Risks for occurrence and chances of recovery from new postoperative neurological deficits (e.g., hemiparesis or language impairment), may be reduced in pediatric patients as a result of developmental plasticity and potential for transfer of eloquent functions. In patients with Rasmussen's encephalitis involving the left (dominant) hemisphere, transfer of language has been described to the right hemisphere during the course of the illness.[38] Language may also develop in unusual regions of the left hemisphere in a congenital malformations or tumors involving the left frontal or posterior temporal region.[39,40] In these cases, the epileptogenic lesion may be resected or disconnected without worsening or producing new language deficits. Motor function may also partially develop outside a damaged or malformed rolandic region, so that resection of a perirolandic lesion results in little or no additional postoperative motor deficit. Factors favoring developmental plasticity include early onset of the lesion (e.g., perinatal infarction or congenital malformation) and surgery performed within the first few years of life.

Mortality in infants undergoing epilepsy surgery

Epilepsy surgery in infants has higher morbidity and mortality compared to adults due to several factors such as perioperative blood loss and hypothermia in the face of lower weight and smaller blood volume, radical surgeries with multilobar or hemispheric resections, and higher likelihood of metabolic derangements. The risk of death in recent larger series from several centers is around ~1–1.5%.[7,22,41–43] However, the mortality from epilepsy surgery in infants still compares favorably against the mortality from uncontrolled seizures treated medically. In a populationbased cohort study in children[44] (1–16 years of age) who developed epilepsy between 1977 and 1985, 26 (3.8%) of 692 children died by the year 1999. Majority (13 of 26) of the children who died had secondarily generalized seizures. Presence of neurological deficit was the only independent factor that determined mortality. Similar results have been reported from a Dutch study.[45,46] These epidemiological data reinforce consideration for early surgical intervention as children with surgically remediable catastrophic epilepsy often have neurological deficits and secondarily generalized seizures.

Conclusions

Presurgical evaluation in infants and young children entails a variety of special challenges, and requires a special set of skills for accurate interpretation of clinical data, EEG, and imaging studies. In addition, decision for surgery requires a careful study of the benefit/risk ratio in every child, keeping in mind the complicated interplay of age-related factors and parental understanding. All children with catastrophic epilepsy, regardless of age, must be promptly evaluated for the possibility of surgically remediable epilepsy. Management of infants with surgically remediable catastrophic epilepsy is best done at centers with experienced and dedicated team of pediatric epilepsy specialists, neurosurgeons, anesthesia, and intensive care staff.

SECTION 4

Presurgical evaluation: general principles

47 General principles of presurgical evaluation

M Carreño and HO Lüders

The main goal of the presurgical evaluation in patients with intractable epilepsy has been the identification of the cortical area capable of generating seizures, and whose removal or disconnection will result in seizure freedom. This area is called the *epileptogenic zone*. It includes not only the actual area that is generating the patient's habitual seizures, but also those regions with potential epileptogenicity, which could give rise to seizures if they were left in place, even though the documented seizure onset zone is removed. The concept of the epileptogenic zone is a purely theoretical one, and its extent and location cannot be determined until we have actually made the patient seizure free after resective surgery. At that point it is possible to state that the epileptogenic zone was indeed included in the removed area.

To estimate where the epileptogenic zone is and what its boundaries are, epileptologists have been using different diagnostic tools of increasing complexity and technical difficulty. This includes careful analyses of seizure semiology, electrophysiological studies (noninvasive and invasive), anatomical neuroimaging, and functional neuroimaging. These diagnostic methods have led to the definition of several cortical zones (*symptomatogenic zone*, *irritative and ictal onset zones*, *epileptogenic lesion*, *and functional deficit zone*), each one of which is a more or less precise index of the epileptogenic zone. During modern presurgical evaluation of patients with intractable epilepsy, an attempt is made to locate and define the boundaries of these five zones. In the ideal surgical candidate, all five zones will show a high degree of overlap and the resection can be performed with a high likelihood of seizure freedom. However, in most patients the different cortical areas are somewhat discordant in location or extent and, in the final decision about surgery, the relative significance of each one of these areas (based on the information presented below) must be weighted carefully.

In this chapter we provide an overview of these five zones, the techniques we use to locate them, and their relative advantages and disadvantages to estimate the epileptogenic zone. We will start with the sympomatogenic zone, which was the first cortical area that epileptologists could define, just by analyses of seizure semiology. The rest of the zones will be reviewed in the order in which they were defined and used in clinical practice, thanks to the growing amount and accuracy of diagnostic techniques.

