveolar margin (the lead line) caused by the deposition of insoluble sulfide in the gums of lead workers. However, the lead line is not seen in edentulous workers, and other metals will deposit sulfide in the same site. A finely mottled brown pigmentation of the skin, with leukodermia, a "rain drop pigmentation" affecting, in particular, the temples, eyelids, and neck is seen in workers in contact with arsenical dusts. Ulceration and perforation of the nasal septum should also alert the clinician to previous long-term exposure to arsenical dusts or to chromates. Chronic ulceration on the fingers is seen after exposure to washing soda or to lime. White striae on the fingernails lines (Mees lines) are indicative of previous exposure to arsenic.

2.3 Toxicological Analysis

A diagnosis of metal poisoning can be confirmed in the acute stage and often in the chronic stage by finding an increased concentration of the suspected metal in the appropriate medium. However, the techniques involved in trace metal analysis in body fluids and tissues present certain difficulties, and such analysis should only be performed in laboratories that are equipped for this purpose and that participate in external quality control. Environmental sampling may need to be performed on air, water, or food. Pills, residues in bottles, may require analysis after an acute poisoning incident, as may blood, urine, feces, vomit, and tissue samples. The examination of blood and urine samples for metal concentration can be considered a routine procedure. However, it should be borne in mind that some metals disappear rapidly from the blood, and others are sparingly excreted in the urine. In thallium poisoning, for example, the diagnosis can be confirmed by taking hair and nail clippings for analysis at a stage when blood and urine concentrations are not helpful. Evidence of methylmercury absorption can be obtained from analysis of hair samples after blood levels have fallen to normal. In the diagnosis of lead poisoning, difficulty may be caused when exposure had ceased some time previously. In such cases, blood lead levels may return to normal by the time diagnosis is attempted. A calcium EDTA provocation test will increase the urinary excretion of stored lead in such a situation.

2.4 Biochemical Investigation

For most metal poisonings, biochemical investigation is required in addition to estimation of metal concentrations in body fluids. The profile of biochemical abnormality is indicated in the chapters on the different metals considered. In general, biochemical tests of renal and hepatic function are always required. Biochemical data are essential for diagnosis with certain toxic metals but are not helpful with others. For example, in the diagnosis of lead poisoning, it is useful to estimate δ-aminolevulinic acid and coproporphyrin in the urine, as well as zinc erythrocyte protoporphyrin and lead concentration in the blood. In contrast, the diagnosis of poisoning by metallic mercury vapor or by alkylmercury compounds is essentially clinical, together with estimation of metal concentrations in blood and for inorganic mercury in urine.

2.5 Physiological Investigation

Electrocardiography, respiratory function tests, electroencephalography, and nerve conduction studies provide examples of possible ancillary investigations for the diagnosis and for the determination of the extent of poisoning by certain metals. The principal disturbances of physiological function in such poisoning are indicated in the chapters on individual metals.

3 TREATMENT

The treatment of metal poisoning includes treatment of the acute and chronic effects and suppression of tissue reaction when sensitization has occurred.

The management of acute metal poisoning requires emergency resuscitative procedures that may need to be initiated in the work or home environment and continued in an acute treatment unit. Those principles on which the management of the acute case of poisoning is based, which are aspects of emergency medicine (see Dreisbach, 1983; Vale and Meredith, 1981), will only be briefly referred to here, whereas therapy related to metal poisoning will be discussed in more detail.

3.1 Prevention of Further Absorption

3.1.1 Removal from Exposure

Absorption of a toxic metal may follow inhalation, ingestion, or skin or mucosal contamination. Occupational exposure most frequently gives rise to absorption after inhalation. After high-level inhalation exposure, the victim should be removed immediately from the contaminated atmosphere. Such an emergency situation may arise with volatile metal compounds such as stibine, arsine, alkylmercury, alkyltin, and alkyl lead compounds. After contamination of the skin with lipid-soluble metal compounds, contaminated clothing should be removed as soon as possible, and the contaminated area must be irrigated and washed, but not rubbed, with copious amounts of cold water. Decontamination may also be required for hair and fingernails.

In chronic, cumulative metal poisoning, it may be sufficient to remove the subject from further exposure. In certain circumstances, for instance, a worker with mild poisoning after exposure to inorganic mercury vapor or to lead fume or dust may require no therapy other than such removal. The normal excretory mechanisms will ensure a gradual recovery from mild toxic effects.

A review of possible routes of absorption in the individual case should include consideration of the possibility of exposure by contamination of food, drink, cigarettes, or clothing. When this possibility exists, food, drink, and cigarettes at the work site should be prohibited, and facilities should be provided for showering and for a complete change of clothing after each shift.

3.1.2 Minimizing Absorption from the Gastrointestinal Tract

3.1.2.1 Removal from the Gastrointestinal Tract

Within about 4 hours after ingestion, some of the poison may be recovered by emptying the stomach. In a fully conscious patient, this may be effected by vomiting. As a first-aid measure in a child immediately after ingestion, this may be induced by pharyngeal stimulation. Ipecacuanha Emetic Mixture 10–15 ml for a child, 30 ml for an adult, may be effective in inducing vomiting.

The stomach may be washed out after the passage of a gastric tube, but this should not be attempted after the ingestion of corrosives or petroleum products or in drowsy or comatose patients because of the danger of inhalation of stomach contents. The procedure of gastric lavage is a skilled one that should only be performed in a properly equipped emergency department, again within about 4 hours of ingestion. If the cough reflex is absent or if consciousness is impaired, a cuffed endotracheal tube should first be passed to protect the lungs from inhalation of stomach contents.

3.1.2.2 Inactivation in the Gastrointestinal Tract

Although gastric lavage can be effectively performed with warm water, some poisons may be inactivated in the stomach by a specific antidote, and after lavage, this may be left in the stomach in a volume not greater than 200–300 ml. However, lavage should not be delayed if the antidote is not immediately available. In an emergency situation, egg white or milk will help to partly inactivate mercury and other heavy metals by precipitation in the stomach. Activated charcoal will effectively absorb many poisons still present in the stomach and will also interrupt the enterohepatic circulation. However, it is ineffective in iron poisoning. Five to ten grams of a thick suspension in water should be given, and this may be repeated at intervals of 20 minutes to a maximum of 50 g. Higher doses may be given, but these may induce vomiting of the suspension. As a first-aid measure, sodium bicarbonate will partly precipitate soluble iron salts in the stomach. Gastric lavage should be performed as soon as possible with desferrioxamine mesylate, 2 g in 1 liter of water. A solution of desferrioxamine, 10 g in 50 mL water, should then be left in the stomach. Effective precipitation of the toxic barium ion can be produced by oral administration or gastric lavage with a 10% solution of sodium or magnesium sulfate. After the ingestion of chromic acid, lavage should be performed with magnesium carbonate. Prussian blue will chelate thallium, and after its ingestion, a colloidal solution should be given by duodenal tube at a rate of 250 mg/kg/day in divided doses.

3.2 General Supportive Therapy

In acute poisoning, resuscitative measures have to take precedence over all others. If the patient can be

kept alive, excretory and detoxicating mechanisms together with the administration of specific antidotes, when these exist, will be able to ensure eventual elimination of the poison. Careful symptomatic medical care is always necessary, with an awareness of delayed effects that may occur.

3.2.1 Maintenance of Respiration and Circulation

Maintenance of respiration and circulation should receive precedence over all other procedures. The patency of the airway must be ensured, especially at the site of the accident and the journey to the treatment center, and artificial respiration may be necessary. At the treatment center, tracheobronchial toilet may be required. The presence of hypoxia should be assessed by determining minute ventilation or preferably arterial oxygen and carbon dioxide tensions. Oxygen may be needed and also mechanical ventilation. Treatment for acute pulmonary edema may be necessary after exposure to beryllium or cadmium fumes, to nickel carbonyl, or to hydrogen selenide.

In an emergency situation, a conscious shocked patient with a blood pressure less than 80–90 mmHg should be reassured, covered with blankets, and kept supine with the legs elevated. Once the patient reaches the treatment center, the circulatory blood volume can be restored with suitable intravenous fluids. Blood transfusion may be required for severe hemolytic anemia after exposure to arsine.

3.2.2 Maintenance of Water and Electrolyte Balance

Imbalance may occur from vomiting, diarrhea, tissue damage, or from measures taken to eliminate the poison. It may be sufficient to give fluids by mouth to prevent dehydration, but an intravenous infusion with appropriate biochemical monitoring is often required. An adequate urinary flow should be ensured, and a catheter may be necessary.

Acute tubular necrosis may give rise to anuria, and dialysis may be necessary. Careful water and electrolyte balance has to be maintained until regeneration of the tubular epithelium leads to recovery.

3.2.3 Control of Nervous System Effects

The general supportive measures just outlined are usually adequate for the management of the patient whose level of consciousness is depressed. There is no indication for the use of analeptic drugs in acute metal poisoning. Convulsions, however, require management with diazepam, 10–30 mg, given parenterally. Cerebral edema may occur, as, for example, in acute lead poisoning. This should be treated with dexamethasone given intravenously. Prolonged sedation with diazepam may be necessary to overcome the hyperactivity and other behavioral disorders that may develop in poisoning with alkyl lead compounds.

3.3 Elimination of Absorbed Poison

3.3.1 Diuresis

The promotion of a diuresis will increase the clearance of many poisons by decreasing their passive reabsorption from the proximal renal tubules. Diuresis can be achieved by giving a fluid load together with osmotic agents like mannitol or by giving a diuretic (e.g., furosemide). Furthermore, the excretion of some poisons is influenced by the pH of the urine, because passive tubular reabsorption is less effective with increased ionization of the solute in the tubular fluid. Although of great value in some common forms of acute poisoning, these methods have limitations in poisoning by metals, although in general, excretion of the toxic metal can be accelerated if a high flow of urine is maintained, as, for example, in acute inorganic mercury and lead poisoning. Forced alkaline diuresis is of limited value in aiding the elimination of lithium salts.

3.3.2 Biliary Excretion

The action of certain toxic metals is prolonged as a result of an enterohepatic circulation where excretion in the bile can occur against a high concentration gradient followed by intestinal reabsorption. The use of activated charcoal in absorbing certain toxic agents from the gut is referred to previously. A promising approach for interrupting the enterohepatic circulation has been described by Clarkson *et al*. (1973). This involves a complexing agent given by mouth that will bind with the metal compound excreted in the bile, prevent reabsorption, and enhance fecal excretion of those heavy metal compounds that undergo an extensive enterohepatic circulation. This synthetic polystyrene resin containing fixed sulfhydryl groups, when added to food in a concentration of 1%, doubled the rate of excretion of methylmercury from mice and lowered blood and tissue levels compared with untreated controls. In man, mercury levels in blood were reduced and the fecal excretion of methylmercury enhanced (Bakir *et al*., 1973).

3.3.3 Dialysis

Hemodialysis will achieve higher clearance rates of toxic metals not irreversibly bound to tissues than can be attained by forced diuresis, although, in general, the yield of metal ion in the dialysate is low. Metals

that may be dialyzable are arsenic, copper, iron, lead, lithium, magnesium, mercury, potassium, sodium, strontium, and zinc. The procedure is indicated when a potentially fatal dose has been absorbed, when the clinical condition is deteriorating despite adequate treatment by other means, and when a complication exists, such as aspiration pneumonia or renal insufficiency. Severe poisoning with lithium salts should be treated with prolonged hemodialysis. Peritoneal dialysis may be used where hemodialysis is not available.

In severe acute inorganic mercury poisoning, dialysis may be performed after giving dimercaprol to remove the mercury complex.

3.3.4 Exchange Transfusion

When there are no facilities for hemodialysis or when the toxic material is poorly dialyzable, exchange transfusion may be lifesaving in severe poisoning by agents that remain in the blood in appreciable concentrations.

3.4 Inactivation of the Absorbed Poison

A limited number of therapeutic agents may be administered to counteract the effects of an absorbed toxic metal. Such a specific antidote may act in different ways. It may combine with the toxic agent to form a less toxic or a nontoxic compound, which may be excreted more effectively in the urine; it may compete with the toxic agent and displace it from its receptor site; or it may displace the poison into a tissue where it cannot exert its toxic effects. The intravenous administration of calcium gluconate will displace lead from its site of action and will temporarily relieve the intense pain of lead colic. An infusion of potassium has been shown to correct the potassium-displacing capacity of absorbed soluble barium salts (Berning, 1975).

Certain antidotes have been designed specifically to compete, for toxic metals, with ligands essential for normal physiological function. These toxic metal antagonists, or chelating agents, form a stable complex with the metal in the form of a heterocyclic ring (Klaassen, 1980). The antagonists and the chelates produced are not themselves without toxic effects, and they should not, therefore, be administered therapeutically in those mild cases of poisoning where removal from further exposure is sufficient to promote recovery. Chelation therapy, because of its value in metal poisoning, is considered in greater detail below.

3.5 Chelation Therapy

Chelation is indicated in the treatment of metal poisoning, in the treatment of metal-storage diseases, in particular in Wilson's disease, in blood transfusion iron overload as in the thalassemias and in hemochromatosis, and to aid the elimination of metallic radionuclides from the body. The pharmacology and therapeutic applications of chelating agents were reviewed by Catsch and Harmuth-Hoene (1976) and updated by Andersen (1999), Andersen and Aaseth (2002), and Andersen (2004). The basic principle underlying chelation is that the therapeutic agent should possess electron donor groups showing a high affinity for the metal to be removed, thus releasing it from complexes with proteins or other endogenous ligands in a form in which it can be readily excreted. The effectiveness of ligand exchange depends on the relative stability constants for the metal–endogenous ligand and the metal–therapeutic ligand complexes, on the rate of ligand exchange, on the effective concentration of the agent in the region of the metal–endogenous ligand complex, and on the stability of the newly formed chelate. The chelating agent should form complexes with the toxic metal that have much greater stability than those formed with physiologically essential metals such as iron, calcium, zinc, or copper. Treatment is most effective if the chelating agent is given while the metal is still in the circulation or in the extracellular fluid compartment, because once intracellular, the metal is less accessible. Many chelating agents are in an ionized form and, therefore, have limited ability to penetrate cell membranes.

Effective chelation forming a less toxic species that may be effectively excreted depends on physical and chemical characteristics of metals and chelators, such as ionic diameter, ring size and deformability, hardness/softness of electron donors and acceptors, administration route, bioavailability, metabolism, organ and intra/extra cellular compartmentalization, and excretion. Account has to be taken that the metal selectivity of chelators may result in depletion of essential metals or to the redistribution of toxic metals to other tissues (e.g., the brain) (Andersen 2004; Andersen and Aaseth 2002).

3.5.1 Dimercaprol

2,3-Dimercaptopropanol (dimercaprol, British antilewisite, BAL), now a classic chelator, was synthesized as a specific antagonist to the vesicant arsenical war gases. It is a dithiol compound that successfully competes with protein sulfhydryl groups for arsenic compounds and for other heavy metals by forming a stable chelate with them. The other metals for which dimercaprol has been shown to be effective are mercury in inorganic form, antimony, bismuth, and gold. In cases with acute lead encephalopathy and increased

intracranial pressure, it has been advised to administer dimercaprol parenterally before calcium EDTA (Griesemer, 2001). The half-life is short, metabolism and excretion being complete within 4 hours.

Dimercaprol is given by deep intramuscular injection as a 5% solution in arachis oil BP (or a 10% solution with benzyl benzoate in vegetable oil, USP). It is usually given in a dose of 2.5–3 mg/kg, every 4 hours, for the first 2 days, every 6 hours on the third day, and thereafter once or twice daily for up to 10 days. In a severe acute case of poisoning, 4–5 mg/kg may be given, every 4 hours for the first 24 hours, but no single dose should exceed 300 mg. There are several variations to this schedule. The drug should be administered at a lower dosage to patients with impaired renal function. It is wise to render the urine alkaline during therapy, because the dimercaprol–metal complex may dissociate in an acidic medium.

Dimercaprol has unpleasant and sometimes alarming side effects when given in full dosage. One of the most consistent is a rise in blood pressure accompanied by tachycardia. Other untoward effects are nausea and vomiting, headache, burning sensations in the mouth and throat, with paresthesia of the hands, a feeling of constriction or pain in the chest, lacrimation, salivation, rhinorrhea, sweating, and abdominal pain accompanied by a feeling of anxiety.

Dimercaprol has been shown in the experimental animal to inhibit the blood pressure–lowering effect of intravenously injected cadmium (Dalhamn and Friberg, 1954) and also of vanadium and cobalt. Although the urinary excretion of cadmium is enhanced by dimercaprol, Tepperman (1947) showed this to be accompanied by a large increase in cadmium concentration in the kidney, and Gilman *et al*. (1946) observed severe renal damage as a sequel. Dimercaprol is, therefore, contraindicated in cadmium poisoning.

The administration of dimercaprol in mercury poisoning effects a redistribution of the body burden of the metal without increasing its excretion. In poisoning with inorganic mercuric salts, dimercaprol decreases the renal concentration and thus protects the kidney. However, with phenylmercury and with alkylmercury compounds, dimercaprol accelerates the uptake of mercury from blood into the tissues and in particular its uptake into the brain (Berlin and Lewander, 1965; Berlin *et al*., 1965). Dimercaprol is, therefore, contraindicated in the treatment of poisoning with both aryl- and alkylmercury compounds. Dimercaprol enhances the toxicity of selenium and tellurium, producing kidney damage, and is contraindicated in poisoning by these metals (Amdur, 1958; Cerwenka and Cooper, 1961).

Because of its high toxicity, dimercaprol is now suited only for brief treatment of acute intoxications (Andersen and Aaseth, 2002). DMPS and DMSA have now superseded dimercaprol in most cases of poisoning.

3.5.1.1 Sodium 2,3-Dimercaptopropane Sulfonate (DMPS; Unithiol)

This water-soluble chemical analog of dimercaprol, with dimercaptosuccinic acid (considered below), is an effective antidote for certain forms of heavy metal poisoning, less toxic than dimercaprol, which has been used extensively in Russia and more recently in the Western world.

Both agents increase the urinary excretion of copper and zinc, but in therapeutic doses, this is not considered to be of clinical significance. Allergic side effects have been reported. The properties and uses of these two chelating agents have been reviewed by Aposhian (1983). DMPS is effective in accelerating metal excretion without causing severe adverse health effects in acute and chronic intoxication by organic and inorganic mercury, bismuth, arsenic, and chronic lead poisoning (Andersen, 1999; Aposhian *et al*., 1995).

DMPS (unithiol) may be given orally or parenterally. It has been given intramuscularly as a 5% solution at the rate of 5 mg/kg three or four times during the first 24 hours, two or three times on the second day, and once or twice on subsequent days.

DMPS has been given successfully in one case of Wilson's disease where intolerance had developed to penicillamine and to triethylene tetramine, resulting in effective cupruresis (Walshe, 1984, 1985). In two other cases reported by the same author, adverse effects were reported. In experimental animals, DMPS has prevented the lethal effects of a number of arsenic compounds, and it has been used in Eastern Europe in the treatment of arsenic poisoning in man. Together with dimercaprol it is, however, contraindicated in arsine poisoning. DMPS has been used successfully in the Soviet Union in the treatment of chronic lead poisoning. It is in the treatment of alkylmercury poisoning that DMPS may have a major role. In a study of the relative effectiveness of DMPS, a thiolated resin, and the penicillamines, in the Iraqi outbreak of alkylmercury poisoning, DMPS was the most effective agent, reducing the mean T 1/2 value for mercury in blood from about 65–10 days (Clarkson *et al*., 1981). Adverse effects of treatment were not seen, and the authors concluded that a reduction in blood mercury level with accelerated excretion would be clinically useful if given before irreversible damage had occurred. DMPS has also been given in inorganic mercury poisoning after the inhalation of mercury vapor and the ingestion of mercuric oxide. It has been shown to be effective in increasing mercury excretion in urine (Mant, 1985).

DMPS has also been given as a diagnostic test for low-level mercury exposure, urinary mercury after DMPS being a better indicator of exposure than unchallenged urinary mercury excretion (Aposhian *et al*., 1995). DMPS has been considered to be the optimal antidote for inorganic mercury poisoning and DMSA as more effective in organic poisoning, but this requires verification (Andersen, 1999).

3.5.1.2 Meso-2,3-Dimercaptosuccinic Acid (DMSA; Succimer)

There are many reports in the Soviet and Chinese literature and more recently in the Western countries testifying to its effectiveness and low toxicity in the treatment of poisoning by arsenic, lead, and mercury (Andersen, 2004). This analog of dimercaprol, among the least toxic of the chelators, may be given parenterally or orally in doses of 30 mg/kg/day for 5–7 days followed by 20 mg/kg/day for 1–3 weeks. DMSA is rapidly excreted in urine and, in particular, decreases the deposition of lead and also of methylmercury in the brain (Cory-Slechka, 1988).

DMSA, being less toxic than DMPS, is usually the preferred antidote for lead poisoning, particularly in children (Angle, 1993). It was registered in the United States in 1991 for the oral treatment of lead poisoning in children, a significant problem in poor population subgroups. Four lead-intoxicated children were treated with DMSA for five courses each lasting 10 days (Chisholm, 1990). After reduction, the blood lead increased again after each course, indicating the need for repeated chelation. A rebound in blood lead concentration occurs after chelation treatment, considered to be predominantly caused by mobilization of bone lead, necessitating the need for repeated chelation.

Five lead-poisoned smelter workers were given DMSA in increasing dosage from the first to the sixth day. A marked fall in blood lead concentration was accompanied by a significant increase in urinary lead and copper excretion but without effect on urinary calcium, iron, magnesium, or zinc excretion (Friedheim *et al*., 1978). The efficacy of DMSA in binding and mobilizing mercury has been shown in a number of animal studies reviewed by Aposhian (1983). The mobilization and removal of methylmercury by extracorporeal complexing hemodialysis with DMSA has given promising results in the dog (Kostyniak, 1982). Although DMSA is effective for the treatment of lead intoxication, adverse effects have been reported. A strong musculocutaneous reaction in one case of chronic lead poisoning (Grandjean *et al*., 1991) and hemolytic anemia was reported in a worker with occupational lead exposure (Gerr *et al*., 1994).

3.5.2 Calcium Disodium Edetate (Calcium EDTA)

Ethylenediaminetetraacetic acid, another classic chelator, and related compounds are able to chelate many divalent and trivalent metals *in vitro*. Infusion of the sodium salt will chelate calcium from the body and may result in hypocalcemic tetany. However, the calcium disodium salt, calcium EDTA, is a valuable therapeutic agent, because it will bind lead with the displacement of calcium from the chelate. However, it has dangerous toxic effects in the chelation of metals other than lead. Calcium EDTA is poorly absorbed from the gastrointestinal tract and so has to be given by intravenous infusion. It is distributed mainly in the extracellular fluid and is excreted rapidly by glomerular filtration, about 50% appearing in the urine within 1 hour. Castellino and Aloj (1965) showed in rats a biphasic pattern of lead excretion, weakly bound extracellular lead being excreted rapidly, with lead complexed within cells being removed very slowly, probably as a direct result of an increased concentration gradient.

The toxic effects of calcium EDTA make it necessary to monitor its administration with care. The most important of these effects is on the kidney. Friberg (1956) showed that cadmium excretion could be increased considerably by giving calcium EDTA to rabbits previously dosed with cadmium. However, severe degenerative and necrotic changes were seen in the tubular epithelium of rabbits with prolonged exposure to the metal. Reversible hydropic degeneration of the proximal tubules was produced in rats by Foreman *et al*. (1956), and proximal tubular damage was also observed in man. It is not known whether this is due to a toxic effect of the chelating agent itself, to the chelated metal, or to breakdown of the chelate in its transfer through the tubule, or even to the binding of a trace metal in an essential enzyme system. Untoward side effects in the treatment of lead poisoning include a febrile reaction with headache, myalgia, nausea, and vomiting. Furthermore, EDTA may redistribute lead to the brain after acute or chronicle lead exposure (Andersen, 2004). Lacrimation, nasal congestion, mucocutaneous lesions, glycosuria, hypotension, and ECG abnormalities have also been reported. Prolonged courses of calcium EDTA give rise to trace-metal depletion, the most marked being due to the excretion of zinc.

Many of the side effects of calcium EDTA have been ascribed to excessive chelation after the administration of too high a dose over a short period of time. The drug is usually administered in adults by the infusion of 1.0 g in 250–500 mL 5% dextrose over a period of 1–2 hours. Two such infusions may be given daily for 3–5 days, but a daily dose of 70 mg/kg body weight should not be exceeded. Not more than 80 mg/kg should be given

daily to a child. After an interval of a few days—during which time redistribution of lead from the intracellular to the extracellular compartments occurs—the course may be repeated. Although a patient is on calcium EDTA treatment, urinalysis should be performed, and blood urea, electrolytes, calcium, phosphorus, and alkaline phosphatase should be monitored regularly. Because of its adverse effects, calcium EDTA is being progressively replaced by DMSA in the treatment of lead poisoning (Aposhian *et al*., 1995).

The local application of calcium EDTA in an ointment is of value in the treatment of chrome ulceration.

3.5.3 Penicillamine (Cuprimine)

b,b′-Dimethylcysteine, or penicillamine, is derived from the hydrolytic degradation of penicillin. The D-isomer is an effective chelating agent for copper, iron, lead, mercury, and zinc, and it will increase the excretion of these metals in the urine. It is probably the chelating agent of choice in the less severe forms of lead poisoning. *N*-Acetyl-DL-penicillamine may be even more effective than D-penicillamine in protecting against the effects of inorganic mercury (Aposhian and Aposhian, 1959), but there have been few valid comparisons. Penicillamine is well absorbed from the gastrointestinal tract and may thus be given by mouth. It is stable once absorbed and is excreted rapidly in the urine.

The most important side effects of penicillamine are acute sensitivity reactions manifested by fever, skin rashes, blood dyscrasias, and occasionally renal tubular damage, proteinuria, and the nephrotic syndrome. There is cross-sensitivity with penicillin, so that people who are allergic to penicillin should not be given penicillamine. Penicillamine antagonizes pyridoxine, although clinical effects after treatment with D-penicillamine are unusual.

Penicillamine is given orally, before meals, in four divided doses at a rate of 0.5–1.5 g daily, although up to 5 g daily has been given without ill effects. The urine should be tested for protein, and a full blood count, including a platelet count, should be performed at weekly intervals, but when treatment continues for longer than 2–3 months, as in the management of Wilson's disease, these tests may then be performed monthly. In Wilson's disease, 500 mg penicillamine is given before meals three times a day. Once stability is attained, this may be reduced to 750 mg/day and continued indefinitely to maintain a negative copper balance. In children, 25 mg/kg is appropriate.

Penicillamine is also effective in the treatment of rheumatoid arthritis and related conditions. Its mode of action is unknown.

3.5.4 Triethylene Tetramine (Trien, TETA)

A new orally active chelating agent, triethylene tetramine 2 HCL (trientine dihydrochloride or Trien), has been used successfully in the treatment of Wilson's disease and is now indicated when intolerance to penicillamine has developed (Walshe, 1983). Initially 600 mg is given three or four times a day, reduced to a maintenance dose of 600 mg twice daily before meals and continued indefinitely. Zinc sulfate or acetate given orally is also helpful in maintaining copper balance by blocking absorption of the metal.

3.5.5 Desferrioxamine (DFOA)

The hydroxylamine desferrioxamine B is a chelating agent with a remarkable affinity for iron. It is poorly absorbed from the gastrointestinal tract, but given parenterally, it complexes with iron in a diffuse chelatable pool and is rapidly excreted as the red ferrioxamine, about two thirds through the kidneys and one third through the bile into feces. Desferrioxamine may be given by the subcutaneous, intramuscular, or preferably intravenous route. Given by mouth, it chelates iron remaining in the lumen of the gut and renders this nonabsorbable and thus nontoxic. It is the treatment of choice in acute iron poisoning, greatly reducing the mortality in children, provided it is given at an early stage. Its effectiveness also depends on an adequate urine output, so that the ferrioxamine complex may be excreted.

If oliguria develops, peritoneal dialysis or hemodialysis may be necessary to aid excretion. Desferrioxamine is also of great value in the treatment of chronic iron overload after multiple blood transfusions. In thalassemia, it is the standard treatment, also given to young children on regular blood transfusion. In this condition it is now given in high-dose subcutaneous infusions. Iron stores can be assessed, by measuring urinary iron excretion in the 6 hours after a test dose of desferrioxamine, 500 mg, given intramuscularly.

Long-term hemodialysis for chronic renal failure has been associated with the accumulation of aluminium in the brain, resulting from high aluminium content in the dialysis water supply causing encephalopathy. Desferrioxamine has been used for the successful removal of aluminum in dialysis encephalopathy (Ackrill *et al*., 1980), resulting in clinical improvement. Desferrioxamine raises serum aluminum to high levels and allows this to be removed by conventional dialysis techniques.

In a severe case of poisoning with shock, desferrioxamine is given by slow intravenous infusion at a rate of not more than 15 mg/kg to a maximum of 80 mg/kg per 24 hours. In the absence of shock, it may be given intra-

muscularly at a rate of 2 g for an adult and 1 g for a child every 12 hours. Gastric lavage may be performed with 5 g desferrioxamine dissolved in 1 liter of water, and 5–10 g desferrioxamine in 50–100 mL water may be left in the stomach to chelate unabsorbed iron from the gut.

While being well tolerated, the rapid intravenous administration of desferrioxamine may cause transient hypotension with histamine-like or anaphylactic reactions. The drug should be used cautiously in patients with impaired renal function.

3.5.6 Deferiprone (L1)

Deferiprone, 1, 2-dimethyl-3-hydroxypyrid-4-one, is effective for long-term iron chelation therapy of transfusional iron overload in thalassemia. Given by mouth, it is suitable for home treatment (Kontoghiorges *et al*., 2000). Deferiprone together with desferrioxamine in lower doses is indicated in cases requiring lifelong chelation (Mourad *et al*., 2003).

3.5.7 Diethylenetriaminepentaacetic Acid (DTPA)

DTPA is another synthetic polyaminopolycarboxylic acid with properties similar to those of EDTA, which also forms stable chelates with calcium. The calcium salt has been used to accelerate the elimination of plutonium and related actinide metals. Because zinc depletion may occur during long-term administration, it has been suggested that the more effective calcium DTPA be replaced by zinc DTPA in the later stages of treatment (Taylor and Volf, 1980). As with all chelators, DTPA is most effective if administered shortly after exposure. Lipophilic derivatives of DTPA are being developed, as, for example, Puchel, which can be administered as an aerosol to decrease the lung concentration of inhaled insoluble plutonium oxide particles (Stradling *et al*., 1981). Small amounts of plutonium and americium have been successfully eliminated with DTPA given in a dose range of about 1 g/day or about 30 mIU mol/kg body weight, in a few cases for long periods without adverse effect (Bair and Thompson, 1974; Taylor, 1982).

3.5.8 Diethyldithiocarbamate (DEDTC)

DEDTC is a chelating agent that has been found to be of value in the treatment of acute nickel carbonyl poisoning, greatly increasing the excretion of nickel in the urine (Sunderman, 1971). DEDTC can be given orally in moderately severe poisoning, initially at a rate of 50 mg/kg in divided doses. At the low pH of gastric juice, DEDTC is degraded to ethylamine and carbon disulfide. This reaction can be minimized by the concomitant administration of 2 g sodium bicarbonate by mouth.

3.5.9 Combinations of Chelating Agents

Combined treatment with EDTA and dimercaprol is most effective in acute lead poisoning in children with encephalopathy or blood lead levels greater than 100 μg/dL (1000 μg/L; 5 μmol/L), showing greater therapeutic effectiveness than EDTA alone. The reason for this is thought to be related to synergistic action of EDTA, which may intensify the inhibitory action of lead on hemosynthesis by a similar action on δ-aminolevulinic acid dehydrogenase. With intravenous EDTA infusion, to prevent a transfer of chelated lead to the brain, intravenous administration of dimercaprol should be given 4 hours before and continued during EDTA treatment (Grisemer, 2001).

The possible therapeutic advantages of using combinations of chelating agents, with particular reference to aiding the elimination of cadmium and plutonium, are considered by Schubert (1983). Experimental observations in mice dosed with cadmium chloride indicated an additive protective effect using the two chelators DTPA and DMPS. Chelator combinations tested for their effectiveness in the elimination of plutonium have included DTPA with desferrioxamine and EDTA together with a number of bidentate ligands. EDTA with bidentate ligands such as *p*-aminosalicylic acid significantly reduced the plutonium content in mouse liver and bone.

The rationale in using two different complexing agents to produce a synergistic effect is that the first agent should be sufficiently lipophilic to mobilize the metal from intracellular binding sites and promote its release into the blood, whereas the second agent will promote ligand exchange to form an ionized chelate that can then be excreted into the urine.

3.6 Modification of Response

Under this heading are included examples of therapeutic measures in metal poisoning that are directed toward a modification of the tissue response to the poison or to an alteration in the biochemical or metabolic state of the subject.

3.6.1 Modification of Tissue Response

Chronic beryllium disease is characterized by an inflammatory reaction that is granulomatous in nature and that seems to result from a hypersensitive response in certain individuals. The inflammatory process may be arrested, although not reversed, by adequate corticosteroid therapy. This treatment has resulted in a change in the clinical course of the disease with a reduction in symptoms and a favorable change in prognosis.

3.6.2 Modification of Biochemical Status

Chronic manganese poisoning has pathological, biochemical, and clinical features that closely resemble those of Parkinson's disease, which, once established, becomes a permanent disabling occupational disorder. The observations of Cotzias *et al*. (1971) on neurochemical similarities between the two conditions have led to the administration of L-dopa in manganese-induced parkinsonism. Modification of the parkinsonian state in chronic manganese poisoning has been obtained with L-dopa (Mena *et al*., 1970). In most patients so treated, hypokinesia and rigidity were markedly reduced, and postural reflexes improved with a restitution of balance. There was no evidence of a decreased body burden of manganese in the parkinsonian ex-miners treated in this way. Beneficial effects can be considered solely as a form of replacement therapy.

CHAPTER

16

Principles for Prevention of the Toxic Effects of Metals

PHILIP J. LANDRIGAN, DAVID KOTELCHUCK, AND PHILIPPE GRANDJEAN

ABSTRACT

Prevention of the toxic effects of metals begins with identification of the populations at risk of exposure. Industrial workers, long the principal focus of concern, remain the group at greatest risk. Nonoccupational populations—young children and pregnant women in particular—are also at risk today through exposures in air, food, water, and consumer products. These nonoccupational exposures are the result of wide environmental dissemination of metals in the past century and affect millions of persons. Toxic effects in occupational and nonoccupational populations may be clinically evident or subclinical. Toxic effects may occur in women and children at levels below those that cause effects in workers.

The tools available for prevention of toxic effects include exposure assessment, environmental monitoring, biological monitoring, medical monitoring, and a range of public health interventions. Medical examinations may sometimes be of use and can pinpoint reasons for increased susceptibility that may require additional action. Preventive interventions should seek ways to target the source of the problem and may require action to remove a subject from a dangerous exposure. Treatment may be necessary as a last resort, when prevention fails.

Five principles guide the prevention of toxic effects: (1) *hazard identification*; (2) *reduction of exposure*; (3) *monitoring*; (4) *training*; and (5) *authority. Hazard identification* includes recognition of the sources and routes of exposure and explanation of the range effects on health, including effects on early development. *Reduction of exposure* may involve outright bans of certain uses of toxic metals—the most effective strategy; reduction of workplace or environmental concentrations using the technologies of industrial hygiene and environmental control; and use of personal protective equipment—the least effective strategy. *Monitoring* may involve monitoring of the workplace or general environment or biological monitoring and health examinations of exposed populations. *Training* involves education of managers, workers, health professionals, policy makers, and the general public about the health risks posed by toxic metals and approaches for risk reduction. To be effective, all of these programs must be supported by *authority*, which usually is based in law.

Great success has been achieved in reducing toxic effects of metals in occupational and nonoccupational populations, but much work still remains to be done. Precaution should guide all decisions on whether to permit further dissemination of metals into the environment.

1 INTRODUCTION

The unique properties of metals—their durability, stability, and resistance to chemical breakdown—are simultaneously the basis for the wide and constantly expanding range of industrial applications of metals but also are the basis for the extensive distribution and persistence of metals in the environment and for the hazards they pose to human health.

Metals cause a wide range of toxic effects. Metals are proven and probable causes of human cancer. Metals can cause asthma, renal failure, reproductive impairment, disruption of the immune system, and pulmonary disease. Metals can cause dysfunction of the central and peripheral nervous systems. Metals are especially toxic when exposures occur early in life. Exposures to metals *in utero* and in the first years of postnatal life can cause injury to the developing brain and other organ systems at very low levels that would be considered safe for adults.

Minimizing or eliminating exposure is the single most effective means of preventing the toxic effects of metals. Current approaches to prevention are based on observations about the toxicity of metals that were first made in classical times and that have repeatedly been updated in light of new knowledge. Three trends in recent decades have greatly influenced strategies for preventing the toxic effects of metals:

1. Metals have become widely disseminated in the environment; they have moved far beyond the workplace, the original and traditional focus of concern.
2. Vulnerable segments of the population, such as women of childbearing age and young children, are increasingly exposed to metals and often require special protections against exposure.
3. Recognition has grown that metals can cause harmful effects at low levels of exposure previously considered safe and that there seem to exist no thresholds for subclinical toxic effects.

The quantities of metals used worldwide in the past two centuries exceed their use in all previous eras combined. In consequence of their extensive use in industry, consumer products, and motor fuels, as well as their release to the environment as by-products of industry and fossil fuel combustion, metals now contaminate the environment worldwide (Mage *et al.*, 1996; Patterson, 1970).

Industrial workers—miners, smelter workers, battery workers, workers in metal fabrication and construction workers—remain, as they have for centuries, the groups at greatest risk of exposure to metals and of toxicity (Hunter, 1969).

Because metals have become widely distributed in the environment, the populations at risk of exposure and toxicity have expanded greatly. Elevated levels of metals are now found in the bodies of humans of all ages (Agency for Toxic Substances and Disease Registry, 2002; 2005).

Women of childbearing age and young children are now recognized to be much more extensively exposed than they were in generations past. These groups are exquisitely susceptible to toxicity even at low levels of exposure (National Academy of Sciences, 1992; 1993b). Millions of cases of metal toxicity are reported worldwide each year among these vulnerable groups. The disease and dysfunction that result from exposures to metals early in life can disrupt the development of the brain and other organ systems, reduce intelligence, alter behavior, increase risk for mental retardation, and place major medical and economic burdens on families and societies (Grosse *et al.*, 2002; Landrigan, 2002; Trasande *et al.*, 2005).

Acute poisoning that results from high-dose exposure and produces clinically obvious symptoms was the first form of metal toxicity to be recognized (Hunter, 1969; Ramazzini, 1940). Subsequently, more sophisticated research has documented the presence of less striking, but nonetheless serious, adverse effects at lower levels of exposure and in a wide range of age groups. This sequence of discoveries has led to the recognition that metals can exert a range of adverse effects. Some are clinically obvious, but others are not evident during standard examination and can be discerned only through special testing; hence the term, "subclinical toxicity." The underlying concept is that there exists a dose-dependent continuum of toxicity, in which clinically obvious effects have their subclinical counterparts (Landrigan, 1989).

The concept of subclinical toxicity traces its origins to pioneering studies of lead toxicity undertaken by Landrigan, Needleman, and collaborators (Landrigan *et al.*, 1975; Needleman *et al.*, 1979). These studies showed that exposures to lead in early childhood could cause decreases in intelligence and alteration of behavior in the absence of clinically visible symptoms. The subclinical toxicity of lead in children has subsequently been confirmed in prospective epidemiological studies (Baghurst *et al.*, 1992; Bellinger and Dietrich, 1994) and has been found to extend down to the lowest measurable levels of exposure—below 100 µg/L (10 µg/dl) blood lead (Canfield *et al.*, 2003; Lanphear *et al.*, 2005). Subclinical toxicity has now been found to result additionally from lower dose exposures to arsenic (Wasserman *et al.*, 2004), mercury (Grandjean *et al.*, 1997), and probably manganese (Mergler *et al.*, 1999; Normandine *et al.*, 2004). The environmental impact of these subclinical toxicities on children and pregnant women is discussed further in Section 3.2.

2 GENERAL PRINCIPLES FOR PREVENTION OF THE TOXIC EFFECTS OF METALS

From a public health viewpoint, prevention must target the population groups at greatest risk (i.e., those who have the highest levels of exposure and those who

are the most vulnerable). The tools available for prevention include exposure assessment, environmental monitoring, biological monitoring, medical monitoring, and a range of public health interventions. Medical examinations may sometimes be of use and can pinpoint reasons for increased susceptibility that may require additional action. Preventive interventions should seek ways to target the source of the problem and may require action to remove a subject from a dangerous exposure. Treatment may be necessary as a last resort when prevention has failed.

Five common principles guide all approaches to prevention of toxicity caused by metals, whether in the workplace or the general population: Hazard identification, reduction of exposure, monitoring, training, and authority. The first of these, and general guidelines for the second, will be discussed in Section 2). The next three will be discussed separately for the workplace and general environments in Sections 2 and 3, respectively.

2.1 Hazard Identification

First, the hazard must be recognized and routes of exposure determined. This knowledge may be readily available or may require substantial research. The historical examples of lead, methylmercury, and arsenic show that, as health hazard information becomes more detailed, the range of effects that are uncovered increases in extent and severity. Several examples demonstrate that early warnings of toxicity have frequently been ignored.

2.1.1 Lead

The first description of lead poisoning in young children was presented in a report from Australia published more than 100 years ago. The source of this outbreak was not immediately obvious and was discerned only after several years of investigation. It was traced to ingestion of lead-based paint by children playing on painted verandas (Gibson, 1895). Further reports of childhood lead poisoning from lead paint ingestion in the United States followed over the next several decades and resulted in bans in many nations on household use of lead-based paint. Lead poisoning was, at that time, considered an acute illness from which a child either recovered or died. The realization that lead could cause long-term neurological sequelae was first documented in the 1940s, when 19 of 20 survivors of acute lead poisoning in a clinical follow-up study conducted in Boston were found to have severe and persistent learning and behavioral problems (Byers *et al.,* 1943).

Despite those early warnings, extensive use of lead in petrol, paints, ceramic glazes, and many other products continued through much of the 20th century and caused widespread toxicity. During the 1970s, subclinical neurobehavioral deficits were documented in asymptomatic children with elevated lead concentrations in blood (Landrigan *et al.,* 1975; Needleman *et al.,* 1979). Further studies from many countries confirmed these findings. In response to these demonstrations of low-dose toxicity, health agencies have serially reduced the permissible concentration of lead in children's blood. Current research on the developmental neurotoxicity of lead focuses on the shape of the dose-response curve at very low exposure levels, which seem to cause surprisingly large functional decrements (Canfield *et al.,* 2003).