Originally published as Chapter 20, pp. 185-199 Epilepsy Surgery 2nd edition, Hans O Lüders, Lippincott, Nov 2000, USA.

Symptomatogenic zone

The symptomatogenic zone is the cortical area that, when activated by the epileptic discharge, reproduces the patient's typical ictal symptoms. The symptomatogenic zone that produces the initial ictal symptoms is usually most important when we use it as an index of the location of the epileptogenic zone. The concept that the symptomatogenic zone was a good index of the epileptogenic zone was a by-product of the pioneering work of John Hughlins Jackson in the nineteenth century. He was the one who first used ictal symptomatology to define cerebral localization in patients with partial epilepsies. Jackson's clinical observations and autopsy studies provided evidence about the role of the cerebral cortex in motor function and in epilepsy. His definition of epilepsy, which still stands today, was made in 1873: 'epilepsy is the name for occassional, sudden, excessive, rapid and local discharges of gray matter'.[1] Until the introduction of the electroencephalogram (EEG) by Berger, localization in epilepsy surgery was based entirely on the determination of the symptomatogenic zone. 'William Macewen,[2] Alexander Hughes Bennett and Rickman Godlee,[3] J. R. Green,[4] and Victor Horsley[5] performed the first operations for the treatment of epilepsy, basing the presurgical localization of the tissue to be resected mainly on seizure symptomatology. Bancaud and Talairach also regarded as crucial the order and sequence of semiological elements to extrapolate the anatomical origin of the seizure discharge. A methodical description of signs and symptoms, with an analysis of their sequential occurrence, led to the definition of seizure patterns that became the topic of the majority of Bancaud's publications.[6–13]

A good analysis of the ictal symptomatology requires in the first place a detailed clinical history. However, the patient's and family's seizure reports are often inaccurate. In addition, experience with patients who have undergone successful resective surgery has shown that some subtle ictal symptoms that may be overlooked are extremely helpful to lateralize or even localize the epileptogenic zone.[14–21] For these reasons, it is now widely accepted that an experienced epileptologist should personally review some of the patient's seizures recorded on video to define correctly the symptomatogenic zone.

Not all the ictal symptoms have the same value to localize the symptomatogenic zone, according to the principles of neurological localization. Some symptoms are highly likely to be produced by one well-defined cortical area; for example, an auditory aura lateralized to the left ear is likely to arise from the vicinity of Heschel's gyrus in the contralateral temporal

neocortex. Localized paresthesias affecting the right side of the face and right arm are probably due to epileptic discharges involving the left SI. Simple visual hallucinations (flashing lights or dots) in the left visual field are probably due to activation of primary visual cortex in the right occipital lobe. However, other ictal symptoms are less specific and less reliable to localize the symptomatogenic zone: Whole-body tingling, for example, can be seen in the context of epilepsy arising from different cortical areas.

It was assumed for a long time that, in patients with partial epilepsy, the symptomatogenic zone was the area from which the seizure was actually originating. However, it is important to stress that the sympomatogenic zone and the epileptogenic zone usually do not overlap. When the conditions of epileptic activation are reproduced experimentally with electrical cortical stimulation, it has been shown that most of the human cortex is 'silent' (it does not produce any symptoms) when it is stimulated. Even in 'eloquent' areas, the electrical stimulus must have certain features (in terms of intensity, duration, and frequency) to produce clinical symptoms. Different eloquent areas have also different thresholds to produce the corresponding symptoms.

This implies that discharges frequently arise from noneloquent areas in the brain, sometimes at a significant distance from eloquent cortex, and that they give rise to clinical symptoms only when they spread and activate an actual symptomatogenic zone. This explains why seizures arising from different locations may present with similar symptoms (and, by extension, with similar 'symptomatogenic zones'). For example, seizures arising from mesial occipital, mesial parietal, mesial frontal, and basal frontal regions may all manifest clinically with bilateral asymmetrical tonic seizures, caused by activation of the supplementary sensorimotor area (SSMA). Removing the SSMA would make seizure free only those patients in whom the seizures were really arising from this region in the mesial frontal lobe. Most likely, seizures would persist in patients with basal frontal, mesial parietal, or mesial occipital lobe epilepsies.

In spite of all these limitations (lack of precise correspondence between ictal symptoms and a clearly defined symptomatogenic zone, as well as lack of overlapping of sympomatogenic zones and epileptogenic zones), seizure semiology still remains an extremely valuable tool in the evaluation of epileptic patients. It has been shown that seizures can be accurately classified according to clinical semiology alone,[22,23] and that ictal symptoms need to be considered together with the electrophysiological and neuroimaging data to define correctly the epileptic syndrome.[22,23] Seizure semiology not infrequently can be used to support or discourage surgery. For example, a patient with seizures starting with a hypermotor phase (symptomatogenic zone probably corresponding to cingulate gyrus and adjacent structures) and then evolving into a dialeptic (quiet staring) phase most likely has frontal lobe epilepsy, even though the EEG may show interictal temporal spikes and a late temporal ictal pattern. A temporal lobectomy in this patient is likely to fail.

Irritative zone

The irritative zone is the area of cortex capable of generating interictal spikes on the EEG. The presence of interictal spikes strongly supports the diagnosis of epilepsy, although some epileptic patients do not exhibit any interictal epileptiform abnormalities even in prolonged recordings. We also know from extensive experience with routine EEGs that the spike location is a good indicator of the area of cortex from which seizures are originating. In general, isolated spikes, independent of whether they arise from silent or even eloquent cortex, do not produce any clinical symptoms. In order to produce symptoms, spikes usually have to give rise to afterdischarges (runs of epileptiform discharges that by tempotal summation have enough strength to activate a symptomatogenic zone when they generate in it or spread to it). There are several methods that can be used to register interictal spikes; all of them have limitations that will be discussed below.

Scalp electroencephalography

History

The greatest advance in EEG came in 1929, when Hans Berger published his first work on scalp recordings of human EEGs.[24,25] Berger developed the EEG to record human brain activity from the scalp, and his findings on interictal EEG activity were mentioned as early as 1933.[26] These were soon confirmed by other authors, including Adrian and Mathews[27] and Jasper and Carmichael.[28] The interictal spike as the hallmark of epilepsy was first described in 1934 by Fischer and Lowenbach.[25,29] Wilder Penfield, who founded the Montreal Neurologic Institute in 1934, soon recognized the great potential of the EEG to define better the epileptogenic zone. The laboratory of EEG and neurophysiology run by Herbert Jasper was the first of its kind to be dedicated to selecting epilepsy patients for surgery and providing the techniques for intraoperative recordings.[30] Jasper published one of the first reviews on the application of EEG to epilepsy and epilepsy surgery in Penfield and Erickson's book titled *Epilepsy and Cerebral Localization*.[31] In 1951, Bailey and Gibbs reported a series of 25 patients who underwent temporal lobectomy based solely on EEG criteria.[32] Their results were encouraging and helped establish the EEG as the primary modality of seizure localization in the workup of patients for surgical resection.

Scalp electroencephalography to determine the irritative zone

Scalp EEG is a convenient technique to give a good overview of the general distribution of the epileptiform activity, especially if it is performed with closely spaced electrodes and special electrodes if needed (sphenoidal or nasopharyngeal electrodes). It can sample extensive areas of the brain, and has no known serious complications because of its noninvasive nature; in addition, there is extensive experience in the identification of spikes in the scalp EEG. Because of these reasons, it continues to be the initial (and at times the only) indispensable step in the evaluation of the irritative zone.

Scalp EEG has, however, some technical limitations:

- The electrical activity recorded by scalp EEG is significantly distorted by high-resistance materials lying between the cortex and the recording electrodes (bone, meninges).
- To be detected, epileptiform discharges must involve synchronized activity of a significant extension of cortex

(around 6 cm^2).[33] Interictal spikes generated by a smaller cortical surface do not show up in scalp recordings.
- Interictal activity arising from deep or midline structures is usually not reflected on scalp EEG.
- Precise localization and determination of the extent of the cortical area that is giving rise to an interictal spike is impossible. From the surface distribution of the epileptiform discharge we can only estimate where the maximum is, and get a rough estimate of the approximate extent of the irritative zone.
- There are a number of factors that may influence frequency and morphology of interictal spikes. Spikes are more frequent and widespread during deep stages of sleep than during wakefulness and rapid eye movement sleep,[34] and there are reports suggesting that spikes also increase in frequency after seizures.[35,36] Levels of antiepileptic medications during the recording may also affect the frequency of interictal spiking, although this issue remains controversial.[35] All these factors, and particularly the duration of the EEG recording, will greatly influence the location and extent of the irritative zone we measure.