2.1.2 Methylmercury

Methylmercury was first established as a neurotoxicant in men exposed occupationally (Hunter and Russell, 1954). The toxicity of methylmercury to the developing fetal brain was first recognized in the 1960s in Minamata, Japan, where an epidemic of spasticity, blindness, and profound mental retardation occurred among infants whose mothers had consumed contaminated fish without being affected themselves (Harada *et al.,* 1995). Recent studies have focused on the neurodevelopmental effects of prenatal exposures to methylmercury at doses insufficient to produce clinically obvious symptoms. (Grandjean *et al.,* 1997) (See also Chapter 33 for more detailed discussion.) The US National Academy of Sciences reviewed these studies and concluded that strong evidence exists for the fetal neurotoxicity of methylmercury, even at low-exposure levels (National Academy of Sciences, 2002). These findings have led food safety and public health authorities in nations worldwide to issue dietary advisories warning populations, especially women of child-bearing ages, of the hazards of consuming predatory fish. Substantial reductions have been achieved in mercury use, as well as in its release from various sources, such as hospitals and waste incinerators.

2.1.3 Arsenic

Ingestion of arsenic-contaminated drinking water has long been recognized to cause peripheral neuropathy in adults (Landrigan, 1981). Dramatic documentation of developmental neurotoxicity caused by arsenic was first reported from Japan, where, in 1955, consumption of powdered infant milk contaminated with arsenic led to more than 12,000 poisoning cases and 131 deaths (Yamashita *et al.,* 1972). Arsenic occurs in groundwater worldwide and has been linked to various forms of cancers (National Academy of Sciences, 2001). (See also Chapter 19 for a detailed discussion of the effects of arsenic.) As in the previous examples, continued research revealed

adverse health effects at levels of exposure previously thought to be safe (Wasserman *et al.*, 2004).

2.2 Reduction of Exposure

The second principle of prevention of metal toxicity is to reduce exposure through elimination or abatement of the hazard. It is now widely understood that there exists a hierarchy of procedures for reducing exposure and that the procedures at the top of this list, such as product substitution and engineering controls, are always and inherently more effective than downstream approaches that require personal action by individuals at risk or use of personal protective equipment. This hierarchy of exposure reduction is as follows:

1. Cessation of use or, if not possible, cessation of unnecessary use of the toxic metal.
2. Substitution or replacement of the toxic metal with less toxic agents.
3. Prevention of exposure caused by the spread of metal dust and fumes.
4. Removal of the metal already spread.
5. Reduction of personal contact with the metal.

For further discussion of these approaches, see Burton (1998) and Raterman (1996).

3 PREVENTION OF THE EFFECTS OF METAL TOXICITY IN THE WORK ENVIRONMENT

3.1 General Considerations

Before any action can be taken to control exposure to a toxic metal in the workplace, the hazard must be recognized. This can be a prolonged process, as illustrated by the history of recognition of occupational lead poisoning in the United States in the 20th century (Hamilton, 1914; 1943; Schilling, 1973).

During recent decades, understanding of the hazards of metals has evolved over time and thus contributed to the perspective of prevention. For example, when the International Agency for Research on Cancer first evaluated beryllium carcinogenicity, only one member of the expert committee requested a minority statement that the epidemiological evidence was sufficient. But at a subsequent meeting, after the publication of additional studies, the experts arrived at a consensus that beryllium should be recognized as a human carcinogen (IARC, 1993). Similarly, dose-response relationships have been better defined, and hazards are now recognized at exposure levels that were previously thought to be safe. Perhaps the clearest example is inorganic lead, but other metals also provide examples. The occupational exposure limit for lead was once 5 mg/m^3, but by 1979 the threshold limit value used in the United States had been lowered 100-fold to 0.05 mg/m^3 (OSHA, 2005). Undoubtedly, new studies will generate additional documentation of low-dose toxicity and additional lowering of exposure limits, thus further strengthening prevention efforts (Landfield *et al.*, 2003).

3.2 Reduction of Exposure

In occupational health, several approaches to exposure reduction are applicable and need to be explored:

3.2.1 Elimination of Unnecessary Uses and Substitution of Safer Materials

In some instances, the use of a toxic metal in a process is unnecessary. Examples of cessation of unnecessary uses of metals in the workplace are:

TABLE 1 A Hierarchy of Prevention

Cessation of Use/Substitution—Outright ban or substitution of the toxic metal with a less hazardous material. This may be termed *primary prevention*. The best example is removal of lead from gasoline, which produced massive declines in blood lead levels worldwide (CDC, 1997). Additional reductions in exposure have resulted from banning certain uses of metals, such as the use of mercury in felt manufacturing, plastics plants, and medical devices.

Prevention of Exposure—This may be termed *secondary prevention*. It seeks to reduce exposures both by prevention of spread of metal dusts and fumes and removal of spread that has already occurred. These efforts are important, but generally less effective than outright ban or metal substitution. *Standards-setting* is an important aspect of secondary prevention of exposure. In most countries, standards-setting is a legal, as well as a scientific, process and is often guided by the paradigm of *risk assessment* and *risk management*. Risk assessment/risk management is sometimes modified by application of the *precautionary principle*.

Other examples include:

- Process enclosure in industry
- Exhaust ventilation from industrial plants
- Removal of lead paint from walls to prevent childhood lead poisoning

Reduction of Personal Contact—Through respirators and personal protective clothing. Protects only the person wearing the items. Least effective of the prevention measures, but appropriately used for emergencies and occasional exposures.

Example: Chelation therapy for metals overexposure.

- Removal of mercury-containing thermometers from hospitals and their replacement by electronic devices.
- The use of copper- or nylon-clad bullets with nonlead primers at indoor firing ranges, instead of lead-containing bullets.
- The use of composite materials and ceramics instead of mercury amalgam for dental fillings.
- The introduction of cement with negligible chromate content.

3.2.2 Reduced Use of Toxic Metals in Plant and Manufacturing Design

It is axiomatic that a properly designed new facility that incorporates state-of-the-art control measures will be safer, more efficient, and more economical than an older facility, where ventilation and safety equipment must be retrofitted. Success is usually greatest when technical and medical knowledge can be applied in the planning stages of a new facility to eliminate or limit the use of toxic materials as much as possible. The focus of toxic use reduction is to eliminate or control use of toxic materials in manufacturing at the plant design stage, rather than cleaning up the environment after its use. In 1989, the Commonwealth of Massachusetts (United States) passed a landmark Toxic Use Reduction Act (TURA) (General Laws of Massachusetts, Ch. 21 I @ *www.mass.gov*). Techniques favored under this Act include substitution, product reformulation, redesign of production processes, improved housekeeping, and further recycling and reuse of waste products. For more information on toxics use reduction see Geiser and Commoner (2001).

3.2.3 Other Technical Control Measures

The technical control of metal exposures in the workplace follows the principles of industrial hygiene. Forms of automation can be used to reduce workers' contact with hazardous processes. Whenever possible, all hazardous types of exposure should be concentrated in specially enclosed areas where control processes can be effectively used. Encapsulation and other isolation methods prevent toxic dusts and fumes from being spread about, and special well-ventilated control rooms can be built within the plant to enclose the most dangerous processes. Surfaces should be smooth to prevent dust from attaching to walls and floors. Nooks and corners, where dusts can accumulate, should be avoided. For example, in the case of metallic mercury, the worst problem is evaporation from spilled droplets. Their removal is facilitated by smooth, nonabsorbing surfaces that round up in the corners and slant toward the center of the floor. Secondary lead smelting is such a hazardous process that priority should be given to automation of transportation and oven-filling phases. The preparation of all metal pigments, very hazardous when done by hand, becomes far less dangerous in closed, automated systems. Instead of dust-producing powders, liquid premixes are preferred.

For more detailed information about these approaches, the reader is referred to basic textbooks in industrial hygiene, such as DiNardi (1998), Harris (2000), LaDou (2004), Levy *et al*. (2000), and Plog *et al*. (1996). In addition, Volume III of the *ILO Encyclopedia of Occupational Health and Safety* is particularly useful for metals use and control measures in various mining and metalworking industries (Stellman, 1998).

3.2.4 Local Exhaust Ventilation

One of the best means for controlling dust or fumes in the workplace is a local exhaust system, in which intake is as close as possible to the point of origin of the dust or fume. The system for removal of the polluted air must be constructed, so as not to draw the contaminated air into the breathing zone of the worker on its way to the exhaust. The air taken into this system must be filtered and the metals removed, so that the general environment outside of the factory will not be polluted. All air filters should be inspected frequently and changed on a regular schedule. Self-made "improvements," such as ductwork extensions, may be deleterious to the efficient functioning of the system and may cause deterioration of system equipment. For further details see Burton (1998; 2005), George and DiNardi (1998), and Soule (2000a).

3.2.5 General Room Ventilation

Good general room ventilation is important to the quality of working life within a facility, but it is not a particularly efficient adjuvant to a local exhaust system—indeed, an improperly designed room ventilation system can undermine the efficient operation of a local exhaust ventilation system. Because general systems involve much higher costs, for example, in energy consumption, the emphasis should be put on local controls. It should be stressed that open windows and doors, as well as changes in the working process, may thwart otherwise efficient room and local exhaust ventilation systems. Proper caution and careful maintenance are especially important when recirculated air is used for workroom ventilation, as in heating, ventilation and air-conditioning (HVAC) systems. For further details see AIHA/ANSI Z9 Committee (2004), Burton (1996; 1998), and Harris and Arp (2000).

3.2.6 Housekeeping

Poor housekeeping can render even the best technical control system ineffective. Education and supervision should be detailed and protective measures enforced. Clothing made of synthetic fibers retains less dust than cotton overalls. Pockets should be as few as possible, especially when metallic mercury is present in the workroom. Working clothes should be vacuumed before removal and changed at least twice a week. Metal workers need to be provided with changing and showering facilities, and work and street clothes should be stored in separate lockers to reduce the exposure to the worker himself and to prevent the worker from exposing his family (Baker *et al.,* 1977a).

Because most metals occur in dust form or precipitate as small particles in fumes, exposure can be reduced by keeping the workplace floor permanently moistened and by frequent vacuum cleaning. Dry sweeping should be avoided, because this will re-entrain settled dust into the workroom air. The use of compressed air to blow dust from floors, walls, and ledges should be prohibited. In principle, all cleaning and other operations that may cause settled dust to whirl about should be performed outside of normal working hours by specially trained, well-protected workers.

When moistening the floor, the water should never come in contact with molten metal, because violent explosions can occur. Operations involving the welding, flame-cutting, or burning of metals coated with paint of unknown composition should not be allowed before samples have been analyzed at least for lead, cadmium compounds, and chromates, or until the composition has otherwise been explained. If such metal-based pigments are present, the burning is extremely dangerous and should be performed under powerful local exhaust ventilation and, if possible, outside the normal working hours. Metals coated with metallic cadmium should be treated in the same way. Even less toxic metals, such as zinc, found in galvanized metals and brass can cause metal-fume fever, and welding and burning these demand the same protective measures.

3.2.7 Influence of Personal Hygiene on Metal Absorption and Toxicity

Both the industrial and the general environment present many possibilities for contamination of hands and clothing with metal compounds. Because of the danger of food becoming contaminated from the environment or from dusty hands or clothes, food should never be prepared, dispensed, or eaten in areas where there is metal dust. Dining rooms should be clean. Personal hygiene should be facilitated by providing sufficient washrooms. Good personal hygiene is also important from the point of view of reducing exposure to the worker's family (Baker *et al.,* 1977a). Smoking is another hazard in the industrial environment. Large amounts of metallic dust may accumulate on smoke particles from cigarettes, cigars, and pipes and be transferred to the human body (of the smokers and nonsmokers alike) through respiration or by direct contact with contaminated hands on sandwiches and other foods. Aerosolized metals may also be inhaled through burning tobacco products, causing even more hazardous products of combustion—all the more reason for prohibiting smoking in the workplace.

3.2.8 Reduction of Worker Contact with Toxic Metals and Personal Protective Equipment

When metal toxicity occurs, the ideal solution is immediate cessation in use of the toxic metal. Typically, such drastic action requires a legally mandated ban enforced by governmental authorities, although it may also be achieved by voluntary agreement. A second, less optimal approach is to remove the worker from exposure whenever the concentrations of the metal in the blood or urine exceed the action level, when early symptoms or signs are present, or when reports of exceptional exposure peaks are made. Ideally, the worker should be transferred to a job that is free from exposure. Otherwise, compensated sick leave may be considered, as well as job transfer at the same level of compensation. For lead workers in the United States, the latter approach is legally required under the Medical Removal Protection program established through the OSHA Lead Standard (OSHA, 2005). The worker should not be allowed to return to exposure until his or her blood lead levels are well below the recommended upper limits.

Workers should spend as little time as possible in areas with unusually high concentrations of metal dust or fumes. These areas include the vicinities of smelting furnaces, welding places, and pasting machines in storage battery factories. When engaged in welding or burning outdoors, the worker should be trained to always place himself upwind, and other workers should not be asked to work downwind from the welding or burning operation.

If large-scale engineering methods such as automation and encapsulation fail to ensure adequate safety, personal protective equipment may be used, but only as a last resort. The only situations in which respirators and other forms of personal protective equipment can be considered a primary choice for worker protection are during emergencies and occasional, brief exposures, such as in repair and maintenance operations.

Many types of respirators are on the market, from air-filtering respirators of various types to self-contained breathing apparatus (SCBAs), for which the worker carries the air on a tank on his or her back. Metal fumes require more efficient respirators than are needed for dust; if both are present concomitantly, respirators designed for fumes must be used. Activated charcoal filters do not retain fine aerosol particles; therefore, combined gas and dust filters should be used in spray painting. In certain operations in which exposure is very high, for example when ships covered with thick layers of red lead are scrapped by flame cutting, protection may require either an air-purifying positive-pressure respirator or an SCBA.

If respirators are used in the workplace, an intensive program of test fitting of the respirators to each person and an active program of cleaning and maintaining the respirators and replacing filters regularly is imperative and is mandated by OSHA Standard 1910.134. For details on respirators, their selection, capabilities, and maintenance see Colton *et al*. (1998), Myers (2000), and Nelson (1998).

3.3 Monitoring of the Work Environment

Two complementary approaches exist for monitoring metal exposure in the workplace—environmental and biological monitoring. Measurements of airborne metal concentrations in the work environment are mandatory to:

1. Localize high-exposure areas.
2. Estimate individual exposure (especially when no satisfactory biological monitoring method exists).
3. Detect engineering failures (leakages, areas of insufficient ventilation).
4. Detect the effects of changes in processes or working methods.
5. Document the impact of preventive measures.
6. Ensure that safety standards are being met.

Only a broad outline of monitoring is presented here. For further information about environmental monitoring for vapors and metal fumes see Burgess (2000), Dietrich (1998), Huey (1996), Hahne (1996), Johnson and Swift (1998), and Soule (2000b). Although environmental monitoring provides information about levels of the metals in air, biological sampling of levels of metals in the bodies of workers provides a time-integrated measure of cumulative exposure (Todd *et al.*, 1996). For further information about biological monitoring see Chapter 4 on Biological Monitoring and Biomarkers and Clarkson *et al*. (1988), LaDou (2004), Lauwerys (1998), Levy *et al*. (2000), Que Hee (1998), Rom (1998), Soule (2000c), and Zenz (1994).

3.3.1 Air Sampling Strategy in the Workplace

Metals usually appear in the workroom air as fumes and solid particles and sometimes as vapor (metallic mercury) or liquid aerosols (e.g., chromates above the electroplating bath). Fumes are formed when molten metal evaporates or when metal or metal compounds are burned. The dust particles are either derived from condensed fumes or from metal-compound dust that has whirled up. Although the particle size distribution varies, the respirable dust is composed of small particles that can stay in the air for many hours. Larger particles settle but may become re-entrained as a result of wind currents or nearby activities.

In recent decades, many new and improved direct-reading instruments have been developed. These are especially convenient for the real-time measurement of concentrations of gases and vapors.

The only metal present in many workplaces primarily in vapor form is mercury, and commercial analyzers are widely used for its detection. However, direct-reading instruments are not so helpful in determining concentrations of aerosols (fumes, particulates and/or liquid droplets), the most common form in which metals are present in the workplace, because they cannot differentiate between types of aerosols. They can, however, be used to size these aerosols by means of optical or linked optical and electrical techniques. For further information about the types, capabilities, and drawbacks of direct-reading instruments, see Todd (1998). Because metals in the workplace usually appear as fumes or particulates, we will focus on them in the following discussion along with their associated sampling and laboratory measurement.

Concentrations of metal in air close to a machine or where a process is carried out are typically maximal. They may vary considerably over a distance of a few meters or even centimeters. For most purposes, samples should be taken in regular work areas (area air samples) and also from the worker's breathing zone.

The number of air samples needed depends on the purpose of the measurement. An overall picture of workplace exposure level is obtained from sampling carried out on a long-term basis with samples taken from multiple, different sites. When individual exposure is to be studied, personal air monitoring is the method of choice. The samples should be taken from the breathing zone, no farther than 30 cm from the nose. They may even be taken from within a welding helmet. The sampler is usually attached to the worker's shoulder or waist. No obstruction can be allowed between the air sampler inlet and the worker's face, and the equipment must not disturb the work, for instance, by blocking sight. Workers representative

of each area, operation, and other special conditions should be chosen, and personal breathing zone air samples collected on them. Workers with predicted high exposure should be included, so that the worst case is assessed (Mulhausen and Damiano, 1998). Air sampling may be performed at regular intervals or randomly over time. However, regular-interval sampling must not coincide with regular cycles of events in the workplace that may cause systematic errors in the measured concentrations, such as start-ups of new processes or periodic downtimes.

Short-term air samples (15–60 minutes) are preferred for assessing intermittent exposures as, for example, in welding operations. Long-term samples (7–8 hours) are most relevant when the goal is to ensure that metal concentrations on an average are below the threshold limit value. Because long-term particulate sampling often has to be restricted to about 10 samples or less for practical reasons (e.g., 8 hours per sample), their average should be well below the hygienic standard if a safety margin is to be ensured for variations.

Compared with biological samples, personal monitoring gives a more limited assessment of exposure, because it focuses on the inhalation route of entry, whereas biological monitoring assesses personal exposures on the basis of all routes of entry (inhalation, skin, ingestion, etc.). Furthermore, personal sampling does not allow for differences in physical activity during exposure, personal hygiene, use of respirators, or differences arising from other sources of exposure, such as food and water. If the metal accumulates in the body, exposure assessment during a single day may not be very informative of long-term health risk. Hence, biological monitoring is always preferable whenever reliable methods exist. Such is definitely the case for lead, arsenic, cadmium, and mercury, whereas the experiences with chromium, nickel, and selenium are still debatable (ACGIH, 2003; Meister, 2004; Soule, 2000c).

3.3.2 Sampling Technique

During sampling of fumes and dusts, a measured volume of air is drawn through the sampling train and then captured either by a filter, a cyclone separator followed by a filter, or a multistage cascade impactor (Johnson *et al.*, 1998). The first case (simple filter collection) is called the gravimetric method and measures total particulates (respirable and nonrespirable) with no size separation. The second method uses the cyclone separator as a size-selective presampler to separate the coarse dust from the respirable fraction and then captures the respirable dust on a filter, which is gravimetrically analyzed. Most popular currently is the third case, in which a multistage cascade impactor separates the dust into several fractions, according to the number of stages in the impactor. The volume of the air sample may vary from a few liters to several cubic meters, depending on the concentration of metal, the sampling equipment, and the sensitivity of the laboratory analytical method. Often the concentrations, especially those around or below the hygienic standard, are so low that a large air-volume and high flow rate are needed before enough metal particles can be collected over a reasonable period of time. The sample size should be large enough to allow rate estimations of concentrations within the magnitude of about a tenth of the hygienic standard to be made.

3.3.3 Analysis

The concentration of the particulate matter in the air is calculated from the weight of the dust particles collected, determined by direct weighing and/or chemical analysis, divided by the volume of the air sample. Also, the particles in a known portion of the sample may be counted using microscopy or automatic particle counters. Because particles in the respirable range are most important from the toxicological point of view, the size distribution should also be determined and taken into consideration. The size distribution is most readily determined by use of cascade impactors, or direct reading optical or optical/electrical analyzers, as noted previously (Todd, 1998). Finally, various analytical methods, described in other sections of this book, may be used to determine the concentrations of a particular metal vapor or fume in the ambient environment. This is especially important for analyses in which more than one metal is known or suspected to be present.

In evaluating exposure measurements, a main consideration is whether the samples analyzed are representative of the exposure situation. Results obtained during one day, or from a few sites only, cannot be given too much weight in the estimation of workers' exposure beyond the actual sampling period. Monitoring must be regular if reliability is to be ensured. Plotting the results of successive measurements on a control chart is recommended. Needless to say, the analytical methods used should be strictly standardized, and quality-control programs should be used both within a single laboratory and between laboratories.

3.3.4 Biological Monitoring

In industry, biological monitoring has been carried out for decades, because the absorbed dose was considered a useful tool to protect the individual. The choice of indicators and biological samples varies from one metal to another. In general, the parameter of dose or internal exposure (i.e., the concentration of the metal itself in some biological medium) is most useful.

At present, lead is more suitable for biological monitoring than other metals, because the dose-effect and dose-response relationships are fairly well known. The concentration of lead in blood represents current exposure to inorganic lead compounds better than any other test. Measurement of lead in blood should be preferred to that of, for example, lead in urine. When a sufficiently low-action level is selected, enough safety can be ensured if blood lead alone is used for health monitoring. If the chosen action level is exceeded, exposure cessation is required, and measures should be initiated to better control the exposures.

In the case of occupational exposures to mercury, exposure tests are less reliable. Mercury in urine has been the most widely used exposure test in industry, when inorganic mercury or mercury vapor were the main exposures. However, current ability to conduct real-time measurements of mercury levels in the workplace air has obviated some of the need for its biological monitoring. Cadmium can be measured in both blood and urine. It is believed that cadmium in blood reflects current exposure, whereas cadmium in urine reflects body burden. After exposure has ceased, blood cadmium also reflects body burden of cadmium (Nordberg and Nordberg, 1988). Hence, both blood and urine tests should be used concurrently.

In principle, the frequency of monitoring is determined by the degree of risk (WHO, 1980). For further information about biological monitoring, as noted previously, see LaDou (2004), Lauwerys (1998), Levy *et al*. (2000), Que Hee (1996), Rom (1998), Soule (2000c), Zenz (1994), and Chapter 4.

3.3.5 Health Examinations

Health evaluations are often warranted in the occupational setting. Two types of examinations are particularly appropriate. Preplacement examinations aim at protecting workers from exposures to which they would be especially sensitive. For example, workers with kidney disease may be excluded from work with toxic metals that are primarily excreted through the urine. Periodic evaluations, on the other hand, are designed to monitor biological response to exposure, to detect toxic effects of metals at an early stage, and to discover other relevant diseases that may weaken the worker's resistance to the workplace exposures. The frequency of periodic examinations is, in some instances, established by legislation or regulation and may vary depending on the degree of risk. Usually an annual examination is considered appropriate unless monitoring shows that the action level has been exceeded.

The routine use of chelating agents to control levels of metals in the bodies of workers is obsolete, dangerous, and deserves condemnation. This type of practice had previously been widespread in European countries and in the United States (Baker *et al.,* 1979). There are several reasons to prohibit this treatment as a form of prophylaxis. First, chelation is a poor substitute for good workplace hygiene. Second, chelating agents also mobilize and remove essential metals, such as zinc and copper. Third, all such agents have adverse side effects, such as nephrotoxicity (penicillamine and EDTA) or myelotoxicity (penicillamine), and they may be allergenic (penicillamine). For these reasons, an ethical physician would not consider the prophylactic use of chelating agents. The treatment of acute metal poisoning by chelation is, of course, quite another matter. In the United States, the OSHA Lead Standard (29CFR1910.1025) bans prophylactic chelation (OSHA, 2005).

3.4 Training

Education and training are important aspects of the prevention of metal toxicity. Most, if not all, preventive efforts will fail if the persons at risk are not informed about the hazards that they face in their work or in their community. The groups who need education include plant managers, health personnel, and engineers, as well as workers and the general public. All of these groups have a right to know about the materials to which they are at risk of exposure, the hazards of these materials, how to protect themselves, and how to detect early signs of overexposure. For further information see Lee *et al*. (1998) and Quinn *et al*. (2000). Information on occupational hazards is made available to workers through Material Safety Data Sheets and worker training, offered by management, unions, or both and/or by government agencies or community groups.

A classic example from heavy industry of the importance of education concerns lead oxide dust. If lead oxide dust is generated in a restricted area of a lead-using factory such as a battery plant, and its elimination is based on effective local exhaust ventilation, the workers should know about the dangers posed by this dust and how to prevent it from spreading to other parts of the plant. Also they need to be provided with changing and showering facilities so that they do not inadvertently transport lead dust home to cause lead poisoning in their children (Baker *et al.,* 1977a).

3.5 Authority

Most prevention programs, at least large-scale programs, are backed by some form of authority. This authority is often based in legislation, which is typically secured after many years of political struggle (examples being the Occupational Safety and Health Act in the United States and the Health and Safety at Work Act in

the United Kingdom). In other instances, the authority derives from regulation by governmental agencies at various levels (federal, state, or local) or from collective bargaining agreements. Before such authority is established, there may be a need to create political pressure.

Those engaged in research must not withdraw into an ivory tower. On the contrary, their responsibility is to provide politicians and policy makers with unbiased data and opinions on the basis of scientific judgment to assist the development of sound prevention programs. Researchers should also offer the public correct facts and should oppose any exaggeration created by mass media, misinformation inspired by industry, administrative indolence, and any forms of misinterpretation. These are core principles of the developing field of risk communication (Gheorghe and Seiler, 1998; Lee *et al.*, 1998; Sandman, 1993).

4 PREVENTION OF THE EFFECTS OF METAL TOXICITY IN THE GENERAL ENVIRONMENT

4.1 General Considerations

Industrial activity during the past 200 years, and especially in the past 50 years, has caused a sharp increase in the concentration of many metals in air, soil, water, and other environmental media worldwide (see Dick, 1991; Lockhart *et al.*, 1992; Mage *et al.*, 1996). Consequently, the likelihood that the general public will be exposed to toxic metals is greater than in the past and growing.

Exposure levels vary greatly, depending on geographical, cultural, and other circumstances (see WHO, 1973). Urban environments are typically more polluted than rural areas, and industrialization increases exposures directly through emissions and indirectly through its products. Local practices—for instance, the use of lead-glazed ceramic containers and battery recycling—may further cause exceptionally high exposures (Romieu and Hernandez-Avila, 2003). Finally, enrichment may take place in food chains, such as the bioaccumulation of methylmercury in marine food webs (Hansen and Gilman, 2005).

4.2. The Unique Vulnerability of Infants and Children to Poisoning by Metals

Children are especially susceptible to adverse health effects from exposure to metals dispersed in the environment. Infants and children have unique patterns of exposure and developmentally determined susceptibilities that differ qualitatively from those of adults and that generally increase their risk of toxicity (National Academy of Sciences, 1993a). The fetus that a pregnant woman carries to work has vulnerabilities that are very different from those of an adult worker.

Children's high degree of vulnerability to toxicity caused by metals reflects the fact that they have exceptionally heavy exposures coupled with unique biological vulnerabilities. Kilogram for kilogram of body weight, children drink more water, eat more food, and breathe more air than adults. In the first 6 months of life, children drink seven times as much water per day as the average adult. Children between 1 and 5 years of age eat three to four times as much food as an adult. The implication of these findings for health is that children have substantially heavier exposures than adults to any metals that are present in water, food, or air (National Academy of Sciences, 1993a).

Children's metabolic pathways, especially in the first months after birth, are immature. Their ability to metabolize, detoxify, and excrete many substances differs from that of adults. In some instances, children are better able to deal with chemical toxicants. More commonly, however, they are less well able to deal with toxic metals, such as lead.

Children are undergoing rapid growth and development, and these highly complex developmental processes are easily disrupted. Organ systems undergo very rapid change prenatally, as well as in the first months and years after birth. These developmental processes are very delicate and may be unable to repair damage caused by environmental toxicants. If chemicals such as lead, mercury, or solvents destroy cells in an infant's brain, the risk is high that the resulting dysfunction will be permanent and irreversible.

Because children have more future years of life than most adults, they have more time to develop chronic diseases triggered by early exposures. Many human diseases, including neurodegenerative diseases and many cancers, are now thought to arise through a series of stages that require years or even decades to evolve form the earliest initiation to the actual manifestation of disease (Landrigan *et al.*, 2005). Recent studies raise the hypothesis that exposures to metals in early life may increase later risk for Parkinson's disease—in relation to manganese exposure (Logroscino, 2005; Zatta *et al.*, 2003)— and for dementia—in relation to exposure to lead (Stewart *et al.*, 2002). Genetically mediated differences in susceptibility among individuals may modulate these effects.

4.3 Reduction of Exposure

4.3.1 Elimination or Reduction of Use

The most effective method for control of the spread of a metal into the general environment is the

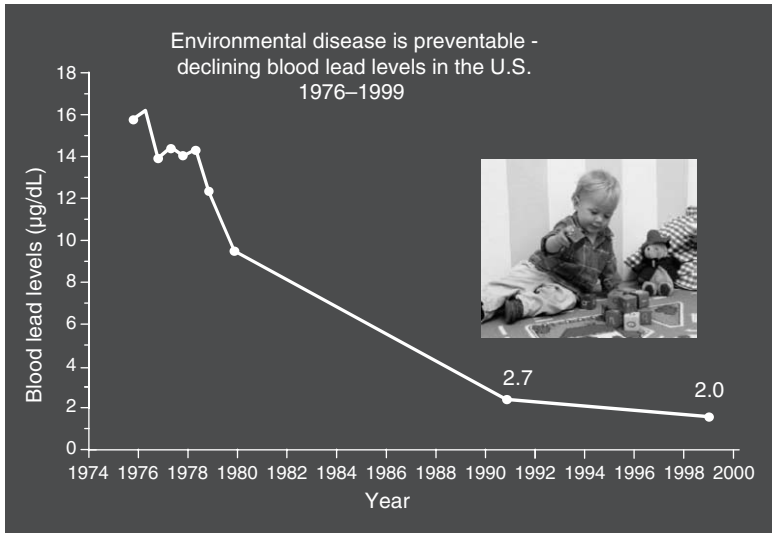

FIGURE 1 Decline in population blood lead levels in the United States (1976–1999). From CDC (2005).

discontinuation of dangerous and unnecessary uses. Such a step also reduces the need for production and, hence, simultaneously eliminates the exposure of workers. Generally, such a drastic measure requires a legislative ban, as in the case of a ban imposed on the use of methylmercury compounds for seed dressing in Sweden in 1966. Sometimes a practice is abandoned voluntarily, as in Finland in 1969, when the pulp industry agreed to discontinue the use of phenyl mercury acetate for slime control.

Major reductions in human exposure and in population blood lead levels have resulted from reduction of the content of tetraethyl lead in gasoline (Landrigan *et al.,* 2000). This advance has required legislation in some countries, while others nations have achieved promising results voluntarily. In the United States, the gradual removal of lead from gasoline produced a 90% decline in population blood lead levels between 1976 and 1997 (Figure 1) (CDC, 1997). In Chile, where lead in gasoline was first regulated in 1993, infants in Santiago experienced a decline of 29% in blood lead levels over the next 18 months (Pino *et al.,* 2004). More than 80 nations worldwide, including nearly all of the industrially developed nations, have now banned lead from gasoline.

In many nations undergoing the transition to industrialization, lead is still used in gasoline. In these nations, lead use in industry is often widespread, environmental contamination may be intense, and blood lead levels in workers, as well as in residents of communities near polluting industries, have been reported to be dangerously elevated (Landrigan, 2002; Landrigan *et al.,* 2000).

4.3.2 Source Control

If use of a metal cannot be eliminated, control of environmental contamination is achieved through prevention of escape as close as possible to the source of pollution. The most important method of preventing metallic emissions to the environment from industry is the purification of smoke, exhaust, and other emissions. The methods vary widely, but the following four principles are fundamental to most methods of particulate control (Johnson *et al.,* 1998):

1. Separation by inertial forces (e.g., cyclones)
2. Separation by dissolution (e.g., water scrubbers)
3. Separation by filters
4. Separation by electrostatic forces (electrofilters)

In addition, cooling traps and absorption into organic polysulfides are used for capturing mercury vapor.

4.3.3 Routes of Environmental Contamination by Metals

Metals can contaminate the general environment through many routes. Because of their stability, they may penetrate environmental compartments, in some cases, many years after the initial deposition.

Contamination of the air and then waterways by metals occurs as a consequence of anthropogenic emissions from coal-burning power facilities, chlor alkali plants, waste incineration, and other industrial activities, which contribute 70% of the mercury pollution into the earth's atmosphere annually (Trasande *et al.,* 2005). Large conventional power plants are the main polluters. In the United States, coal-burning

electricity–generating plants are major sources of atmospheric mercury emission and accounted for the release of 48 tons of mercury emissions in 1999, 41% of all anthropogenic mercury emissions in the United States that year (Trasande *et al.,* 2005).

Soil and water near large smelters or other major emitters are often heavily contaminated (Benin *et al.,* 1999; Liu, 2003; Sterckeman *et al.,* 2000). Vegetables and grain grown in such environments usually contain undesirably high concentrations of metal (Kalac *et al.,* 1996). Community and well water often become contaminated (Baker *et al.,* 1977b; Polissar *et al.,* 1990). Preventing undue exposure from such sources requires, in addition to reducing the emissions, the monitoring of food and water and a ban on the sale of foodstuffs containing excessive amounts of metals. Hence, the risk for adverse effects is highest among those living in these vicinities. Taller chimney stacks distribute the emissions over larger areas and thereby dilute the concentrations, but this practice is no substitute for efficient exhaust purification in the case of toxic metals and should, therefore, be condemned. The same can be said of the practice of leading unpurified sewage water containing, for example, mercury or cadmium far out into the sea.

The aquatic system becomes contaminated when industries—especially small factories—discharge untreated, metal-containing waste directly into the water, when rainwater washes away the metal-containing dust that has settled around industries, or when metal trapped in air-purification systems is carelessly handled and allowed to enter the waste water stream. Water scrubbers constitute a particular problem in the last respect. The purification of sewage water is based on recirculation and various precipitation processes. For example, mercury can be precipitated into sulfide and absorbed into aluminum hydroxide, which is then removed as foam. Iron oxide can also be used. Unfortunately, the control of the spread of dust from the surroundings of industries sometimes entails a liberal use of water, thereby placing an extra load on water-cleaning systems, and, in some cases, polluting rivers and lakes.

Pollution of the soil and water systems may also arise from the weathering of disposed metal products. The reuse of scrap decreases both these types of pollution and the need for exploiting ores. However, most scrap for reuse goes to iron and steel works, where the melting process releases impurities (e.g., cadmium and lead) stemming from alloys, paints, etc. The impurities are seldom regained but are emitted into the environment with the smoke. Unless effective exhaust purification is applied, such recycling, in fact, can increase rather than decrease exposure to toxic metals.

Careless dumping of metal waste can severely pollute water basins. For example, old gravel quarries are definitely unsuitable as dumps, because dissolved metal compounds then have easy access to the ground water. All dumps must be without any contact with water supplies. A specific problem has arisen caused by sewage sludge being used as a fertilizer. Such sludge may contain fairly high concentrations of many metals (e.g., cadmium), which may then enter the food chain. Because mercury is transformed into methylmercury by microorganisms in the environment, it is important to take care of mercury waste.

Pollution may arise acid when industrialized societies ship waste material containing toxic metals to developing nations. Severe episodes of contamination have resulted from uncontrolled export of products such as lead batteries.

Metal objects such as cans and batteries often end up in community incinerators together with other waste. Burning such waste may cause significant emissions of the most common toxic metals, especially lead.

Food and wine may be contaminated from lead-glazed ceramic ware, which releases large amounts of lead into food, especially in an acid environment, such as fruit juice. Canned food may contain lead that has been released from soldered joints in food containers. Several cases of cadmium poisoning have occurred because of the ingestion of food and drink into which this metal had dissolved from cadmium-plated articles (e.g., ice trays, juice makers, roasters). Toxic metals, such as cadmium and arsenic, have been found in high amounts in seafood in some areas. Preventing poisoning from such foods requires systematically organized analyses of their metal contents and the regular reporting of results to the public. Ceramic ware should be tested for lead and cadmium release during acid treatment before being allowed onto the market (Galvez *et al.,* 2004).

The consumption of illicit whiskey, which is often distilled in discarded car radiators or lead-soldered tubing, causes many cases of severe poisoning each year in the United States (Kaufmann *et al.,* 2003). The household use of mercury in religious Santeria rituals among some Latin American persons has produced high levels of mercury in the blood of these persons and their family members (EPA, 2003; Tarabar and Su, 2003). Folk medicines imported from developing to developed nations may be another source of lead poisoning that may come to be recognized only after extensive investigation. (Markowitz *et al.,* 1994; Silva, 2005) Effective consumer information seems to be the only method for preventing such poisoning.

4.4 Environmental Monitoring

The need for monitoring metal concentrations in food and drinking water, whenever there is reason to suspect excessive amounts, is critically important. In

addition, air and water monitoring help ensure that regulations are being met. In principle, two types of sampling procedures should be used. First, metal concentrations should be measured at representative sites, so that compliance with environmental standards can be ensured. Second, emissions from particular point pollution sources should be checked, so that individual polluters will comply with emission standards.

In public health, few regular monitoring programs for metals have existed until recently. Hence, most experience in the general environment derived from specific campaigns, such as lead screening programs in the United States, and studies of fish consumers in Sweden and Japan, to assess their exposure to mercury. However, in a number of countries in recent years, national health surveys have provided important new information on metal levels in the human body and in the diet. Data from these surveys have become an invaluable source of information about metals in the environment and their impact. For example, in the United States, the National Health and Nutrition Examination Survey (NHANES), a program of the Centers for Disease Control and Prevention, has been collecting data on various metal levels in adults and children for the past 30 years. These data helped guide and shape major public health programs related to these metals. Currently, NHANES samples blood levels for 13 different heavy metals, including lead, mercury, cadmium, and uranium, and reports the levels of these in ongoing reports through the National Center for Environmental Health (NCEH, 2005).

4.5 Public Education

Communities in the vicinity of toxic industrial facilities or hazardous waste disposal sites have a right to be informed of the nature of the hazards and of releases to the environment. In the United States, this right to know is protected by law, and the necessary information is available on the web site (*www.scorecard.org*). In Europe, the Aarhus Convention states that everybody has the right to access information on the quality of the environment in which they live (*www.unece.org/env/pp/*).

To protect the public against metal contamination of food, dietary advisories may be appropriate, such as those published by state health departments in the United States in regard to mercury in fish. Similarly, warnings are sometimes released by regulatory agencies (e.g., when contamination of food, toys, or consumer products has been discovered). Government agencies issuing such advisories have a special obligation to ensure that these are properly communicated to the affected communities in language that is understandable and culturally acceptable to the community.

Workers who live in communities surrounding metals plants are doubly exposed to these metals in their homes, along with their families, when plant emissions enter the community air, soil, and water. Thus, it is doubly important that they be aware of and avoid metal contamination in their food and exposures from consumer products. They urgently need to be aware of dietary metals health advisories and consumer warnings released by regulatory agencies.

4.6 Regulatory Authority

The possibilities for the accidental intake of toxic metals are almost unlimited. For example, although the rate of lead poisoning deaths has dropped sharply in the United States in recent decades, there were still an estimated 200 such deaths in the United States between 1979 and 1998, many of them caused by the ingestion of moonshine alcohol (Kaufmann *et al.*, 2003). Accidentally ingested lead shot has also been reported to cause lead poisoning (Gustavsson and Gerhardsson, 2005). There is also evidence of long-term mortality effects from instances of childhood lead poisoning (McDonald and Potter, 1996). When mercury thermometers are broken indoors, especially in bedrooms, hazardous mercury concentrations may result, unless the spilled droplets are meticulously removed. The preventive action lies in banning the use of toxic metals both as components and as paints, in such consumer goods as toys and ceramics, as well as requiring consumer warnings for products in which metal contamination cannot be avoided. In some communities, special lead abatement task forces, with both enhanced legislative and judicial powers, have been effective in reducing childhood residential exposures (Campbell *et al.*, 2005).

In some countries, campaigns specifically aiming to increase awareness in the general population not to spread trash have been initiated (e.g., to collect thermal thermometers with mercury, not to put Cd batteries in trash).

5 PERSPECTIVES ON PRECAUTION AND PREVENTION

5.1 Populations at Risk

Identification of populations at high risk of exposure is of paramount significance for the prevention of metal toxicity in the general population. Some of these groups have already been noted in this chapter (i.e., populations living around smelters and other emitters [all toxic metals], inner-city children living in deteriorated housing [lead], consumers of illicit

whiskey [lead], heavy fish consumers [mercury], dwellers in districts with lead-plumbing systems [lead], users of primitive ceramic ware [lead], children drinking well water in Bangladesh [arsenic], and children living near highways in Australia [manganese]). From time to time new hazards are recognized—for example, the recent recognition in the United States of the lead hazards that result from use of imported medications containing lead and mercury among Asian immigrants (Markowitz *et al*., 1994).

Special attention must always be directed to determining whether young children or women of childbearing age are at risk of exposure. In the United States, in certain states where there are large populations of young children at risk of exposure to lead-based paint and to the dust released from this paint, mandatory blood lead screening of all children is required at 12 months and 24 months of age.

5.2 Widening Implications of Subclinical Toxicity

If a metal is in wide use and has become extensively dispersed in the environment, the subclinical toxicity that it causes can be equally widespread and can affect the well-being and the security of entire societies. Moreover, such widespread subclinical toxicity can be extremely costly. Such population-wide toxicity occurred in nations around the world in the 20th century as a consequence of the nearly universal use of tetraethyl lead as an additive in motor fuel.

Between 1950 and 1975, approximately 100 million children in the United States and hundreds of millions more worldwide were exposed to lead emitted to the environment by the burning of leaded gasoline. This widespread exposure produced a mean national blood lead level in US children in the 1970s of nearly 200 μg/L (20 μg/dL) (today the mean is less than 20 μg/L [2 μg/dL]) and comparable elevations in children of many other nations. This widespread elevation of blood lead levels was associated with loss of intelligence that extended across entire populations and resulted in a 50% decline in the number of truly gifted children (IQ scores >130) and a corresponding increase in the number of children with mental retardation (IQ <70). This widespread loss of intelligence caused lifelong reduction in economic productivity in the affected birth cohorts, which, in the United States, is estimated to have cost between $110 billion and $319 billion (USD) in each annual birth cohort (Grosse *et al.*, 2002). The costs worldwide are many times that sum. Even today, continuing elevations of blood lead levels in many thousands of American children are estimated to cost $43 billion in each annual US birth cohort (Landrigan *et al.*, 2002). Decreased lifetime economic productivity, a consequence of the diminution in intelligence caused by lead, is the principal contributor to these great economic costs attributable to metal toxicity.