Invasive recording methods

History

Direct recording from the brain surface was attempted initially during surgery using the technique of electrocorticography (ECoG). However, chronic intracranial recordings were not reported until 1954, when Penfield used epidural strips of wires[37] The use of depth electrodes was developed and popularized by Bancaud and Talairach during the 1960s; their method, stereoelectroencephalography (SEEG), used a stereotactic technique to place accurately the electrodes and allowed recording of electrical activity of structures involved at different times during the course of a seizure.[38] Evaluation with depth electrodes soon became an essential step in the evaluation of surgical candidates in epilepsy surgery centers in Europe. Depth electrodes were introduced in North American by the Montreal Neurological Institute, and they soon became part of the standard evaluation of epilepsy surgery candidates.[39]

Invasive Recordings for Evaluation of the Irritative Zone

Direct recording from the brain surface by epidural, subdural, or depth electrodes should detect all interictal epileptiform discharges (even the ones generated by a small cortical area) without the distortion introduced by the high-resistance materials interposed between cortex and scalp. It should also permit a more accurate delineation of the boundaries of the irritative zone. However, invasive recordings have also some significant disadvantages:

- They are invasive techniques that may be associated with a number of complications, including infection, hemorrhage, and increase of intracranial pressure.
- Because of their invasive nature, they can be used to cover only a limited amount of cortical surface. An adequate coverage should be carefully planned based on the scalp EEG and neuroimaging data; however, once the electrodes have been implanted, information will be limited to the cortex that is being sampled. Potentially important information from other areas may be missed, making exact assessment of the boundaries of the irritative zone impossible.
- Experience with invasive recordings is much more limited than with scalp EEG, and there have been no recordings of normal activity in nonepileptic patients. For this reason the degree of abnormality of the recorded activities is subject to personal interpretations and also to error.
- It is unclear if the special conditions imposed by chronic invasive recordings may artificially enhance or decrease the epileptiform activity over the underlying cortex.

Electrocorticography (ECoG)

Interictal epileptiform activity can also be recorded directly from the cerebral cortex during surgery. The first report of direct electrical activity measurement from the human cerebral cortex during surgery was published in 1935 by Foerster and Altenburger.[40] By the early 1950s, it was extensively used and considered an indispensable technique in the evaluation of surgical candidates to define the irritative zone.[37] However, some studies pointed out similar outcomes in patients with total or partial removal of the irritative zone as defined by ECoG.[41,42] For this reason, ECoG was abandoned in some centers, but continues to be performed in others, as an adjunctive technique in the definition of the irritative zone.

ECoG is a safe technique, and possible complications derive from the craniotomy and surgery themselves, not from the recording. However, it has a number of inconvenient aspects: the area that can be sampled is limited by the exposure during surgery, and some regions, such as the mesial temporal structures or the medial surface of the brain, are difficult to reach (intraoperative recording from depth electrodes may solve this issue). ECoG prolongs the time of the intervention and requires immediate decision making. In addition, the particular circumstances of the recording during surgery (surgical trauma to brain surface, anesthetic agents that reduce or enhance spikes) may alter the amount and location of the epileptiform abnormalities. As with subdural or depth recordings, the experience with ECoG is limited and, once again, the degree of abnormality is subject to personal interpretations (Penfield had already described 'red and green' spikes with different epileptogenic potential). However, ECoG may still contribute to a better delineation of the irritative zone in selected cases, particularly in patients who have not been evaluated with chronic invasive recordings.

Magnetoencephalography

Magnetoencephalography (MEG) detects magnetic fields induced by epileptic discharges and has recently been introduced as an aid in the identification of the irritative zone. The advantages over scalp EEG are the lack of distortion of the magnetic signal by meninges or skull, and the optimal detection of dipoles oriented parallel to the cortical surface. However, limitations include a small signal-to-noise ratio due to the low amplitude of the magnetic signal generated by electric brain activity, rapid magnetic field falloff with distance, and an inconvenient recording device that limits the patient's mobility and therefore the possibility of performing

prolonged recordings. Some studies have shown that MEG has an accuracy in source location similar to that of scalp EEG.[43] Both techniques can complement each other in defining the extent and location of the epileptogenic zone.

Relationship of the irritative zone with the epileptogenic zone

The main goal of defining the location and boundaries of the irritative zone is trying to delineate the epileptogenic zone. However, we know that the irritative zone is not a fixed and static region; rather, its boundaries are subject to change.

- Different recording methods yield different irritative zones; scalp recordings and MEG only permit vague definition of the extent of the irritative zone. Invasive recordings are significantly more sensitive, detecting irritative cortex invisible to scalp electrodes or MEG, However, as mentioned above, only a very limited amount of cortex can be investigated with invasive electrodes. Besides, because of the possible complications and the conceptual limitations of the invasive recordings used to define the irritative zone (see above), it does not seem reasonable to use them routinely in every patient.
- The irritative zone also varies depending on the sampling period, the number of seizures, the state of wakefulness, and the level of antiepileptic medications.

We also know that the irritative zone and the epileptogenic zone often do not overlap. This variable topographical relationship was already demonstrated by Talairach and Bancaud.[44] The irritative zone usually is more extensive than the epileptogenic zone. For example, patients with temporal lobe tumors often have interictal spikes in both temporal regions; however, no seizures (or spikes) occur when the tumor is removed.[45] Some patients with tuberous sclerosis, infantile spasms, and multiregional spikes may be seizure free after focal resections.[46–48] Some patients in whom it is not possible to remove the entire irritative zone because it involves eloquent cortex may also become seizure free after partial resections. On the other hand, the opposite situation may also hold true in some patients, with the epileptogenic area being more extensive than the irritative zone. For example, we know that some patients with documented seizures display no interictal epileptiform abnormalities even during prolonged recordings in monitoring units.

Ictal onset zone

The ictal onset zone is the cortical region from which we can objectively demonstrate that seizures are arising. Some authors, such as Bancaud and Talairach, soon understood the limitations of interictal recording techniques to define the epileptogenic zone. At that time scalp EEG and ECoG were the main presurgical evaluation techniques. Scalp EEG, however, was used mainly in the interictal period, and corticography was also an interictal investigation requiring decision making in the setting of the operating room. Bancaud and Talairach's method of SEEG allowed epileptologists for the first time to perform long-term recordings and record seizures directly from the brain structures involved in their generation. They expected that a better knowledge of the spatial and temporal dynamics of seizure discharges should provide a better estimate of the epileptogenic zone. Besides, SEEG gave investigators enough time to analyze the recordings and decide on a surgical technique.

Methods to determine the ictal onset zone

We have two different ways to objectively demonstrate which is the cortical area from which the seizures are arising: EEG recordings and ictal single-photon emission computerized tomography (SPECT).

Determination of the ictal onset zone by electroencephalographic recordings

The ictal onset zone determined by EEG is usually a subset of the irritative zone: It includes not all the regions capable of generating spikes, but only those whose spikes are able to generate 'spontaneous' afterdischarges (runs of epileptiform discharges that have sufficient 'strength' to induce symptoms when they invade a sympomatogenic zone). The EEG recordings to demonstrate seizure onset may be obtained from all the methods describe above for the irritative zone, except for MEG and ECoG, which, with few exceptions, are used as interictal diagnostic tests.

Scalp EEG

Widespread use of long-term EEG monitoring has allowed direct recording of seizures in the setting of epilepsy monitoring units. Closely spaced electrodes and semi-invasive techniques such as sphenoidal, foramen ovale, or nasopharyngeal electrodes provide a better estimation of the cortical area involved in seizure generation. However, scalp EEG still has important limitations:

- Seizure activity is recorded by scalp electrodes only when a threshold amount of cortex is involved by the seizure discharge. That means that the EEG-recorded seizures almost invariably must spread to a significant degree before they can be detected with scalp EEG. Simultaneous scalp and invasive recordings demonstrate that the scalp recordings are usually silent at seizure onset and that the surface distribution of the EEG-recorded seizure is not infrequently misleading since it only represents a spread pattern.
- The ictal onset cortical area can be estimated only roughly by scalp EEG. There is extensive experience with this technique, and many patterns have now been closely linked to certain epileptogenic zones (as confirmed by results of surgical interventions). However, there are still some ictal patterns of unclear localizing value (rhythmical slowing in the delta range located in the temporal chain, for example, may represent mesial temporal or lateral neocortical temporal onset), and some seizures on scalp EEG may mislocalize or even mislateralize the epileptogenic focus, especially in extratemporal epilepsies.
- Seizures arising from certain areas may be difficult to record, or their ictal pattern may be nonlocalizable. For example, mesial frontal seizures usually have subtle and diffuse EEG changes (background attenuation, diffuse fast activity in the midline) or no EEG change at all.