Widespread neurotoxicity could result again, if the organic manganese compound MMT (methylcyclopentadienyl manganese tricarbonyl) is allowed to be used extensively as a fuel additive (Weiss, 2005). Manganese is a known cause of parkinsonism in occupationally exposed adults (Hunter, 1969; Lucchini, 2005). Lower dose exposures to manganese have been associated with developmental neurotoxicity (Mergler *et al.*, 1999; Normandine *et al.*, 2004; Wasserman *et al.*, 2004). The potential consequences of population-wide exposure to manganese emitted to the environment from the combustion of MMT in motor fuels are poorly understood. Information is especially lacking on potential consequences of exposures to pregnant women and young children.

5.3 Precautionary Approaches

The history of metal toxicity provides a wealth of examples, in which opportunities for prevention were missed, despite early warnings (Hernberg, 2000). More than 300 years ago, a German state enacted capital punishment for adulteration of wine with lead, and the use of lead for water pipes was subsequently outlawed (Eisinger, 1982). Nonetheless, these uses continued elsewhere in the world and caused countless cases of lead poisoning. In the early 20th century, the introduction of tetraethyl lead as an octane booster of gasoline happened, despite early warnings of neurotoxicity that were disregarded (Needleman, 2000; Rosner and Markowitz, 1985). Although preventive measures are often initiated long after ample documentation of toxicity has been accumulated, long experience with metal toxicity would suggest that more stringent measures ought to be considered earlier. Typically, early studies of the health effects of metals document the existence of toxicity, whereas later research shows that metals possess toxic properties at low exposure levels that had previously been considered "safe" and that toxicity is more widespread than had originally been imagined. In the future, it would be prudent to compress this cycle and to intervene on the basis of early warnings (Harremoes *et al*., 2002).

To prevent recurrence of such disasters as the addition of tetraethyl lead to gasoline, the precautionary principle has recently been formally introduced into national and international law (Foster *et al.*, 2000; Grandjean, 2004). The key element of the precautionary principle is that it provides justification for acting in the face of uncertainty. It is a tool for acting on

the basis of early warnings to avoid possible future harm associated with suspected, but not yet conclusively proven, environmental risks. With the precautionary principle, the burden of proof is shifted from demonstrating the presence of risk to demonstrating the absence of risk (www.sehn.org/precaution.html). Scientific uncertainty should not be an excuse invoked to limit preventive efforts, and debates over minute details in risk assessments should not result in delayed action to protect the public health and the environment.

A recent application of the precautionary principle is to be found in the Declaration of Brescia on Prevention of the Neurotoxicity of Metals (Landrigan *et al*., 2006). This Declaration, which was developed under the auspices of the International Commission on Occupational Health (ICOH) states that intensified attention must be paid to early warnings of neurotoxicity. It calls for an immediate halt in all nations to the addition of manganese compounds to gasoline. This call is based on published data on the developmental neurotoxicity of manganese (Mergler *et al*., 1999; Wasserman *et al*., 2004). The call was specifically intended to prevent a recurrence of the worldwide tragedy of tetraethyl lead. The Declaration of Brescia is reproduced in full at the conclusion of this chapter.

The tools for preventive action outlined in this chapter will still be relevant in the future, and we should be prepared to use these tools vigorously and proactively. Although upper limits of exposure to some metals have unfortunately been set too high and later reduced, because of recognition of adverse health effects at the levels previously considered safe, the precautionary principle would suggest that the limits should initially be set well below the threshold for disease and later raised as safe experience with the exposure is documented in the literature. Although some would argue that such a practice would make most new metallurgical processes economically unfeasible, one cannot measure all of the potential negative human and economic consequences of an unmitigated overexposure in a large population.

THE DECLARATION OF BRESCIA ON PREVENTION OF THE NEUROTOXICITY OF METALS

Brescia, Italia

17–18 June 2006

On 17–18 June 2006, the Scientific Committee on Neurotoxicology and Psychophysiology and the Scientific Committee on the Toxicology of Metals of the International Commission on Occupational Health (ICOH) convened an International Workshop on *Neurotoxic Metals: Lead, Mercury and Manganese—From Research to Prevention (NTOXMET)* at the University of Brescia. Scientists and physicians from 27 nations participated.

Data were presented for each of the three metals on environmental sources, fate, and distribution; human exposure; clinical, subclinical, and developmental neurotoxicity; epidemiology; risk assessment; and prospects for prevention. Ongoing and future studies were described and discussed.

For each of the metals, initial recognition of neurotoxicity occurred in the context of high-dose exposure. For example, lead poisoning was first recognized in miners, smelters, and typesetters, methylmercury poisoning in inhabitants of the fishing community of Minamata, and manganese poisoning in miners and ferroalloy workers. Subsequent development of more sensitive and sophisticated analytical instruments led to the recognition of subclinical toxicity and developmental neurotoxicity at progressively lower levels of exposure. In each case the extent of toxicity was much greater than initially appreciated and the size of the affected population much larger. Many decades typically elapsed between the initial recognition of neurotoxicity and the initiation of programs for prevention. Early warnings were frequently ignored and even actively resisted.

The historical observation that long delays had typically elapsed before the initiation of prevention prompted extensive discussion at the Workshop about the need to develop more effective strategies. From this discussion, a series of recommendations emerged on future directions for research and prevention of the neurotoxicity of metals.

At the closing session of the International Workshop at Brescia, the following recommendations on the Prevention of the Neurotoxicity of Metals were adopted by consensus:

1. *Intensified attention must be paid to early warnings of neurotoxicity*. Clinical observations or toxicological data suggesting the existence of neurotoxicity—including subclinical and developmental toxicity—must be taken very seriously. Such observations should prompt consideration of prudent preventive action.
2. *All uses of lead including recycling should be reviewed in all nations* and uses contributing to environmental and human exposures, such as uses in toys, paint, water pipes, building materials, solder, electronics, medications, and cosmetics ended. The transfer of these products from one country to another should also be avoided. This approach has been adopted successfully in the EU and needs to be extended worldwide.
3. In particular, *tetraalkyllead must be eliminated without delay from the gasoline supplies of all nations*. The removal of organic lead from gasoline has produced declines of >90% in population mean blood lead levels in industrially developed nations, and this success is now being repeated in some of the developing nations. This action represents one of the great

public health triumphs of the late 20th century and needs urgently to be extended to all nations.

4. *Current exposure standards for lead need urgently to be reduced*. Current standards were established many years ago and do not reflect recent advances in scientific knowledge about toxic effects at levels of exposure below these standards. The Brescia Workshop recommends that:
   - *For children*, the action level, which triggers community prevention efforts to reduce exposure sources, should be immediately reduced to a blood lead concentration of 50 µg/L in nations worldwide. This level is proposed as a temporary level that may need to be revised further downward in future years as new evidence accumulates on toxicity at still lower blood lead levels. This reduction of the blood lead action level will reduce the incidence of subclinical neurotoxicity in children as well as the delayed consequences of developmental toxicity.
   - *For industrial workers*, the standard for lead in blood should be reduced immediately to 300 µg/L in nations worldwide. Additional consideration should be given to further reducing this standard to 200 µg/L and below in the years ahead. This reduction in exposure standard will reduce the incidence of subclinical neurotoxicity and other toxic effects during the working life and responds to new documentation presented at the Workshop that long-term lead exposure increases the risk of dementia in later life.
   - *For female industrial workers of reproductive age*, the standard for lead in blood should be reduced immediately in nations worldwide to the lowest obtainable, preferably to 50 µg/L, a level consistent with the recommended blood lead standard for children. Lead passes freely across the placenta from the maternal to the fetal circulation to enter the developing brain where it causes prenatal brain injury. This recommended reduction in maternal lead exposure will reduce the incidence of fetal neurotoxicity in the offspring of women workers.
5. Exposures of pregnant women and women of reproductive age to methylmercury need to be reduced to prevent subclinical fetal neurotoxicity. Evidence is strong that prenatal exposure to methylmercury causes fetal neurotoxicity. Consumption of fish with high mercury concentration by pregnant women is the primary route of exposure. More than 50% of the mercury in fish may be of industrial origin.

   Strategies for reducing mercury exposure recommended by the Brescia Workshop are the following:
   - All industrial uses, recycling processes, and other industrial input of mercury into the environment should be reviewed in all nations, and non-essential uses should be eliminated and releases controlled. This approach has been successfully introduced in the EU and is actively promoted by the United Nations Environmental Program.
   - Mercury emissions from coal-fired power plants need to be curtailed.
   - All chlor alkali plants worldwide should be urgently converted to alternative technologies that are not based on mercury, and mercury stores and wastes must be safely deposited.
   - Gold mining with mercury must be controlled and enforced with safety guidelines, and alternative technology should be promoted.
   - Dietary advisories should be developed as effective, culturally appropriate means to limit childbearing women's consumption of fish contaminated with methylmercury. Taking into account nutrient contents and availability, healthy diets should be recommended with fish and seafood containing minimal levels of contamination.
6. *Exposures of pregnant women and young children to manganese need to be reduced to prevent subclinical neurotoxicity*. Important new data on the neurotoxicity of manganese were presented at Brescia. In adult workers, these data suggest that manganese produces subclinical neurotoxicity at levels of exposure below those that produce parkinsonism. In children, evidence from two recent epidemiological studies suggests that exposure to manganese in early life causes subclinical developmental neurotoxicity.
7. *The addition of organic manganese compounds to gasoline should be halted immediately in all nations*. The data presented at the Brescia Workshop raise grave concerns about the likelihood that addition of manganese to gasoline could cause widespread developmental toxicity similar to that caused by the worldwide addition of tetraalkyllead to gasoline. In light of this information, it would be extremely unwise to add manganese to gasoline.
8. *Exposure standards for manganese need to be reconsidered* .The drinking water standards for manganese in many countries are not based on health concerns, and those that are do not protect against developmental neurotoxicity resulting from exposures *in utero* and in early postnatal life. The current occupational exposure standard may not protect workers against subclinical neurotoxicity. The value for air manganese concentration in inhalable/total dust of 100 µg/m^3

should be adopted to protect the workers from prolonged exposure and consequent long-term effects.

9. *Economic impacts of the neurotoxicity caused by metals must be considered.* The costs of toxicity may be far greater than the costs of pollution control. The major contributor to these costs is damage to the developing central nervous system. Such injury can result in lifelong loss of intelligence and motor capacities, permanent psychological disturbances, and disruption of behavior. These effects can produce reduction of economic productivity, and when this reduction occurs widely across a society, the resulting economic impacts are great. The costs of pollution recur annually in each exposed birth cohort, adults, and elderly while the costs of control are one-time costs.
10. *Need is great for continuing research into the neurotoxicity of metals.* Recent studies of neurotoxicology of each of the metals discussed at the Brescia Workshop inform us that we can anticipate harmful effects of increasingly lower levels of exposure to metals previously considered safe as larger studies using sensitive measures of exposure and outcome, and better statistical techniques are conducted.
    a. For lead, mercury, and manganese, much remains to be learned about the delayed consequences of developmental toxicity and the prolonged exposure to low levels in the adults, as possible causes of neurodegeneration. This research is critical to guide both future research in metals as paradigms of neurotoxic pollutants and targeted programs of prevention.
    b. Prospective cohort studies from birth are needed, parallel to study on adults and elderly with a retrospective assessment of exposure
    c. Neurotoxicological research, including research on developmental neurotoxicology, is needed on metals not considered at the Brescia Workshop—arsenic and aluminum in particular, and on interactions with essential elements, pesticides and persistent organic pollutants.
    d. Research is needed into genetic and other factors that contribute to susceptibility to metal toxicity.
    e. Research is needed into various determinants of the rearing environment, including the social setting, that can modify the exposure indicators to neurotoxic metals and subsequently the magnitude of neurodevelopmental effects.
    f. Research is needed into the potential consequences of global warming for human exposures to neurotoxic metals—especially mercury.

Signatories (Organizing Committee of the Brescia Workshop)

Philip J Landrigan, MD, MSc, Professor

Aluminum

BENGT SJÖGREN, ANDERS IREGREN, CARL-GUSTAF ELINDER, AND ROBERT A. YOKEL

ABSTRACT

Aluminum is ubiquitous in the environment. Its proportion of the earth's crust is about 8%. Aluminum can be absorbed from the gastrointestinal tract and from the lungs. Excretion is mainly by the kidneys, probably as aluminum citrate. Aluminum is a well-known neurotoxicant. Accumulation in the human body has been related to the presence of aluminum in dialysis fluids and the concomitant intake of aluminum-containing drugs. This accumulation has resulted in dialysis encephalopathy that was often fatal. Neurotoxic effects have been observed in welders with aluminum urine >100 μg/L. The upper reference limit among nonexposed individuals is 16 μg/L. Aluminum has been suggested to be one of several factors contributing to Alzheimer's disease, although this has not been satisfactorily demonstrated.

Occupational exposure to aluminum powder has resulted in pulmonary fibrosis.

Asthma has been associated with the inhalation of aluminum sulfate, aluminum fluoride, potassium aluminum tetrafluoride, and the complex environment in potrooms during aluminum production.

Cancer and coronary heart disease have been observed among aluminum production workers. However, it is unlikely that aluminum per se is responsible for these diseases.

1 PHYSICAL AND CHEMICAL PROPERTIES

Aluminum (Al): Atomic weight, 26.98; atomic number, 13; density, 2.7 g/cm^3; melting point, 660.4°C; boiling point, about 2400°C.

Pure aluminum is a light ductile metal with a density of approximately one third that of iron. Aluminum is a good conductor of both heat and electricity. It is easy to weld. These properties make it especially suitable for industrial purposes. When aluminum is exposed to air or water, a thin film of oxide (about 0.01 μm) is formed on the surface, creating a protective coating that is resistant to corrosion. By further forced oxidation, this coating can be made thicker to increase corrosion resistance. Aluminum is used in alloys with copper, zinc, manganese, and magnesium.

Aluminum is the third most abundant element in the earth's crust and constitutes about 8% by mass. In nature, it only exists in very stable combinations with other materials (particularly as silicates and oxides).

The chemical form (chemical speciation) has a great influence on aluminum toxicokinetics and toxicodynamics. As with most metals, soluble forms of aluminum are better absorbed and better able to distribute to target organs of its toxicity. In the absence of associating ligands, aluminum, as the hydroxide, is least soluble at pH 6.2 (Harris *et al.*, 1996). The rate constant for water (~sec^{-1}) and ligand exchange with aluminum are slower than for most metals (Burgess, 1992).

2 METHODS AND PROBLEMS OF ANALYSIS

Because of the ubiquitous distribution of aluminum in nature, contamination may be a serious problem during sampling and sample preparation. In the 1970s, reported "normal" values of aluminum in serum or plasma were around 100 μg/L, which was a reflection of contamination (Versieck and Cornelis, 1980).

In 1994, we reported on a case of aluminosis, an aluminum-induced condition that was first recognized in 1946. Many years after exposure, the patient developed a dementia with motor disturbances. His cerebrospinal fluid aluminum level was found to be 259 µg/L (Sjögren *et al*., 1994). In 1998, he died, and his cerebrospinal fluid contained 7 µg Al/L, which is normal. The first reported high concentration of aluminum was most probably caused by contamination during sampling or storage (Sjögren *et al*., 1999). This case illustrates the importance of avoiding contamination.

Instrumental methods most commonly applied to the determination of aluminum include inductively coupled plasma-atomic emission spectroscopy (ICP-AES) and graphite furnace-atomic absorption spectroscopy (GF-AAS). ICP can also be combined with a mass spectrometer to further increase sensitivity (WHO/IPCS, 1997).

Certified reference materials for aluminum are available in some useful matrices but are generally lacking in mammalian tissue, including brain (Yokel, 2004).

3 PRODUCTION AND USE

In 1825, the Danish chemist Örsted produced minute quantities of aluminum metal by using dilute potassium amalgam to react with anhydrous aluminum chloride. Bauxite is the most commercially important form of weathered igneous minerals that contain aluminum. It is abundant in the earth's crust in large areas of the world. The Bayer process of obtaining aluminum oxide (alumina) from bauxite was invented in the 1880s and remains the most economical means to do so. In 1886, Héroult from France and Hall from the United States, invented, simultaneously and independently, an electrolytic process for aluminum production. The Hall–Héroult process is still the basis for aluminum production. They discovered that molten aluminum was produced when an electric current was passed through a bath of molten cryolite (Na_3AlF_6) with dissolved alumina. The presence of cryolite in the Hall–Héroult process enables electrolysis to proceed at a temperature <1000°C, lower than the melting point of alumina (Abramson *et al*., 1989). A modern aluminum smelter contains a series of reduction cells or a potline. There are two types of pots: prebaked and Söderberg. In prebaked pots, anodes are prepared in a carbon plant from calcined petroleum pitch and coal pitch. This mixture is baked in solid blocks and subsequently attached to conductive rods and inserted into the pots. In the Söderberg process, the carbon paste is dropped into a steel casing hanging above the pot and baked *in situ*.

Enormous quantities of energy are necessary for the electrolytic reduction of aluminum, almost 16,500 kWh per ton. Because of this fact, aluminum plants are usually located close to relatively cheap power sources (e.g., in the vicinity of hydroelectric power plants). In the beginning, aluminum production was very modest, but it increased rapidly in the 20th century, especially after the Second World War. Annual aluminum production in the beginning of the 21st century was 20–22 million tons (*www.world-aluminium.org*). The metal and its alloys are used in airplanes, trains, trucks, cars, in the construction industry, and in food preparation and storage. Aluminum powders are used in paints, explosives, and fireworks.

The adjuvant effect of aluminum compounds was first described by Glenny and coworkers (1926). They investigated the immunogenicity of various diphtheria toxoid precipitates, including those precipitated by addition of potassium alum ($KAl(SO_4)_2.12H_2O$). Alum precipitates led to a significant increase in the toxoid-induced immune response. Vaccines prepared by this method are referred to as alum-precipitated vaccines. Another procedure is antigen adsorption onto preformed aluminum hydroxide hydrated gels. Such gels can be preformed in a standardized way. They adsorb protein antigens from an aqueous solution. These vaccines are called aluminum-adsorbed vaccines. Aluminum hydroxide ($Al(OH)_3$) and aluminum phosphate ($AlPO_4$) are now the most commonly used adjuvants and have almost completely replaced the alum precipitation method in vaccine preparation (Lindblad, 2004). Their safety has been questioned by some, but alternatives to replace aluminum as adjuvants are not likely soon (Baylor *et al*., 2002).

Some aluminum-containing drugs, such as hydroxide and sucralfate, have been used as antacids and phosphate binders (Yokel and McNamara, 2001). Alum is used to treat urinary bladder hemorrhage. Aluminum salts are used in antiperspirants; styptic pencils; in products for dermatitis, diaper rash and prickly heat, insect stings, and bites and for athlete's foot (tinea pedis); in antidiarrheal products; in vaginal douches; and as a keratolytic in anorectal preparations (Allen *et al*., 2000).

Aluminum silicate functions as an abrasive, anticaking agent, bulking agent, and opacifying agent in cosmetics. Magnesium aluminum silicate is also used as a viscosity-increasing agent in aqueous cosmetics. According to the FDA, it was used in 629 formulations in 1998 (Elmore, 2003). The use of aluminum-containing food additives is approved by many governments. These are major contributors to dietary aluminum intake.

Substantial amounts of aluminum salts are commonly used as flocculents during the treatment of drinking water.

4 DIETARY, ENVIRONMENTAL, AND OCCUPATIONAL EXPOSURE

The primary normal source of aluminum for the human is food. Daily aluminum intake averages 5–10 mg. The aluminum content of food is highly variable. The average aluminum content of spices and herbs ranged from less than 0.005 mg/100 g for salt to 200 mg/100 g for thyme. Although the quantities of spices and herbs used in foods is generally very small, a diet high in spicy foods may be high in aluminum (e.g., a teaspoon of cayenne powder could contribute about 4 mg of aluminum). Baking powder containing aluminum additives was extremely high in aluminum, providing more than 2 g of aluminum per 100 g. The most commonly used foods that may contain substantial amounts of aluminum-containing food additives except baking powder are processed cheese, cake mixes, frozen dough, pancake mixes, and pickled vegetables (Saiyed and Yokel, 2005). Concentrations of aluminum in tea leaves and tea powder can be quite high, up to 140 mg/100 g. Based on these values, a cup of tea could contain 1 mg of aluminum (Pennington, 1987). Tea and aluminum utensils were estimated to increase aluminum in the diet by approximately 4 and 2 mg per day, respectively (Jorhem and Haegglund, 1992).

Beverages from aluminum cans contained generally higher levels of aluminum than beverages from glass bottles. Noncola and cola soft drinks averaged 900 and 660 µg/L from cans and 150 and 240 µg/L from glass bottles, respectively, whereas beer in cans or bottles averaged about 160 µg/L. The highest concentration in a noncola soft drink can was 10,000 µg/L (Duggan *et al*., 1992).

The contribution of aluminum from drinking water is about 100 µg/day (Yokel and McNamara, 2001).

Air aluminum concentrations vary between 20 and 500 ng/m^3 in rural settings and 1000 and 6000 ng/m^3 in urban settings. Humans exposed to ambient aluminum concentrations of 2000 ng/m^3 and particle size <5 µm and who have a normal ventilatory volume of 20 m^3/day would inhale 40 µg aluminum/day (WHO/IPCS, 1997).

Occupational exposure to aluminum particles reached 100 mg/m^3 during production of stamped aluminum powder in the 1950s (Mitchell *et al*., 1961). However, in the 1990s reported levels were 5–21 mg/m^3 during production of aluminum powder and 1–4 mg/m^3 during production of aluminum paste (Letzel *et al*., 1996). Aluminum welding (Figure 1) produced levels of 0.2–5 mg/m^3 (Sjögren *et al*., 1988). Powder production and aluminum welding are generally associated with the highest occupational aluminum exposure.

FIGURE 1 Metal Inert Gas (MIG) welding of aluminum.

5 METABOLISM

5.1 Absorption

There have been several studies in animals and humans dosed with ^{27}Al using atomic absorption spectroscopic analysis and dosed with ^{26}Al using accelerator mass spectrometric analysis to estimate the percentage of aluminum absorbed from drinking water. The results suggest ~0.3% is orally absorbed (Priest *et al*., 1998; Stauber *et al*., 1999; Yokel *et al*., 2001). On the basis of daily aluminum dietary consumption and urinary aluminum excretion, the oral bioavailability of aluminum from the diet has been estimated to be 0.1–0.3% (Ganrot, 1986; Priest, 1993; Nieboer *et al*., 1995). Bioavailability of ^{26}Al that was incorporated into two FDA-approved food additives, acidic and basic sodium aluminum phosphate, which were then incorporated into a biscuit and a processed cheese, respectively, was ~0.02% from the biscuit and ~0.05% from the cheese (Yokel *et al*., 2005). Several studies demonstrated increased aluminum absorption when taken with citrate. Aluminum hydroxide is still used as an antacid and a phosphate binder. The recommended dose can deliver up to 1.6 g of aluminum per day. Thus, the absorption from this dose may exceed 1 mg/day (Yokel and McNamara, 2001). The site of aluminum absorption is the upper intestine. The mechanisms of gastrointestinal aluminum absorption have been suggested to include passive (diffusion) and active (carrier- and vesicular-mediated) transport across intestinal cells and paracellular diffusion between these cells. There is evidence for an energy-dependent component of uptake. Aluminum absorption is enhanced by processes that mediate calcium uptake. Citrate may enhance aluminum absorption through the paracellular pathway by increasing permeability between cells

(Provan and Yokel, 1988; Whitehead *et al.*, 1997; Zhou *et al.*, 2005).

Aluminum-containing welding fume consists of particles smaller than 1 μm (Ulfvarson, 1981). Aluminum flake powders vary from 5–200 μm in diameter and from 0.05–1 μm in thickness (Ljunggren *et al.*, 1991). Volunteers previously unexposed to welding fume inhaled welding fume for 1 day and excreted 0.1–0.3% of the inhaled aluminum during the following 2 days (Sjögren *et al.*, 1985). Daily urinary aluminum excretion by aluminum welders, who may have been approaching a steady state for their lung aluminum burden, averaged 0.1 mg. Calculated daily aluminum lung deposition was estimated to be 4.2 mg, suggesting base ~2.4% absorption (Sjögren *et al.*, 1997). Results from workers exposed to the air suggest ~0.2–0.5 mg soluble Al/m^3 in ~2% absorption (Pierre *et al.*, 1995). Estimated aluminum absorption was similar in the workers in another study (Gitelman *et al.,* 1995). In an experiment, a solution of aluminum nitrate, containing ^{26}Al, was dispersed to produce an aerosol, which was dried and calcined in a furnace. The produced oxide particles had a mean aerodynamic diameter of 1.2 μm and were inhaled by two subjects. The ^{26}Al levels were determined in urine. Measurements were made at different times after inhalation and had ceased 900 days after exposure. The calculated fraction of the respiratory deposit of aluminum that was transferred to the blood was 1.9% (Priest, 2004). Despite this relatively low absorption, occupational exposure to aluminum-containing particles has resulted in increased aluminum concentrations in urine (Table 1).

TABLE 1 High, Intermediate, and Low Aluminum Exposures Based on Urine Levels in Different Occupations

High aluminum exposure (urine concentrations often >100 μg/L)t
Aluminum powder production (Iregren *et al.*, 2001; Letzel *et al.*, 1996 and 2000)
Welding (Buchta *et al.*, 2005; Kallio *et al.*, 1999; Sjögren *et al.*, 1985)
Cryolite production (Grandjean *et al.*, 1990)
Intermediate aluminum exposure (urine concentrations sometimes >100 μg/L)
Electrolytic production (Röllin *et al.*, 1996)
Corundum production (Valentin *et al.*, 1976)
Low aluminum exposure (urine concentrations seldom >100 μg/L)
Electrolytic production with better technology (Röllin *et al.*, 2001)
Aluminum sulfate production (Sjögren *et al.,* 1983)
Grinding (Elinder and Sjögren, 1990; Harwerth *et al.*, 1987)
Melting and foundry (Elinder and Sjögren, 1990; Sinczuk-Walczak *et al.*, 2003)
Optoelectronic industry (Liao *et al.,* 2004)

Salts of aluminum such as chlorohydrate are extensively used as antiperspirants. The estimated dermal absorption of aluminum is about 0.01% (Flarend *et al.*, 2001). Some results suggest aluminum might be absorbed from the nasal cavity directly into the brain through the olfactory neurons. The extent of absorption by this route is unknown (Yokel, 2000).

5.2 Distribution

The total body burden of the normal human is 30–50 mg. The skeleton contains about 50% and the lungs 25% of the body burden. In the blood, aluminum is approximately equally distributed between plasma and erythrocytes. The brain has lower concentrations than many other tissues (Priest, 2004; Yokel and McNamara, 2001). Increased brain aluminum is seen in patients with dialysis encephalopathy (Alfrey and Froment, 1990). Studies of Alzheimer's disease victims inconsistently show elevated brain aluminum levels (Yokel, 2000). The primary site of brain entry of aluminum is through the blood–brain barrier. It has been suggested that brain aluminum influx is mediated by transferrin receptor–mediated endocytosis of aluminum transferrin (Roskams and Connor, 1990) and transferrin-independent mechanisms influxing aluminum citrate (Yokel, 2001). There is also evidence for carrier-mediated efflux of aluminum from the brain, probably as aluminum citrate (Yokel, 2001).

5.3 Excretion

Urine accounts for more than 95% of aluminum excretion. Reduced renal function markedly increases the risk of aluminum accumulation. Biliary aluminum accounts for less than 2% of the elimination. Chelators can increase aluminum clearance, and citrate seems to act as a chelator (Yokel, 2002). Renal clearance of aluminum may be as the citrate.

After intravenous injection of aluminum citrate, the half-lives for blood, trabecular, and cortical bone were about 1 hour, 1.4, and 29 years, respectively. Thus, a small fraction of the absorbed aluminum could be retained in the body for years (Priest, 2004).

5.4 Biological Monitoring

Accurate measurements of aluminum in human biological fluids such as blood and urine are difficult because of risks for contamination. Aluminum contamination can derive from airborne particles, reagents, glass lab ware, and insufficiently cleaned lab ware that comes into contact with the sample. Plasma aluminum of occupationally nonexposed

humans was most often <5 µg/L (House, 1992). In Finland, the upper reference limit among nonexposed humans was 2.7 µg/L (0.1 µmol/L) in serum and 16 µg/L (0.6 µmol/L) in urine (Kallio *et al.*, 1999; Valkonen and Aitio, 1997). A linear relationship has been observed between the air concentration of aluminum and the urinary concentration at the end of a work shift among electrolytic production workers (Pierre *et al.*, 1995) and welders (Sjögren *et al.*, 1988). In welders, urine aluminum levels are also related to the years of exposure. A welder exposed to aluminum for 20 years had an average urine aluminum of 300 µg/L (Figure 2). The highest aluminum exposures on the basis of urine levels have been reported among welders and aluminum powder production workers (Table 1). Normalization of urinary aluminum clearance to creatinine clearance is usually not done and does not seem to be useful, because aluminum clearance relates to urine output, not creatinine clearance (Alessio *et al.*, 1985; Schlatter and Steinegger, 1992).

Biological exposure limits are established in some countries (e.g., Finland and Germany).

6 EFFECTS

6.1 Gastrointestinal Symptoms

On July 6, 1988, at the Lowermoor water treatment works near Camelford, Cornwall, England, 20 tons of 8% aluminum sulphate solution was inadvertently deposited directly into the chlorine contact tank where chlorine disinfects the water and which is immediately upstream of the treated water reservoir from which water is distributed to consumers, rather than into the storage tank. The domestic water supplies of an estimated 20,000 people in the area were affected. The pH plunged to as low as 3, and the aluminum rose as high as 109 mg/L at one location. Flushing of the water system led to the death of thousands of fish in the rivers (*www.advisorybodies.doh.gov.uk/cotnonfood/lowermoor.htm*). Two patients, who had acute symptoms including mouth and nasal ulcers, still felt unwell 6–7 months later. Bone biopsy specimens showed aluminum staining (Eastwood *et al.*, 1990). The first Lowermoor Incident Health Advisory Group report, published in July 1989, concluded that: "Early symptoms, which were mostly gastrointestinal disturbances, rashes and mouth

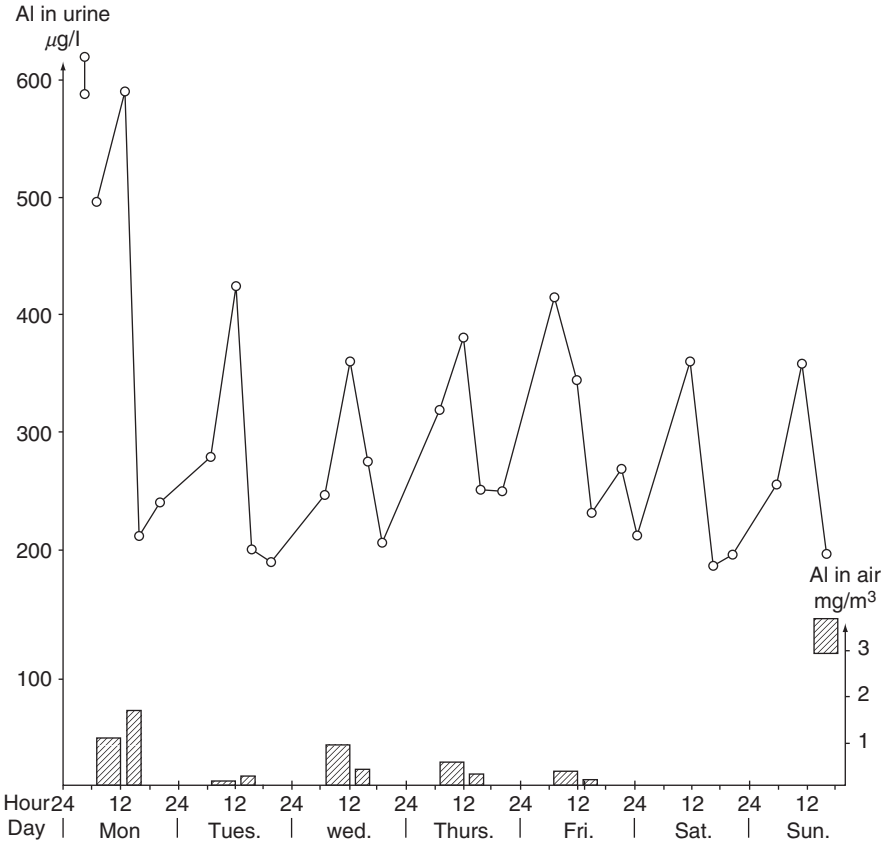

FIGURE 2 Concentrations of aluminum in air and urine in a welder exposed to aluminum-welding fumes for 20 years.

ulcers, can most probably be attributed to the incident. It would appear that symptoms were mostly mild and short lived, as general practitioners experienced no increase in consultation rates at the time and in the subsequent month. A substantial number of residents and holiday makers are known to have complained later of continuing or new symptoms after the incident. These symptoms have included joint and muscle pains, memory loss, hypersensitivity and gastrointestinal disorders. We consider it unlikely in the extreme that long-term effects from copper, sulphate, zinc or lead would result from exposures of the degree and short duration that occurred after this incident. Although the possibility of effects because of the interaction of these chemicals cannot be wholly excluded, we can find no supportive evidence. Increased absorption of aluminum may have occurred in some individuals who persisted in drinking the heavily contaminated water. However, all the available evidence suggests that such increases would have been transient, with most of the aluminum being excreted rapidly and only trace amounts being deposited in tissue, chiefly bone. All the known toxic effects of aluminum are associated with chronically elevated exposure and we have concluded therefore that delayed or persistent effects following such brief exposures are unlikely. In our view it is not possible to attribute the toxic effects of the incident except insofar as they are a consequence of the sustained anxiety naturally felt by many people." In 2005, a subgroup basically agreed with these previous conclusions but recommended further study of those who were exposed bottle-fed infants at the time of the incident (i.e., <1 year of age) (*www.advisorybodies.doh.gov.uk/cotnonfood/lsgreportjan05.pdf*). A summary of the subgroup's report and some dissenting opinions have been published (Khanna, 2005).

6.2 Restrictive Pulmonary Disease

Exposure to aluminum-containing minerals such as bauxite and corundum is often accompanied by silica. This combined exposure may lead to the development of fibrosis of the lung, Shaver's disease (Shaver and Riddell, 1947). The ability of industrial exposure to aluminum, which did not contain silica, to cause pulmonary fibrosis is somewhat contradictory.

Cases of severe lung fibrosis caused by aluminum exposure were reported from Germany during the 1930s and 1940s (Doese, 1938; Koelsch, 1942; Meyer and Kasper, 1942), from Sweden (Ahlmark *et al*., 1960; Swensson *et al*., 1962), and from England (Jordan, 1961; McLaughlin *et al*., 1962; Mitchell *et al*., 1961). Similar cases have rarely been reported from North America (Gross *et al*., 1973). German, Swedish, and British occupational health studies have shown that stamped aluminum powder, even in the absence of silica, causes lung fibrosis. Stamped aluminum powder is produced by crushing and grinding hard unmelted aluminum metal. This aluminum powder is mainly used in the manufacture of pyrotechnical products but also in the production of some aluminum metal dyes. Ninety-five percent of stamped aluminum powder particles are smaller than 5 μm. Stamped aluminum powder has a rather large surface area because of the flake-like form of the particles. The powder reacts with water to form hydrogen and aluminum hydroxide (Corrin, 1963). Granular aluminum particles, which are manufactured from melted aluminum, display a more regular particle structure and are not as reactive as stamped aluminum powder (Corrin, 1963). Different types of lubricating agents are used in the production of the powder, generally stearin or mineral oils. Cases of lung fibrosis were first reported from industries using mineral oil. Cases of the disease have, however, been reported from at least one industry where only stearin was used (McLaughlin *et al*., 1962).

The first signs of lung fibrosis caused by stamped aluminum powder exposure were respiratory problems, occasionally in conjunction with coughing. X-ray of the lungs revealed fibrosis accompanied by atrophy and secondary emphysema (Edling, 1961). Pneumothorax was a typical complication. The fibrosis, also known as aluminosis, could progress rapidly and in severe cases lead to death within a few years after onset (Ahlmark *et al*., 1960; Swensson *et al*., 1962). No clear LOAEL could be estimated, because cases of fibrosis occurred after exposure to 4–50 mg aluminum/m^3 (Elinder and Sjögren, 1986).

Since the beginning of the 1990s, a few new cases of fibrosis from the aluminum powder industry in Germany were identified and compensated (Kraus *et al*., 2000). A 40-year-old worker was employed as a stamper for 14 years in a plant producing aluminum powder. He was exposed to high levels of aluminum and had a urine concentration of 400 μg aluminum per liter. He also had signs of pulmonary fibrosis on high-resolution computed tomography and a vital capacity of 58% of expected. Between 1960 and 1989, only a few individuals were compensated because of lung disease induced by aluminum dust in Germany (Kraus *et al*., 2000). Thus, it seems that this type of fibrosis is not yet eradicated. Aluminum powder has also been associated with a case of sarcoid-like lung granulomatosis (De Vuyst *et al*., 1987).

In North America, exposure to McIntyre powder, consisting of finely ground aluminum and aluminum oxides, has been used as a prophylactic (Denny *et al*., 1939; Godin, 1955) and in the treatment of silicosis (Crombie *et al*., 1944). A comprehensive evaluation of the studies that used inhalation of aluminum particles in the treatment of silicosis has, however, resulted in total rejection of this form of treatment (Kennedy,

1956). The British Medical Council concurred with this evaluation and did not recommend the use of aluminum powder in the treatment or prevention of silicosis. Despite this recommendation, aluminum powder was used as a prophylactic agent until 1979 in the mines in northern Ontario, Canada (Rifat *et al.,* 1990).

Grinding and polishing aluminum have sometimes been associated with an extremely dusty work environment. One case of pulmonary fibrosis (De Vuyst *et al*., 1986) and one case of alveolar proteinosis (Miller *et al*., 1984) have been reported after long-term exposure.

In a factory producing aluminum oxide abrasives employing about 1000 workers, nine workers had abnormal chest X-rays. The mean exposure duration was 25 years. In each of three lung biopsies, interstitial fibrosis with honeycombing was found with an absence of asbestos bodies and silicotic nodules. The authors concluded that aluminum oxide dust was the most likely cause, although mixed dust exposure may explain the findings (Jederlinic *et al*., 1990).

Long-term exposure to aluminum welding fumes in three case reports has been associated with chronic interstitial pneumonia (Herbert *et al*., 1982), pulmonary granulomas (Chen *et al*., 1978) and pulmonary fibrosis (Vallyathan *et al*., 1982). However, in a group of 64 aluminum-exposed welders with a duration of exposure between 1 and 24 years, no signs of pulmonary fibrosis were observed (Sjögren and Ulfvarson, 1985).

Aluminum-containing fibers have been detected in lung parenchyma and bronchial alveolar lavage in aluminum smelter workers despite a nonexposure period of several years (Voisin, 1996). Small opacities or accentuations of the bronchopulmonary markings on chest X-ray were more common (29%) among 119 potroom workers exposed for more than 10 years from two plants in northern Italy compared with 15% of a similar sized referent group made up of unexposed clerical and maintenance workers from the same factories. Signs of pneumoconiosis were more common among long-term than short-term exposed workers (Saia *et al*., 1981).

In a cross-sectional study, 670 aluminum workers from Alabama were compared with 659 pipe fitters. Both groups were asbestos exposed. Irregular opacities observed on X-rays were more common among aluminum workers (21% vs. 15%) and pleural abnormalities less common (2% vs. 12%) than the referents. These findings suggest an influence of particles or fibers other than asbestos (Kilburn and Warshaw, 1992). Some cases of pulmonary fibrosis have also been reported after long-term exposure during electrolytic aluminum production (Akira, 1995; Al-Masalkhi and Walton, 1994; Gaffuri et al., 1985; Gilks and Churg, 1987).

To conclude, exposure to high levels of small particles of aluminum powder has caused pulmonary fibrosis, also called aluminosis. Sometimes a mixed dust exposure can explain pulmonary fibrosis among exposed workers. It is not clear whether these workers are very sensitive or susceptible regarding exposure to particles or belong to a small fraction of heavily exposed workers. Aluminum-containing fibers have been detected in lung parenchyma and bronchial alveolar lavage fluid in aluminum smelter workers; however, it is not clear whether these fibers play a causal role in the development of pulmonary fibrosis.

6.3 Obstructive Pulmonary Disease

In 1936, asthma was described among Norwegian workers in electrolytic aluminum production (Frostad, 1936). This is often called potroom asthma. Symptoms of asthma, airflow limitation, and increased bronchial responsiveness have been described from aluminum smelters around the world. The likely causes are irritant airborne particulates and fumes contributed by cryolite, gaseous hydrogen fluoride, and other agents that may be adsorbed onto aluminum (WHO/IPCS, 1997). In a cross-sectional study of 1760 Norwegian potroom workers, 11% reported work-related asthmatic symptoms (Kongerud *et al*., 1990). A relationship between the levels of fluoride exposure and work-related asthmatic symptoms was also observed among such workers (Kongerud and Samuelsen, 1991). A cross-sectional study comprised 1615 male employees of two Australian aluminum smelters. After adjusting for smoking and age, workers with a cumulative exposure for fluoride >0.16 mg/m^3-years or inspirable dust >2.9 mg/m^3-years were two to four times more likely to report work-related wheeze and chest tightness than were unexposed subjects. The effect of these two exposures could not be separated, because there was only one subject with work-related chest tightness and no subjects with work-related wheeze who were exposed to fluoride without being exposed to inspirable dust (Fritschi *et al*., 2003).

Production of aluminum fluoride and aluminum sulfate has been associated with reversible bronchial obstruction or asthma (Simonson *et al.,* 1985). In 1975 and 1976, six and seven cases of asthma occurred, respectively, in a Swedish plant producing aluminum fluoride. The number of exposed workers was 35–40, and the mean concentrations of aluminum fluoride during these two years were 3–6 mg/m^3. In 1977, environmental improvements were made, and the exposure was reduced to 0.4–1.0 mg/m^3. During the years 1978–1982, only two cases of asthma occurred (Simonson *et al*., 1985).

During 1971–1980, an average of 37 workers produced aluminum sulfate in a Swedish plant. Four workers had short-lasting asthma develop, mainly in

connection with heavy dust exposure during rinsing and repair work. The mean aluminum sulfate concentrations varied between 0.2 and 4 mg/m^3 (Simonsson *et al*., 1985).

Potassium aluminum tetrafluoride is sometimes used as a flux for aluminum soldering. Exposure to this flux has been associated with asthma and bronchial hyperreactivity (Hjortsberg *et al*., 1986 and 1994).

One case of asthma related to aluminum welding has been reported. Challenge exposure to aluminum welding with flux-coated electrodes and electrodes without flux elicited marked asthmatic reactions. However, welding on mild steel did not cause a significant bronchial response (Vandenplas *et al*., 1998). Exposure to aluminum powder has been observed to cause asthma in a worker after mixing aluminum and minimal amounts of cement powders to make safes in a closed room. He reacted with a decrease of FEV_1 after inhalation of aluminum powder or aluminum chloride but not after inhalation of lactose powder (Park *et al.*, 1996). A 46-year-old smoker had cough and chest tightness starting 3 h after coming to work. He had worked as a caster of molten aluminum for 19 years. The challenge test showed a dual reaction to aluminum chloride with a 28% immediate fall in FEV_1 and a 34% late fall in FEV_1 after 7 hours (Burge *et al*., 2000).

A historical cohort study comprised 5627 men who had worked in two Norwegian aluminum plants. An increased number of deaths from chronic obstructive lung diseases (bronchitis, emphysema, and asthma) was observed, which related to fluoride exposure (Romundstad *et al*., 2000b).

In conclusion, potroom asthma is a well-known disease associated with the complex exposure in the potrooms of the aluminum electrolytic production industry. Exposure to several other aluminum salts such as aluminum fluoride, aluminum sulfate, and potassium aluminum tetrafluoride has also been associated with asthma. In some case reports, aluminum welding fume, foundry fume, and aluminum powder were also linked to asthma.

6.4 Central Nervous System

6.4.1 Dialysis Encephalopathy

Dialysis encephalopathy is a complication of prolonged hemodialysis first described in 1972 (Alfrey *et al*., 1976). The main symptoms are speech disorder followed by the development of dementia, convulsions, and myoclonus. The mean duration of dialysis was 48 months. The dialysis fluids were made from untreated tap water (WHO/IPCS, 1997). Death occurred within 12 months of symptom onset, and recovery was exceptional (Bugiani and Ghetti, 1990). Between 1968 and 1976, 55 patients with dialysis encephalopathy were identified from six dialysis centers in the United States. The overall attack rate of dialysis encephalopathy was 4%. Encephalopathy was the cause of death in most cases (Schreeder *et al*., 1983). Dialysis encephalopathy was related to the presence of aluminum in dialysis fluids and the concomitant intake of aluminum-containing drugs used to decrease serum phosphate levels. Elevated aluminum was found in the brain, muscle, and other tissues of the affected patients. Serum aluminum >80 µg/L has been associated with dialysis encephalopathy (Nieboer *et al*., 1995). Many outbreaks of encephalopathy have been described in association with the use of dialysis fluids containing aluminum levels >200 µg/L (WHO/IPCS, 1997). Today, aluminum exposure of dialysis patients is minimized, because the dialysis fluid water is monitored at most dialysis centers and the aluminum level is kept <10 µg/L. However, accidents happen, causing occasional incidences of aluminum-associated dialysis encephalopathy (de Wolff *et al*., 2002). Thus, overt dialysis encephalopathy is rare, but less obvious intoxications may occur. An aluminum-associated low turnover bone disease and a hypochromic, microcytic anemia can occur at lower aluminum exposures and body burden than those producing encephalopathy.

6.4.2 Other Medical Aluminum Exposures

During the last decades, there were several reports describing aluminum accumulation and toxicity in patients without chronic renal failure. These include preterm infants, largely fed intravenously, patients on total parenteral nutrition, patients with severe burns, patients undergoing cranial bone reconstruction, and patients receiving alum irrigation of their urinary bladder (Flaten *et al*., 1996).

Premature infants with gestational ages of less than 34 weeks were assigned to receive either standard or aluminum-depleted intravenous-feeding solutions. When tested 18 months later, those who received more aluminum exposure had impaired neurological development (Bishop *et al*., 1997). Some patients with severe burns experience reduced bone formation at least partially attributed to aluminum from human serum albumin, calcium gluconate, and other sources (Klein *et al*., 1994). An aluminum-containing cement, with calcium aluminum fluorosilicate, has been used as a bone reconstruction material in neurosurgical operations. In five reported cases, symptoms and signs of encephalopathy developed, including seizures. The concentrations of aluminum in the cerebrospinal fluid were typically >100 µg/L (Renard *et al*., 1994). Two of the five patients died of brain failure with persistent

convulsions (Hantson *et al*., 1994) and a third from septic complications (Reusche *et al*., 2001).

Intravesical alum instillation is a treatment for hemorrhagic cystitis. This treatment has resulted in acute aluminum intoxication among patients with some degree of renal insufficiency (Phelps *et al*., 1999).

6.4.3 Neurobehavioral Effects of Occupational Aluminum Exposure

Several studies of welders have been performed in Finland to assess the potential for occupational aluminum exposure to produce adverse neurobehavioral effects. The first, comprising 17 participants, did not use a control group but compared data for subgroups of welders with differing exposures. Dose-effect relationships between aluminum levels in serum and urine and performance on four tests of memory function (symbol learning, memory-for-designs, digit span, and associative learning) were found (Hänninen *et al*., 1994). The mean level of aluminum in urine was 75 µg/L. The second article (Akila *et al*., 1999) reported data from 51 aluminum welders and 28 controls, who were divided into three groups according to the levels of aluminum in urine. The low exposure group had a mean of 12 µg/L, the medium exposed group had 60 µg/L, and the high exposure group had 269 µg/L. Dose-related impaired performance attributed to aluminum was found on the digit symbol, synonyms, embedded figures, memory for designs, and block design tests. The third article from this research team reported on the same worker groups, with the addition of further welders (Riihimäki *et al*., 2000). Welders were assigned to one of three groups according to a combined measure of aluminum in serum and in urine to provide an indication of aluminum body burden. The three groups were composed of 25, 29, and 30 workers. The median urinary aluminum levels were 11, 49, and 192 µg/L, respectively. Significant group differences were found with respect to symptoms of fatigue, memory and concentration, and emotional lability. Six of 18 psychological tests of memory and concentration also showed significant group differences, with a lower performance in the highly exposed groups. Furthermore, there were EEG differences between the exposure groups. A number of subjects in the exposed groups exhibited mild or moderate diffuse or epileptiform abnormalities. To evaluate dose-response relationships, the prevalence of findings in six critical domains (symptoms, visual accuracy, attention, verbal, visuospatial memory, and EEG) was examined. The proportion of deviant findings in these domains was between 15 and 20%. A plot of the number of deviant findings against the measure of aluminum body burden suggested a critical level of aluminum was 110–160 µg/L in urine.

A Swedish study compared 38 aluminum welders with a control group of 39 steel welders (Sjögren *et al*., 1996). The median employment time as aluminum welder was 15 years. Aluminum welders performed less well than the reference group on four tests of motor function: finger tapping, two tasks of the Luria-Nebraska battery, and a pegboard test. For the former three tests, this effect was dose-related and observed in a subgroup of 19 highly exposed welders who had a median urine concentration of 59 µg aluminum/L. In five of the 19 welders, the urine aluminum exceeded 100 µg/L.

A Norwegian study compared a group of 20 aluminum welders with a reference group of construction workers (Bast-Pettersen *et al*., 2000). The welders performed better than the construction workers in several of the tests used. However, when performance of the welders was analyzed separately, significant correlations were found between exposure duration in years and poorer performance on the tremor test. Performance on a test of reaction time was found to be worse for workers exposed to higher levels of aluminum in the air. The median urine aluminum for this group was 41 µg/L, and the range was 19–129 µg/L.

In two German longitudinal studies of aluminum welders' psychometric measurements were performed 2 years apart. One study had 98 aluminum welders from the car industry and 50 nonexposed car production workers (Buchta *et al*., 2003). The median urinary aluminum was 58 µg/L in 1999 and 52 µg/L in 2001, and the median exposure time was 6 years. No significant differences in psychomotor performance or other neurobehavioral tasks, except for reaction time, were observed. A second study compared 44 aluminum welders in the train body and truck trailer industry with 37 nonexposed production workers (Buchta *et al*., 2005). Median urinary aluminum was 130 µg/L in 1999 and 150 µg/L in 2001. Mean exposure time was 11 years. Welders showed significantly poorer performance in symbol-digit substitution, block design, and, to some extent, in switching attention, but not in reaction time. The first study (Buchta *et al*., 2003) revealed a small, but statistically insignificant, increase in the reaction-time difference between the first and second examination. In the second study (Buchta *et al*., 2005), no trend differences compared with the controls were seen. The lack of any differences between the two examinations might be explained by the short period for follow-up. A third examination, which is planned for both studies, may clarify this picture, unless further nonparticipation biases the group comparison.

There are two studies of psychometric performance by workers exposed to aluminum powder. Neither of

the studies observed any differences compared with referents. A German study composed of 32 exposed subjects with a mean aluminum of 110 µg/L urine (Letzel *et al.*, 2000). A Swedish study contained 16 subjects with a mean urine aluminum of 83 µg/L (Iregren *et al.*, 2001). A study of Canadian miners, inhaling aluminum powder as a prophylactic against silicosis, reported a higher proportion of workers with impaired cognitive functions among those being treated for longer periods of time (Rifat *et al.*, 1990). However, neither blood nor urine concentrations of aluminum were measured.

In summary, neurotoxic effects have been observed in welders with urine aluminum >100 µg/L compared with welders with lower levels. The consistency in these observations is probably explained by the fact that the welders were compared with other welders, being similar in most respects except the aluminum exposure. It should be emphasized that it is unknown whether these effects are reversible. Most studies of exposed groups other than welders compare one occupational group with another occupational group. Comparison of workers with different training and occupations may well bias the results, especially when psychological outcome variables are used.

6.4.4 Alzheimer's Disease

Alzheimer's disease (AD) is a progressive deterioration of brain function, initially characterized by cognitive deficits, with loss of recent memory and language ability, impairment of orientation, problem solving, and abstract thinking. The typical neuropathological signs of the disease are neurofibrillary tangles and senile plaques.

A large number of studies have been performed to replicate the first observation that the concentration of aluminum is generally higher in the brains of patients with AD than in other patients at autopsy (Crapper *et al.*, 1973). Some investigations found higher levels of aluminum and some did not (Yokel, 2000).

The results of several epidemiological studies suggest a small increased risk of dementing illnesses, including Alzheimer's disease, for people living in areas of high water aluminum concentrations. However, there are also several reports of no associations.

The inconsistent findings from autopsy and epidemiological studies of water aluminum contribute to the controversy concerning the role of aluminum in the etiology of AD.

Even if the level of aluminum is elevated in the brain in AD, it would not prove a cause–effect relationship, because AD might produce plaques and neurofibrillary tangles that may bind the metal. Thus, aluminum may be one of several factors contributing to AD, although this has not been satisfactorily demonstrated (Gupta *et al.*, 2005; Yokel, 2000).

6.5 Bone

Clinical and experimental research has shown that high doses of aluminum inhibit bone remodeling. Aluminum slows osteoblast and osteoclast activities and produces osteomalacia and an adynamic bone disease (Jeffery *et al.*, 1996).

A survey of 1293 patients from 18 dialysis centers in the United Kingdom showed a correlation between the dialysate aluminum concentration and the incidence of fracturing dialysis osteodystrophy (Parkinson *et al.*, 1979).

Serum aluminum >30 µg/L has been associated with dialysis-associated bone diseases (Nieboer *et al.*, 1995). Bone biopsy is needed for definitive diagnosis (Cronin and Henrich, 2004).

Persons without renal failure who take several grams of aluminum per day as antacids on a long-term basis may have osteomalacia. This is attributable to phosphate imbalance secondary to aluminum intake (Insogna *et al.*, 1980; Woodson, 1998). A marked decrease of gastrointestinal phosphate absorption can be observed after a rather small antacid dose (Spencer *et al.*, 1982).

Thirty-two aluminum powder–producing workers were compared with 29 nonexposed workers from the same factory. Lumbar spine bone density did not differ between the groups. The median preshift urine aluminum of exposed workers was 110 µg/L and the referents 7 µg/L (Schmid *et al.*, 1995).

6.6 Hematopoietic Tissue

Some patients receiving dialysis treatment may develop a hypochromic, microcytic anemia. This anemia is caused by aluminum and will not respond to iron therapy (Jeffery *et al.*, 1996).

6.7 Skin

Applications of 2 g magnesium aluminum silicate to human skin onto a 6 cm^2 (1-inch) area daily for 1 week did not cause any observable effects. Magnesium aluminum silicate was tested on rabbits and was regarded as a weak primary skin irritant (Elmore, 2003).

6.8 Allergic Effects

Allergic contact dermatitis from aluminum is rare. Two routes of sensitization have been described. Aluminum can be administered on the surface of the skin in antiperspirants, medicaments, and the aluminum disc used in routine patch testing (Finn Chamber®), or injected in aluminum-adsorbed vaccines, hyposensitization extracts, and other forms. The risk of sensitization is higher from the latter route (Peters *et al.*, 1998). Cutaneous granulomas after immunization

may take some years to heal or decrease (Kaaber *et al*., 1992). Itching nobulus were found in 645 children out of 76,000 vaccines (0.8%) after both subcutaneous and intramuscular injections. A majority of the children (75%) had symptoms after a month duration of 4 years, and 77% of the children with nodulus showed contact hypersensitivity to aluminum (Bergfors *et al.*, 2003). Sensitization has also occurred after aluminum particles were accidentally impelled into the skin from a compressed air pistol (Peters *et al*., 1998). Tattooing with aluminum silicate to create blepharopigmentation has resulted in a delayed-hypersensitivity granulomatous reaction (Schwarze *et al*., 2000).

6.9 Coronary Heart Disease

Some studies of aluminum production workers have observed an increased risk of coronary heart disease (Rönneberg, 1995; Theriault *et al*., 1988). This effect might be explained by the possible association between exposure to air pollutants and the occurrence of coronary heart disease mediated by an inflammatory response that increases blood coagulation (Sjögren, 2004). It is unlikely that aluminum per se is responsible for this effect, but more likely that it is due to air pollutants in general. Slightly higher levels of fibrinogen were observed among aluminum smelter workers at Söderberg pots exposed to high levels of air pollutants compared with those working with prebaked electrodes and exposed to lower levels of air pollutants (Sjögren *et al*., 2002). A high plasma fibrinogen level is an established risk factor for coronary heart disease (Danesh *et al*., 1998). However, there are studies that do not support the association between potroom exposure and coronary heart disease (Romundstad *et al*., 2000a).

6.10 Carcinogenic Effects

Most animal studies have failed to demonstrate carcinogenicity attributable to aluminum powder or several aluminum compounds (Léonard and Gerber, 1988).

The German Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area classifies aluminum oxide as a category 2 carcinogen because of the unequivocally positive results of intrapleural injections in animals (Deutsche Forschungsgemeinschaft, 2004).

In 1987, the International Agency for Research on Cancer (IARC) concluded that there is sufficient evidence that certain exposures occurring during aluminum production cause cancer of the lung and bladder (Group 1). Pitch volatiles have fairly consistently been suggested in epidemiological studies as possible causative agents (IARC, 1987).

Synthetic abrasive materials containing aluminum oxide, silicon carbide, and different additives have been used for more than 70 years (Wegman and Eisen, 1981). Exposure to these compounds occurs during production and when they are used for metal grinding and polishing. An increased risk for stomach cancer has been observed in two studies (Järvholm *et al*., 1982; Wegman and Eisen, 1981), and an increased risk for lung cancer has been observed in one (Siemiatycki *et al*., 1989). During the past decade, studies observed an increased risk of lung cancer (Infante-Rivard *et al.*, 1994; Romundstad *et al*., 2001) and stomach cancer (Romundstad *et al*., 2001) associated with silicon carbide production. These workers are, however, also exposed to crystalline silica. Thus, further studies are needed to explore whether components in synthetic abrasive materials are carcinogenic.

7 OTHER ALUMINUM COMPOUNDS

Aluminum phosphide is used as a fumigant to protect stored grain from insects and rodents. In the presence of moisture, aluminum phosphide releases phosphine, which is highly toxic. The fatality rate was 59% among 195 patients admitted to a hospital in Northwest India. The fatal dose was 1.5 g, and the predominant clinical feature was hypotension (Singh *et al*., 1996). Two children and 29 of 31 crew members aboard a grain freighter became acutely ill after inhaling phosphine originating from aluminum phosphide. One of the children died (Wilson *et al*., 1980).

8 RECOMMENDATIONS

Aluminum is used as a coagulant in water treatment. According to the WHO, a health-based guideline value cannot be derived; however, practical levels based on optimization of the coagulation process in drinking-water plants using aluminum-based coagulants were derived: 0.1 mg/L or less in large water treatment facilities, and 0.2 mg/L or less in small facilities (WHO, 2004). Similarly, Health Canada established an operational guidance value of <0.1 mg/L for drinking water from treatment plants using aluminum-based coagulants and <0.2 mg/L for other types of treatment systems (*http://www.hc-sc.gc.ca/ewh-semt/pubs/water-eau/doc_sup-appui/aluminum/aluminum-aluminium_e.html#1*).

The occupational exposure limits for aluminum have decreased during the last decade in many countries (Table 2). Occupational biological exposure limits are established in some countries. Finland has a urine biological action level (BAL) of 160 µg/L (6 µmol/L) (Kallio *et al*., 1999). Germany has a biological tolerance value for occupational exposure of 200 µg aluminum/L

TABLE 2 Occupational Exposure Limits for Aluminum in Some Countries Expressed as Time-Weighted Averages (TWA, mg/m^3)

Form of aluminum	Country or organization	TWA	Source
Metal dust	ACGIH	10	ACGIH (2005)
	NIOSH	10	NIOSH (2005)
	Sweden	5	Swedish Work Environment Authority (2005)
Respirable metal dust	Germany	1.5	Deutsche Forschungsgemeinschaft (2006)
	NIOSH	5	NIOSH (2005)
	Sweden	2	Swedish Work Environment Authority (2005)
Pyro powder as Al	ACGIH	5	ACGIH (2005)
	NIOSH	5	NIOSH (2005)
Welding fume as Al	Germany	1.5	Deutsche Forschungsgemeinschaft (2006)
Soluble salts	ACGIH	2	ACGIH (2005)
	NIOSH	2	NIOSH (2005)
	Sweden	1	Swedish Work Environment Authority (2005)

of postshift urine (Deutsche Forschungsgemeinschaft, 2006).

Physicians determine dialysate aluminum levels twice a year. It has been recommended that dialysate aluminum be <10 µg/L (AAMI, 2001) and stated that it must be <5 µg/L but should be <2 µg/L. Serum aluminum should be <20 µg/L (Rob *et al*., 2001).

Aluminum compounds are the only adjuvants used in the manufacture of currently licensed vaccines in the United States. Chapter 21 of the US Code of Federal Regulations governs the amount of aluminum permitted in the recommended single human dose of a product. The amount of aluminum is limited to 0.85 mg/dose if the level is assayed or 1.14 mg if determined by calculation on the basis of the amount of aluminum compound added (Baylor *et al*., 2002).

The daily intravenous intake of more than 4–5 µg aluminum/kg from total parenteral nutrition solutions can produce aluminum accumulation and central nervous system and bone toxicity. To avoid this problem, the US FDA established a labeling requirement that large and small volume additives used in parenteral nutrition must state the maximum aluminum concentration (US FDA, 2002; Canada, 2005).

CHAPTER

18

Antimony

CAROLYN A. TYLENDA AND BRUCE A. FOWLER

ABSTRACT

Antimony is a silvery white brittle metal of medium hardness and exists in four valence states: 0, −3, +3, and +5. Most absorbed antimony is excreted rapidly through urine and feces. Elimination and route of excretion depend on the type of antimony compound. Urinary excretion is higher for pentavalent than for trivalent antimony compounds, whereas the gastrointestinal excretion is higher for trivalent than for pentavalent antimony. Some data on humans, as well as on animals, indicate that a small part of absorbed and retained antimony may have a long biological half-life, especially in the lung. After acute or chronic oral or parenteral exposure to antimony, highest concentrations are found in the thyroid, adrenals, liver, and kidney.

Industrial exposure may give rise to symptoms of irritation in the respiratory tract. Pneumoconiosis, occasionally in combination with obstructive lung changes, has been reported after long-term exposure in humans. Focal fibrosis of the lung has been seen in animal trials. Effects on the heart, even fatal, have been related to long-term industrial exposure to antimony trioxide. Secondary cardiovascular effects as a result of treatment of parasitic disease with antimony compounds have also been reported. In addition, cardiovascular effects have been observed in animal experiments. Rats exposed to antimony trioxide through inhalation for long periods of time showed a high frequency of lung tumors.

1 PHYSICAL AND CHEMICAL PROPERTIES

Antimony (Sb): atomic weight, 121.8; atomic number, 51; density, 6.7; melting point, 631°C; boiling point, 1750°C; crystalline form silvery white metal; oxidation states: 0, −3, + 3, and + 5. Compounds to be referred to in this chapter are antimony trioxide (Sb_2O_3), CAS No. 1309-64-4, antimony trisulfide (Sb_2S_3)', CAS No. 1345-04-6, antimony trichloride ($SbCl_3$), CAS No. 10025-91-9, antimony pentasulfide (Sb_2S_5), antimony potassium tartrate ($C_8H_4K_2O_{12}Sb_2.3H_2O$), CAS No. 28300-74-5, antimony pentoxide (Sb_2O_5), stibine (SbH_3), and sodium antimony dimercaptosuccinate.

Antimony belongs to the same periodic group as arsenic, which it resembles both chemically and physically. Arsenic is, however, much more toxic. Antimony exists in both organic and inorganic complexes. Stibine is an odorless gas. Antimony potassium tartrate, or tartar emetic, has a relatively high solubility in water (83 g/L), whereas most other inorganic antimony compounds have a low solubility.

2 METHODS AND PROBLEMS OF ANALYSIS

The main methods used to analyze antimony in both biological and environmental samples are atomic absorption spectroscopy (AAS) and inductively coupled plasma-atomic emission spectroscopy (ICAP-AES), with or without preconcentration or

separation steps. Instrumental neutron activation is also used but has the disadvantages of being slow, costly, and requiring special facilities (ATSDR, 1992). Alimonti *et al*. (2005) compared two types of inductively coupled plasma mass spectrometry, quadrupole and sector field, in analyzing urinary Sb in the general population. Detection limits were 1.09 and 0.43 ng/L, respectively.

The United States Occupational Safety and Health Administration (OSHA) publishes several fully validated methods for analyzing for antimony (U.S. Department of Labor, 2005). The principal method (OSHA ID-121) uses atomic absorption spectroscopy to analyze antimony in air samples collected on a mixed-cellulose ester membrane contained in a styrene cassette using a calibrated personal sampling pump to filter 480–960 liters of air. Maximum flow rate is 2 L/min. Wipe samples and bulk samples can also be analyzed with this method. The analytical detection limit is 0.1 µg/mL. Advantages to this method are that it is specific for antimony, the equipment is inexpensive, and no special training is required. Disadvantages are that the method does not distinguish different compounds and cannot distinguish different particle sizes. Alternative digestion procedures are used if samples are not digested using the standard protocol. Alternative methods, also fully validated, use ICAP-AES (OSHA ID-125G and OSHA ID206). An advantage to using ICAP-AES is the rapid simultaneous analysis of a number of elements, as opposed to the need for separate analyses that use conventional atomic absorption techniques.

Other methods are available. Antimony in air and biological materials has been determined polarographically, spectrographically, and colorimetrically with rhodamine B (Tabor *et al*., 1970). A spectrophotometric method based on the liberation of iodine from acidified potassium iodide by antimony (III) has a detection limit of 6 µg Sb/L. The method has been used successfully to analyze the antimony content of silicate rocks, natural water, waste water, plant leaves, soil, and biological samples (Tiwari *et al*., 2006). A stibine generation technique, with subsequent AAS, was reported to have a detection limit of about 0.5 µg Sb/L in blood (Bencze, 1981). A method that uses inductively coupled plasma-mass spectrometry after nitric acid/hydrogen peroxide digestion of blood samples has a detection limit of 0.03 µg Sb/L (Bazzi *et al*., 2005). A colorimetric method used for determination of stibine in air had a detection limit of 50 µg Sb/m^3 (Short and Wheatley, 1962).

For the speciation of antimony in algae and animal and plant tissues, extraction methods have been studied (Miravet *et al*., 2005). It was noted that commonly used solvents for metal extraction are not appropriate for antimony speciation (Foster *et al*., 2005).

3 PRODUCTION AND USES

3.1 Historical Background

Although antimony was not described in detail as an element until the 17th century, it is believed to have been recognized in various compounds as early as 4000 BC, when it was used by the Chaldeans for its fine casting qualities. It was also used in coloring glass.

Antimony compounds have historically been used as cosmetics. Antimony sulfide was found in an Egyptian cosmetic case from 2500 BC, intended for use as a rouge for lips. In Roman times, black mineral containing antimony (III) sulfide was applied as makeup to eyelashes and around women's eyes to embellish them (McCallum, 1977).

Antimony was used for medicinal purposes since ancient times for its emetic and diaphoretic-inducing properties and was a favored remedy in the Middle Ages for the treatment of a wide variety of conditions. Paracelsus, a physician in 16th century Europe, and a proponent of alchemy, and his followers, favored the use of metals, including antimony, as drugs. The view of the Paracelsus followers diverged from the teachings of Galen (ca AD 130–201), a preeminent Roman physician who considered metals to be poisonous. The period of ca 1560–1660 was termed the "antimony war" and reflects the conflict in medicine between Galenic medicine and the practices of Paracelsus. (Koehler, 2001). Cups made of antimony were popular in the 17th and 18th centuries as a means to induce therapeutic sweating, vomiting, and purging. Wine was poured into the cup and allowed to sit for many hours during which time antimony leached from the cup into the wine, presumably combining with the tartaric acid found in most wines. Small amounts of the wine were swallowed at intervals until the intended effect was achieved. Although antimony was recognized as a poison and claimed many fatalities among patients administered antimony-containing medicinals, it was believed that a poison would attract other poisons and rid the body of them (McCallum, 1977; 2001).

3.2 Production

Antimony is most commonly found in sulfides and sulfo salts such as stibnite, tetrehedrite, bournite, boulangerite, and jamesonite, as well as in some oxides such as valentinite, stibiconite, and semarmontite. Of

the more than 100 minerals of antimony that are found in nature, the predominant one is stibnite (Sb_2S_3). The principal world resources of antimony are Bolivia, China, Mexico, Russia, and South Africa. The global mine production of antimony in 2003 was 81,600 metric tons and in 2004 it was 112,000 metric tons (estimated) (U.S. Geological Survey, 2005).

3.3 Uses

Antimony is a common constituent of metal alloys (e.g., with lead and copper). In fact, the most important use of antimony metal is as a hardener in lead storage batteries (U.S. Geological Survey, 2005). Antimony trioxide is used in fire retardants formulations for plastics, rubbers, textiles, paper, and paints; as an additive in glass and ceramic products; and as a catalyst in the chemical industry. Antimony trisulfide is used in explosives, pigments, antimony salts, and ruby glass (IARC, 1989). Antimony is a component of important thermoelectric materials, which are being synthesized and studied in the form of nanoparticles (Quarez *et al*., 2005; Schlecht *et al*., 2006; Xie *et al*., 2004).

Pentavalent antimony has been used for more than 50 years to treat both visceral and cutaneous leishmaniasis, parasitic diseases. One proposed mode of action is the inhibition of energy metabolism and macromolecular biosynthesis by means of inhibition of glycolysis and fatty acid β-oxidation (Berman *et al*., 1985; 1987). Wyllie *et al*. (2004) demonstrated that antimony affects both the thiol-buffering capacity and the thio redox potential within the cells of *Leishmania donovani*. The authors suggest that Sb(V) in pentavalent antimonial drugs is reduced to Sb(III), which is the biologically active form.

A major problem with pentavalent antimony drug therapy is that increasingly larger doses for longer durations are needed to be effective. In India, where more than half the cases of leishmaniasis occur, large-scale unresponsiveness to antimony treatment is occurring (Murray, 2000; Thakur *et al*., 2004). In addition, treatment is limited because of the toxicity of the drugs. The results of one study suggest that residual Sb (III) in the pentavalent meglumine antimonate drug is responsible for the cytotoxicity of the drug, and the multiple resistance-associated protein 1 (MRP-1)–mediated resistance (Dzamitika *et al*., 2006). Although alternative therapies have become available (Blum *et al*., 2004; Murray, 2000; 2004; Sundar 2002), treatment with pentavalent antimony compounds is still an accepted form of therapy (Laguna, 2003; MMWR, 2003; 2004). Uzun *et al*. (2004) described a technique of intralesional application of meglumine antimonate solution to treat 890 patients with cutaneous leishmaniasis and reported an efficacy of 97.2% with no serious adverse side effects.

4 ENVIRONMENTAL LEVELS AND EXPOSURES

4.1 General Environment

4.1.1 Food and Daily Intake

Meat, freshwater fish, poultry, cereal, fruit, and vegetables contain about 1–10 ng/g wet weight (Health Canada, 1997). A study of 12 table-ready foods showed antimony content to range from 0.22–2.81 µg/kg (Cunningham, 1987). Other reports on antimony levels in food include pooled human milk, 13 µg/kg (Iyengar *et al*., 1982); dorsal muscle of white suckers and brown bullheads (fish) from two acidified Adirondack, New York, lakes, <0.014–0.20 µg/g, and <0.04–<3.0 (dry wt.), respectively (Heit and Klusek, 1985); crayfish, redbreast sunfish, stonerollers from a stream in Tennessee that receives effluent from a U.S. Department of Energy facility, 20.24 µg/kg, 8.73 µg/kg, and 18.51 µg/kg, respectively (Rao *et al*., 1996); bivalves from the Gulf of Mexico, <0.05 µg/g (wet wt.) (Reish, *et al*., 1983); mollusk tissue, crustacean tissue, and fish tissue, 0.031–0.060, 0.018–0.116, and <0.009–0.010 µg/g (dry wt.) (Maher, 1986).

A study of nutrients in the diet conducted by the U.S. Food and Drug Administration estimated the average daily intake of antimony from food and water to be 4.6 µg/day (Iyengar *et al*., 1987). Using data on levels of antimony in the United States, Health Canada estimated a daily intake for adults of 7.44 µg of antimony per day, with about 38% coming from drinking water (Health Canada, 1997).

4.1.2 Air, Soil, and Water

Antimony is present in the earth's crust at a concentration of about 0.2–0.5 mg/kg (McCutcheon *et al*., 1995) and is released naturally into the atmosphere in the form of particulate matter or adsorbed to particulate matter. It is estimated that 41% of antimony present in air is due to natural sources, including wind-borne soil particulates (32.5%), volcanoes (29.6%), sea salt spray (23.3%), forest fires (9.2%), and biogenic sources (12.1%) (Nriagu, 1989). Anthropogenic sources include nonferrous metal mining, nonferrous metal primary and secondary smelting and refining (Crecelius *et al*., 1974, Pacyna *et al*., 1984; Shotyk *et al*., 2005b), coal combustion (Gladney *et al*., 1978), and refuse and sludge combustion (Greenberg *et al*., 1978). Data regarding levels of antimony in ambient air are insufficient to report mean or median levels (ATSDR, 1992). The EPA (1992 revised 2000) has established a respiratory benchmark dose (BMD) for antimony of 0.087 mg/m^3 and an RfC for antimony trioxide of 0.0002 mg/m^3.

Studies have found antimony concentration in air particulate matter in remote, rural, and urban areas in the United States to be 0.00045–1.19, 0.6–7, and 0.5–171 ng/m^3, respectively (Arimoto *et al*., 1987; Austin *et al*., 1988). Peirson *et al*. (1973) reported levels of 1.4–55 ng/m^3 in air from seven sites in the United Kingdom. Emissions from antimony-containing ore-processing facilities can reach levels greater than 1000 ng antimony/m^3 (ATSDR, 1992).

In soil, antimony usually ranges from 0.1–10 mg/kg dry weight (Bowen, 1966; Khatamov *et al*., 1967). Soil around industrial sites that process antimony-containing ores can be much higher (ATSDR, 1992). A study of soil from eight orchards in the state of Washington found levels of antimony ranging from 0.4–1.5 mg/kg. The authors attributed these antimony levels to the use of insecticides containing antimony as an impurity, because the levels were higher than nearby areas where insecticide was not used.

Because antimony is naturally present in soil, it would be expected to be found in runoff. In a study of runoff samples from 19 cities in the United States, 14% contained antimony in concentrations ranging from 2.6–23 µg/kg (Cole *et al*., 1984). Levels in other areas include groundwater in Switzerland, 0.3–1.0 µg/kg; Canadian surface water, range 0.001–9.1 mg/L (Health Canada 1997); open ocean water, 1×10^{-9} moles/L; filtered and unfiltered seawater from the North Adriatic Sea, 0.31–0.45 µg/kg, respectively (Johnson *et al*. 1992); and surface water samples from Gniezo city, Poland, 1.61 ng/ml (Niedzielski, 2006). Sediments can be significant sinks for antimony (ATSDR, 1992). Levels up to 900 µg/g of antimony have been found in sediment in areas where antimony-containing ore was mined or processed (ATSDR, 1992). By using an analytical method developed for the determining trace element concentrations in polar snow and ice, which gave a detection limit of 30 pg Sb/L, Shotyk *et al*. (2005a) measured the antimony level of water from natural flows and wells in Springwater Township, Ontario, Canada. The average concentration in 34 samples was 2.2 ± 1.2 ng/L, and the maximum concentration 5.0 ng/L.

The World Health Organization recommends that drinking water contain no more than 0.02 mg antimony/liter (World Health Organization, 1993). This equates to 10% of a total recommended maximum daily intake (TDI) of 6 µg/kg of body weight.

4.1.3 Tobacco

Antimony in cigarettes has been studied by means of neutron activation (Nadkarni and Ehman, 1970; Wyttenbach *et al*., 1976). The tobacco contained an average of 0.1 mg Sb/kg dry weight. The amount of inhaled antimony was estimated to be 20% of the total amount of antimony in one cigarette.

4.2 Working Environment

Air concentrations of antimony on the order of 1–10 mg/m^3 have been reported from different smelter operations. Renes (1953) found average working zone concentrations of antimony ranging from 4.7–10.2 mg/m^3 in smelting works. In an abrasives plant studied by Brieger *et al*. (1954), the average air concentration was 3.0 mg/m^3. It should be mentioned in this context that arsenic frequently occurs as a contaminant in the production and handling of antimony. Thus, risks for simultaneous exposure to arsenic, when antimony and its compounds are used, are always present. Some of the health effects that were previously thought to be primarily related to antimony have, indeed, subsequently been questioned by some researchers and considered to be an effect of simultaneous exposure to arsenic rather than antimony (Brooks, 1981). Stibine (SbH_3) was found to evolve during charging of lead storage batteries in which antimony was a compound of the negative grid (Haring and Compton, 1935). Because of improved working conditions over the years, there are relatively few instances of high exposure to antimony over long periods of time (McCallum, 2005). The OSHA permissible exposure limit (PEL) is 0.5 mg Sb/m^3 (8-hour time-weighted average) (U.S. Department of Labor, 2006).

5 METABOLISM

Antimony is considered a nonessential metal.

5.1 Absorption

No correlation was found between soil levels of antimony and antimony levels in urine, blood, or hair of area residents (Gebel *et al*., 1998a,b). On the other hand, in another study, significant correlation was found between antimony concentrations in air and in blood and urine (Kentner *et al*., 1995).

5.1.1 Inhalation

Quantitative data on the absorption of inhaled antimony compounds are not available. It can, however, be deduced from the experiments on rats by Djuric *et al*. (1962) that inhaled trivalent antimony is, to a great extent, absorbed from the lungs, distributed to various organs, and excreted in urine and feces. It has been shown that absorption of antimony compounds

from the respiratory tract is influenced by particle size. One study showed that 1.6 µm particles were absorbed in the upper respiratory tract to a greater extent than 0.7 or 0.3 µm particles (Felicetti *et al*., 1974b). The 1.6 µm particles were cleared by mucociliary clearance within a few hours, whereas the smaller particles were cleared over several weeks (Thomas *et al*., 1973). No differences were seen in body burden between trivalent and pentavalent antimony tartrate 1 day after exposure (Felicetti *et al*., 1974a). In a study of workers in the lead battery production industry, pulmonary absorption of antimony trioxide and stibine were found to be virtually equal (Kentner *et al*., 1995). Although no differences in the rate of absorption of antimony compounds were noted, it is likely that there are differences related to solubility (ATSDR, 1992).

5.1.2 Ingestion

No quantitative data on absorption of antimony from the gastrointestinal tract in humans is available. In animals, absorption rates for antimony tartrate and antimony trichloride are estimated at 2–7% (Felicetti *et al*., 1974a; Gerber *et al*., 1982). At least 15% of a single oral dose of labeled antimony potassium tartrate (trivalent) given to mice is absorbed (i.e., recovered in urine and tissues) (Waitz *et al*., 1965). Absorption may, however, be higher, because gastrointestinal excretion starts immediately after the metal is taken up from the gut. Thus, Gellhorn *et al*. (1946) observed a fecal excretion of 50% of the given dose (0.43 mg) within 24 hours after intraperitoneal administration of antimony potassium tartrate to hamsters.

The therapeutic doses in humans of antimony and potassium tartrate that produce a diaphoretic/expectorant or emetic response are 2.8 mg and 30–60 mg, respectively; see Section 3.1. (Martindale, 1941).

5.2 Distribution

5.2.1 Animals

Antimony given as a single dose or by repeated injections is found in kidney and liver (Boyd *et al*., 1931 [pentavalent antimony to monkeys]; Hassan, 1938 [trivalent antimony to dogs and monkeys]; Goodwin and Page, 1943 [pentavalent antimony to mice]) as well as in thyroid (Brady *et al*., 1945 [trivalent antimony to dogs]). There are remarkable differences in the distribution of trivalent and pentavalent antimony in blood of rats. Two hours after an intraperitoneal injection of trivalent antimony (3 µg), more than 95% of the amount of antimony in blood was incorporated in the red blood cells. On the other hand, about 90% of pentavalent antimony was mainly found in plasma (Edel *et al*., 1983). In hamsters, trivalent antimony levels increased more rapidly in the liver than pentavalent antimony levels, whereas pentavalent antimony was taken up more rapidly by the skeletal system than trivalent antimony (Felicetti *et al*., 1974a). In rats fed a diet containing 2% antimony trioxide for 1.5 months, the highest concentrations of antimony were found in the thyroid and adrenal glands, values of 88.9 and 67.8 mg/kg, respectively (wet or dry weight not stated). Spleen, lungs, liver, and kidneys had concentrations between 6.7 and 18.9 mg/kg (Westrick, 1953). The highest concentrations of antimony in rats given antimony in drinking water (38 µg/L) for 26 months were found in blood and spleen; 185 µg/kg and 31.5 µg/kg wet weight, respectively (Edel *et al*., 1983). As is the case for arsenic (Chapter 19), there seem to be important species differences with regard to the metabolism of antimony. Djuric *et al*. (1962) noticed that in rats exposed to antimony trichloride by inhalation, a large proportion of the body burden of antimony was recovered in blood. A couple of weeks after exposure, about 10% of the body burden of antimony was found in blood. This was a higher proportion than in any other organ. Comparative studies with rabbits and dogs intratracheally exposed to antimony trichloride revealed that these animals had less than 1% of the blood antimony concentrations found in rats.

5.2.2 Humans

A study conducted in Ireland to establish a reference range for antimony in serum and urine of infants in the first year of life found levels of 0.09–0.25 µg/L in serum. Urinary antimony concentration for 95% of the infants was <2.6 ng/mg creatinine (Cullen *et al*., 1998). An earlier study also detected antimony in very low levels in both serum and urine of infants in the United Kingdom (Dezateux *et al*., 1997). A Japanese autopsy study examined the levels of antimony in tissues in unexposed humans. The mean body burden was 0.7 mg, with the highest levels of antimony found in skin and hair (Sumino *et al*., 1975). Surface body scanning of people given intravenous injections of labeled antimony as sodium antimony dimercaptosuccinate revealed the highest amounts in liver, thyroid, and heart. Forty-three days after the last injection, the liver still showed values of about 1/6 of the maximum, which was reached 1 day after the last injection (Abdallah and Saif, 1962; Abdel-Wahab *et al*., 1974). Certain inhaled antimony compounds seemed to be retained in the lung for long periods. Gerhardsson *et al*. (1982) found that former smelter workers occupationally exposed to

several different types of metals, of which antimony was one, on an average had 12 times higher lung concentrations of antimony (315 µg/kg) than persons not previously occupationally exposed (26 µg/kg).

5.3 Excretion

5.3.1 Animals

Rate and route of excretion are dependent on the valency of the compound. Certain species differences are also seen. In general, pentavalent organic antimony is mainly excreted in urine, trivalent mainly in feces (Edel *et al*., 1983; Otto and Maren, 1950).

Cows given antimony orally as $^{124}SbCl_3$ at an average dose of 21.1 mg Sb/kg body weight excreted 82% of the antimony in feces. Milk and urine accounted for 0.008 and 1.1%, respectively. Highest tissue concentrations were found in the spleen, liver, bone, and skin. A single cow administered $^{124}SbCl_3$ intravenously at a dose of 1.5 mg Sb/kg body weight showed fecal excretion of only 2.4%, whereas milk and urine accounted for 0.08 and 51%, respectively (Von Bruwaene *et al*., 1982).

Six hours after intravenous and intraperitoneal injections of pentavalent antimony compounds to mice, about 50–60% was found in urine (Goodwin and Page, 1943). The initial excretion rate was less rapid for the trivalent form, but after 48 hours, the differences between the forms declined; total urinary excretion in 48 hours was around 70%.

Twenty-four hours after intraperitoneal administration of trivalent and pentavalent antimony to hamsters, about 15% of the trivalent and 65% of the pentavalent antimony were found in urine. The fecal excretion over the same period of time was about 50% for trivalent antimony and less than 10% for pentavalent antimony (Gellhorn *et al*., 1946). Likewise, Edel *et al*. (1983) found that 6% and 88% of a given dose of trivalent and pentavalent antimony in rats was eliminated in urine within 24 hours of the administration. The fecal elimination of trivalent and pentavalent antimony during the same period was 33% and 1%, respectively.

5.3.2 Humans

Healthy subjects in the general population in central Italy were found to have a urinary antimony level of 60.8 ng/L (Alimonti *et al*., 2005).