- Seizures recorded in the monitoring unit may not be the best representation of the patient's habitual seizures as they are recorded after medication withdrawal.

Invasive recordings

As we explained above, invasive methods of EEG recording may have serious complications. In addition, an accurate delineation of the seizure onset zone is limited by the same factors that limited the accurate localization of the irritative zone:

- Only seizures arising from areas adequately sampled by the invasive electrodes can be recorded. Unfortunately, it is unusual that the entire seizure onset zone is covered due to difficulties in placing electrodes over extensive cortical areas. The experience with invasive recording methods has shown that, if the seizure onset zone is adequately covered, we should see ictal activity (paroxysmal fast frequencies, relative electrodecrement, repetitive spikes, etc.) arising from a small number of electrodes, and it should spread in a logical fashion to adjacent areas (e.g., paroxysmal fast frequencies in the mesial temporal electrodes spreading to more lateral temporal and frontal contacts). The seizure onset on EEG should also precede in time any clinical symptoms. If a large number of electrodes are involved by the discharge from the beginning of the EEG seizure (e.g., all the mesial and lateral contacts of depth electrodes situated in the temporal lobe), it is assumed that this corresponds to a spread pattern and the seizure originated in an area outside the recording electrodes.
- Even with a clear ictal pattern arising from a small number of electrodes, it is usually not possible to delineate the extent of the ictal onset zone. It is generally assumed that those regions invoved by the discharges early in the seizure are a part of the ictal onset zone and should be removed during resective epilepsy surgery. However, this has not been studied in depth, and the interpretation of what is meant by 'early spread' (how many seconds) certainly varies greatly among different epileptologists.
- As we mentioned before when we talked about the irritative zone, several factors (no antiepileptic medications, abnormal pressure over cortical surface, etc.) may alter the ictal patterns during invasive recordings.

Determination of ictal onset zone by ictal single-photon emission computerized tomography

SPECT measures blow flood, and, comparing interictal and ictal SPECT studies, we can evaluate the relative increase in blood flow of certain cerebral regions during the ictal phase with respect to the interictal period. Presumably, the neurons located in these areas are hyperactive due to epileptic activation and the increase in blood flow is an autoregulatory response. This technique can evaluate all brain areas with similar accuracy, including deep regions of gray matter that are difficult to monitor with scalp and even with invasive EEG.[49,50] However, determination of ictal onset zone by ictal SPECT has some practical limitations:

- The scan shows only the areas that have been activated at the time the isotope reaches that brain region. Therefore, invariably ictal SPECT will only provide information about areas to which the seizure has spread, which do not necessarily overlap with areas from which the seizure originated. In the monitoring units, specialized personnel are trained to perform the injection during the first seconds of the seizure. However, because of technical difficulties, this does not always occur. Besides, it will take approximately 20 seconds for the agent to reach the brain region of interest after the injection of the radioactive agent. Moreover, we know from invasive recordings that the EEG-recorded seizures usually start long (seconds and occasionally even minutes) before the patient experiences the first clinical signs. Therefore, in general the dye reaches the brain at least 1 minute after seizure onset, a time at which significant seizure spread has already occurred.
- The spatial resolution of the images is low compared to other anatomical neuroimaging techniques such as magnetic resonance imaging (MRI) or positron emission tomography (PET).
- The global sensitivity of ictal SPECT to detect increase in cerebral blood flow may be similar to or slightly lower than scalp EEG (e.g., epileptic auras that occasionally have an EEG correlate consistently do not show any changes in ictal SPECT). However, it is clearly inferior to the invasive EEG recordings, which always show seizure onset if adequate coverage is provided. Moreover, the 'time constant' of ictal SPECT (which is an expression of compensatory increased blood flow in response to a metabolic activation of cortex) is significantly larger (5 to 10 seconds) than the time constant of EEG, which is measured in milliseconds.

In summary, ictal SPECT, as ictal EEG, can only define approximately the location and extent of the ictal onset zone. Presently, ictal SPECT is only used to provide complementary information to the EEG data with respect to ictal onset zone.