Median exposure to antimony in air of workers in a lead battery production facility ranged from 4.5 µg Sb/m^3 for casting workers to 12.4 µg Sb/m^3 for formation workers. Average urine values were 3.9 µg Sb/g creatinine for the casters and 15.2 µg Sb/g creatinine for the formation workers. Characteristics of pulmonary absorption and urinary excretion for antimony trioxide and stibine were very similar (Kentner *et al*., 1995). Single intravenous or intramuscular injections to volunteers produced higher 24-hour urinary excretion of pentavalent (80%) than of trivalent (25%) antimony compounds, a pattern similar to the one found in animals (Abdallah and Saif, 1962; Boyd and Roy, 1929; Goodwin and Page, 1943).

Bartter *et al*. (1947) studied the elimination of a single intravenously administered dose of labeled antimony potassium tartrate (trivalent). The urinary excretion was about four times higher than the fecal. In one patient, 73% of a total single dose was eliminated within 4 weeks. Rees *et al*. (1980) studied the renal clearance of pentavalent antimony. When pentavalent antimony in the form of sodium stibogluconate was given intramuscularly to patients, about 95% was recovered in urine within 6 hours after the administration.

In workers exposed to air containing around 3 mg Sb/m^3, a colorimetric method showed urinary values ranging from 0.8–9.6 mg/L (Brieger *et al*., 1954), which are highly elevated compared with normal values (see Section 6). Likewise, Smith and Griffiths (1982) found considerably higher urinary concentrations of antimony (10–220 µg/L) in urine samples from workers exposed to antimony compared with urine from nonexposed subjects (1–5 µg/L).

5.4 Biological Half-Life

5.4.1 Animals

5.4.1.1 Inhalation

A study of beagles exposed to labeled antimony aerosols indicated an initial fast clearance of up to 80% of the initially deposited material within a few days (whole-body measurements). This fast excretion phase was followed by a slow clearance, with a biological half-life in whole-body on the order of 36–100 days (Felicetti *et al*., 1974b). The retention in the lung of initial lung burden, after 4 months, ranged from 0.0–6%, depending on the type of particles. Excretion of antimony took place through urine and feces, with a ratio of 0.8. The particles had been nebulized from an antimony potassium tartrate solution passing through a heating column at 100, 500, and 1000°C, which yielded particles with aerodynamic diameters of 0.3, 1.0, and 1.3 µm, respectively. Similar results have also been reported by Djuric *et al*. (1962), who exposed rats, and by Thomas *et al*. (1973), who exposed mice under conditions similar to those used by Felicetti *et al*. (1974a). After a rapid elimination of about 80% of the initially deposited amount

of antimony in the lung, the whole-body burden biological half-life was found to be in the order of 30–140 days in the two different species. It is possible that the half-life would have been even longer if the animals had been followed up for an extended period of time.

Leffler *et al*. (1984) studied lung retention of antimony and arsenic after intratracheal instillation of industrial dust—which had been neutron activated—from a Swedish copper smeltery. Comparison was made with pure substances of antimony trioxide and arsenic trioxide. There were two phases in the clearance curves. The approximate half-life for the initial phase was about 40 hours for Sb_20_3, and about 30 hours for antimony dust. The second phase had an approximate half-life of 20–40 days for Sb_20_3 and antimony dust. The low solubility of antimony in factory dust combined with a long biological half-life may, according to the present authors, be of importance in explaining the observed lung accumulation of antimony in exposed workers (see Section 5.2.2).

5.4.1.2 Parenteral Administration

Most data indicate an initial rapid clearance of antimony, involving gastrointestinal and urinary excretion (see Section 5.3.1). Twenty-four hours subsequent to an intraperitoneal injection in hamsters, Gellhom *et al*. (1946) found about 70% of trivalent and pentavalent antimony compounds in feces and urine together.

5.4.2 Humans

The initial excretion of antimony in humans is rapid (see Section 5.3.2). When pentavalent antimony compounds are given intravenously or intramuscularly, more than 90% of the dose will be found in the urine within 24 hours (Rees *et al*., 1980). There might, however, be a long-term component according to a study by Mansour *et al*. (1967). They studied antimony in blood and urine (neutron activation) in patients who, 1 year earlier, had been treated with antimony for bilharzia. They found average blood and urine values of 6.7 and 27.6 µg/L, respectively, in three patients. Three untreated subjects had averages of 3.4 and 6.2 µ/L in blood and urine, respectively. Data from measurements of antimony in lung tissue obtained from former occupationally exposed smelter workers show that inhaled antimony may be deposited and retained in the lung for extended periods of time (several years) (Gerhardsson *et al*., 1982). In a study of workers in a lead battery production facility, who were exposed to antimony trioxide and stibine in air, the half-life of renal excretion was found to be approximately 4 days (Kentner *et al*., 1995).

6 BIOLOGICAL MONITORING

Relatively high antimony concentrations (around 0.5 mg/kg dry weight about 0.1 mg/kg wet weight) are found in the lung. Liver and kidney contain about one third of the lung concentration (Kennedy, 1966; Nixon *et al*., 1967; Schicha *et al*., 1972, all using neutron activation). More recently, Gerhardsson *et al*. (1982) using the same technique arrived at somewhat lower normal values: 26, 7, and 5 µg Sb/kg wet weight in lung, liver, and kidney, respectively. Japanese autopsies have shown that skin and adrenal glands contain slightly higher concentrations of antimony than lung and liver, 100 µg/kg and 70 µg/kg wet weight compared with 60 µg/kg and 20 µg/kg. The total body burden of antimony in an average Japanese was estimated to be about 0.7 mg by use of the rhodamine B method (Sumino *et al*., 1975).

Blood and serum concentrations of antimony in normal subjects have been reported to be around 3 and 1 µg/L, respectively (Mansour *et al*., 1967; Wester, 1973—both studies used neutron activation; Bencze, 1981—AAS used). The 24-hour urinary excretion of 16 subjects ranged from 0.5–2.6 µg (Wester, 1973). Smith and Griffiths (1982) found a median antimony concentration of less than 1 µg/L for persons not occupationally exposed to antimony and 54 µg/L for occupationally exposed workers. Because quality control programs were not reported in any of the studies cited, the results concerning normal levels of antimony in biological materials, especially in urine and blood, must be regarded as tentative only.

More recent studies on workers occupationally exposed to antimony in a variety of industries and using modern analytical methods have found that determination of urinary antimony is useful for biological monitoring of exposure (Bailly *et al*., 1991; Kentner *et al*., 1995; Ludersdorf *et al*., 1987). Significant correlation was found between the concentration of antimony in air and in the blood and urine of workers in a lead battery factory. In this study, levels of exposure to antimony-containing dust and stibine gas were 10 times lower than threshold limit values (Kentner *et al*., 1995). A study of workers in a textile factory that uses antimony-containing flame retardants compared urinary antimony levels in two groups of workers and controls. Levels of antimony in ambient air were very low (1.45 µg/m^3). A statistically significant ($P < 0.001$) difference was observed in the mean antimony urinary level between workers in a "lower" exposure group and a "higher" exposure group and between the two groups and the control group. The "high" exposure group had a urinary antimony level of 0.39 ± 0.26 µg/L compared with 0.10 ± 0.06 µg/L in the controls. Thus,

increases in urinary antimony levels are seen in cases of exposure to very low levels of antimony in air (Iavicoli *et al*., 2002).

7 EFFECTS AND DOSE-RESPONSE RELATIONSHIPS

7.1 Animals

The major sites of accumulation of antimony in animals after oral exposure, other than the gastrointestinal tract, are the liver, kidney, bone, lung, spleen, and thyroid. This accumulation, however, is not dose-related (Sunagawa, 1981). With peroral exposure, both acute and chronic, antimony potassium tartrate is more toxic than antimony trioxide and pentoxide. In dogs and cats, acute symptoms such as vomiting and diarrhea were produced by antimony potassium tartrate in doses on the order of 10 mg/kg. Antimony trioxide and pentoxide could be given to the same animals in doses above 100 mg/kg for months without toxic manifestations (Bradley and Fredrick, 1941; Flury, 1927). In a long-term study, rats given 5 mg/L as antimony potassium tartrate in drinking water showed a significantly shortened average length of life (about 15%) compared with controls (Schroeder *et al*., 1970). Rats given a diet containing 0.5–2% antimony or antimony trioxide had a decreased weight gain (Sunagawa, 1981).

7.1.1 Local Effects and Dose-Response Relationships

After inhalation of antimony trioxide at an average concentration of 45 mg/m^3, 2–3 hours daily for several weeks, guinea pigs showed interstitial pneumonitis (Dernehl *et al*., 1945). Rats and rabbits exposed to antimony trioxide (90–125 mg Sb_20_3/m^3 during 100 hour/month) for periods of up to 14 months, in addition to pneumonitis, also developed lipoid pneumonia, fibrous thickening of alveolar walls, and focal fibrosis (Gross *et al*., 1951; 1955). Rabbits seemed to be more susceptible than rats (Gross *et al*., 1955). Watt (1983) used 148 female CDF-rats and 8 miniature swine to examine the long-term toxicity of inhaled antimony trioxide. Both species were divided into a control group, a low-exposure (1.6 mg Sb/m^3), and a high-exposure group (4.2 mg Sb/m^3). The animals were exposed for 6 hours a day, 5 days per week, for about 1 year. In the miniature swine, there were no histopathological changes in the lungs, but in the rats, there were pronounced morphological changes in the lung with focal fibrosis, adenomatous and pneumonocytic hyperplasia, and cholesterol clefts. The histopathological changes were most pronounced in the high-exposure group.

7.1.2 Systemic Effects and Dose-Response Relationships

In a study of the effects of subchronic oral exposure of Wistar rats to antimony or antimony trioxide, growth retardation was observed. The addition of 0.1% or 1.0% antimony or 1.0% antimony trioxide to the diet for 12 weeks resulted in a decrease in body weight that returned to normal after 12 weeks on an antimony-free diet (Hiraoka, 1986). A decrease in body weight was also observed in a study of Sprague–Dawley rats exposed to potassium ammonium tartrate in drinking water at concentrations of 0.5, 5, 50, or 500 mg/L for 13 weeks. As with the study by Hiraoka, the rats returned to their normal weight within several weeks post exposure (Poon *et al*., 1998).

7.1.2.1 Circulatory System Effects

Intravenous injections of antimony produce an acute circulatory response with a drop in blood pressure (Chopra, 1927; Cotten and Logan, 1966). Pathological ECG changes have been observed. In dogs injected for 4 days with antimony potassium tartrate, 5 mg/kg body weight, one of the most prominent features was inversion of the T wave (Girgis *et al*., 1970). Several of the dogs died as a result of the treatment.

Chronic effects with parenchymatous degeneration in the myocardium were observed on histopathological examination of hearts from rats and rabbits exposed to 3.1 and 5.6 mg/m^3 as antimony trisulfide for 6 weeks (Brieger *et al*., 1954). On the other hand, Watt (1983), in his long-term study on swine exposed to antimony trioxide (1.6 and 4.2 mg Sb/m^3), found no evidence of cardiovascular effects.

7.1.2.2 Liver and Kidney Effects

Fatty degeneration occurred in the convoluted tubules of the kidney and the liver after a single administration of 60 mg antimony potassium tartrate solution to rabbits. The kidney changes appeared a few hours after the administration, and preceded the changes in the liver (Franz, 1937). Fatty degeneration in the liver, but no effects in the kidney, was recorded in an inhalative exposure study on guinea pigs (Dernehl *et al*., 1945). Long-term peroral exposure to high doses of antimony may also induce signs of liver toxicity. Sunagawa (1981) gave rats 0.5–2% antimony and antimony trioxide in the diet. After 24 weeks, the most exposed animals had elevated serum levels of a liver enzyme, GOT.

7.1.2.3 Endocrine Effects

Antimony is among a group of metal ions, termed metalloestrogens, shown to bind to estrogen receptors and cause estrogen agonist responses *in vitro* and

in vivo. Thus, these metalloestrogens can mimic the actions of physiological estrogens (Darbre, 2006).

7.2 Humans

Data on acute and chronic toxicity of antimony come essentially from results found in connection with industrial atmospheric exposure. Adverse effects from treatment of tropical diseases with antimony compounds are discussed only briefly. Stibine (SbH_3), like arsine (AsH_3), when inhaled, damages the red blood cells and causes hemolysis. Signs of poisoning include symptoms of shock and hemoglobinuria (Stokinger, 1963).

7.2.1 Local Effects and Dose-Response Relationships

7.2.1.1 Gastrointestinal Effects

Acute antimony poisoning, manifested as vomiting, nausea, and diarrhea, was reported in 150 children who drank a contaminated lemon drink (about 30 mg/L) (Werrin, 1963). In former times, wine and other drinks stored in antimony cups were used to induce vomiting (Fairhall and Hyslop, 1947; McCallum, 1977), the emetic dose for adults being in the range of 30–60 mg (Martindale, 1941).

7.2.1.2 Respiratory Effects

Acute respiratory exposure to antimony trichloride (73 mg/m^3) caused irritation and soreness of the upper respiratory tract in seven workers (Taylor, 1966). Three cases, two of them fatal, of severe pulmonary edema evoked by antimony pentachloride have been described by Cordasco and Stone (1973); concentrations in air were not available.

Chronic respiratory effects related to antimony were reported by Renes (1953). He examined 78 workers engaged in smelting processes, for periods exceeding 2 weeks. Exposure concentrations ranged from 4.7–11.8 mg/m^3, 20% of the workers suffered from rhinitis, 8% from pharyngitis, 5.5% from pneumonitis, and 1% from tracheitis. Soreness in the nose and nosebleed were experienced by more than 70%. The workers were, however, also exposed to arsenic at concentrations around 0.7 mg/m^3. In view of the more severe toxic properties of arsenic (Chapter 19), several of the effects that were related to antimony by Renes (1953) could actually have been caused by exposure to arsenic (ACGIH, 1983). Brieger *et al*. (1954) did not mention respiratory tract irritation in their extensive study discussed in Section 7.2.2 in which workers were exposed to antimony trisulfide at levels ranging from 0.6–5.5 mg Sb/m^3.

Several authors have remarked on pneumoconiosis-like X-ray pictures obtained from workers with long-term occupational exposure to antimony (Browne, 1968; Cooper *et al*., 1968; Karajovic, 1958; Le Gall, 1969; McCallum, 1963; Parkes, 1982; Potkonjak and Pavlovich, 1983). It is likely that silica was present in some of these instances. McCallum *et al*. (1970) have developed an X-ray method for measurement of inhaled antimony trioxide. On examination of 113 antimony process workers, they found a significant correlation between estimated lung antimony and period of employment (Figure 1). Parkes (1982), in his textbook on occupational lung disorders, regards the antimony pneumoconiosis as being benign, having no detrimental effect on health or life expectancy.

Potkonjak and Pavlovich (1983) reported on the examination of 51 workers with X-ray changes indicating antimoniosis, in a Yugoslavian antimony smelter. The men had been exposed to a total dust concentration of 17–86 mg/m^3 for 9–31 years. The dust mainly consisted of antimony trioxide (40–90%) but also contained lesser amounts of antimony pentoxide (2–8%) and free silica (1–5%). The X-ray findings were characterized by the presence of diffuse, densely distributed punctate opacities, having a diameter of less than 1 mm. Confluence of opacities was not seen. Pulmonary function tests revealed obstructive changes in 17.6% and mixed restrictive-obstructive changes in 9.8% of the examined workers with X-ray changes. Increased airway resistance was seen in 26.3%, and a decreased

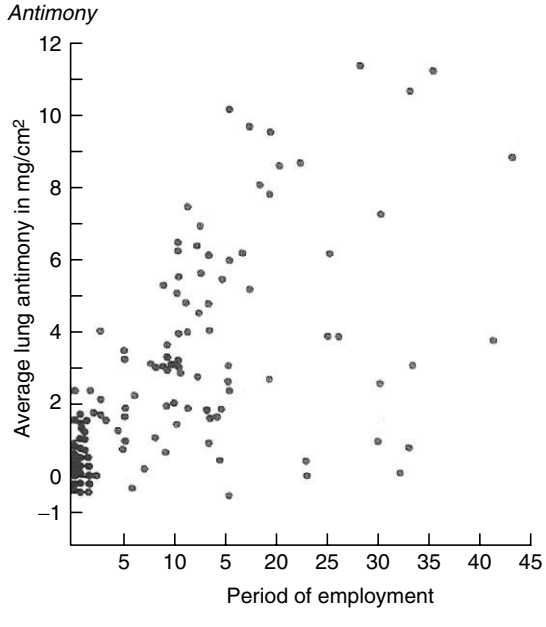

FIGURE 1 Lung antimony (mg/cm^2) in 113 antimony workers, measured with an X-ray spectrometry method, in relation to period of employment in year. Mc Callum *et al.* (1970).

forced expiratory flow rate in 16.7%. In addition, 61% of the workers complained of chronic coughing.

Two other groups of investigators have also observed lung changes among antimony workers (Karajovic, 1958; Klucik *et al*., 1962). Klucik *et al*. (1962) reported on workers exposed to antimony trioxide for up to 28 years (concentration and number of workers were not given). The prevalence of pneumoconiosis and symptoms of emphysema were given as 21 and 42%, respectively.

It thus seems that antimoniosis is commonly regarded as a relatively benign condition, but nevertheless chronic respiratory effects have been reported in a number of studies. Therefore, heavy antimony exposure cannot, according to our interpretation, be regarded as harmless.

7.2.1.3 Skin Effects

Pustular skin eruptions, "antimony spots," are sometimes seen in persons working with antimony and antimony salts. These eruptions are transient and mainly affect skin areas exposed to heat and those areas where sweating occurs (McCallum, 1963; Paschoud, 1964; Potkonjak and Pavlovich, 1983; Renes, 1953; Stevenson, 1965). Thirty-two (62.7%) of the antimony smelter workers examined by Potkonjak and Pavlovich (1983) had "antimony dermatosis."

7.2.2 Systemic Effects and Dose-Response Relationships

7.2.2.1 Circulatory System Effects

Antimony is associated with ECG abnormalities and an increased risk of sudden death that is likely due to arrhythmias (Sullivan and Krieger, 1992). Brieger *et al*. (1954) reported hypermortality and morbidity among workers in an abrasive industry. In all, 124 workers were exposed to air concentrations of antimony trisulfide ranging from 0.6–5.5 mg/m^3 for 8–24 months. During this period, six workers died suddenly and two others died of chronic heart disease. Of the deceased, four were under 45 years of age. ECG changes, mostly of the T wave, were seen in 37 of 75 examined. During the preceding 16 years before introduction of antimony in the plant, only one death had occurred in this department. No control group was examined.

Renes (1953) reported abdominal cramps, diarrhea, and vomiting among certain workers subject to heavy exposure to antimony fumes in a smelter. A higher prevalence of ulcer, 6% of 111 examined antimony workers compared with that of the total plant population, 1.5% of 3912 employees, was seen by Brieger *et al*. (1954).

7.2.2.2 Immunological Effects

Kim *et al*. (1999) reported altered cytokine and immunoglobulin levels in workers exposed to antimony. The sera from exposed workers showed lower levels of IgG1 and IgE compared with the sera from controls. A positive correlation between IgG4 and urine serum Sb levels in the exposed group was noted.

7.2.2.3 Hemolytic Effects of Stibine Gas

Stibine gas (SbH_3) is another important chemical form of antimony (Andrewes *et al*., 2004; Gallicchio *et al*., 2001; Hussain *et al*., 1998) that has toxic properties similar to those of arsine gas. Information on the carcinogenic or other toxic potential of stibine is currently very limited (Andrewes *et al*., 2004; Gallicchio *et al*., 2001; Husain *et al*., 1998) relative to that of arsine gas. Stibine releases have been reported in the production of lead automobile batteries (ATSDR, 1992), and it is also currently used in the production of some III–V semiconductors. Stibine has been reported to produce hemolysis and hemoglobinuria, although it seems to be less acutely toxic than arsine gas (Gallichio *et al*., 2001).

7.2.3 Adverse Effects During Antimony Treatment

Various side effects, and in several studies cases of sudden death, have been recorded in connection with clinical treatment of parasitic diseases with antimony (El Halawani, 1968; Rugemalila, 1980). Nausea and vomiting are common features (Hamad, 1969; Pedrique *et al*., 1970; Zaki *et al*., 1964). Effects on the liver, with rises in serum concentrations of two liver enzymes (GOT and GPT) at the onset of therapy, were reported by Woodruff (1969). As in animal studies, ECG changes, particularly in the T wave, were frequently reported during long-term treatment (Abdalla and Badran, 1963; Davis, 1961; Mainzer and Krause, 1940; Sapire and Silverman, 1970; Schroeder *et al*., 1946). Mansour and Reese (1965) have proposed that the influence of tartar emetic is an augmenting factor in the development of schistosomal myopathy.

8 CARCINOGENIC AND GENOTOXIC EFFECTS

There are few studies on the carcinogenicity of antimony (Gebel, 1997; Hayes, 1997). One reason is that the environmental distribution of antimony is low. In an inhalation study using Wistar rats, antimony ore concentrates and antimony trioxide have been linked to lung cancer. After inhalation of 45 or 36–40 mg/m^3 Sb_2O_3 or Sb, 7 hours per day, 5 days per week, for 52 weeks, followed by a 5-month observation period,

female rats, but not male rats, developed lung neoplasms. The authors attributed this difference to a lower immunological responsiveness in female rats (Groth *et al*., 1995). A subchronic and chronic inhalation study of Sb_2O_3 in rats did not lead to increased frequencies of neoplasms (Newton *et al*., 1994). Watt (1983) found that female rats exposed to antimony trioxide at concentrations of 1.6 and 4.2 mg Sb/m^3 for 6 hours per day, 5 days per week for 1 year followed by a 15-month observation period, showed a high frequency of lung neoplasias (see also Section 7.1.1). The lung neoplasias were either scirrhous carcinomas, squamous cell carcinomas, or bronchioalveolar adenomas. There was evidence of local invasion, but no metastasis was observed.

Human carcinogenicity of antimony is difficult to evaluate because of the frequent coexposure to arsenic (De Boeck *et al*., 2003). In a study of U.S. antimony workers, excess mortality from cancers of the liver, biliary tract, and gallbladder was found in a cohort of antimony smelter workers (Schnorr *et al*., 1995). The American Conference of Governmental Industrial Hygienists (ACGIH, 1983) refers to unpublished data on mortality among workers in a large antimony smelter in the U.K. In the 1960s, exposure to antimony, mainly in the form of antimony trioxide, ranged from 0.5–40 mg/m^3. Apart from antimony, the workers were also exposed to zirconium. The data cited are difficult to interpret, but there seems to be an increased proportional mortality from lung cancer among the most heavily exposed men. On the basis of these data, the ACGIH (1983) concluded that antimony oxide should be regarded as a suspected carcinogen.

Overall, the International Agency for Research on Cancer (IARC) finds the available data on the carcinogenicity of antimony to be inconclusive. IARC classifies antimony trioxide as *possibly carcinogenic to humans* (Group 2B) and antimony trisulfide as *not classifiable as to its carcinogenicity to humans* (Group 3) (IARC, 1989).

Antimony compounds display genotoxic activity *in vivo* and *in vitro*. They behave clastogenically (Gurnani *et al*., 1992a; 1992b; 1993) but are not directly mutagenic (Kuroda *et al*., 1991). Genotoxicity is valence-dependent. The trivalent species (Sb_2O_3 and $SbCl_3$) were genotoxic in the sister chromatid exchange test with V79 cells, whereas the pentavalent species (Sb_2O_5 and $SbCl_5$) were not (Kuroda *et al*., 1991). Gebel *et al*. (1997) used the sister chromatid test to assess the genotoxicity of extracts of soil containing high concentrations of antimony and arsenic, both in the pentavalent state. They found low genotoxicity, as well as partial antagonism. Andrewes *et al*. (2004) tested five antimony compounds for genotoxicity. Stibine and trimethylstibine were genotoxic when tested using a pBR 322 plasmid DNA-nicking assay, whereas potassium antimony tartrate, potassium hexahydroxyantimonate, and trimethyl antimony dichloride were not. There is a scarcity of data on the mechanism of action. A biomonitoring study of 23 textile workers exposed to Sb_2O_3 assessed genotoxicity using the sister chromatid assay and cytokinesis-block micronucleus (MN) tests and the enzyme (Fpg)-modified comet assay. Results support the theory that genotoxicity is due to oxidative DNA damage (Cavallo *et al*., 2002; USEPA, 2004).

CHAPTER

19

Arsenic

BRUCE A. FOWLER, C.-H. SELENE J. CHOU, ROBERT L. JONES, AND C.-J. CHEN

ABSTRACT

Arsenic in the environment occurs in both organic and inorganic compounds in its trivalent or pentavalent state. Certain fish and crustaceans contain very high levels of organic arsenic, often as arsenobetaine. In most other foodstuffs, levels of arsenic are low, and the form is not known. The total daily intake of arsenic in the general population is reported to be approximately a few tenths of a milligram but varies to a great extent, depending on the amount of fish consumed.

Both organic arsenic in seafood and inorganic arsenic in water, beverages, and drugs have been shown to be readily absorbed (70–90%) by the gastrointestinal tract. Some reports also indicate a fairly high degree of absorption after inhalation of arsenic.

Absorbed arsenic, irrespective of form, is widely distributed in the body. After exposure to inorganic arsenic, clearance of arsenic from the skin, upper gastrointestinal tract, epididymis, thyroid, and skeleton is slower than from other organs. The highest levels of arsenic in humans are normally found in hair, nails, and skin. The main route of excretion is through the kidneys. After ingestion of arsenite or arsenate, approximately 35% of the dose is excreted within 2 days. From animal experiments it seems that insoluble inorganic arsenic inhaled through the airway is deposited and retained in lung tissue for a relatively long time. Animal data indicate accumulation of arsenobetaine in cartilage, testes, epididymis, and muscle. Of ingested arsenobetaine, 50–80% is excreted by the urine within 2 days.

Biotransformation of inorganic arsenic has been shown to occur in both animals and humans. Methylated compounds, such as methylarsonic acid and dimethylarsinic acid, have been detected in urine after ingestion or inhalation of inorganic arsenic. Reduction of arsenate and oxidation of arsenite *in vivo* have been demonstrated in experimental animals. Recently, a human arsenic methyl transferase has been identified.

Medications, contaminated food, beverages, and drinking water have given rise to a number of episodes of arsenic poisoning.

Inorganic arsenic-induced skin lesions such as dermatoses, which may include eruption, pigmentation, or leukodermal hyperkeratosis, may ultimately lead to the development of skin cancer and Bowen's disease. Effects on the nervous system (e.g., peripheral nervous disturbance), as well as on the heart and circulatory system (e.g., abnormal electrocardiograms, and peripheral vascular disturbances with gangrene of the extremities), have also been reported after chronic exposure to inorganic arsenic. Hematological changes after inorganic arsenic exposure are characterized by anemia and leukopenia. Chronic oral ingestion of inorganic arsenic in drinking water has also been reported to cause internal cancers (lungs, bladder, kidneys, and liver).

Arsenic poisoning among industrial workers is characterized by perforation of the nasal septum, skin changes, and peripheral neuritis. There is substantial epidemiological evidence of an excessive risk of lung cancer among workers exposed to arsenic.

Arsine gas is a powerful hemolytic poison encountered under some industrial conditions. Arsine poisoning is characterized by nausea, vomiting, headache, shortness of breath, and hemoglobinuria. The literature on toxicology and environmental aspects of

arsenicals has recently been reviewed by the World Health Organization (1981; 2001), in International Agency for Research on Cancer (IARC) Monographs (1982; 2004; 2006), Fowler (1983), and by the National Research Council (NRC) (1999).

1 PHYSICAL AND CHEMICAL PROPERTIES

Arsenic (As): atomic weight, 74.9; atomic number, 33; metalloid; allotropes: crystalline (hexagonal-rhombic) grey arsenic (stable); density, 5.727 (25°C/4°C); melting point, 818°C (36 atm); boiling point, 615°C (sublimate); vapor pressure, 1 mmHg (372°C), yellow arsenic (metastable); density, 1.97; melting point, 815°C (under additional pressure), and black arsenic; valence states −3, 0, +3, and +5. When elemental arsenic is heated at atmospheric pressure without oxygen, it sublimes without melting and forms a yellow gas. Heating arsenic in air will yield a white smoke consisting of arsenic trioxide.

From both the biological and the toxicological points of view, arsenic compounds may be classified into three major groups: (1) inorganic arsenic compounds; (2) organic arsenic compounds; and (3) arsine gas. The toxicology of this last compound, which has special properties, will be dealt with separately in Section 10 of this chapter. The most common inorganic trivalent arsenic compounds are arsenic trioxide, sodium arsenite, and arsenic trichloride. Pentavalent inorganic compounds are arsenic pentoxide, arsenic acid and arsenate (e.g., lead arsenate and calcium arsenate). Common organic arsenic compounds are arsanilic acid, methylarsonic acid, dimethylarsinic acid (cacodylic acid), and arsenobetaine (NRC, 1999).

Arsenic trioxide is only slightly soluble in water; in sodium hydroxide it forms arsenite, and with concentrated hydrochloric acid it forms arsenic trichloride. Sodium arsenite and sodium arsenate are highly soluble in water. Interchanges in valence state may occur in water solutions, depending on the pH of the solution, as well as the presence of other substances that can be reduced or oxidized (Reay and Asher, 1977).

2 METHODS AND PROBLEMS OF ANALYSIS

Until a few decades ago, the only available methods for analyzing arsenic, such as Reinsch's method, Marsh's test, and Gutzeit's test, were qualitative rather than quantitative in nature. Because of this limitation, results of studies based on these methods must be evaluated with caution.

The molybdenum blue method and the silver diethyldithiocarbamate method are two reasonably good quantitative colorimetric methods that have a limit of detection in the range of 1–50 µg/L in a 5-mL solution (Sandell, 1959; Vasak and Sedivec, 1952). Atomic absorption spectrophotometric (AAS) measurement of generated arsine gas (Holak, 1969) has been widely used for determination of total arsenic and has a detection limit of 0.04 µg. Atomic fluorescence spectrometry (AFS) with online hydride generation (Karthiheyan and Hirata, 2003) has the advantage of less scattering and matrix effects and has a detection limit of 0.03 ug/L. Neutron activation analysis (NAA) has a detection limit of 0.1 ng for total arsenic (Liebscher and Smith, 1968). Proton-induced X-ray emission analysis (PIXEA) with a detection limit of 0.1 mg/kg has been used for the simultaneous determination of arsenic and a number of other elements in biological samples (Fowler *et al.*, 1975; Walter *et al.*, 1974). Advancements in inductively coupled plasma spectroscopy (ICP) have resulted in the general use of either ICP optical emission spectroscopy (ICP-OES) or the mass spectroscopy (ICP-MS) detection method. Although the ICP-OES method showed promise (Hueber and Winefordner, 1995), it has been largely replaced with the ICP-MS method with its higher sensitivity and less interferences than ICP-OES with the ICP-MS detection limits of 0.002 ug/L (Marawi *et al.*, 1993). The primary drawback of ICP-MS is the generation of the Ar-Cl interference in the plasma, which can be overcome by either high-resolution ICP-MS (Townsend, 1999), the use of a dynamic reaction cell (Nixon *et al.*, 2004; Tanner *et al.*, 1999) or collision cell (B'Hymer *et al.*, 2004; Nakazato *et al.*, 2002) technology. The ICP-MS is the most widely used method for the determination of total arsenic (Hung, 2004). All these methods are suitable for the measurement of total arsenic.

Several methods for the quantitative determination of the various valence states and chemical forms of arsenic have also been developed. Pulse polarography (detection limit of 0.3 µg As/L water) is capable of distinguishing the polarographically active As(III) from the inactive As(V) (Myers and Osteryoung, 1973). A method to collect generated arsines in a cold trap, evaporate them at different temperatures, and measure them by atomic emission spectroscopy has been found to have a detection limit in the order of 1 ng (Braman and Foreback, 1973). With this method, it is possible to distinguish As(III), As(V), methylarsonic acid, and dimethylarsinic acid.

Speciation of arsenic in water and other matrices like urine has seen major advances because of coupled techniques like ion chromatography (IC)

coupled to ICP (Sheppard *et al*., 1992). In this technique, the IC separates the species of arsenic before the introduction into the ICP-MS (or other detection method). This allows for the automation of the speciation method(s) for the different matrices. The method most used for speciation of the various arsenic species is high-performance liquid chromatography (HPLC) in various forms. Arsenic(III), As(V), monomethylarsonic acid (MMAA), dimethylarsinic acid (DMAA), and arsenobetaine (AsB) are separated by HPLC and determined on-line by inductively coupled plasma mass spectrometry (ICP-MS). Two forms of HPLC may be used: ion pairing and ion exchange, with absolute detection limits for arsenic ranging between 50 and 300 pg (Beauchemin *et al*., 1989). An ICP-MS detector in combination with HPLC has been used for the analysis of six arsenic compounds with detection limits for arsenic species in the range from 10–30 pg. (Demesmay *et al*., 1994).

Methods and problems of arsenic analysis, including speciation in various matrices, have been reviewed by Braman (1977, 1983), Brinckman *et al*. (1977), Hung *et al*. (2004), Munoz and Palmero (2005), Gong *et al*. (2002), and Rose *et al*. (2001).

3 PRODUCTION AND USES

3.1 Production

Arsenic is widely distributed in the earth's crust, which contains about 3.4 ppm arsenic (Wedepohl, 1991). It usually exists in nature in sulfide ores. Arsenopyrite is by far the most common arsenic-containing mineral. There are more than 150 arsenic-bearing minerals (Budavari *et al*., 2001; Carapella, 1992). Arsenic trioxide (white arsenic) is principally obtained as a by-product in the smelting of copper, lead, or gold ores. When these ores are smelted, the arsenic becomes gaseous and is trapped by electrostatic precipitators as a crude dust that is then roasted, whereby the arsenic trioxide is driven off. The purified arsenic trioxide is collected in a cooling chamber. The principal impurity is Sb_2O_3 (Pinto and McGill, 1953). Most commercially available arsenic compounds are produced from arsenic trioxide. The average annual world production of arsenic on the basis of limited data (1975–1977) was approximately 60,000 tons, and this production seems to be stable (WHO, 1981). In 2003, China was the world leader in the production of commercial-grade arsenic, followed by Chile and Peru (Brooks, 2003). The United States is the world's leading consumer of arsenic; however, the United States ceased production in 1985.

3.2 Uses

Arsenic was known as a therapeutic agent as early as 400 BC and has since been widely used as such. From the 19th century onward, an inorganic arsenic compound known as Fowler's solution (liquor arsenicalis B.P. 1963, arsenite solution containing 7.6 g As/L) has been used for the treatment of leukemia, psoriasis, and chronic bronchial asthma, and organic arsenic compounds have been extensively used in the treatment of spirochetal and protozoal disease (Martindale, 1977; NRC, 1999). Many countries have now banned the use of Fowler's solution. Recently, there has been reported use of arsenic trioxide in the treatment of acute promyelocytic leukemia (APL) (Gallagher, 1998; Wang, 2001).

The major current uses of arsenic are in pesticides (e.g., lead arsenate, calcium arsenate, and sodium arsenite), herbicides (e.g., monosodium arsenate and cacodylic acid [dimethylarsinic acid]); cotton desiccants (e.g., arsenic acid); and wood preservatives (e.g., copper chromium arsenate). Arsenic is also used as a bronzing or decolorizing agent in the manufacture of glass and in the fabrication of opal glass and enamels. It has also been used in the manufacture of dyestuffs and chemical warfare gases and is still used in the purification of industrial gases (removal of sulfur). Elemental arsenic is used as an additive in the production of several alloys to increase hardness and heat resistance. In the livestock industry, organic arsenical is sometimes added to swine and poultry feed as antimicrobial medicine. In 1999–2000, approximately 70% of the broiler industry added roxarsone to broiler poultry feed (Garbarino *et al*., 2003). Recently, gallium arsenide and indium arsenide, artificial crystals, have become important materials in semiconductors, solar cells, and space research (Brooks, 2005; IARC, 2006; Yamauchi *et al*., 1992).

4 ENVIRONMENTAL LEVELS AND EXPOSURES

4.1 Food and Daily Intake

With the exception of some kinds of fish, crustaceans, and seaweed, most food contains low levels of arsenic, normally below 0.25 mg/kg (Jelinek and Corneliussen, 1977). The degree of arsenic uptake in plants is apparently related to the concentration of soluble arsenic in the soil, the chemical composition of the soil, and plant species (Walsh *et al*., 1977). Surface contamination with insecticides may increase the concentrations of arsenic in plants. Extensive lists of arsenic concentrations in foodstuffs have been published by the National Academy of Sciences (NRC,

1999). However, all the chemical forms of arsenic in food have not yet been established. Recently, Adair *et al*. (2005) reported on two chemical and enzymatic extraction methods followed by IC-ICP-MS analysis for analysis of dimethylarsinic acid (DMA) and inorganic arsenic iAs from rice cooked in arsenic contaminated water. Measured concentrations of DMA ranged from 22–270 ngAs/g rice and for iAs, 31–108 ngAs/g rice.

Arsenic concentrations in marine organisms and seaweed are, in general, considerably higher than those in other foods. Many species of bony fish contain between 1 and 10 mg/kg, whereas certain bottom-feeding fish, crustaceans, and seaweed may contain more than 100 mg As/kg (Lunde, 1973). Both lipid-soluble and water-soluble organic arsenic compounds have been isolated from marine organisms (Kurosawa *et al*., 1980; Lunde, 1975; Penrose *et al*., 1977). Certain algae grown in the presence of arsenate may contain arsenophospholipids (Cooney *et al*., 1978; Irgolic *et al*., 1977), whereas other studies have shown that brown kelp contains mainly arsenosugars (Edmonds and Francesconi, 198la). Arsenosugars are also found in mussels, oysters, and clams (Le *et al*. 2004). Anaerobic decomposition of the brown kelp produced dimethyloxarsylethanol, a possible precursor of arsenobetaine (Edmonds *et al*., 1982). Arsenobetaine, the arsenic analog of betaine, seems to be the most commonly occurring water-soluble arsenical in fish and *Crustacea* (Cannon *et al*., 1981; Edmonds and Francesconi, 1981b; Edmonds *et al*., 1977; Kurosawa *et al*., 1980; *Luten et al*., 1982). Indications of the presence of arsenocholine in some species have also been reported (Norin and Christakopoulos, 1982). Arsenobetaine does not seem to be harmful to humans and is excreted rapidly and unchanged in urine (Cullen, 1998).

The amount of arsenic ingested daily by humans through food is greatly influenced by the amount of seafood in the diet. Jelinek and Corneliussen (1977) noted that foods belonging to the meat, fish, and poultry groups contributed most of the arsenic ingested. They estimated the average daily intake of arsenic from food in the United States in the early seventies to be 0.01–0.02 mg. The daily intake of total arsenic in Japan is reported to be 0.07–0.37 mg per person (Ishinishi *et al*., 1974).

Schoof and colleagues (1999b) reported on the analysis of 40 commodities accounting for 90% of dietary inorganic arsenic intake. Average inorganic arsenic in seafood ranged from <1–2 ng/g. The highest inorganic arsenic concentrations were found in raw rice (74 ng/g), followed by flour (11 ng/g), grape juice (9 ng/g), and cooked spinach (6 ng/g). Schoof *et al*. (1999a) estimated that intake of inorganic arsenic in the U.S. diet ranges from 1–20 µg/day, with a mean of 3.2 µg/day. Nriagu and Lin (1995) analyzed 26 brands of wild rice sold in the United States and found arsenic levels ranging from 0.006–0.142 µg/g dry weight. At a mean level of chicken consumption of 60 g/person/day, Lasky *et al*. (2004) estimated that people may ingest 1.38–5.24 µg/day of inorganic arsenic from chicken, assuming ingestion of 60 g/per person/per day of chicken.

Wine made from grapes sprayed with arsenic-containing insecticides may contain high levels of arsenic. Levels up to 0.5 mg/L have been reported, most of the arsenic being in the trivalent inorganic form (Crecelius, 1977a). Zoeteman and Brinkmann (1976) reported a mean concentration of 0.02 mg/L (range, 0.001–0.19 mg/L) in bottled mineral water. The arsenic in mineral water is probably of natural origin.

4.2 Water

Arsenic is widely distributed in surface water, groundwater, and finished drinking water. Seawater generally contains 0.001–0.005 mg As/L (Ferguson and Gavis, 1972). The arsenic concentrations of rivers and lakes vary considerably. Most levels are well below 0.01 mg/L, but in some instances, they may even be as high as about 1 mg/L (Andreae, 1978; Durum *et al*., 1971; Sagner, 1973). A survey of 293 stations in two nationwide sampling networks on major U.S. rivers found median arsenic levels to be 1 µg/L; the 75th percentile level was 3 µg/L (Smith *et al*., 1987).

The natural concentration of total arsenic in groundwater depends on the arsenic content of the bedrock. Arsenic levels in groundwater average about 1–2 µg/L, except in some western states with volcanic rock and sulfide mineral deposits high in arsenic, where arsenic levels up to 3.4 mg/L have been observed (Robertson, 1989; Welch *et al*., 1988). Approximately 13% of groundwater samples from 800 wells in an area in Nova Scotia, Canada, where the arsenic content in the bedrock is high, had concentrations exceeding 0.05 mg As/L (Grantham and Jones, 1977). Arsenic was detected in 1298 of 3452 surface water samples recorded in the STORET database for 2004 at concentrations ranging from 0.138–1700 µg/L (EPA, 2005a). In Japan, concentrations of up to 1.7 mg As/L have been recorded in hotspring water (Kawakami, 1967). In Cordoba, Argentina, groundwater levels of up to 3.4 mg As/L have been reported (Arguello *et al*., 1938). In Taiwan, artesian well water has been shown to contain up to 1.8 mg/L (Kuo, 1968).

Braman and Foreback (1973) and Crecelius (1974) noted several different forms of arsenic in natural waters: arsenate, arsenite, methylarsonic acid, and dimethylarsinic acid, the methylated forms generally being in lower concentrations than the inorganic

ones. Andreae (1978) reported that arsenate is generally the dominant form in seawater. Clement and Faust (1973) found that only approximately 8% of the total arsenic in well-aerated stream water was in the form of As(III), whereas all of the arsenic in anaerobic reservoirs seemed to be in the form of As(III). The chemical form of arsenic in different ground waters is largely unknown. Clement and Faust (1973) found that 25–50% of the total arsenic in a few groundwater samples was in the form of As(III).