We want to mention also that functional MRI is currently being explored as a possible future way to determine the ictal onset zone. However, it is still not used in routine presurgical evaluations.

Relationship of the ictal onset zone and the epileptogenic zone

The ictal onset zone and the epileptogenic zone do not necessarily overlap. Even if we could accurately delineate the extension of the ictal onset zone, the epileptogenic zone may be more or less extensive. We know from clinical experience that some patients become seizure free even though the ictal onset zone is not entirely removed during resective surgery; for example, some patients with benign mesial temporal tumors and documented seizures arising from both sides may become seizure free after resection of the tumor.[45] That means that the remaining seizure onset zone becomes inactive after surgery (it was dependent on the other ictal onset zone to generate seizures).

On the other hand, some patients continue to have seizures in spite of complete removal of the ictal onset zone as evidence by EEG recordings. In some cases, the failure can be explained because the EEG recording techniques were inadequate to define properly the location or extent of the actual ictal onset zone. In other cases, however, the epileptogenic zone may be

more extensive than the actual ictal onset zone, including regions that remain silent as long as another active, lower threshold area generates the seizures. When the actual seizure onset zone is removed, however, the other 'potentially epileptogenic' regions become clinically apparent.

From a practical point of view, it is impossible to overcome these limitations. In other words, at present we cannot identify the patients whose epileptogenic area is more extensive or more limited than the actual ictal onset zone that can be defined by EEG or SPECT recordings.

Epileptogenic lesion

The epileptogenic lesion is a structural lesion visible by neuroimaging techniques that is responsible for generation of seizures. Before the computerized tomography (CT) scan era, a 'lesional zone' was defined by Bancaud and Talairach as the cortical space occupied by abnormal slow-wave activity as defined by its frequency, reactivity, and waveform.[51] Talairach and Bancaud, using SEEG, mapped the exact extent of such tumors as astrocytomas or oligodendrogliomas and their relationships with stererotactically defined cortical areas. Their use of the term *lesional zone* presumed macroscopic alteration of neural tissue, which has since been demonstrated radiologically by neuroimaging techniques. The 'epileptogenic lesion' era in epilepsy surgery began with the introduction of the CT scan as a clinical tool. However, the real impact of anatomical neuroimaging was the development of MRI. It became routinely available for clinical use (including the evaluation of epilepsy patients) by the early 1980s.[52,53] High-resolution MRI, which became available in the mid-1980s, had the highest impact on the evaluation of lesions that cause seizure disorders, turning a significant proportion of formerly 'nonlesional' cases into 'lesional' epilepsies. High-resolution MRI made visualization of mesial temporal sclerosis possible, and it was recognized that malformation of cortical development was a frequent cause for intractable epilepsies.

However, not all the lesions evidenced by MRI in epileptic patients are epileptogenic. In other words, the patient's seizures may be unrelated to the lesion. In other cases, two or more lesions are seen on MRI, and it is difficult to establish which one is responsible for the patient's seizures. To solve this problem, video-EEG monitoring is routinely used as part of the presurgical evaluation, even in patients in whom the location of the lesion and the seizure semiology are congruent. The goal is to have neurophysiological confirmation of seizure origin in the area occupied by the lesion. In cases of dual (e.g., a cavernous angioma located in the posterior left temporal lobe that coexists with a sclerotic hippocampus in the same side) or multiple (e.g., multiple tubers) pathology with lesions located close to each other, it may be difficult to establish with scalp EEG which one is generating the patient's seizures. Invasive EEG recordings may be necessary in these cases.

Relationship of epileptogenic lesion with epioleptogenic zone

It was soon evident from studies by Bancaud and Talairach on cerebral tumors that the relationship between the lesional and the epileptogenic zone may be complex. We have already mentioned that a lesion visible on MRI may be unrelated to the patient's seizures; if lesions are multiple, one or many may be responsible for the patient's seizures. These issues can be generally solved by noninvasive or invasive recordings.