The average daily intake of arsenic through drinking water can vary widely, depending on the source of the water. McCabe *et al*. (1970) reported that less than 1% of more than 18,000 community water supplies in the United States had concentrations exceeding 0.01 mg As/L. Engel and Smith (1994) investigated the levels of arsenic in drinking water throughout the United States between 1968 and 1984. They found that 30 counties in 11 states had mean arsenic levels of >5 µg/L, 15 counties had mean levels from 5–10 µg/L; 10 counties had mean levels from 10–20 µg/L; and 5 counties had levels >20 µg/L. The highest levels were found in Churchill County, Nevada, where 89% of the population was exposed to a mean arsenic concentration of 100 µg/L and 11% to a mean of 27 µg/L. More recently, investigators at the USGS (Focazio *et al*., 2000) have developed an extensive map of the occurrence of arsenic in ground water in the United States on the basis of 18,850 sample locations; 2262 of these were identified as public water supplies. The results of these studies indicate a number of states in specific regional areas (e.g., New England, the Midwest, Rocky Mountain states, and the Pacific Coast with elevated concentrations (>10.0 µg/L) in the ground water supplies, so the issue of elevated arsenic concentrations in groundwater is national in scope. In January 2001, the EPA lowered the MCL for arsenic from 50–10 µg/L (EPA, 2001). With an assumed daily intake of 1.5 L drinking water, a concentration of 0.01 mg/L will result in the daily ingestion of 0.015 mg arsenic.

Some developing countries, such as Mexico, Bangladesh, India, and Vietnam, have highly elevated levels of arsenic in drinking water in some regions (Bagla and Kaiser, 1996; Berg *et al*.. 2001; Tondel *et al*., 1999; Wyatt *et al*., 1998a; 1998b). In Bangladesh and West Bengal, India, it is estimated that more than 1 million people are drinking arsenic contaminated water and tens of millions more could be at risk in areas that have not been tested for contamination. Analysis of 20,000 tube-well waters indicated that 62% have arsenic levels in drinking water above the WHO permissible exposure limit of 10 µg/L, with some as high as 3700 µg/L (Bagla and Kaiser, 1996). Arsenic concentrations in water samples from private small-scale tube-wells in Hanoi, Vietnam, averaged 159 µg/L, ranging from 1–3050 µg/L (Berg *et al*., 2001).

4.3 Soil

Arsenic is widely distributed in the earth's crust, which contains about 3.4 ppm (Wedepohl, 1991). It is mostly found in nature as minerals, and in its elemental form only to a small extent. Typical arsenic concentrations for uncontaminated soils range from 1–40 ppm (µg/g), with the lowest concentrations in sandy soils and soils derived from granites. Higher arsenic concentrations are found in alluvial soils and soils with high organic content (Mandal and Suzuki, 2002).

Soils in mining areas or near smelters may contain high levels or arsenic. Arsenic concentrations up to 27,000 mg/kg were reported in soils contaminated with mine or smelter wastes (EPA, 1982). Soils at an abandoned mining site in the Tamar Valley in southwest England have arsenic concentrations that may exceed 50,000 mg/kg (Erry *et al*., 1999).

Soil on agricultural lands treated with arsenical pesticides may retain substantial amounts or arsenic. A study reported an arsenic concentration of 22 mg/kg in treated soil compared with 2 ppm for nearby untreated soil (EPA, 1982). Soil samples from 13 old fruit orchards in New York state, where lead arsenate was used for pest control for many years, had arsenic concentrations from 1.6–141 mg/kg (Merwin *et al*., 1994).

Natural concentrations of arsenic in sediments are usually <10 µg/g dry weight but can vary widely around the world (Mandal and Suzuki, 2002). Contamination by heavy metals is a serious problem in some developing countries. Sepetiba Bay, a semi-enclosed coastal lagoon in Brazil, had sediment arsenic concentrations up to 80,000 µg/g in an area adjacent to a plant that produced zinc and cadmium (Moreira, 1996). The literature regarding the cycling and effects of arsenic in coastal marine environments has been reviewed by Sanders *et al*. (1994).

It has recently been suggested that the wood preservative, chromated copper arsenate (CCA), commonly used in dock pilings and bulkheads, can be toxic to estuarine organisms. Wendt *et al*. (1996) measured arsenic in surface sediments from creeks with high densities of docks and from nearby reference creeks with no docks. The average concentrations in the sediments ranged from 14–17 µg/g throughout the study area, which is within the range of natural background levels.

4.4 Air

Arsenic naturally occurs in soil and is present in the atmosphere as airborne dust. It is also emitted

from volcanoes and in areas of dormant volcanism. Arsenic naturally occurs in seawater and vegetation and is released into the atmosphere in sea salt spray and forest fires (ATSDR, 2005). Smelting of nonferrous metals, burning of coal, oil and wood combustion, and the use of arsenicals as pesticides are major anthropogenic sources of airborne arsenic. Chilvers and Peterson (1987) estimated global natural and anthropogenic arsenic emissions to the atmosphere as 73,500 and 28,100 metric tons per year, respectively. Copper smelting and coal combustion accounted for 65% of anthropogenic emissions. There is evidence that anthropogenic emissions from smelters are lower than they had been in the 1980s. The National Air Toxics Assessment reported that total anthropogenic emissions for arsenic compounds in the United States in 1996 were 355 tons/year (EPA, 2005c).

Arsenic in ambient air is usually a mixture of particular arsenite and arsenate (EPA, 2005). Mean levels in ambient air in the United States have been reported to range from <1–3 ng/m^3 in remote areas and from 10–20 ng/m^3 in urban areas. The 133 stations of the U.S. National Air Sampling Network reported in 1964 that the annual average concentrations of arsenic in air ranged from nondetectable (<0.01 µg/m^3–0.75 µg/m^3) (Sullivan, 1969). The overall average was approximately 0.02 µg/m^3. The highest value (1.4 µg/m^3) was a quarterly average in El Paso, Texas, where a large copper smelter is located. Daily mean concentrations of up to 1.6 µg/m^3 have been found near a smelter in Romania (Gabor and Coldea, 1977).

Vondracek (1963) reported a summer mean air concentration of 0.07 µg/m^3 and a winter mean of 0.56 µg/m^3 in Prague, Czechoslovakia, probably because of the use of coal with a high arsenic content for heating purposes.

Inorganic arsenic, primarily as arsenic trioxide, has been reported from fossil fuel and industrial processes (Pacyna, 1987). Arsenic trisulfide has also been reported from coal combustion, organic arsines from oil combustion, and arsenic trichloride from refuse incineration.

Measurements of arsenic concentrations in cases of occupational exposure have been rare. Patty (1962) identified the highest exposure in insecticide manufacturing was usually found in the mixing, screening, drying, bagging, and drum-filling operations. He reported concentrations of arsenic in air ranging from 0.5–45 mg/m^3 during these operations. High exposure to arsenic fumes and dusts may occur in smelting industries. Lundgren (1954) reported an average concentration ranging between 0.06–2 mg/m^3 in a Swedish copper smelter. In a Japanese copper refinery, arsenic concentrations in the air of nine workshops were measured at 0.006–0.011 mg/m^3 under normally ventilated conditions and 0.08–0.19 mg/m^3 under unventilated conditions. Average arsenic concentrations in air of 0.001–0.012 mg/m^3 were found around furnaces in copper and ferronickel smelters (Kodama *et al*., 1976).

When the airborne arsenic in a U.S. copper smelter was measured during the years 1943–1965, 8-hour average levels in the arsenic roaster, arsenic refinery, and main flue ranged between 6.9 and 20 mg/m^3 (Welch *et al*., 1982). Enterline and Marsh (1982) summarized some reports of airborne arsenic concentrations in the area around an arsenic plant in the United States for the period 1938–1957. They found that the levels varied but were very high, particularly before 1951 (e.g., 0.8–62.4 mg/m^3 in 1938). All levels were very high in relation to the current permissible exposure level of 0.01 mg/m^3.

Substantial exposure to airborne arsenic may also take place in work with arsenic-containing insecticides and wood preservatives. Handling, including burning, of preserved wood could constitute a risk for the general population as well (Peters *et al*., 1984). Nygren *et al*. (1992) investigated the occupational exposure to airborne dust, chromium, copper, and arsenic in six joinery shops in Sweden where impregnated wood was used for their production. The mean airborne concentration of arsenic around various types of joinery machines ranged from 0.54–3.1 µg/m^3.

Workers at three microelectronics industries where gallium arsenide was used have been reported to have exposure at or above the OSHA action level for arsenic of 5 µg/m^3, with a maximum exposure of 8.2 µg/m^3 (Sheehy and Jones, 1993). The toxicological literature and carcinogenic potential of gallium arsenide (GaAs) have been recently reviewed by IARC (2006), and GaAs was identified as a Class I human carcinogen on the basis of the inorganic arsenic component.

The current OSHA PEL is 0.010 mgAs/m^3 (TWA). The ACGIH TLV value is 0.01 mgAs/ m^3 (TWA) (NIOSH, 2006a). For arsine, the OSHA PEL is 0.05 mgAs/m^3 (TWA). ACGIH TLV for arsine is 0.05 mg/m^3 (NIOSH, 2006b).

4.5 Tobacco

Arsenic in tobacco originates from insecticides, especially lead arsenate. In the past, the arsenic content of various brands of American cigarettes averaged 12.6 µg/cigarette in 1932–1933 and increased to 42 µg/cigarette in the early 1950s (Satterlee, 1956). After the ban of arsenical pesticides, the maximum arsenic levels were reduced to 3 µg/g (Kraus *et al*., 2000). An international literature survey reports arsenic yields of 0–1.4 µg/cigarette from mainstream (inhaled) cigarette

smoke (Smith *et al*., 1997). Arsenic emission of 0.015–0.023 µg/cigarette have been measured for sidestream smoke from a burning cigarette (Landsberger and Wu, 1995). In Japan, cigarettes have been reported to contain less than 1 µg/g (Maruyama *et al*., 1970).

5 METABOLISM

This section regarding arsenical metabolism is focused on historical descriptive *in vivo* information related to biological monitoring for arsenic in humans and animal models. Section 5.6.1 that follows reviews more mechanistic studies of arsenical metabolism and the relationships between formation of methylated arsenic species and mechanisms of toxicity at the cellular and molecular levels of biological organization.

5.1 Absorption

5.1.1 Inhalation

Airborne arsenic is usually in the form of As_2O_3. More than 23% of the particles (by particle count) in samples of arsenic-polluted air were reported to be larger than 5.5 µm (Pinto and McGill, 1953). Particles of this nature will undergo a high deposition in the upper respiratory tract. Because of deposition in the nasopharyngeal region and because of mucociliary clearance in the airways, much of the inhaled arsenic may be swallowed and then absorbed from the gastrointestinal tract. Analytical data on fly ash emitted from a coal-fired power plant have indicated a pronounced concentration of arsenic in particles of 1.1–2.1 µm diameter (Davison *et al*., 1974).

Very few data are available on the deposition and absorption of inhaled arsenic in humans. In eight terminal lung cancer patients, Holland *et al*. (1959) found that deposition was estimated to be approximately 40%, of which 75–85% was absorbed; thus, the overall absorption (expressed as a percentage of inhaled arsenic) was approximately 30–34%. Great caution must be exercised in relating these data to healthy humans. In workers exposed to arsenic trioxide dusts in smelters, the amount of arsenic excreted in the urine (the main route of excretion) was approximately 40–60% of the estimated inhaled dose (Pinto *et al*., 1976; Vahter *et al*., 1986). Absorption of arsenic trioxide dusts and fumes (assessed by measurement of urinary metabolites) correlated with time-weighted average arsenic air concentrations from personal breathing zone air samplers (Offergelt *et al*., 1992). In contrast, arsenic sulfide and lead arsenate were cleared slowly (Marafante and Vahter, 1987), indicating that the rate of absorption may be lower if the inhaled arsenic is in a highly insoluble form.

5.1.2 Ingestion

Both human and animal data indicate that more than 90% of an ingested dose of dissolved inorganic trivalent or pentavalent arsenic is absorbed from the gastrointestinal tract (Bettley and O'Shea, 1975; Charbonneau *et al*., 1978; Crecelius, 1977b; Marafante *et al*., 1981; Pomroy *et al*., 1980; Vahter and Norin, 1980). The most direct evidence is from a study that evaluated the 6-day elimination of arsenic in healthy humans who were given water from a high-arsenic sampling site and that reported approximately 95% absorption (Zheng *et al*., 2002). In contrast, ingestion of arsenic triselenide did not lead to a measurable increase in urinary excretion (Mappes, 1977), indicating that gastrointestinal absorption may be much lower if highly insoluble forms of arsenic are ingested. Organic arsenic compounds in seafoods are also readily absorbed (< 80%) from the gastrointestinal tract, both in animals and humans (Charbonneau *et al*., 1978; Marafante *et al*., 1984; Munro, 1976; Tarn *et al*., 1982; Vahter *et al*., 1983). On the basis of urinary excretion studies in volunteers, it seems that both MMA and DMA are well absorbed (at least 75–85%) across the gastrointestinal tract (Buchet *et al*., 1981a). Animal experiments indicate that growth promoters, such as arsanilic acid, are absorbed to only 15–40% (Calvert, 1975).

In the case of arsenic trioxide, which is only slightly soluble in water, the gastrointestinal absorption will depend on factors such as particle size and pH of the gastric juice.

5.1.3 Skin Absorption

Systemic toxic effects have resulted from occupational accidents where arsenic acid or arsenic trichloride have been splashed on workers, indicating that the skin is a possible route for absorption of arsenic (Garb and Hine, 1977). However, no quantitative studies were located on absorption of inorganic arsenicals in humans after dermal exposure. Percutaneous absorption of ^{73}As as arsenic acid has been measured in skin from cadavers (Wester *et al*., 1993). Labeled arsenic was applied to skin in diffusion cells, and transit through the skin into receptor fluid measured. After 24 hours, 0.93% of the dose passed through the skin, and 0.98% remained in the skin after washing. Dermal absorption of arsenic has been measured in Rhesus monkeys (Wester *et al*., 1993). After 24 hours, 6.4% of ^{73} As as arsenic acid was absorbed systemically.

5.2 Transport and Distribution

After absorption by the lungs or the gastrointestinal tract, arsenic is transported by the blood to other parts of the body. After exposure to arsenite or arsenate, most arsenic is cleared from the blood at a very high rate (Charbonneau *et al*., 1978; Marafante *et al*., 1981; Mealey *et al*., 1959). In rats, however, a substantial part of the absorbed arsenic is accumulated in the red blood cells, where it is firmly bound to hemoglobin (Hisanaga, 1982; Marafante *et al*., 1982). Data from a number of investigators indicate that the main form of arsenic bound to rat hemoglobin is dimethylarsinic acid (Lerman and Clarkson, 1983; Rowland and Davies, 1982; Vahter *et al*., 1984). As a consequence of the efficient biotransformation of both trivalent and pentavalent inorganic arsenic *in vivo* (see later), the tissue partitioning is somewhat similar for the different exposure forms. In man, as well as in most animal species, exposure to either arsenite or arsenate leads to an initial accumulation in the liver, kidneys, and lungs (Bertolero *et al*., 1981). Tissue analysis of organs taken from an individual after death from ingestion of 3 g of arsenic (in the form of arsenic trioxide) showed a much higher concentration of arsenic in liver (147 μg/g) than in kidney (27 μg/g) or muscle, heart, spleen, pancreas, lungs, or cerebellum (11–12 μg/g) (Benramdane *et al*., 1999). Small amounts were also found in other parts of the brain (8 μg/g), skin (3 μg/g), and hemolyzed blood (0.4 μg/g). The clearance from these tissues is, however, rather rapid, and a long-term retention of arsenic is seen in hair, skin, squamous epithelium of the upper gastrointestinal tract, epididymis, thyroid, lens, and skeleton (Lindgren *et al*., 1982). Human autopsy data have also shown high arsenic levels in hair, nails, teeth, bone, and skin (Kadowaki, 1960; Liebscher and Smith, 1968; Sumino *et al*., 1975; Yukawa *et al*., 1980).

Arsenic passes through the placenta in hamsters after intravenous injections of high doses of sodium arsenate (Ferm, 1977). Kadowaki (1960) reported an increase in arsenic levels in the human fetus as pregnancy progressed. The arsenic levels in bone, liver, skin, and brain were 2–4 times higher in newborn babies than in 7-month-old fetuses. In a population of Andean women exposed to high concentrations (about 200 ppb) of inorganic arsenic in drinking water, concentrations of arsenic in breast milk ranged from about 0.0008–0.008 ppm (Concha *et al*., 1998).

Although the distribution pattern after exposure to different chemical forms of inorganic arsenic is similar, recent studies in mice and rabbits have shown that arsenite gives rise to higher concentrations than arsenate in most tissues (Lindgren *et al*., 1982; Vahter and Marafante, 1983; Vahter and Norin, 1980). Only the kidneys and the skeleton had higher levels in the arsenate-treated than in the arsenite-treated animals. In mice, radiolabel from orally administered ^{74}As was widely distributed to all tissues, with the highest levels in skin, kidney, and liver (Hughes *et al*., 2003). The major part of injected radioactive arsenic accumulating in the tissues of mammals has been found in the protein fraction (Marafante *et al*., 1981). Trivalent arsenicals can combine chemically with sulfhydryl groups, which may explain the inhibition of enzymatic reactions (Webb, 1966), as well as the accumulation in keratin-rich tissues such as hair, skin, and epithelium of the upper gastrointestinal tract.

It has also been found that the toxic effects of arsenic can be reversed by parenteral administration of thiol compounds of the reduced type (e.g., glutathione, cysteine, and BAL (British antilewisite) (Peters, 1955; Vallee *et al*., 1960; Webb, 1966). Arsenate, on the other hand, may interfere with metabolic phosphorylation reactions, probably because of its chemical similarities with phosphate (Fowler *et al*., 1975; Mitchell *et al*., 1971). Such chemical similarities can also explain the accumulation of arsenate in the skeleton (Lindgren *et al*., 1982; 1984).

When particles of inorganic arsenic compounds such as arsenic trioxide, calcium arsenate, and arsenic trisulfide were intratracheally instilled into the lung of rat or hamster, arsenic trioxide and arsenic trisulfide rapidly disappeared from the lung decreasing to a level of approximately 0.1–1% of the given dose over a time period of 24 hours to 1 week. However, half the given dose of calcium arsenate given to Syrian Golden hamsters was retained in the lung for 1–5 weeks (Inamasu *et al*., 1982; Pershagen *et al*., 1984).

In hamsters, MMA and DMA formed *in vivo* by methylation of inorganic arsenic seem to be distributed to all tissues (Takahashi *et al*., 1988; Yamauchi and Yamamura, 1985). This is supported by studies in animals in which MMA and DMA were found in all tissues after acute oral doses (Yamauchi and Yamamura 1984; Yamauchi *et al*., 1988). Studies on the tissue distribution of arsenobetaine in mice and rabbits have shown that this arsenical is rapidly cleared from most tissues (Vahter *et al*., 1983). The longest retention was observed in cartilage, testes, epididymis, and muscles. Animal data indicate that arsenocholine, like choline, may be incorporated into phospholipids (Marafante *et al*., 1984).

5.3 Biotransformation

The biotransformation of inorganic arsenic is complicated by the different metabolites induced and by differences among species. Two basic processes

are involved: (1) reduction/oxidation reactions that intervert As(III) and As(V), and (2) methylation reactions, which convert arsenite to MMA and DMA. The resulting series or reactions result in the reduction of inorganic arsenate to arsenite (if necessary), methylation to MMA(V), reduction to MMA(III), and methylation to DMA(V). These processes seem to be similar whether exposure is by the inhalation, oral, or parenteral route.

That trivalent inorganic arsenic is oxidized *in vivo* is indicated by the finding of pentavalent arsenic in urine of both animals and humans exposed to arsenite (Bencko *et al*., 1976; Mealey *et al*., 1959; Vahter and Envall, 1983). Also, the opposite reaction (i.e., the reduction of arsenate to arsenite) has been demonstrated in mice and rabbits (Vahter and Envall, 1983). Both arsenite and arsenate, after reduction to arsenite (McBride *et al*., 1978), are methylated *in vivo*. The major metabolite in urine of experimental animals exposed to inorganic arsenic is dimethylarsinic acid (Bertolero *et al*., 1981; Charbonneau *et al*., 1979; Inamasu, 1983; Tam *et al*., 1978; Vahter, 1981). The guinea pig, marmoset, and tamarin monkey do not methylate inorganic arsenic (Healey *et al*., 1998; Vahter and Marafante, 1985, Vahter *et al*., 1982; Zakharyan *et al*., 1996). Exposure of humans to either arsenites or arsenates results in increased levels of inorganic As(III), As(V), MMA, and DMA in urine (Aposhian *et al*., 2000a, 2000b). In man, the urinary excretion at low-dose levels consists of approximately 20–25% inorganic arsenic, 15–25% methylarsonic acid, and 40–75% dimethylarsinic acid (Buchet *et al*., 198l**a;** Crecelius, 1977b; Hopenhayn *et al*., 2003; Loffredo *et al*., 2003; Mandal *et al*., 2001; Smith *et al*., 1977; Tam *et al*., 1979; Yamauchi and Yamamura, 1979a,b). Methylation efficiency decreases with increasing dose levels (Mahieu *et al*., 1981; Vahter, 1981**).** The substrate for methylation is As(III), and As(V) is not methylated unless it is first reduced to As(III) (Buchet and Lauwerys 1985, 1988; Lerman *et al*., 1983). Reduction of arsenate to arsenite can be mediated by glutathione (Menzel *et al*., 1994). The main site of methylation seems to be the liver, where the methylation process is mediated by methyltransferases that use S-adenosylmethionine as cosubstrate (Buchet and Lauwerys, 1985; 1988). The relative proportions of As(III), As(V), MMA, and DMA in urine can vary, depending on the chemical administered, time after exposure, dose level, and exposed species. Arsenic derived from exposure to particles of GaAs or InAs is methylated in manner similar to that of As(III) (Yamauchi *et al*., 1986; 1992).With relatively constant exposure levels, these metabolic proportions remain similar over time (Concha *et al*., 2002) and seem to be similar among family members (Chung *et al*., 2002). It is expected that measurements of MMA and DMA in urine will provide useful information for risk assessment purposes once the relationships between *in vivo* formation of these major metabolites of inorganic arsenic and risk of toxicity or cancer are more fully delineated.

Arsenobetaine is apparently not biotransformed *in vivo* but excreted as such mainly in urine (Cannon *et al*., 1981; Vahter *et al*., 1983). Arsenocholine is, to a great extent, oxidized to arsenobetaine (Marafante *et al*., 1984).

Cacodylic acid and arsanilic acid are not converted to inorganic arsenic *in vivo* (Buchet *et al*., 1981a; Marafante *et al*., 1987; Stevens *et al*., 1977; Vahter *et al*., 1984; Yoshida *et al*., 2001).

5.4 Excretion

The major route of excretion after exposure to inorganic arsenic is through the kidneys. Only a low percent is excreted in feces (Apostoli *et al*., 1999; Bertolero *et al*., 1981; Ducoff *et al*., 1948; Hunter *et al*., 1942; Mealey *et al*., 1959). The rate of excretion in urine varies, depending on the chemical form of arsenic and the species exposed. The primary forms of arsenic found in the urine of inhalation-exposed humans are DMA and MMA, with inorganic arsenic making up <25% of the total urinary arsenic (Apostoli *et al*., 1999). In humans exposed to a single low dose of arsenite, approximately 35% was excreted in the urine over a period of 48 hours (Buchet *et al*., 1980; 1981a**).** At low exposure levels, urinary arsenic levels generally increase linearly with increasing arsenic intake (Calderon *et al*., 1999). Rabbits exposed to a similar low dose excrete approximately 80% (Bertolero *et al.,* 1981), mice as much as 90% (Vahter, 1981), and marmoset monkeys as little as 15% within the same period of time (Vahter *et al*., 1982). In the case of continuous human intake over a few days, 60–70% of the daily dose is excreted in urine (Buchet *et al*., 1981b; Mappes, 1977). After exposure to arsenate, the limited human data available indicate a rate of excretion similar to that for arsenite (Pomroy *et al*., 1980; Yamauchi and Yamamura, 1979b). Animal data indicate a somewhat faster excretion for arsenate than for arsenite (Charboneau *et al*., 1978; Hollins *et al*., 1979; Vahter, 1981).

During lactation, a very small percent of ingested arsenic may also be excreted in the breast milk (Concha *et al*., 1998a). Other routes of elimination of inorganic arsenic, although of less importance, include skin, hair, nails, and sweat (Molin and Wester, 1976).

Studies in humans indicate that ingested MMA and DMA are excreted mainly in the urine (75–85%), and this occurs mostly within 1 day (Buchet *et al*., 1981a). After ingestion, by humans, of organic arsenic

compounds present in seafoods, 50–80% of the dose was eliminated in the urine within 2 days (Tam *et al*., 1982). A similar rate of excretion was seen in rabbits exposed to arsenobetaine (Vahter *et al*., 1983).

Elimination of organic arsenic compounds used as drugs was noted by Hogan and Eagle (1944). They found that trivalent organic arsenicals were eliminated at a much slower rate than the pentavalent arsenicals in the urine of rabbits. More recent studies by Lin *et al*. (2005) reported that the tissue-specific distribution and elimination rates for inorganic and methylated arsenic species in rabbits after a single acute administration of arsenic trioxide (AsIII) over a dose range of 0.2–1.5 mgAs/kg for up to 30 and 60 days. The elimination pattern was nonlinear, and the liver and lung showed the highest concentrations of DMA, which was the major metabolite measured, on day 30. Similar organ-specific differences were observed in B6C3F1 mice after acute oral administration of arsenate (AsV). As with the rabbits, DMA was the predominant methylated species at later time points (Kenyon *et al*., 2005).

5.5 Biological Half-Time

Animals exposed to arsenic through inhalation or drinking water will have increased levels in tissue during the first weeks or months, but the levels will decrease even if the exposure is prolonged (Bencko and Symon, 1969; 1970; Hisanaga, 1982; Katsura, 1958). It has been suggested that the decrease of arsenic concentrations in internal organs, such as the liver, after long-term exposure may be due to a higher rate of excretion. Changes in tissue retention in the case of chronic exposure should be considered when evaluating biological half-times for arsenic compounds.

The biological half-time of arsenic in rats after a single exposure is long (approximately 60 days) because of the accumulation of arsenic in the blood. In humans and in other animals, the major part of the arsenic is eliminated at a much higher rate. Generally, whole body clearance is fairly rapid, with half-times of 40–60 hours in humans (Buchet *et al*., 1981b; Mappes, 1977). Three different phases of urinary excretion have been demonstrated in man after a single intravenous injection of radiolabeled arsenite, having half-times of approximately 2 hours, 8 hours, and 8 days, respectively (Mealey *et al*., 1959). After oral intake of radiolabeled pentavalent arsenic, 66% was excreted with a half-time of 2.1 days, 30% with a half-time of 9.5 days, and 3.7% with a half-time of 38 days in the three phases (Pomroy *et al*., 1980).

As stated previously, the major part of arsenic in ingested seafood is eliminated rapidly through the kidneys. The biological half-time for these organic compounds can be estimated to be less than 20 hours. Studies in humans indicate that ingested MMA and DMA are excreted mainly in the urine (75–85%), and this occurs mostly within 1 day (Buchet *et al*., 1981a).

The WHO/IPCS (2007) has examined a number of issues related to the roles of elemental speciation in human health risk assessment.

5.6 Mechanisms of Arsenical Toxicity

5.6.1 Mechanisms of Arsenical Metabolism and Toxicity

Arsenical inhibition of cellular respiration as a primary cause of cell death has been appreciated for a number of decades (ATSDR, 2005; NRC, 1999; 2001), and the methylation of inorganic arsenic to form methylated species such as methyl arsenic acid (MMA) and dimethylarsinic acid (DMA) has also been studied for a number of decades (Braman and Foreback, 1973; Challenger, 1945; 1951). In recent years, scientific attention has been focused on understanding the relationships that must exist between the *in vivo* methylation of inorganic arsenic and mechanisms of arsenical toxicity. This issue is of great practical importance, because the methylation of inorganic arsenic was originally thought to be a detoxification pathway, but more recent studies (NRC, 1999) have suggested that highly toxic reactive oxygen species (ROS) generated by MMA (III) and DMA (III) mitochondrial toxicity may also play an important role in both cellular toxicity and carcinogenicity of this element. The increased presence of MMA (III) in the urine of a Mexican population exposed to inorganic arsenic in drinking water on a chronic basis was found to be a basis for identifying subpopulations at greater risk for arsenic-induced toxicity and cancer (Steinmaus *et al*., 2005a,b; Valenzuela *et al*., 2005). These studies also reported a strong linkage between dietary intakes of protein and other nutrients and the ability to methylate arsenicals such that persons with low dietary intakes of these nutrients would be more susceptible than others to arsenic-induced cancers. The central role of oxidative stress induced by arsenic in cell death via apoptosis or necrosis and carcinogenicity via oxidative damage to cellular DNA cannot be underestimated, because it may permit attenuation of these deleterious cellular effects through nutritional interventions and stimulation of cellular antioxidant systems.

5.6.2 Metabolism

This section regarding arsenical metabolism is focused on reviewing mechanistic linkages between mechanisms of inorganic arsenical methylation and mechanisms of toxicity at the cellular and molecular levels of biological organization.

5.6.2.1 Arsenical Reduction/Oxidation

A key step in the methylation pathway for inorganic arsenicals is the reduction and oxidation of the arsenic between the ±3 and +5 oxidation states during the various steps in the methylation pathway. Studies by Styblo and Thomas (1995) reported the inhibition of glutathione reductase by arsenoglutathione *in vitro* and demonstrated that reduced glutathione (GSH) was required for the *in vitro* methylation of arsenic.

More recent studies by Nemeti and Gregus (2005) demonstrated reduction of As 5+ to As3+ via human erythrocyte lysates and rat liver cytosol through an arsenic reductase, which required glycolytic substrates, GSH, and nicotinamide diamide (NAD) for the activity of the enzyme. Zakharyan *et al*. (2005) studied the interaction of selenite with the omega class human glutathione transferase, which is an identical protein with MMA 5+ reductase, which catalyzes the reduction of As (V), MMA (V), and DMA(V). They found that selenite acted as a noncompetitive inhibitor of this enzyme. The tissue dosimetry of pentavalent and trivalent MMA was studied by Hughes *et al*. (2005), and they found that a much greater percentage of the administered dose of MMA (III) was converted to DMA than after administration of MMA (V).

5.6.2.2 Arsenical Methylation

The main characteristics of the pathway for inorganic arsenic methylation have been appreciated since the pioneering work by Challenger in the 1940s (1945). The pathway involves a series of reductions and oxidation steps which interconvert As 5+ to As 3+ to As 5+ during the methylation steps, ultimately resulting in the formation of MMA (V) and DMA (V). The further metabolism and excretion of DMA and trimethylarsine oxide has been extensively studied in rodents by Yamauchi and coworkers (Yamauchi and Yamaura, 1984; Yamauchi *et al*., 1989; 1990). The enzyme responsible for reduction of AsV to AsIII has not been identified, but a glutathione (GSH) and NAD-dependent AsV reductase activity that is linked to glycolysis has been recently identified in rat liver cytosol and human erythrocyte lysate by Nemeti and Gregus (2005). During this metabolism MMA (III) and DMA (III) are also formed, and MMA(III) and DMA(III) in particular have been demonstrated to be a highly toxic and reactive chemical species (Mass *et al*., 2001). The kinetics of *in vitro* arsenic methylation in mouse hepatocytes have been recently reported by Kedderis *et al*. (2006), who found a concentration-dependent formation of MMA(III) up to a concentration of about 2 μmol/L As(III) followed by a decline at higher concentrations. They also suggested a role for a glutathione complex–based mechanism for this methylation pathway. This hypothesis is consistent with observations from a number of other laboratories (Chang *et al*., 1991; Csanaky *et al*., 2003; Hayakawa *et al*., 2005; Hirano *et al*., 2004; Kala *et al*., 2004; Kobayashi *et al*., 2005; Waters *et al*., 2004). The formation of arsenic–glutathione complexes has also been reported (Cui *et al*., 2004; Suzuki *et al*., 2001) to play important roles in the biliary and urinary excretion of arsenic in rats.

In recent years, an arsenic methyl transferase (AsMT) has been identified (Drobna *et al*., 2005; Li *et al*., 2005; Wood *et al*., 2006) and demonstrated to exist as a number of polymorphic forms (Wood *et al*., 2006). Zakharyan *et al*. (2005) studied the interactions of arsenic species with selenite, glutathione, and the omega class of human glutathione transferase. They found that human monomethylarsenate reductase and human glutathione S- transferase omega 1-1 were identical proteins and that selenite inhibition of the MMA (V) was reversed by dithiothreitol but not GSH, which is the required substrate of this enzyme. They found that three selenium atoms and three GSH molecules were bound to the monomeric form of the enzyme. This enzyme and its demonstrated polymorphic forms may well explain observed differences in methylation patterns for both animals and humans (NRC, 1999) and differences in susceptibility to a variety of toxic effects including various cancers (Smith *et al*., 2005), hepatomegally (Guha Mazumder *et al*., 2005), and heme and porphyrin metabolism (Fowler *et al*., 2005; Garcia-Vargas *et al*., 1994; Ng *et al*., 2005; Woods and Fowler, 1978; Yamauchi *et al*., 1998).

5.6.3 Mechanisms of Arsenical Toxicity

5.6.3.1 Mitochondrial Inhibition and Oxidative Stress

Arsenical inhibition of mitochondrial respiration supported by NAD-linked substrates that use the lipoic acid cofactor for the pyruvate dehydrogenase complex is regarded as a primary mechanism by which arsenicals produce cell injury/cell death and cancer (Fowler and Woods, 1979; Fowler *et al*., 1979; NRC, 1999). Inorganic arsenicals, monomethyl arsenic acid, and dimethyl arsenic acid have each been shown to produce oxidative stress by means of inhibition of mitochondrial respiration resulting in the formation of reactive oxygen species (ROS), which may cause DNA mutations and ultimately play a role in the development of cancer (Liu *et al*., 2005). In addition, either acute or chronic exposure to arsenicals had been shown to produce a characteristic porphyrinuria pattern in experimental animals (Conner *et al*., 1993; 1995; Fowler *et al*., 2005;

Woods and Fowler, 1978) and humans (Garcia-Vargas *et al.*, 1994; Garcia-Vargas and Hernandez-Zavala, 1996; Ng *et al*., 2002; 2005; Yamauchi *et al*., 1998) dominated by elevated levels of uroporphyrins with lesser amounts of coproporphyrin. This pattern is, hence, conserved across species and may serve as a useful biomarker for early arsenical toxicity to target organs such as the liver and hematopoietic system. It should also be noted that porphyrins are also toxic and capable of catalyzing formation of ROS, thus exacerbating direct arsenical toxicity.

5.6.3.2 Reactive Oxygen Species

The reactive oxygen species generated by inhibition of mitochondrial respiratory function and ATP depletion (Chen *et al*., 1987) produce oxidative stress in a number of major organ systems (Flora *et al*., 2005; Li *et al*., 2002; Ramos *et al*., 1995) and elicit a number of cellular responses, including up-regulation of glutathione synthesis (Flora *et al*., 2005), induction of the major stress protein families (Lee *et al*., 2005; Madden *et al*., 2002, Sen *et al*., 2005), and altered regulation of signaling pathways involving nitric oxide synthetase (eNOS) (Tsou *et al*., 2005), and nuclear factor kappa-B and activator protein-1 (Felix *et al*., 2005). These various cellular responses to arsenical-induced oxidative stress are discussed later in greater detail.

5.6.3.3 Antioxidant Cellular Defense Systems

5.6.3.3.1 Glutathione A major intracellular antioxidant is reduced glutathione (GSH), which exists in many cell types at millimolar concentrations (Reed, 2001). Increased production of this small SH-rich molecule may occur by induction of glutathione synthetase in response to ROS mediated oxidative stress (Reed, 2001). Glutathione depletion studies using L-butathionine sulfoximine (BSO) have produced increased sensitivity among arsenic-exposed cells exposed to arsenic (III) *in vitro* (Maiti and Chatterjee, 2001; Shimizu *et al*., 1998), indicating the importance of this intracellular antioxidant molecule in mediating arsenical toxicity in target cell populations.

5.6.3.4 Stress Proteins/Heat Shock Proteins (HSPs 25/27, 32, 60, 70, 90)

Arsenicals are known to induce a number of the major stress protein families presumably as a consequence of ROS formation with attendant oxidation of protein side chains and the onset of proteotoxicity. Cells of similar nature vary in their a susceptibility to arsenicals in part because of the ability to produce stress proteins as demonstrated by Madden *et al*. (2002), who showed that rat and human kidney cell lines varied in their sensitivity as a function of 60-, 70-, and 90-kDa stress protein expression patterns. For both cell lines, toxicity occurred once the capacity to produce the stress proteins was exceeded at elevated dose levels. Similar results have been reported for hsp70 in lung cells (Han *et al*., 2005; Lau *et al*., 2004) and in human epidermal cells (Lee *et al*., 2005). Similar responses have been observed in female rat urothelial cells after *in vivo* exposure to DMA for 28 days (Sen *et al*., 2005) and the human UROtsa cell line exposed to arsenite (Rossi *et al*., 2002). Arsenite induction of hsp70 has been consistently observed by a number of investigators in a variety of cell types, including hepatoma cell lines (Farzaneh *et al*., 2005; Gottschlag *et al*., 2006), human MCF-7 breast cancer cells (Barnes *et al*., 2002), human lung fibroblasts (HEL cells) or human leukemia cells (THP-1 cells) (Rossner *et al*., 2003), rat oligodendrocytes (Goldbaum *et al*., 2001), and chick embryos (Papacanstantinou *et al*., 2003).

In addition to the major stress protein families, the formation of ROS also induces the SH-rich protein metallothionein (MT), which also has antioxidant properties (Gottschlag *et al*., 2006; Liu *et al*., 2001). It should also be noted that studies by Shimizu *et al*. (1998) reported that zinc induction of MT exerted no discernible protective effects on arsenical toxicity, so the potential mechanisms of protection against arsenical toxicity may be complex and system dependent. The lower molecular mass hsps 25(rat)/27(human) have also been reported to be induced by arsenite exposure in mouse kidney podocyte cultures (Eichler *et al*., 2005; 2006) seem to also play major roles in roles in the regulation of apoptosis via the extrinsic caspase 8 pathway (Eichler *et al*., 2006). It is interesting to note that arsenic (III) induction of the stress protein response for hsp 27 and hsp 70 has been shown to be regulated by reducing agents such as dithioerythritol (Kato *et al*., 1997) and by reduced levels of glutathione (GSH) in arsenic-exposed cells (Ito *et al*., 1998), indicating the strong linkage between arsenic-induced oxidative stress and stress protein induction patterns. In addition, arsenite exposure of cells has also been well documented to induce hsp32 (heme-oxygenase-1), which is the rate-limiting enzyme in the heme degradative pathway (Gong *et al*., 2002; Lee *et al*., 2005) and plays a major role in the recycling of heme iron.

5.6.3.5 Altered Cell Signaling Pathways

Arsenic-induced alterations of the blood vasculature leading to the development of "Blackfoot disease" are common findings among persons exposed to arsenic in drinking water. Studies by Tsou *et al*. (2005) reported down-regulation of nitric oxide synthetase (eNOS), supporting the hypothesis that alteration of eNOS function may play an important role in mediating this

clinically important outcome. Studies by others (Wu *et al*., 1999; 2002) demonstrated a number of alterations in cell signaling pathways, including the MAP kinases and extracellular regulated kinase (ERK) and Ras via the epidermal growth factor (EGF) receptor pathway in a human airway epithelial cell line (BEAS-2B). Similar alterations in the c-jun/AP-1 and NFkappaB signal transduction systems with concomitant alterations in the expression of a number of the major stress protein families (hsp32 and hsp 72) were observed by Wijeweera *et al*. (2001) in precision-cut rat lung slices.

5.6.3.6 Mechanisms of Cell Death

5.6.3.6.1 Apoptosis Arsenite at low *in vitro* dose levels has been demonstrated to produce apoptosis in rat thymocytes (Bustamente *et al*., 1997). Subsequent studies (Tian *et al*., 2005) demonstrated that As_2O_3 induces opening of the mitochondrial membrane permeability transition pore with attendant release of cytochrome *c* and intramitochondrial calcium stores. Other investigators (Zhang *et al*., 2003; Zheng *et al*., 2005) have shown that As_2O_3 also induces Bax activation in hematopoietic cells secondary to ROS formation. In agreement with the roles of ROS in mediating arsenical induction of apoptosis, administration of antioxidants such as ascorbic acid and alpha-tocopherol have been shown (Ramanathan *et al*., 2005) to reduce TNF-alpha levels and activation of the caspase cascade system. The value of arsenicals in mediating apoptosis has been explored in relation to the treatment of various cancers such as acute megakaryocytic leukemia (Lam *et al*., 2005) or promyelocytic leukemia (Zheng *et al*., 2005), where As_2O_3 has been shown to activate a number of central factors in the apoptotic pathway. Similar delays in recovery of leukocytopenia and neutropenia during acute promyelocytic leukemia have been reported after treatment of patients with As_2O_3 relative to treatment with all-trans retinoic acid (Shinjo *et al*., 2005). On the other hand, long-term, low-level exposure of cultured human keratinocytes to arsenite has been shown (Pi *et al*., 2005) to produce a generalized resistance to induction of apoptosis, which may provide a role for arsenic as a cocarcinogen with UV light in skin cancer as discussed later. A number of other investigators have reported similar arsenic-induced alterations of apoptosis regulation in other cell types such as neuronal (Jou *et al*., 2004; Namgung and Xia, 2000) and lymphoma cell lines (Muscarella and Bloom, 2002) and in developing mouse embryos (Liu *et al*., 2003). Interestingly, the heat shock protein 70 (hsp70) discussed earlier has been reported to protect against arsenic-induced apoptosis (Mosser *et al*., 2000) at a step in apoptotic pathway after cytochrome *c* release and before caspase 3 activation (Li *et al*., 2000).

5.6.3.7 Necrosis

As with many toxic metals, cellular necrosis is usually observed at high dose levels after administration of arsenicals (Shen *et al*., 2006) such that there is strong dose dependency as to whether apoptosis or necrosis is observed after exposure to this agent.

5.6.3.8 Cancer

In recent years, there have been many detailed reports on the diagnosis, molecular markers, and possible underlying mechanisms of arsenic-induced cancers in various organ systems. As with the mechanisms of cell injury and apoptosis discussed previously, the generation of oxidative stress from mitochondrial production of ROS seems to be a central feature for initiation of cancers (NRC, 1999). Yu *et al*. (2006) reviewed the arsenic-induced skin cancers and the probable combined roles of arsenic exposure and UVB radiation in producing skin lesions. Kuo *et al*. (1997) examined the possible roles of overexpression of the p53 gene in skin cancer and concluded that overexpression of this gene was not a prerequisite for development of skin cancer. Dong (2002) noted increased phosphorylation of extracellular signal-regulated kinases in cell lines and that arsenic did not induce p53 transactivation. Waalkes *et al*. (2004) reported altered estrogen signaling in male mice with hepatocellular carcinoma produced by *in utero* exposure to arsenic. They concluded that overexpression of estrogen receptor-alpha (ER-alpha) through probable hypomethylation of the promoter region of this gene may play a role in hepatocarcinogenesis in these mice. Subsequent studies by Cui *et al*. (2006) have demonstrated that arsenic trioxide does inhibit DNA methyl transferase and activates methylation-inhibited genes in human HepG2 liver cancer cells. Hour *et al*., (2006) reported differential expression of various molecular markers in surgical samples of uroepithelial cells from arsenic- exposed and nonarsenic-exposed patients. They found decreased GSH content in cells from the arsenic-exposed patients and increased expression of *bcl-2* and *c-Fos*. Shen *et al*. (2006) examined the effects of three methylated arsenicals (MMA [V], DMA [V], and TMAO) on the urinary bladder epithelium of both male and female rats exposed to these substances for 13 weeks. They noted both metabolic differences between males and females with regard to further metabolism and concluded that DMA (V) is more toxic to the bladder epithelium of female rats, which are also more susceptible to bladder carcinogenesis from this agent.

Mizoi *et al*. (2005) reported that oxidative stress caused by DMA(III) generated as a reduction product of DMA (V) seemed to play a central role in lung and skin tumors in mice exposed to DMA (V) as judged by

the increased formation of 8-oxo-2'deoxyguanosine (8-OHdG) DNA adducts. It is also important to note the increased presence of 8-OHdG adducts has been reported in urine samples of persons living in Inner Mongolia (Fujino *et al*., 2005) and Cambodia (Kubota *et al*., 2006) exposed to arsenic in contaminated drinking water, suggesting that these adducts may be potentially useful biomarkers for long-term risk for arsenic-induced cancers such as Bowen's disease (Matsui *et al*., 1999). It is important to note that the stress protein response discussed previously may play an important regulatory role in mediating carcinogenic or cocarcinogenic effects of arsenic by means of interactions with a number of proto-oncogenes and apoptotic caspase system (Khalil *et al*., 2006; Stanhill *et al*., 2006; Yaglom *et al*., 2003).

6 BIOLOGICAL MONITORING

In a review by Mandal and Suzuki (2002), they document many cases of human arsenic exposures around the world, as well as documenting sources of arsenic in the environment.

6.1 Organs

Median arsenic concentrations in organs of healthy people from Scotland who died in accidents ranged from 0.012 mg/kg in brain to 0.46 mg/kg in hair, all dry weight (Liebscher and Smith, 1968). Median concentrations in organs of people from Japan, who generally had consumed relatively high amounts of seafood, ranged from 0.02 mg/kg wet weight in the pancreas to 0.89 mg/kg in the nails (Kadowaki, 1960). The two first-mentioned authors used NAA on vacuum dried samples, and the third used polarography. Values for all organs analyzed in the two studies are given in Table 1.

Tissue analysis of organs taken from an individual after death from ingestion of 8 g of arsenic trioxide (approximately 3g of arsenic) showed a much higher concentration of arsenic in the liver (147 μg/g) than in the kidneys (27 μg/g) of muscle, heart, spleen, pancreas, lungs, or cerebellum (11–12 μg/g) (Benramdane, *et al*. 1999). Small amounts were also found in other parts of the brain (8 μg/g), skin (3 μg/g), and hemolyzed blood (0.4 μg/g).

Inorganic arsenic can easily pass through the placenta. High levels of arsenic were found in the liver, kidney, and brain during autopsy of an infant prematurely born to a young mother who had ingested inorganic arsenic at week 30 of gestation (Lugo *et al*., 1969).

Arsenic was detected in human breast milk at concentrations of 0.00013–0.00082 ppm (Somogyi and Beck, 1993). In a population of Andean women exposed to high concentrations (approximately 200 ppb) of inorganic arsenic in drinking water, concentrations of arsenic in breast milk ranged from about 0.0008–0.008 ppm (Concha *et al*., 1998a).

It is not known to what extent concentrations in human organs represent inorganic arsenic or organic arsenic originating in the diet. Concentrations of 0.014–0.21 mg As/kg wet weight have been observed in the lungs of smelter workers who had retired 2–19 years before death, whereas unexposed controls had 0.001–0.018 mg/kg, indicating a long retention time of arsenic in the lungs after inhalation, which may occur in certain occupations (Brune *et al*., 1980).

6.2 Urine

Most arsenic that is absorbed from the lungs of the gastrointestinal tract is excreted in the urine within 1–2 days. Therefore, measurement of urinary arsenic levels

TABLE 1 Arsenic Concentrations in Human Organs and Tissues in Scotland and Japan

	Arsenic concentration (mg/kg)		
	Scotland (dry wt.)		Japan (wet wt.)
Tissue/organ	Median	Range	Median
Adrenal	0.029	0.002–0.293	
Aorta	0.031	0.003–0.570	
Whole blood	0.038	0.001–0.920	
Bone	0.057	0.010–0.240	0.118(femur)
Bone			0.074(rib)
Brain	0.013	0.001–0.036	0.034
Hair	0.460	0.020–8.17	0.174
Heart	0.024	0.002–0.078	0.041
Intestine, large			0.025
Intestine, small			0.022
Kidney	0.033	0.002–0.363	0.041
Liver	0.028	0.005–0.246	0.042
Lung	0.082	0.006–0.514	0.047
Muscle	0.063	0.012–0.431	0.029
Nail	0.300	0.020–2.90	0.892
Ovary	0.037	0.013–0.260	
Pancreas	0.045	0.005–0.410	0.020
Prostate	0.046	0.010–0.090	
Skin	0.090	0.009–0.590	0.064
Spleen	0.020	0.001–0.132	0.021
Stomach	0.037	0.003–0.104	0.022
Teeth	0.050	0.003–0.635	0.078
Thymus	0.015	0.003–0.332	
Thyroid	0.042	0.001–0.314	
Uterus	0.031	0.010–0.188	0.036

(Compiled from Liebscher and Smith, 1968; and Kadowaki, 1960, respectively).

is generally accepted as the most reliable indicator of recent arsenic exposure, and this approach has proved useful in identifying above-average exposures in populations living near industrial point sources of arsenic (Polissar *et al.,* 1990). Normal levels of arsenic in the urine of people with no known high exposure are apparently in the range of 5–50 µg As/L (Baker *et al*., 1977; Bencko and Symon, 1977; Braman and Foreback, 1973; Buchet *et al*., 1980; Smith *et al*., 1977). Ingestion of seafood may, however, increase the concentrations to more than 1 mg As/L (Buchet *et al*., 1980; Norin and Vahter, 1981; Pinto *et al*., 1976; Schrenk and Schreibeis, 1958).

In a study of As_2O_3 exposure in a smelter, Pinto *et al*. (1976) found an average urinary arsenic concentration of 0.053 mg/L among 200 workers who had not been exposed to arsenic. The average arsenic concentration in urine of 24 men who had been exposed to a mean air concentration of 53 µg/m^3 (range, 3–295 µg/m^3) in the same factory ranged from 0.038–0.539 mg/L, with an overall average of 0.174 mg/L. They found a correlation between airborne arsenic concentrations and arsenic in urine, but the values showed a wide scatter.

Watrous and McCaughey (1945) determined urinary levels of arsenic among workers in a factory producing arsphenamines from arsanilic acid. The mean arsenic level was 0.44 mg/L with a range of 0.04–3.8 mg/L.

Calderon *et al*. (1999) found a correlation between the log of the mean total urinary arsenic concentration/creatinine (TAs/c, µg/mg) in people living in areas with arsenic-contaminated drinking water sources and the log of the inorganic arsenic concentration in the drinking water (lnAs, µg/L).

Arsenic concentration in urine may be used as an index of exposure, but a number of factors such as a diet containing mainly seafood and the time between exposure and urine sampling have to be considered. Because "fish arsenic" (arsenobetaine) is essentially nontoxic, total urinary arsenic content may overestimate exposures to arsenic species that are of health concern. Experience has shown that total urinary arsenic may lead to overestimation of exposure to inorganic arsenic even if the subjects are requested to refrain from eating seafood (Pinto *et al*., 1976). Dietary habits should be examined thoroughly when the total urinary arsenic concentration is to be used as an index of exposure. Analytical differentiation of the different forms of arsenic in the urine is an appropriate way of determining how much and what form of arsenic has been absorbed (Buchet *et al*., 1980; Norin and Vahter, 1981). The sum of urinary excretion of inorganic arsenic and its monomethylated and dimethylated metabolites is a good indicator of exposure to inorganic arsenic when there is some fish consumption. Buchet *et al*. (2003) determined such values by means of hydride generation combined with AAS or AAF and reported a mean value of approximately 7 µg/g creatinine and a 95% cut off of 18 µg/g creatinine in a group from the general population of Belgium. In a population group from China not known to be exposed to inorganic arsenic, there was a mean of approximately 25 µg/g creatinine and a 95% cut off of 50 µg/g creatinine (Buchet *et al*., 2003).

6.3 Blood

By using NAA, Brune *et al*. (1966) found a mean concentration of 0.004 mg/kg in whole blood of normal people and 0.035 mg/kg in uremic patients. Heydorn (1970) reported a mean arsenic concentration in whole blood of 0.022 mg/L in Taiwanese subjects. He also used NAA.

In three studies of As-exposed populations, Vahter *et al*. (1995), Concha *et al*. (1998a), and Concha *et al*. (1998b) found the average blood total As to be 7.6, 9, and 10 µg/L, respectively. In one of these studies, the range of blood As concentration of an unexposed population was 1–2 µg/L (Concha *et al*., 1998b). By use of HPLC-ICP-MS, Suzuki *et al*. (2002) and Mandal *et al*. (2004) were able to separate and quantify the As species in the blood of an As-exposed population. They found AsB, DMA, MMA, and inorganic As in the blood samples by speciating the blood. They also found the total As concentration of 10.1 µg/L As in blood from an As-exposed individual. Mandal *et al*. (2004) also separated the blood into red blood cells (RBCs) and plasma and determined the fraction of the various species in these blood components.

As stated in Section 5.2, the clearance of arsenic from blood is very rapid. The time lapse between exposure and sampling will, therefore, be of importance if the blood levels are being related to the exposure. Furthermore, intake of seafood may greatly influence the blood arsenic levels. For these reasons, blood arsenic cannot be regarded as a useful indicator of exposure.

A review article by Taylor *et al*. (2004) tabulates both the technologies used for the determination of As in blood, hair, nails, and urine and summarizes the basic findings for the different biological matrices.

6.4 Hair

Attempts have been made to correlate normal concentrations of arsenic in hair to exposure to inorganic arsenic. Smith (1964) found that 80% of 1000 people tested had a concentration below 1 mg As/kg in hair, with an average of 0.81 mg/kg and a median of 0.51 mg/kg. Liebscher and Smith (1968) gave

0.02–8.17 mg/kg as the range for arsenic concentrations in hair, based on an examination of 1250 people without known exposure to high levels of this element. Linsheng *et al*. (2002), Mandal *et al*. (2003), and Uchino *et al*. (2005) examined correlations between hair As and As intake from water. They all found that there was a correlation, but the results differed by a factor of 2–3 in the level of As in the hair versus the level of As in the water. This could be due to many factors that include the mode of washing the hair before analysis (external contamination), analytical methods (both ICP-MS), or digestion techniques. Linsheng *et al*. (2002) looked at the average hair As as a function of the extent of arsenism in the patients and found a range of 2– 4.5 μg/g As, depending on the extent of hyperkeratosis, depigmentation, and pigmentation. Mandal *et al*. (2003) found an average concentration of 4.5 μg/g As in the hair, with a range of 0.7–16.2 μg/g. Mandal *et al*. (2003) also speciated the hair by HPLC-ICP-MS and found As(III), As(V), MMA(V), and DMA(V) in the hair. The difficulty with the interpretation of the results is the variation in the speciation results depending on the technique in which the As was extracted from the hair. The average percent recovery of the species versus the total As analysis value was 57%. This is common in these types of analysis in which the laboratory is extracting analytes form solid matrices. Raab *et al*. (2005) speciated As in the hair of a exposed population and found As(III), As(V), MMA(V), and DMA(V). The study also found that the method of extraction varied with the relative species and the extraction efficiency of the specific species relative to the total As concentration. In all of these As speciation studies, the presence of arsenobetaine was not detected; therefore, the assumption is that it does not accumulate in hair.

The mean concentration of arsenic in hair has been found to reflect the degree of arsenic pollution in community air (Bencko and Symon, 1977; Bencko *et al*., 1971; Hammer *et al*., 1971). Concentrations of arsenic in hair were generally found to increase as the concentrations of arsenic in air increased. Hinwood *et al*. (2003) looked at the general types of environmental and personal As exposures and classified the population into exposure categories and determined the hair As concentration of these relative exposures. They classified the exposures into high water, high soil, and personal exposure. The greatest effect was for the high water exposures in which they found a mean of 5.5 μg/g As in the hair with a range of 1.2–20 μg/g.

In evaluating hair As from unexposed populations like the U.S. National Human Exposure Assessment Survey (NHEXAS), there is no correlation of hair As with food, drinking water, dust intake, or exposure (Pellizzari *et al*., 2006). The average hair As in this population was 0.17 μg/g As in the hair, with a range of 0.06–0.33 μg/g As (10–90 percentiles).

Arsenic trioxide (As_2O_3) has been used as a chemotherapeutic agent for some leukemia treatments. Shen *et al*. (1997) looked at the incorporation of As in hair while arsenic trioxide was being administered to several patients. They found that As was incorporated into the hair soon after the arsenic trioxide was administered to a level of 2.5–2.7 μg/g, about five to seven times greater than the baseline levels, and then the hair As decreased after the drug was no longer being administered. The literature on the medicinal uses of arsenical has been recently reviewed by Ratnaike (2003).

It should be noted that there are several caveats related to the analysis of hair As that must be taken into consideration when evaluating an individual or population suspected to have a chronic or acute As exposure or poisoning. It may not possible to distinguish between arsenic adsorbed onto hair from external contamination and arsenic incorporated into hair from the internal body burden. Hindmarsh (2002) has shown that one can measure As in hair well before the As could have been incorporated through hair growth. This could be due to As in the sweat or other mechanisms contaminating the hair. He has also shown that hair can uptake As directly from water containing As and that As is not removed by the normal washing procedures used in analytical methods. Therefore, one must use caution in using hair As as an indicator of absorbed arsenic, if the external contamination cannot be controlled in some way (Vahter *et al*., 1983).

7 EFFECTS

Inorganic arsenic has been recognized as a human poison since ancient times. The arsenic-related human toxicity is systemic, involving a number of organ systems. Acute, subacute, and chronic toxic effects of inorganic arsenic exposed through inhalation and ingestion have been reviewed periodically (ATSDR, 2005; Chen *et al*., 1997ab; IARC, 2004; 2006; NRC, 1999; WHO, 1981; 2001).

7.1 Lethality

It has been estimated that the acute lethal dose of ingested inorganic arsenic in humans is about 1–3 mg/kg/day, whereas inhalation and dermal exposures to inorganic arsenic have not been associated with acute lethality (ATSDR, 2005). Animals are not as sensitive to inorganic arsenic as humans, and this difference may be due to differences in gastrointestinal absorption and methylation capability (Vahter *et al*., 1994).

7.2 Acute and Subacute Effects

Both acute and subacute toxicity of arsenic are shown in Table 2. They involve many organ systems, including the gastrointestinal, dermal, nervous, renal, hepatic, hematological, cardiovascular, respiratory, and ophthalmic systems. The earliest and most common presentation of ingestion of large dose of arsenic is the acute gastrointestinal syndrome, which starts with metallic or garlic-like taste associated with dry mouth, burning lips, and dysphagia. The gastrointestinal syndrome, which is caused by paralysis of the capillary control in digestive tract, may lead to a decrease in blood volume and blood pressure, electrolyte imbalance, and shock. In acute arsenic poisoning, the fundamental lesion of endothelial cellular toxicity accounts for the predominant clinical features. Capillary damage leads to generalized vasodilation, transudation of plasma, and multiorgan failures. The sites of arsenic damage in the kidney include capillary, tubules, and glomeruli. Neuropathy is produced mainly by axonal degeneration, although myelin disruption is also present. Most studies on acute and subacute toxicity of inorganic arsenic do not have details of exposure dose and/or adequacy of sample size for the assessment of dose-response relationships (ATSDR, 2005; Chen *et al*., 1997a; Gorby, 1994; IARC, 2004; Morton and Dunnette, 1994; NRC, 1999; 2001; WHO, 1981; 2001).

TABLE 2 Acute and Subacute Toxicity of Arsenic

Organ system	Symptoms and sign
Gastrointestinal	Nausea, vomiting, thirst, anorexia, heartburn, abdominal pain, diarrhea with bloody stool
Dermal	Dermatitis, vesticulation, melanosis
Neural	Encephalopathy (hyperpyrexia, convulsion, tremor, coma, disorientation), neuritis, peripheral neuropathy (primarily sensory type, paresthesia, hyperesthesia, numbness of extremities, neuralgia, muscular cramp, and weakness)
Renal	Cortical necrosis, leukocyturia, glycosuria, hematuria, oliguria, uremia
Hepatic	Congestion, fatty infiltration, central necrosis, acute yellow atrophy, cholangitis, cholecystitis
Hematological	Anemia, thrombocytopenia, leukopenia, bone marrow suppression
Cardiovascular	Cardiac abnormality (ventricular fibrillation and atypical tachycardia), prolonged Q-T interval, abnormal T wave; congestive heart failure, hypotension
Respiratory	Irritation of nasal mucosa, pharynx, larynx and bronchi, pulmonary edema, tracheobronchitis, bronchial pneumonia, nasal septum performation
Ophthalmic	Conjunctivitis

Source: WHO, 1981, 2001; ATSDR, 2005; Gorby, 1994; Morton and Dunnette, 1994; Chen *et al*. 1994; NRC, 1999.

7.3 Chronic Noncardiovascular Effects

Chronic noncardiovascular effects of inorganic arsenic also involve multiorgan systems as shown in Table 3. The clinical appearance of these clinical manifestations of arsenic intoxication in humans is insidious in onset and depends on the magnitude of the dose and the time course of exposure. A multitude of effects might ensue from the interference of arsenic on the action of enzymes, essential cations, and transcriptional events in cells throughout the human body (ATSDR, 2005; Chen *et al.*, 1997a; Gorby, 1994; IARC, 2004; Morton and Dunnette, 1994; NRC, 1999; WHO, 1981; 2001).

7.3.1 Dermal Effects

The most distinct characteristic of arsenic toxicity is the classical cutaneous manifestations, including hyperpigmentation with depigmentation and palmoplantar hyperkeratosis. These have been consistently observed among those with occupational, environmental, and medicinal exposures to arsenic through inhalation and ingestion. The dermal effects were most commonly reported after ingestion of arsenic containing water in various regions of the world, including Argentina, Bangladesh, Chile, China, Japan, Mexico, Inner Mongolia, and Taiwan (IARC, 2004; NRC, 1999; WHO, 1981; 2001). The magnitude of arsenic dose and exposure duration needed to induce hyperpigmentation and hyperkeratosis has been investigated to a limited extent. A dose-response relationship between arsenic concentration in drinking water and prevalence of hyperpigmentation and hyperkeratosis was observed in a survey of 40,421 inhabitants in coastal areas of southwestern Taiwan (Tseng *et al*., 1968), and a survey of 7683 residents in West Bengal, India (Guha Mazumder *et al*., 1998). More recent studies in Inner Mongolia (Guo *et al*., 2001; 2006), Bangladesh (Ahsan *et al*., 2006), and West Bengal (Haque *et al*., 2003; Mukherjee *et al*., 2005) have reported similar dose-related increases in characteristic skin lesions in human populations consuming arsenic-contaminated drinking water.

7.3.2 Gastrointestinal Effects

Long-term low-dose exposure to ingested arsenic was reported to induce various gastrointestinal symptoms, including gastroenteritis, dyspepsia, nausea, diarrhea, anorexia, and abdominal discomfort in Japan, Chile, China, India, and Mexico. However, arsenic dose and exposure duration required to induce the gastrointestinal effect were well characterized (IARC, 2004).

TABLE 3 Chronic Noncardiovascular Toxicity of Arsenic

Organ system	Symptoms and signs
Dermal	Hyperpigmentation with depigmentation, facial edema, palmoplantar hyperkeratosis, desquamation
Gastrointestinal	Esophagitis, gastritis, colitis, abdominal discomfort, anorexia, malabsorption, weight loss
Neural	Hearing loss, mental retardation, encephalopathy, symmetrical peripheral polyneuropathy (sensimotor type resembling Landry-Guillain-Barre syndrome), electromyographic abnormalities
Hepatic	Cirrhosis, hepatomegaly, portal hypertension without cirrhosis, fatty degeneration
Hematological	Bone marrow hypoplasis, aplastic anemia, anemia, leukopenia, thrombocytopenia, impaired folate metabolism, karyorrhexis
Respiratory	Rhino-pharyngo-laryngitis, tracheobronchitis, pulmonary insufficiency (emphysematous lesions), chronic restrictive/obstructive diseases
Metabolic	Diabetes mellitus
Immunological	Decreased progression of lymphocytes from S-phase to M-phase of cell cycle
Ophthalmic	Lens opacity

Source: WHO, 1981, 2001, 2004; ATSDR, 2005; Gorby, 1994; Morton and Dunnette, 1994; Chen *et al*., 1997a; NRC, 1999; Chen *et al*., 2005.

7.3.3 Neural Effects

Peripheral polyneuropathy is often among sequelae of acute oral arsenic poisoning. However, the occurrence of the polyneuropathy is inconsistent in individuals chronically exposed to arsenic at low concentrations. Abnormal electromyographic findings suggestive mostly of sensory neuropathy were reported in Canada, India, Japan, and China. But the neuropathy was not reported among residents drinking arsenic-containing water in Taiwan, Argentina, and Chile (IARC, 2004; NRC, 1999). There was no significant association between nerve-conduction-velocity measurements and arsenic exposure in Alaska (Kreiss *et al*., 1983) and Utah (Southwick *et al*., 1983). Peripheral neuritis and cognitive and memory impairment have been reported in arsenic-exposed residents in Texas (Kilburn, 1997), whereas reduced intellectual function has been found to be associated with arsenic exposure from drinking water in Thailand (Siripitayakunkit *et al*., 1999) and Bangladesh (Wasserman *et al*., 2004). A cross-sectional study on neurobehavioral development in adolescents in northeastern Taiwan found a significant association with cumulative arsenic exposure for pattern memory and switching attention but not for continuous performance and symbol digit (Tsai *et al*., 2003).

7.3.4 Hepatic Effects

Chronic exposure to arsenic in medicines and drinking water was reported to induce liver cirrhosis, portal hypertension without cirrhosis, and fatty degeneration (IARC, 2004; Morton and Dunnette, 1994; NRC, 1999; WHO, 1981; 2001). Vineyard workers who ingested arsenic-contaminated wine substitute were found to have a high prevalence of cirrhosis (Luchtrath, 1983). The simultaneous use of excessive ethanol may also contribute to the occurrence of liver cirrhosis. Increased mortality from liver cirrhosis was also observed in two cohorts of arsenic-exposed copper smelter workers (Axelson *et al*., 1978; Welch *et al*., 1982). Hepatomegaly has also been reported in cases of chronic arsenic toxicity caused by drinking arsenic-contaminated water in India and China (Guha Mazumder *et al*., 2005; IARC, 2004).

7.3.5 Hematological Effects

Long-term exposure to arsenic has a general depressant effect on the hematopoietic system. The hematological changes included normochromatic normocytic anemia, megaloblastic anemia, erythrocyte karyorrhexis, granulocytopenia, thrombocytopenia, aplastic anemia, and myelodysplasia. However, no hematological abnormality was found to be associated with chronic arsenic exposure through ingestion in Alaska, Arizona, Michigan, and Utah (Morton and Dunnette, 1994; NRC, 1999).

7.3.6 Respiratory Effects

Chronic respiratory effects of arsenic have been reported primarily as a result of occupational exposure through inhalation of arsenic containing dust or fumes (Morton and Dunnette, 1994), as well as environmental exposure through ingestion of arsenic-containing drinking water (IARC, 2004; NRC, 1999). The respiratory effects included rhinitis, pharyngitis, laryngitis, tracheobronchitis, chronic cough, crepitation, shortness of breath, and chronic restrictive and/or obstructive lung diseases. More recent studies in West Bengal (Guha Mazumder *et al*., 2000, 2005; von Ehrenstein *et al*., 2005) and Chile (Adonis *et al*., 2005; Smith *et al*., 2006) have reported increased rates of both obstructive lung lesions, including bronchiectasis and lung cancer in persons exposed to arsenic through drinking water that were exacerbated by smoking. Adonis *et al*. (2005) reported that in men the estimated risk of lung cancer was correlated with the enzymes MspI and CYP 1A1 2A but not GSTM1.

7.3.7 Metabolic Effects

An increased prevalence of diabetes mellitus was observed among residents in the endemic area of

arseniasis in southwestern Taiwan, and there was a dose-response relationship between cumulative arsenic exposure and prevalence of diabetes mellitus (Lai *et al*., 1994). There was an excess mortality from diabetes mellitus among residents who lived in arseniasis-endemic area of southwestern Taiwan (Tsai *et al*., 1999). Both arsenic-exposed workers in copper smelter and glass-producing plants were reported to have an increased risk of diabetes mellitus (Rahman and Axelson, 1995; Rahman *et al.,* 1996). A dose-response relationship was reported between prevalence of diabetes mellitus and arsenic in drinking water in Bangladesh (Rahman *et al*., 1998; 1999) and between incidence of diabetes mellitus and arsenic in drinking water in southwestern Taiwan (Tseng *et al*., 2000; 2002). Glycosylated hemoglobin was significantly higher among arsenic-exposed workers than unexposed ones in Denmark (Jensen and Hansen, 1998). The previous epidemiological studies are consistent with prior experimental animal studies (Ghafghazi *et al*., 1980, Schiller *et al*., 1981) which demonstrated marked exacerbating interactive effects between arsenic exposure, altered insulin responsiveness, and urinary markers of diabetes in an alloxan-induced diabetes rodent model. More recent studies (Diaz-Vilasenor *et al*., 2006) have reported impaired insulin secretion and transcription in rat pancreatic cells treated *in vitro* with arsenite (AsIII) over a concentration range of 0.5–10 μmol/L As for 72 or 144 hours. They observed both altered cellular insulin secretion at 144 hours in response to glucose at the 5 μmol/L As concentration and decreased insulin mRNA expression at 72 hours at the 5 μmol/L As concentration. Possible underlying mechanisms for arsenic-induced diabetes have been recently reviewed by Tseng (2004). In addition to these suggestions, which are centered on altered molecular regulatory mechanisms, it should be noted that the metabolic impairments of carbohydrate metabolism at the level of mitochondrial respiration noted in Section 5.6 might represent an important basic aspect of altered glucose regulation by arsenic. This is reasonable, because mitochondria actively take up arsenic, thus concentrating this element at even low dose levels. The mitochondrion is also known to be the major intracellular source of reactive oxygen species (ROS) in cells. The specific inhibition of NAD-linked substrate respiration/loss of respiratory control by arsenic at low-dose levels has been shown to increase the formation of ROS, which will stimulate a number of the stress protein and intracellular signaling mechanisms on a secondary basis. The overall concept with regard to arsenic stimulation of the diabetic response is that, even at low-dose levels, arsenic inhibition of mitochondrial respiration will tax the finite capacity of hormonal/intracellular carbohydrate regulatory systems to compensate for this basic derangement of cellular metabolism. The ability of these regulatory systems to regulate carbohydrate metabolism would eventually be overwhelmed, resulting in the development and/or exacerbation of an arsenic-induced insulin-resistant diabetic state for susceptible individuals. This would be of particular concern under chronic exposure conditions.

7.3.8 Immunological Effects

The peripheral blood lymphocyte count of arsenic-exposed subjects was slightly increased relative to the unexposed controls, and the progression of lymphocytes from the S-phase to M-phase of cell cycle after phytohemagglutinin incubation was decreased (Gonsebatt *et al*., 1994). The retardation in cell replication of lymphocytes was much more striking in arsenic-induced skin cancer patients than matched controls (Hsu *et al*., 1997).

7.3.9 Ophthalmic Effects

Long-term exposure to arsenic was reported to be associated with an increased prevalence of lens opacity. There was a dose-response relationship between cumulative arsenic exposure and prevalence of posterior subcapsular opacity, but not with prevalence of nuclear opacity and cortical opacity, after adjustment for age, gender, diabetes mellitus, and sunlight exposure (See, 2000).

7.4 Chronic Cardiovascular Effects

Table 4 shows chronic cardiovascular effects of long-term exposure to arsenic through ingestion or inhalation. The cardiovascular effects included electromyographic abnormalities, especially QT prolongation and increased dispersion; peripheral, coronary, and cerebral artery diseases; carotid atherosclerosis; hypertension; and microcirculation abnormality (Chen *et al*., 1997a; IARC, 2004; NRC, 1999; WHO, 1981; 2001).

TABLE 4 Chronic Cardiovascular Toxicity of Arsenic

Organ system	Symptoms and signs
Heart	Arrythmias, pericarditis
Peripheral artery	Blackfoot disease (gangrene with spontaneous amputation), Rayuand's syndrome, acrocyanosis, intermittent
Coronary artery	Ischemic heart disease
Cerebral artery	Cerebral infarction
Atherosclerosis	Carotid atherosclerosis
Blood pressure	Hypertension
Microcirculation	Microcirculation abnormalities

Source: WHO, 1981, 2001, 2004; ATSDR, 2005; Chen and Lin, 1994; Engel *et al*., 1994; Huang, 1995; Tseng *et al*., 1995; Chen *et al*., 1997a; NRC, 1999; Chen *et al*., 2005.

7.4.1 Cardiac Effects

Characteristic arsenic-induced electromyographic abnormalities include decreased nerve conduction amplitude with little change in nerve conduction velocity. Pericarditis and arrhythmias have also been documented as arsenic-induced cardiac effects (Gorby, 1994; Morton and Dunnette, 1994). A dose-response relationship has been reported between cumulative arsenic exposure and heart rate–corrected increased QT dispersion and QT prolongation from the endemic area of arseniasis in southwestern Taiwan (Wang, 2003).

7.4.2 Peripheral Vascular Diseases

Blackfoot disease, a unique peripheral arterial disease characterized by the severe systemic arteriosclerosis as well as dry gangrene and spontaneous amputations of affected extremities and end stages, has been well documented as a characteristic vascular disease associated with long-term arsenic exposure (Chen *et al.*, 1988b; Tseng, 1977). Diagnostic criteria for Blackfoot disease include objective signs of ischemia (i.e., absence or diminution of arterial pulsations, pallor on elevation, or rubor on dependency of ischemic extremities) and various degrees of ischemic changes in the skin, as well as subjective symptoms of ischemia (i.e., intermittent claudication, pain at rest, and ischemic neuropathy). Not all patients are affected with black, mummified dry gangrene (Tseng *et al*., 1961). Extensive pathological study showed that 30% of Blackfoot disease patients had histological lesions compatible with thromboangiitis obliterans, and 70% showed changes of arteriosclerosis obliterans. Marked generalized atherosclerosis was observed in all autopsied cases of Blackfoot disease, and the fundamental vascular changes of the disease represent an unduly developed severe arteriosclerosis (Yeh and How, 1963).

The dose-response relationship between ingested inorganic arsenic and Blackfoot disease has been well documented in the endemic area of southwestern Taiwan, where residents had used high-arsenic artesian well water for more than 50 years (Tseng, 1997). Patients affected with Blackfoot disease have a high prevalence of arsenic-induced skin lesions, including hyperpigmentation, hyperkeratosis, and skin cancers (Tseng, 1997). They also have a high mortality from cancers of the lung, liver, bladder, kidney, and prostate, as well as ischemic heart disease (Chen *et al*., 1988b). In addition to the duration of consuming artesian well water and the arsenic-induced skin lesions, the development of Blackfoot disease is also associated with undernourishment and a family history of Blackfoot disease (Chen *et al*., 1988b).

In Blackfoot disease, overt peripheral vascular disease was not reported in other arsenic-exposed populations. However, comparable peripheral vascular disorders with varying degrees of severity, including Raynaud's syndrome, microangiopathies, vasospastic tendency, and acrocyanosis, have also been reported among workers who were exposed to inorganic arsenic through copper smelting (Lagerkvist *et al*., 1986), pesticide handling, wall painting, and wood burning; among vintners who had consumed arsenic-contaminated wine in Germany; among patients treated with arsenic-containing drugs; and among inhabitants exposed to high-arsenic drinking water in Poland, Chile, Mexico, Argentina, Japan, Bangladesh, and Xinjiang, China (Cebrian *et al*., 1994; Chen *et al*., 1997a; Engel *et al*., 1994; Hotta, 1989; IARC, 2004; NRC, 1999; Rahman *et al*., 1999; Wang and Huang, 1994; WHO, 1981; 2001). Lynn *et al*. (2000) reported that NADH oxidase activation is involved in oxidative DNA damage to human aorta vascular smooth muscle cells produced by As(III). Such an underlying mechanism is consistent with the broad spectrum of oxidative damage produced by arsenical exposure in a number of organ systems (NRC, 1999).

There was a decline in the incidence of Blackfoot disease after the implementation of a surface water supply system in the endemic area, and most newly developed cases were older residents who had consumed high-arsenic artesian well water (Wang *et al*., 1985). A survey has shown a dose-response relationship between cumulative arsenic exposure and subclinical peripheral vascular disorder detected by Doppler ultrasonography among seemingly normal subjects after cessation of drinking artesian well water in the endemic area of Blackfoot disease in Taiwan (Tseng *et al*., 1995a). In a recent ecological study, the prevalence of peripheral vascular disease among diabetic and nondiabetic residents was significantly higher in arseniasis-endemic than nonendemic areas in southwestern Taiwan (Wang *et al*., 2002; 2003).

7.4.3 Ischemic Heart Diseases

Both ingested and inhaled inorganic arsenic have been related to an increased mortality from cardiovascular disease, especially ischemic heart disease (Chen *et al*., 1997a; Engel *et al*., 1994; IARC, 2004; WHO, 1981; 2001). The mortality from cardiovascular disease was significantly higher among residents in endemic areas of Blackfoot disease than among the general population in Taiwan (Wu *et al*., 1989). A significant dose-response relationship between ingested arsenic level and risk of ischemic heart disease were observed

in cohort and case-control studies in southwestern Taiwan (Chen *et al*., 1996). In a recent ecological study, the prevalence of coronary artery disease among diabetic and nondiabetic residents was significantly higher in arseniasis-endemic than nonendemic areas in southwestern Taiwan (Wang *et al*., 2003). Myocardial infarction has been related to high-arsenic drinking water in several autopsy studies in Antofagasta, Chile (Chen *et al*., 1997a; Engel *et al*., 1994). But details of arsenic exposure and population at risk were not available for further evaluation of the dose-response relationship.

The association between long-term exposure to arsenic and increased mortality from cardiovascular disease has also been reported among copper-smelter worker in the United States and Sweden, among chimney sweeps in Sweden and Denmark, among glassblowers in Sweden, and among workers and neighboring residents of an arsenic refinery in Japan (Chen *et al*., 1997a; Engel *et al*., 1994; IARC, 2004; WHO, 1981; 2001).

A significant reverse dose-response relationship was observed between arsenic-induced ischemic heart disease and serum level of α- and β-carotene after adjustment for age, gender, body mass index, hypertension, as well as the ratio between total cholesterol and high-density lipoprotein cholesterol (Hsueh et *al*., 1998).

7.4.4 Stroke

A survey carried out in I-Lan County of northeastern Taiwan showed a significant dose-response relationship between arsenic concentration in drinking water and the prevalence of strokes, especially cerebral infarction (Chiou *et al*., 1997). The biological gradient of stroke by arsenic in drinking water remained statistically significant after adjustment for age, gender, body mass index, disease status of hypertension and diabetes mellitus, cigarette smoking, and alcohol consumption. In an ecological study in southwestern Taiwan, an increased mortality from stroke was observed for residents who lived in arseniasis-endemic area of southwestern Taiwan (Tsai *et al*., 1999). In a recent ecological study, the prevalence of coronary artery disease among diabetic and nondiabetic residents was significantly higher in arseniasis-endemic than nonendemic area in southwestern Taiwan (Wang *et al*., 2003).

7.4.5 Carotid Atherosclerosis

In a cross-sectional survey of residents in southwestern Taiwan, a dose-response relationship between prevalence of carotid atherosclerosis and long-term exposure to arsenic from drinking well water was observed (Wang *et al*., 2002). The biological gradients remained significant after adjustment for age, gender, hypertension, diabetes mellitus, cigarette smoking, alcohol consumption, waist-to-hip ratio, and serum levels of total cholesterol and low-density lipoprotein cholesterol.

7.4.6 Hypertension

A cross-sectional study in southwestern Taiwan has reported an increased prevalence of hypertension among residents in the arseniasis-endemic area than those in nonendemic area, as well as a dose-response relationship between ingested inorganic arsenic and prevalence of hypertension (Chen *et al*., 1995). The biological gradient remained significant after adjustment for age, gender, diabetes mellitus, proteinuria, body mass index, and serum triglyceride levels. Another study in Bangladesh also found a dose-response relationship between ingested arsenic and hypertension prevalence after adjustment for age, gender, and body mass index (Rahman *et al*., 1999b). Increased hypertension prevalence was also observed among patients affected with arsenic-induced skin lesions in the area where well water had a high arsenic concentration in Chile (Borgono *et al*., 1977; Zaldivar, 1980). Arsenic-exposed workers were reported to have a higher systolic blood pressure than unexposed workers in Denmark (Jensen and Hansen, 1998).

7.4.7 Microcirculation Abnormality

Based on the laser Doppler flowmetry, seemingly normal men living in villages where Blackfoot disease was hyperendemic were found to have poorer peripheral microcirculation than matched ones in nonendemic areas (Tseng *et al*., 1995b). However, the dose-response relationship between ingested inorganic arsenic and abnormality of peripheral microcirculation was not examined.

7.4.7.1 Microvascular Diseases

In a recent ecological study, the prevalence of microvascular diseases, including renal disease, retinopathy, and neurological disorders among diabetic and nondiabetic residents, was significantly higher in arseniasis-endemic than nonendemic area in southwestern Taiwan (Wang *et al*., 2003).

A significant ecological correlation between the arsenic content in drinking water and the mortality from cancer of the nasal cavity was reported recently (Chen and Wang, 1990). Although perforation of the nasal septum has been documented among smelter workers exposed to high levels of inorganic arsenic

(WHO, 1981), there were no other reports on the association between nasal cavity cancer risk and exposure to arsenic through inhalation or ingestion.

7.5 Carcinogenic Effects

Ingested and inhaled arsenic through occupational, environmental, and medicinal exposure is involved in the development of several cancers in humans without showing any organotropism as shown in Table 5 (Chen *et al*., 1997b; IARC, 2004; NRC, 1999; WHO, 1981; 2001). Ecological, case-control and cohort studies have shown a significant dose-response relationship between arsenic in drinking water and increased risk of cancers of the liver, nasal cavity, lung, skin, urinary bladder, kidney, and prostate in southwestern and northeastern Taiwan (Chen *et al*., 1988a, 1992; 2004; Chiou *et al*., 1995; 2001). Based on the sufficient evidence in humans that arsenic in drinking water causes cancers of the urinary bladder, lung, and skin, arsenic in drinking water has been classified as a group 1 carcinogen to humans (IARC, 2004).

7.5.1 Skin Cancer

There is clear evidence that long-term oral exposure to inorganic arsenic through drinking water, grape wine, or medication increases the risk of skin cancer (Chen *et al*., 1997b; IARC, 2004; NRC, 1999; WHO, 1981; 2001). Inhaled arsenic has also been documented to induce skin cancer among workers producing sheep-dip powder from sodium arsenite (Hill and Faning, 1948). The largest study of arsenic-induced skin cancer was carried out in southwestern Taiwan, and a dose-response relationship between the arsenic content in drinking water and the prevalence of skin cancer was observed (Tseng *et al*., 1968). In addition to long-term exposure to high-arsenic artesian well water, chronic liver disease and malnutritional status have recently been reported to be associated with the development of arsenic-induced skin cancer (Hsueh *et al*., 1995). The risk of skin cancer was significantly associated with the elevated serum arsenic level and decreased serum beta-carotene level in a dose-response relationship, but no significant differences in serum levels of selenium and zinc were observed between patients affected with arsenic-induced skin cancer and matched healthy controls (Hsueh *et al*., 1997). Arsenic methylation capability has been found to be associated with the development of skin cancer. Increased skin cancer was observed among those who had an elevated proportion of monomethylarsonic acid in total urinary metabolites of inorganic arsenic (Hsueh *et al*., 1997; Yu *et al*., 2000). An increased risk of arsenic-induced skin cancer was observed among those who had at least one null or variant genotypes of glutathione S-transferase M1, T1, or P1 (Tseng, 1999).

7.5.2 Lung Cancer

An increased risk of cancers of the lung and nasal cavity has been associated with long-term exposure to inorganic arsenic through inhalation and ingestion in a dose-response relationship (Chen *et al*., 1997b; IARC, 2004; NRC, 1999; Pinto *et al*., 1978; WHO, 1981; 2001). An excess of deaths caused by lung cancer has been observed among workers exposed to inorganic arsenic through inhalation in the production and use of

TABLE 5 Various Cancers with Increased Risks Caused by Arsenic Exposure Through Inhalation and Ingestion

	Ingestion			Inhalation	
Cancer site	Drinking water	Contaminated wine	Fowler's solution	Copper smelter	Pesticide factory
Skin	+	+	+		+

Brain and nervous system				+	

pesticides, in gold mining, and in the smelting of nonferrous metals, especially copper. Individuals living within several kilometers of inorganic arsenic–emitting industries were also reported to have increased risk of lung cancer (Chen *et al*., 1997b; WHO, 1981; 2001). The dose-response relationship between inhaled inorganic arsenic and lung cancer risk was observed mainly in two large cohorts of copper-smelter workers in Anaconda, Montana (Brown and Chu, 1983; Higgins *et al*., 1982; Lee-Feldstein, 1983), and in Tacoma, Washington (Enterline and Marsh, 1982). The observed effects might be confounded by cigarette smoking and exposures to other chemicals. An interaction between inhaled inorganic arsenic and cigarette smoking for the risk of developing lung cancer has been reported (Jarup and Pershagen, 1991).

Significant association between ingested arsenic and lung cancer risk has been observed in patients treated with arsenic-containing medicine, in vintners exposed to arsenic pesticide-contaminated grape wine, and in persons exposed to inorganic arsenic from drinking water (Chen *et al*., 1997b; Guo, 2004; IARC, 2004; NRC, 1999; WHO, 1981; 2001). The dose-response relationship between ingested inorganic arsenic and lung cancer has been reported in cohort studies in Taiwan (Chiou *et al*., 1995) and in Japan (Tsuda *et al*., 1995). Both cigarette smoking and signs of arseniasis (i.e., skin cancer or Blackfoot disease) were reported to increase the risk of arsenic-induced lung cancer in these two studies. A synergistic effect on the development of lung cancer between cigarette smoking and ingested arsenic was observed in the endemic areas of arseniasis in southwestern and northeastern Taiwan (Chen *et al*., 2004).

These results are consistent with the positive interactive effects between benzo-a-pyrene and arsenic in producing lung cancers in hamsters after concomitant exposures to both agents (Pershagen *et al*., 1984).

7.5.3 Urothelial Cancer

Both inhaled and ingested inorganic arsenic have been well documented to induce cancers of the bladder and kidney, especially urothelial cancers (Chen *et al*., 1985; 1986; 1997b; IARC, 2004; NRC, 1999; WHO, 2001).

There have been several reports on the increased risk of bladder cancer among patients treated with Fowler's solution (Chen *et al*., 1997b). In a cohort study of patients treated with Fowler's solution, a significant association between the cumulative dose of arsenic intake and mortality from bladder cancer was observed (Cuzick *et al*., 1992). Moselle vintners who consumed arsenic pesticide–contaminated grape wine were found to have an increased mortality from bladder cancer (Luchtrath, 1983).

Ecological studies in Taiwan have well documented the dose-response relationship between ingested arsenic from drinking water and mortality from cancers of the urinary bladder and kidney in Taiwan (Chen and Wang, 1990; Chen *et al*., 1988a). A significant dose-response relationship between ingested inorganic arsenic from drinking water and risk of bladder cancer has been documented in cohort studies in Taiwan (Chiou *et al*., 1995; 2001), Japan (Tsuda *et al*., 1995), and, more recently, in Finland (Kurttio *et al*., 1999), Argentina (Bates *et al*., 2004), and the United States (Steinmaus *et al*., 2006). Those who have signs of arseniasis (i.e., skin cancer or Blackfoot disease) were found to have an increased risk of bladder cancer from drinking high-arsenic well water (Chiou *et al*., 1995; Tsuda *et al*., 1995). Cigarette smoking was not significantly associated with the development of arsenic-induced bladder cancer in Taiwan (Chiou *et al*., 1995); but a significant dose-response relationship between bladder cancer risk and arsenic exposure was observed only among cigarette smokers in the United States (Bates *et al*., 1995). The decreased ratio between urinary levels of dimethylarsinic acid (DMA) and monomethylarsonic acid (MMA) was associated with an increased risk of bladder cancer (Chen *et al*., 2003). Studies by Steinmaus *et al*. (2006) support the findings from Taiwan and demonstrated that persons with higher urinary levels of MMA were at greater risk for development of arsenic-induced cancers.

Inhaled inorganic arsenic has also been found to be associated with the risk of mortality from bladder cancer among copper smelter workers in the United States and Japan (Bates *et al*., 1992; Chen *et al*., 1997b) and among residents who lived near a plant roasting arsenopyrite and were exposed to inorganic arsenic through inhalation and ingestion in Japan (Hotta, 1989). There was no report examining the dose-response relationship between inhaled arsenic and bladder cancer.

Excess mortality from kidney cancer was observed among copper smelter workers and patients treated with Fowler's solution (Chen *et al*., 1997b). A dose-response relationship between ingested inorganic arsenic and kidney cancer mortality was observed among residents in the endemic area of arseniasis in Taiwan (Chen *et al*., 1988a, 1992; Chiou *et al*., 1995).

7.5.4 Liver Cancer

Both hepatic angiosarcoma and hepatocellular carcinoma have been associated with long-term exposure to ingested and inhaled arsenic (Bates *et al*., 1992; Chen *et al*., 1997b; Falk *et al*., 1981ab; IARC, 2004; NRC, 1999; WHO, 1981; 2001). Exposure was from ingestion of arsenic-contaminated wine, high-arsenic

drinking water and Fowler's solution; and from inhalation through copper smelting and production and application of arsenic-containing pesticides. Because hepatic angiosarcoma is a very rare disease, its association with exposures to inorganic arsenic does not seem likely to be a matter of chance.

Long-term exposure to inorganic arsenic through ingestion and inhalation has been associated with the development of hepatocellular carcinoma. The exposure of ingested arsenic was from high-arsenic artesian well water and arsenic-contaminated grape wine, and that of inhaled arsenic was from copper smelting (Chen *et al*., 1997b). Ecological studies have shown a dose-response relationship between ingested inorganic arsenic from drinking water and risk of hepatocellular carcinoma among residents in the endemic area of arseniasis in southwestern Taiwan (Chen and Wang, 1990; Chen *et al*., 1988a).

7.5.5 Other Internal Cancers

Inhaled and ingested inorganic arsenic have been associated with an increased risk of gastrointestinal cancers, hematolymphatic malignancies, and malignant neoplasms of the nervous system (Chen *et al*., 1997b; IARC, 2004; NRC, 1999; WHO, 1981; 2001). Excess mortality from cancers of the digestive tract has been observed among copper smelter workers, Moselle vintners, and residents in the endemic area of arseniasis in Taiwan. Workers in copper smelters and pesticide manufacturing plants were reported to have an increased mortality from malignant neoplasms of lymphatic and hematopoietic tissues. Copper smelter workers also had an increased mortality from malignant neoplasms of the brain and nervous system.

There were no reports on the association between exposure to ingested inorganic arsenic and mortality from malignant neoplasms of the hematolymphatic and nervous systems. Ingested inorganic arsenic through drinking high-arsenic artesian well water has been found to be significantly associated with mortality from prostate cancer in a dose-response relationship (Chen and Wang, 1990; Chen *et al*., 1988ab). There were no reports on the association between inhaled inorganic arsenic and prostate cancer.

A significant ecological correlation between the arsenic content in drinking water and the mortality from cancer of the nasal cavity was reported recently (Chen and Wang, 1990). Although perforation of the nasal septum has been documented among smelter workers exposed to high levels of inorganic arsenic (WHO, 1981), there were no other reports on the association between nasal cavity cancer risk and exposure to arsenic through inhalation or ingestion.

7.5.6 Lifetime Cancer Risk Induced by Arsenic

As shown in Table 6, the lifetime risk of developing cancers of the skin, lung, bladder, liver, and kidney have been estimated on the basis of Armitage–Doll multistage models. The lifetime risk of developing skin cancer from the ingestion of 1μg/kg/day inorganic arsenic was estimated according to the prevalence of skin cancer among residents in an endemic area of arseniasis and an unexposed control area (Tseng *et al*., 1968). The lifetime risk of developing lung cancer from 1μg/kg/day arsenic through inhalation was based on the data from copper smelter workers in Anaconda, Montana (Brown and Chu, 1983; Higgins *et al*., 1982; Lee-Feldstein, 1983), and in Tacoma, Washington (Enterline and Marsh, 1982).

The lifetime risks of developing cancer of the lung, liver, bladder, and kidney from 1μg/kg/day inorganic arsenic through ingestion were based on the mortality date of residents in the endemic area of arseniasis southwestern Taiwan (Chen *et al*., 1992). The lifetime risks of

TABLE 6 Lifetime Risk of Developing Cancers of Skin, Lung, Liver, Bladder, and Kidney Caused by 1μg/kg/day Inorganic Arsenic Through Ingestion and Inhalation

Cancer site	Exposure type	Study area	Reference	Lifetime risk (per 1000)	
				Male	Female
Skin	Ingestion	Taiwan	Tseng *et al*., 1968	3.0	2.1
Lung	Inhalation	Anacoda	Higgins *et al*., 1982	17.0	—
			Lee-Feldstein, 1983	9.8	—
			Brown and Chu, 1983	4.6	—
		Tacoma	Enterline and Marsh, 1980	24.0	—
	Ingestion	Taiwan	Chen *et al*., 1992	1.2	1.3
Bladder	Ingestion	Taiwan	Chen *et al*., 1992	1.2	1.7
Kidney	Ingestion	Taiwan	Chen *et al*., 1992	0.4	0.5
Liver	Ingestion	Taiwan	Chen *et al*., 1992	0.4	0.4

Source: US Environmental Protection Agency, 1984; Chen *et al*., 1992.

developing cancers of the skin, lung, liver, bladder, and kidney from ingested inorganic arsenic were within a sevenfold range of magnitude. The risks were practically identical for both men and women within a twofold range of magnitude, indicating no gender difference in arsenic-induced carcinogenic responses.

Epidemiological studies on arsenic-induced development and reproductive effects have been reviewed periodically (Chen *et al*., 1997b; NRC, 1999; WHO, 1981; 2001). Babies born to female employees of a copper smelter, who were exposed to inorganic arsenic through inhalation during pregnancy, were reported to have an increased incidence of congenital malformation, low birth weight, and spontaneous abortion (Nordstrom *et al*., 1979ab). Low birth weight was also observed among newborns in smelter areas than in nonsmelter areas (Tabacova *et al*., 1994).

An increased, but not statistically significant, risk of coarctation of the aorta was found to be associated with elevated arsenic level in drinking water (Zierler *et al*., 1988). Arsenic in drinking water has been reported to increase the mortality from congenital anomalies of the heart in females, and the mortality from congenital anomalies of the circulatory system for both sexes in the United States (Engel and Smith, 1994). Arsenic in drinking water was reported to be associated with an increased risk of spontaneous abortion in two studies (Aschengrau *et al*., 1989; Borzsonyi *et al*., 1992), and with a significantly increased risk of stillbirths in two studies (Borzsonyi *et al*., 1992; Ihrig *et al*., 1998). Arsenic in drinking water was also reported to be associated with an increased neonatal mortality in Chile (Hopenhayn-Rich *et al*., 1999). Similar findings of increased rates of spontaneous abortions, stillbirths, and infant mortality have been reported among populations consuming arsenic-contaminated well water in Bangladesh (Milton *et al*., 2005) and West Bengal (von Ehrenstein *et al*., 2006).

7.6 Experimental System Cancer Studies

No studies on cancer in humans after oral exposure to organic arsenicals have been located, but there are some animal studies on the carcinogenicity of organic arsenicals. In an early 2-year study of roxarsone (3-nitro-4-hydroxyphenylarsonic acid) toxicity in animals, no increase in tumor frequency was detected in dogs, rats, or mice given 1.5, 2.9, and 3.8 mg arsenic/kg/day, respectively (Prier *et al*., 1963). Lifetime studies of roxarsone at doses up to 1.4 mg arsenic/kg/day yielded no evidence of carcinogenicity in male or female mice or female rats, but a slight increase in pancreatic tumors was noted in male rats (NTP, 1980). Carcinogenesis studies with inorganic arsenic in hamsters (Inamasu *et al*., 1982; Pershagen *et al*., 1984) were also positive, particularly in combination with other organic carcinogens (see Section 7.7). Arnold *et al*. (2003) exposed male and female rats to 0, 50, 400, or 800 ppm MMA (monoarsonic acid) and male and female B6C3F1 mice to 0, 10, 50, 200, or 400 ppm MMA in the diet for 104 weeks; estimated average daily doses were up to 47.3 mg arsenic/kg/day for female rats and up to 48.5 mg arsenic/kg/day for female mice. No treatment-related neoplastic changes were seen in either sex of either species. A similar lack of carcinogenicity of MMA was reported by Shen *et al*. (2003a), who exposed male F344 rats to 0, 50, or 200 ppm of MMAA(V) in the drinking water for 104 weeks. Wei *et al*. (1999; 2002) exposed male F344 rats to 0, 12.5, 50, or 200 ppm DMAA (dimethylarsinic acid) for 104 weeks in the diet, the average daily doses were 0, 0.03, 0.14, or 0.53 mg arsenic/kg/day. Increases in the number of animals with bladder tumors were seen in the two highest dosed groups. No increases in tumor incidence were seen in other organs. Hayashi *et al*. (1998) reported that mice exposed to 400 ppm of DMA for 50 weeks, but not those exposed to 50 or 200 ppm, showed an increased incidence of papillary adenomas and an elevated number of average lung tumors per mouse. Dimethylarsinic acid (DMAA), which is a major methylated metabolite of inorganic arsenic, has been reported by Hayashi *et al*. (1998) to exhibit tumorigenicity and to stimulate tumor progression in mice after drinking water exposure at 400 ppm for up to 50 weeks. These data are in concert with epidemiological studies of humans who developed lung cancer from drinking water exposures noted above.

7.6.1 Developmental and Reproductive Effects

7.6.1.1 Teratogenic Effects

Until recently, there were very few reports on the teratogenicity of inorganic arsenic in humans. Congenital malformations were observed in children whose mothers worked, during pregnancy, at a Swedish copper smelter and were exposed to arsenic, other heavy metals, and sulfur dioxide. The observed incidence was five times greater than that in children born to other mothers from the same region (Nordstrom *et al*., 1979ab). No conclusion can be drawn as to whether arsenic is responsible for these malformations. Teratogenic effects have been shown to occur after a single administration of high doses (6–10 mg As/kg body weight) of sodium arsenate to pregnant golden hamsters (Ferm, 1977). The compound was given intravenously to the hamsters on the 8th day of gestation. Both the reabsorption and malformation rates in the fetus increased with increasing doses of the arsenate.

The teratogenic effects were characterized by anencephaly, renal agenesis, and rib malformations. Similar teratogenic effects have been induced in mice intraperitoneally injected with sodium arsenate at a dose of 11 mg As/kg body weight (Hood and Bishop, 1972) and in rats intraperitoneally injected with 5–12 mg As/kg body weight (Beaudoin, 1974). However, in all cases, the doses required to cause these effects resulted in significant maternal toxicity or even lethality. Recent studies in mice, rats, and rabbits found no evidence of developmental effects at exposure levels that did not produce maternal toxicity (Holson *et al*., 1999; 2000; Nemec *et al*., 1998; Stump *et al*., 1999).

7.6.2 Genotoxic Effects and Mutagenicity

There have been a large number of studies of the genotoxic effects of arsenic. The results are mixed, but in general, it seems that the inorganic arsenicals are either inactive or weak mutagens (Jacobson-Kram and Montalbano 1985) but are able to produce chromosomal effects (aberrations, sister chromatid exchange) in most systems. Increased incidence of chromosome abnormalities has been observed in lymphocytes of workers exposed to arsenic (Beckman *et al*., 1977) and patients therapeutically treated with arsenicals (Petres *et al*., 1977).

When cultured human lymphocytes were exposed to $NaAsO_2$ (trivalent) and Na_2HAsO_4 (pentavalent), significantly increased frequencies of chromosome aberrations have been found for trivalent, but not for pentavalent, arsenic (Nordenson *et al*., 1981). Sodium arsenite was found to be effective in increasing sister chromatid exchanges, but cultured lymphocytes obtained from 13 patients with Blackfoot disease were not different from those of healthy persons in terms of frequency of sister chromatid exchanges after exposure to sodium arsenite (Wen *et al*., 1981). Arsenical interference with normal DNA repair processes has also been noted (Fong *et al.*, 1980; Jung *et al*., 1969; 1971; Rossman *et al*., 1977), suggesting the induction of cellular genome damage.

Mutagenicity tests using *Salmonella, Escherichia coli* system, and Chinese hamster cell line V79 failed to produce point mutations with trivalent or pentavalent inorganic arsenic (Lofroth and Ames, 1978; Rossman *et al*., 1980). Arsenic trichloride, sodium arsenite, and arsenic pentoxide, however, gave positive results in *rec* assay in *Bacillus subtilis* (Kada *et al*., 1980; Nishioka, 1975).

Morphological transformation of Syrian hamster embryo cells derived from 13- to 14-day-old embryos occurred at concentrations of 2.5–5.0 µg/mL sodium arsenate using a cell culture method (DiPaolo and Casto, 1979).

The genotoxic effects of organic arsenicals such as DMA and roxarsone have been tested. They are shown to be able to cause mitotic arrest, chromosome aberrations, mutations and DNA strand breaks (ATSDR, 2005).

7.7 Interaction Between Arsenic and Other Compounds

Interaction between arsenic and selenium has been described by Levander (1977). He concluded that arsenic has a protective effect against the toxicity of selenium in several species. Likewise, selenium can decrease the effects of arsenic, including clastogenicity, cytotoxicity, and teratogenicity (Babich *et al*., 1989; Biswas *et al*., 1999; Holmberg and Ferm, 1969). The mechanism of this mutual inhibition of effects is not known, but may be related to the formation of a complex that is excreted more rapidly than either arsenic or selenium alone (Cikrt *et al*., 1988; Levander, 1977) or caused by selenium-induced changes in arsenic methylation (Styblo and Thomas 2001; Walton *et al*., 2003).

A combined exposure to arsenic and lead had additive effects on tissue respiration and functional changes in the CNS (Novakova, 1969). Mahaffey and Fowler (1977) first reported that rats given cadmium and arsenic (50 mg/kg) in food for 10 weeks showed lower serum alkaline phosphatase levels than those treated with either metal alone. Additive effects of dietary arsenic and lead (200 mg/kg) in coproporphyrin excretion were also subsequently noted (Fowler and Mahaffey, 1978, Mahaffey *et al*., 1981). More recent studies in rats using combined drinking water exposures to lead (25 mg Pb/L), cadmium (10 mg Cd/L), and arsenic (5.0 mgAs/L) for 30, 90, or 180 days at LOEL dose levels produced similar biochemical effects that showed variation with strong duration of exposure-dependence (Fowler *et al*., 2004). Please see Chapter 7 and review by Madden and Fowler (2000) on interactions among metals for a more complete discussion.

Arsenic has been shown to cause an increase in total plasma cholesterol in rats; coadministration of chromium (III) counteracts this effect (Aguilar *et al*., 1997).

The interaction between cigarette smoking, inhalation of arsenic, and the risk of lung cancer has not been extensively investigated. Smoking seemed to increase lung cancer risk synergistically in one study of smelter workers (Pershagen *et al*., 1981), although the data are not adequate to exclude a simple additive interaction (Thomas and Whittemore, 1988). Cigarette smoking has been shown to increase the occurrence of lung cancer in people with high levels of arsenic in the drinking water (Chiou *et al*., 1995; Tsuda *et al*., 1995).

Coexposure to ethanol and arsenic may exacerbate the toxic effects of arsenic. Simultaneous exposure of rats to ethanol (10% in drinking water) and arsenic for 6 weeks produced a significant increase in the concentration of arsenic in the kidney, a nonsignificant increase or arsenic in the liver, and a significant increase in the concentration of glutathione in the liver, compared with rats treated with either ethanol or arsenic alone (Flora *et al*., 1997ab). Histological damage to the liver, but not the kidneys, was increased in rats treated with both ethanol and arsenic compared with those receiving only arsenic.

Please see Chapter 7 on interactions in metal toxicology for a more detailed discussion.

8 DOSE-EFFECT AND DOSE-RESPONSE RELATIONSHIP IN ARSENIC POISONING

The dose-effect relationship in acute exposure to arsenic may be estimated from the 220 poisoning cases associated with an episode of arsenic contamination of soy sauce in Japan reported by Mizuta *et al*. (1956). The soy sauce was contaminated with approximately 0.1 mg As/mL, probably as calcium arsenate. Arsenic intake in the cases was estimated by the researchers to be 3 mg/day (0.05 mg/kg/day, assuming 55-kg average body weight for the Asian population). The duration of exposure was 2–3 weeks in most cases. The primary symptoms were edema of the face and gastrointestinal and upper respiratory symptoms initially, followed by skin lesions and neuropathy in some patients. Other effects included mild anemia and leukopenia, mild degenerative liver lesions, and hepatic dysfunction, abnormal electrocardiogram, and ocular lesions. An acute oral guidance value of 0.005 mg/kg/day (ATSDR, 2005) may be derived based on the LOAEL of 0.05 mg/kg/day, by applying an uncertainty factor of 10 for extrapolation from a LOAEL to a LOAEL and 1 for intrahuman variability. This guidance value is supported by the case of a man and wife in upstate New York who experienced gastrointestinal symptoms (nausea, diarrhea, abdominal cramps) starting almost immediately after beginning intermittent consumption of arsenic-contaminated drinking water at an estimated dosed of 0.05 mg/kg/day (Franzblau and Lilis, 1989). The UF of 1 for intrahuman variability reflects the fact that the database includes persons of different ethnicities and age groups, including infants.

Hamamoto (1955) reported on Japanese infants who ingested milk contaminated with arsenic over a period of 33 days. The amount of arsenic ingested was about 1.3–3.6 mg/day. When a total of about 80 mg arsenic had been ingested, these victims developed symptoms of arsenic poisoning, including pigmentation, swelling of the liver, and anemia. A total of 12,131 cases of poisoning with 130 deaths were reported. Impairment of learning and of clinical functions such as hearing had been described among those who survived (Yamashita *et al*., 1972).

In areas in Cordoba, Argentina, with endemic arsenicism, the main symptoms described among the inhabitants are symmetrical palmar and plantar hyperkeratosis. Concentrations in drinking water have been reported to be 0.9–3.4 mg As/L (Wickstrom, 1972).

The dose-effect relationship in chronic exposure may be estimated from the report by Tseng *et al*. (1968) and Tseng (1977), who investigated the incidence of Blackfoot disease and dermal lesions in a large number of poor farmers (both males and females) exposed to high levels of arsenic in well water in Taiwan. A control group consisting of over 7,500 people was identified. The incidence of dermal lesions increased with dose, but individual doses were not provided. The incidence data were provided based on stratification of the exposure population into low (<300 μg/L), medium (300–600 μg/L), or high (>600 μg/L) exposure levels according to arsenic concentration in the well water. Doses were calculated from group mean arsenic concentrations in well water, assuming the intake parameters described by Abernathy *et al*. (1989). The arithmetic mean concentration of arsenic in well water was converted to exposure doses assuming a water intake of 4.5 L/day, a body weight of 55 kg, and an estimation of arsenic intake of 0.003 mg/As/kg/day from food. The control, low, medium, and high exposure levels corresponded to doses of 0.0008, 0.014, 0.038, 0.065 mg/kg/day, respectively. A clear dose-response relationship was observed for characteristic skin lesions: 0.0008 mg/kg/day was identified as the NOAEL, at 0.014 mg/kg/day hyperpigmentation and keratosis of the skin were observed, and at 0.038–0.065 mg/kg/day increased incidence of dermal lesions was observed. A chronic health guidance value of 0.0003 μg/kg/day may be derived from the NOAEL of 0.0008 mg/kg/day, an UF of 3 was applied in consideration of the fact that most of the control population was less than 20 years of age and the incidence of skin lesions increased as a function of age, and because the estimates of water intake and dietary arsenic intake are highly uncertain (ATSDR, 2005). Schoof *et al*. (1998) estimated that dietary intakes of arsenic from rice and yams might have been 15–211 μg/day (mean, 61 μg/day), based on arsenic analyses of foods collected in Taiwan in 1993–1995. Use of the 50-μg/day estimate would result in an approximate doubling of the NOAEL (0.0016 mg/kg/day). This health

guidance value is supported by a number of well-conducted epidemiological studies that identify reliable NOAELs and LOAELs for dermal effects. Southwick *et al*. (1981) identified a NOAEL of 0.006–0.007 mg/kg/day for dermal lesions in several small populations in Utah. Harrington *et al*. (1978) identified a NOAEL of 0.003 mg/kg/day for dermal effects in a small population in Alaska. Guha Mazumder *et al*. (1988) identified a NOAEL of 0.009 mg/kg/day and a LOAEL of 0.006 mg/kg/day for pigmentation changes and hyperkeratosis in a small population in India. Haque *et al*. (2003) identified a LOAEL of 0.002 mg/kg/day for hyperpigmentation and hyperkeratosis in a case-control study in India. Cebrian *et al*. (1983) identified a NOAEL of 0.0004 mg/kg/day and a LOAEL of 0.022 mg/kg/day in two regions in Mexico. Borgono and Greiber (1972) and Zaldivar (1974) identified a LOAEL of 0.02 mg/kg/day for abnormal skin pigmentation in patients in Chile, and Borgono *et al*. (1977) identified a LOAEL of 0.01 mg/kg/day for the same effects in school children in Chile. Valentine *et al*. (1985) reported a NOAEL of 0.02 mg/kg/day for dermal effects in several small populations in California. Collectively, these studies indicate that the threshold dose for hyperpigmentation and hyperkeratosis is approximately 0.002 mg/kg/day.

Fierz (1965) discussed the dose-response relationship between skin cancer and the total dose of Fowler's solution ingested as medication. He reviewed 262 patients who had been treated for weeks or for several years with Fowler's solution for various chronic dermatoses. Of the solution, 10–2600 mL had been administered to the patients. Among those patients who developed late effects from this treatment, 40% had hyperkeratosis and 8% had skin cancer. A clear relationship between the increase in the incidence of both hyperkeratosis and cancer and the increased dose of arsenic was indicated (Fierz, 1965).

Dose-response relationships between skin cancer and arsenic have been discussed by Tseng *et al*. (1968) and Tseng (1977) for Taiwanese populations exposed to arsenic-contaminated well water. Of a total population of 40,421, arsenical skin cancer was found in 428 persons (10.6/1000). There were no patients younger than 20 years of age. The minimal amount of arsenic in well water necessary to induce skin cancer was estimated at less than 0.29 mg/L. The WHO Task Group on Environmental Health Criteria for arsenic (WHO, 1981) concluded, based on this study, that the lifetime risk for skin cancer is approximately 25% per mg As/L drinking water. Based on the Taiwan skin cancer data using the multistage model, the U.S. EPA has calculated a cancer unit risk for drinking water of 5E-5 per (μg/L) (EPA, 2005).

There is increasingly convincing evidence that long-term exposure to arsenic can result in the development of bladder cancer (Bates *et al*., 2004; Chen *et al*., 1992; Chiou *et al*., 1995, 2001; Cuzick *et al*., 1992; Guo, 2000), with transitional cell cancers being the most prevalent. Chiou *et al*. (1995) reported a dose-response relationship between long-term arsenic exposure from drinking artesian well water and the incidence of lung cancer, bladder cancer, and cancers of all sites combined (after adjustment for age, gender, and cigarette smoking) in four townships in Taiwan exposed to inorganic arsenic in drinking water (0–1.14 mg/L). In a later follow-up study of the same cohort, the increase in bladder cancer was found to be statistically significant only in subjects exposed for 40 years or longer (Chiou *et al*., 2001). Cuzick *et al*. (1992) evaluated a cohort treated with Fowler's solution (potassium arsenite) in Lancashire, England, during the period 1945–1969 and followed through 1991; the cohort of 478 patients showed a significant excess of bladder cancer, but no excess for other causes of death. Of a subcohort of 142 patients examined for signs of arsenicism around 1970, all 11 subsequent cancer deaths occurred in those with signs of arsenicism ($P = 0.0009$). Hopenhaya-Rich *et al*. (1996) investigated bladder cancer mortality for the years 1986–1991 in 26 counties of Cordoba, Argentina, and reported that bladder cancer SMRs were consistently higher in counties with documented arsenic exposure; a later case-control study by the same authors (Bates *et al*., 2004) did not report statistically significant increases in bladder cancers resulting from arsenic exposure, except in individuals exposed for 50 years or longs. Guo (2000) reported significantly increased rate differences for bladder cancer in men and women in Taiwan exposed to 0.64 mg arsenic/L in the drinking water, but not at lower exposure levels.

A study of arsenic-exposed individuals in northern Chile reported significantly increased odd ratios for lung cancer among subjects with >30 μg As/L of drinking water (Ferreccio *et al*., 2000), although when adjusted for socioeconomic status, smoking, and other factors, the increase was only significant at 60 μg/L or greater. Guo (2004) reported significantly increased rates differences (RD) for lung cancer for Taiwanese men and women exposed to 0.64 mg arsenic/L or greater, with those older than 50 years of age being particularly at risk. Nakadaira *et al*. (2002) suggested that even comparatively short exposure durations (less than 5 years) might be sufficient for the development of arsenic-induced lung cancer.

The National Academic Sciences (NRC, 1999; 2001) has analyzed the Taiwan data and estimated excess lifetime risk of bladder and lung cancer with various arsenic levels in drinking water: at a concentration of

arsenic in drinking water of 3 µg/L, the lifetime risk estimates for bladder and lung cancer combined are approximately 4 and 10 per 10,000 using the Taiwan or U.S. background rates of these cancers, respectively. The U.S. EPA has not yet calculated a unit risk value or slope factor for arsenic-induced internal tumors.

Some data on dose-response relationships for respiratory cancer have been given by Pinto *et al*. (1977). They found an almost linear increase in respiratory cancer with an increasing "exposure index." From the data, it can be estimated that exposure to airborne arsenic of about 50 µg/m^3 for more than 25 years might increase the risk for developing respiratory cancer nearly threefold.

The data must be interpreted with caution because of the possible influence-complicating factors. As for workers engaged in production of insecticides such as lead arsenate, calcium arsenate, copper acetoarsenite, and magnesium arsenite, a positive dose-response relationship between the degree of arsenic exposure and lung cancer was indicated (Blejer and Wager, 1976; Ott *et al*., 1974). The ratio of observed to expected respiratory cancer deaths ranged from 0.6 in the lowest exposure category to 7.0 in the highest. However, this dose-response relationship in regard to lung cancer should be reevaluated after epidemiological adjustment of the smoking histories of the workers.

Jarup *et al*. (1989) reported significantly increased lung cancer mortality (SMR = 372, 95% confidence interval [CI] = 304–450) based on 106 lung cancer deaths in a cohort of 3916 male workers employed for at least 3 months between 1928 and 1967 at the Ronskar smelter and followed for mortality through 1981. Workers were separated into low, medium, and high arsenic exposure groups, with mean time-weighted average exposure estimates of 0.05, 0.2, and 0.4 mg/m^3, respectively. Lung cancer mortality was significantly increased in all three exposure groups in a concentration-related fashion (SMR = 201, 353, and 480, respectively). A nested case-control analysis of 102 lung cancer cases and 190 controls from the cohort showed that lung cancer risk increased with increasing arsenic exposure in nonsmokers, light smokers, and heavy smokers (Jarup and Pershagen, 1991).

Enterline and Marsh (1982) reported a significant increase in respiratory cancer mortality (SMR = 189.4) based on 104 observed respiratory cancer deaths and only 54.9 expected over the years 1941–1976 in a cohort of 2802 male workers employed for at least 1 year between 1940 and 1964 at the ASARCO smelter. Enterline *et al*. (1987) reanalyzed these data using improved exposure estimates that incorporated historical measurements of arsenic in the ambient and personal breathing zone of workers. Respiratory cancer mortality was significantly increased in a concentration-related fashion in the low (SMR = 213.0), medium (SMR = 312.1), and high (SMR = 340.9) arsenic exposure groups, which had mean estimated time-weighted average arsenic exposure of 0.213, 0.564, and 1.487 mg/m^3, respectively.

Respiratory cancer mortality was significantly increased (SMR = 285) on the basis of 302 observed respiratory cancer deaths between 1938 and 1977 in a cohort of 8045 white male workers employed for at least 1 year at the Anaconda smelter (Lee-Feldstein, 1986). Analysis of a subset of the Anaconda cohort (n = 1800, including all 277 employees with heavy arsenic exposure) that included information on smoking and other occupational exposures showed that lung cancer mortality increased with increasing time-weighted average arsenic exposure, with a small nonsignificant increase in the low group (SMR = 138) exposed to 0.05 mg/m^3 and significant increases in the medium (SMR = 303), high (SMR = 375), and very high (SMR = 704) groups exposed to 0.3, 2.75, and 5.0 mg/m^3, respectively. Lubin *et al*. (2000) reweighed the exposure concentration on the basis of duration and time of exposure and reevaluated the effects of exposure. Relative risks for respiratory cancer increased with increasing duration. SMRs were significantly elevated after exposure to 0.58 mg/m^3 (SMR = 3.01, 95% CI = 2.0–4.6) or 11.3 mg/m^3 (SMR = 3.68; 95% CI = 2.1–6.4) for 10 or more years, and after exposure to 0.29 mg/m^3 (SMR = 1.86, 95% CI = 1.2–2.9) for 25 or more years.

On the basis of the dose-response relationships between arsenic exposure and excess lung cancer mortality in workers at the Anaconda smelter and the ASARCO smelter, the U.S. EPA (2005) has derived a unit risk estimate (the excess of lung cancer associated with lifetime exposure to 1 µg inhaled inorganic arsenic/m^3) of 4.3×10^{-3} per (µg/m^3).

9 DIAGNOSIS, TREATMENT, AND PROGNOSIS

When specific exposures have occurred, poison control centers and medical toxicologists should be consulted for medical advice. There are several medical toxicology texts that provide specific information about clinical treatment after exposures to arsenic (Ellenhorn, 1997; Goldfrank *et al*., 1998; Tintinalli *et al*., 1996).

9.1 Acute Poisoning

9.1.1 Inhalation Diagnosis

Acute intoxication caused by inhalation of arsenic is unusual except in the case of arsine (see Section 10),

although respiratory symptoms may occur among workers suddenly exposed to high concentrations of arsenic in smelters. Gerhardson *et al*. (1988) reported a case of a smelter worker who inhaled a large quantity of arsenic-containing dust (80% As_2O_3) who died several hours later. Autopsy findings disclosed widespread hemorrhages in the respiratory tree and congestion of the major organs. Acute skin lesions such as contact and allergic dermatitis may be observed around the eyes and mouth, as well as on the face and neck. The diagnosis of such cases is based on the knowledge of a history of arsenic exposure. The measurement of arsenic in urine may be useful, provided the specimen is taken within a few days after exposure.

9.1.1.1 Treatment and Prognosis

Conservative treatment is usually applied to the skin lesions. Dimercaprol (BAL) may be given in cases of severe symptoms of the respiratory system or the skin. Chelation therapy is most effective when instituted within a few hours after exposure, and efficacy decreases as time after exposure increases (McFall *et al*., 1998; Peterson and Rumack, 1977). In general, chelating agents should be used with caution, because they may have serious side effects such as pain, fever, hypotension, and nephrotoxicity. Some water-soluble and less toxic analogs of BAL such as dimercaptosuccinic acid (DMSA), dimercaptopropyl phthalamadic acid (DMPA), and dimercaptopropane sulfonic acid (DMPS) are currently under investigation and may prove to be promising treatments for arsenic poisoning (Aposhian *et al*., 1997; Guha Mazumder, 1996; Kreppel *et al*., 1995). A recent article by Vantroyen *et al*. (2004) described a case of a massive arsenic trioxide overdose that was successfully treated by continuous gastric irrigation with sodium bicarbonate, forced diuresis, and administration of BAL and DMSA.

9.1.2 Ingestion Diagnosis

The determination of arsenic in urine, hair, and, in some cases, blood or stomach contents, is useful for diagnosis if exposure to arsenic cannot be readily identified.

9.1.2.1 Treatment and Prognosis

The treatment for acute arsenic poisoning by oral ingestion is referred to in standard medical textbooks (e.g., Haddad and Winchester's *Clinical Management of Poisoning and Drug Overdose*, 2nd edition (1990). Prognosis will depend on both dose and time span between the ingestion of arsenic and first treatment. In some cases where the patient has recovered from acute poisoning, dermatitis and peripheral neuritis may persist for a relatively long time (Le Quesne and McLeod, 1977).

9.2 Chronic Poisoning

9.2.1 Diagnosis

In the diagnosis of chronic arsenic poisoning, it is important to differentiate between senile pigmentation, senile leukodermia, and arsenical dermatoses, as well as between peripheral polyneuritis caused by arsenic poisoning and caused by other diseases. This is especially true for individuals exposed to arsenic by ingestion.

Concentrations of arsenic in biological tissues may be within the normal range at the time diagnosis is made. In such cases, a well-designed epidemiological study may be required if it is thought that a whole group of people might have been exposed to arsenic. White striae in the fingernails (Mees' lines) are also a useful clue in the diagnosis of arsenical polyneuritis, because urine and hair arsenic concentrations may be within normal limits despite the presence of this condition (Heyman *et al*., 1956).

Recognition of damage to the upper respiratory tract, specifically perforation of the nasal septum, may be quite helpful in the diagnosis of chronic arsenic poisoning caused by somewhat higher exposures to inorganic arsenic.

Liver damage, including cirrhosis and angiosarcoma, which may be seen in an arsenic-exposed individual, may require differentiation in terms of the cause-effect relationship. Among younger people exposed to inorganic arsenic–contaminated food and water, cardial and pulmonary symptoms are useful in diagnosis.

9.2.2 Treatment and Prognosis

BAL has been used for the treatment of chronic arsenic poisoning, particularly in cases of dermatosis. Pinto and McGill (1953) administered BAL to people with arsenic dermatitis. They succeeded in augmenting the excretion of arsenic into urine, but not in improving skin changes such as melanosis and keratosis. A randomized placebo trial of 2,3-DMSA as a therapy for chronic arsenosis caused by drinking contaminated water found no significant difference between patients treated with 2,3-DMSA and those treated with a placebo (Guha Mazumder *et al*., 1998a). Apart from the often-questionable use of BAL, the treatment of chronic arsenic poisoning should generally be conservative.

Skin changes and neuropathy may persist for a number of years. The skin changes seen in simple keratosis may progress into Bowen's disease, which will spread over the entire body in multiple forms.

10 ARSINE

Arsine (hydrogen arsenide, AsH_3) is a colorless, inflammable gas with a slight garlic odor. It is generated whenever nascent hydrogen is liberated in material containing arsenic. Because arsenic is present as an impurity in many metal ores, arsine may be generated in metal industries, nonferrous metal refineries, and in the manufacture of silicon steel, if the ores being processed accidentally come into contact with acid. Arsine may also be released when the hydrogen ion is formed by hydrolysis and in the reaction of moisture with arsenic-containing dross.

The toxicity and toxicological mechanisms of arsine are quite different from those of other inorganic or organic arsenic compounds. Arsine acts as a powerful hemolytic poison in cases of both acute and chronic exposure.

Henderson and Haggard (1943) observed that the lethal dose of arsine for humans was 250 mg/m^3 for 30 minutes, and that symptoms of poisoning occur after a few hours of exposure to 3–10 mg/m^3. Elkins (1959) reported a serious, nonfatal, acute case of arsine poisoning in a person who had worked in an atmosphere contaminated with an average of 0.5 mg arsine/m^3. Five workers, examined by Kipling and Fothergill (1964), developed typical arsine poisoning when working a plant where an acetylene-like odor was detected. This odor occurred during the slag-dissolving process that took place in a rotating drum. The concentration of arsine in this factory was 5 mg/m^3.

Morse and Setterlind (1950) studied two fatal cases of arsine poisoning in which aluminum had been used to extract arsenic. The concentration of arsine in this instance was 70–300 mg/m^3.

Arsine poisoning is characterized by nausea, abdominal colic, vomiting, backache, and shortness of breath, followed by dark blood urine and jaundice (Kipling and Fothergill, 1964). According to Bulmer *et al*. (1940), the following symptoms appeared after various lengths of exposure to arsine: shortness of breath on exertion, general malaise, nausea, poor appetite, palpitation on exertion, and headache. In some groups of workers, a tingling sensation in the feet, chills, garlic breath, changes in complexion, weakness, vomiting, and drowsiness were observed. Jaundice was also noted in a number of people. Some of the workers with the longest exposure had anemia. Arsenic in urine was almost always elevated and ranged from 0.04–4.3 mg/L. Even after the workers had left the arsine-contaminated area, arsenic in urine ranged from 0.04–0.1 mg/L. Peripheral neuritis was seen in arsine-exposed workers (Dudley, 1919). Liver disturbances may accompany arsine poisoning. In most fatal cases, renal failure caused by blockage of the renal tubules by hemoglobin casts seems to be the cause of death (Fowler and Weissberg, 1974). Residual functional impairment of the kidneys has been reported in one person after an acute episode of arsine poisoning (Muehrcke and Pirani, 1968).

The use of BAL for arsine poisoning has not had desirable results. Symptomatic therapy, which is generally used, is considered more reliable, particularly in the treatment of anuria. Blood transfusions may be necessary for severe anemia. Arsine toxicity and treatment have been reviewed extensively by Fowler and Weissberg (1974).

The mechanisms of arsine gas toxicity and more recent studies in experimental animal/*in vitro* model systems have also been studied over the last 20 years primarily because of possible health effects related to its use in the semiconductor industry.

Arsine is used in doping the silicon-based chips and in producing III-semiconductors, such as GaAs and InAs. Before the recent uses of arsine gas in the semiconductor industry, the main concerns regarding human health were related to its use as a war gas and from industrial accidents (Fowler and Weisberg, 1974). In the past, the chief clinical effects observed in persons with acute occupational arsine exposure were massive hemolysis followed by death from renal failure. Patients typically presented with decreased hematocrit values and red "port wine"–colored urine because of the presence of hemoglobin. Histopathological evaluations of postmortem kidney samples demonstrated the presence of renal tubular obstruction from hemoglobin casts that resulted in renal failure. With the development of renal dialysis, mortality from acute exposure has been greatly reduced in recent decades (Fowler and Weisberg, 1974).

10.1 Experimental Model Studies

Prolonged inhalation exposures of rodents to arsine at sublethal lower doses (Blair *et al*., 1990ab; Fowler *et al*., 1989; Hong *et al*., 1989; Morrissey *et al*., 1990; Rosenthal *et al*., 1989) have been shown to produce a regenerative anemia with immature erythrocytes and the presence of Howell–Jolley bodies in the peripheral blood. Splenomegaly and the characteristic arsenical-induced porphyrinuria (Woods and Fowler, 1978) dominated by increased excretion of uroporphyrins with lesser quantities of coproporphyrin (Fowler *et al*., 1989) are also major manifestations of arsine toxicity to the hematopoietic system. Other effects include alterations in immune system function that have been noted in animals exposed to arsine for prolonged periods of time (Rosenthal *et al*., 1989), indicating concomitant perturbation of this important biological defense

system. No negative reproductive and developmental outcomes in rodents exposed to arsine (Morrissey *et al*., 1990).

Studies conducted in cell culture systems exposed to arsine *in vitro* (Ayala-Fierro and Carter, 2000; Carter *et al*., 2003; Hatelid and Carter, 1997; Hatelid *et al*., 1996; Rael *et al*., 2000; Winski *et al*., 1997) have shown methemoglobin formation and ultrastructural effects on erythrocyte membrane structure with concomitant loss of ion regulation capabilities with attendant red cell lysis. Based on these *in vivo* and *in vitro* experimental studies, arsine is clearly a highly toxic chemical agent that exerts toxicity on a number of organ systems. Target cells in the hematopoietic, liver, kidney, and the immune systems are clearly sensitive to arsine toxicity after either short-term or more chronic exposures. The mechanisms by which this agent produces hemolysis seem to require oxygen and the internalization of arsine into the red cells with subsequent oxidation and inhibition of membrane ion regulatory mechanisms. Pharmacological factors such as dose and duration of exposure, as well as susceptibility factors such as age and nutritional status of those exposed, will also have an impact on prognosis.