But even in the presence of a unique lesion that seems to be causing the seizures, its complete resection does not always guarantee seizure freedom. Seizure freedom associated with complete removal of the radiographic epileptogenic lesion is usually seen in cases of well-circumscribed lesions such as benign tumors, discrete vascular malformations such as cavernous angiomas, or sclerotic hippocampi. Other types of epileptogenic lesions, such as malformations of cortical development or gliotic scars seen in the context of posttraumatic epilepsy, are more often associated with persistent seizures after surgery, for two reasons. First, their boundaries are more difficult to establish radiologically and also macroscopically during intervention. Some malformations of cortical development are seen just as subtle blurring of the gray-white matter junction with poorly defined limits. The area around this lesion may be radiographically normal, but abnormal at a microscopic level; we have been able to demonstrate that, in certain types of malformations of cortical development, this area surrounding the radiographic abnormality is significantly more epileptogenic (as evidenced by intraoperative ECoG) than the lesion itself. When that is the case, this region has to be resected in order to make the patient seizure free. Failure to do so results in persistent seizures, and this is one of the explanations for the relatively high frequency of surgical failure in patients with neocortical dysplasia.

Second, it is also true that at times incomplete lesion removal may be associated with seizure freedom. For example, some patients with congenital hemiplegia, automotor seizures, and extensive porencephaly on MRI benefit from a standard anterior temporal lobectomy.[54]

At present we have no definite way to predict if the lesion seen on MRI overlaps completely with the epileptogenic zone, in spite of electrographic confirmation of seizure onset in the vicinity of the lesion. Extent of resection must be guided by clinical experience (as outlined above), including ECoG if possible in malformations of cortical development.

Functional deficit zone

The functional deficit zone is the area that shows abnormal functioning in the interictal period. This may be the result of a lesion with a destructive effect, or of abnormal synaptic transmission due to aberrant connections or imbalanced neurotransmitters in the area.

There are a number of ways to define the location and extent of the functional deficit zone. The first one is a *detailed neurological examination.* Using the principles of localization in neurology, the area responsible for certain deficits (e.g., hemiparesis, homonimous hemianopsia, or cortical sensory deficit) can be estimated. As early as the mid-nineteenth century, the standard neurological exam was understood well enough to allow localization of functional deficits if they were severe and affected some of the highly eloquent areas of the brain. These deficits, however, are present only in a minority of surgical candidates. Many cortical regions may be dysfunctional and clinically silent (e.g., slow-growing frontal lobe

tumors, which can go unnoticed for a long time before they result in clinical symptoms).

Detailed neuropsychological evaluation can provide some information about lateralized or even localized deficits[55] in patients without major focal findings in the general neurological examination. Brenda Milner and her group first applied this modality for localization of the epileptogenic zone in patients who were candidates for epilepsy surgery.[56] Because of the availability of more powerful tests to evaluate the cortical zones with functional deficit, the neuropsychological evaluation no longer has a major role regarding localization of the epileptogenic zone, but remains an indispensable tool for prognosis of neuropsychological deficits after surgery,[57] and it may significantly influence the final decision about surgery.

The *intracarotid amobarbital procedure* (Wada test) can provide some additional information about lateralized memory deficits that may help localize the epileptogenic zone and predict if the contralateral hemisphere is able to adequately support memory when focal resections are being planned, especially in temporal lobe cases.[58,59] However, the protocols used by the different centers are highly variable, and the results are occasionally discordant with the neuropsychological evaluation; overall, the information provided by the test regarding the functional deficit zone is considered only supportive and complementary of other tests' results.

It was the development of *functional neuroimaging techniques* (PET and interictal SPECT) that has had the greatest impact on the study of the functional deficit zone of patients with intractable epilepsy. In many epilepsy centers, PET scan has now become a routine test in the presurgical evaluation of patients with intractable epilepsy.

Interictal PET with 2-[^{18}F]-fluoro-2-deoxyglucose (FDG) has proven to be a reliable test for identifying dysfunctional cortex with hypometabolism. The first report of the use of FDG PET to help localize seizures was published in 1980.[60] Engel, Kuhn, and colleagues then showed that areas of interictal cortical hypometabolism imaged by FDG PET in patients with temporal lobe epilepsy correlated extremely well with the presumed lateralization of the epileptogenic zone as defined by depth electrodes.[61–63] A number of investigators have demonstrated the value of FDG PET in the lateralization and even localization of extratemporal lobe epilepsies.[64,65]

Interictal SPECT is another technique that provides information about dysfunctional cortex (with decreased blood perfusion in this case). However, interictal SPECT is less reliable than PET and currently is mainly used as a baseline exam for comparison with the scans obtained during the ictal phase.

^{1}H magnetic resonance spectroscopy (^{1}H MRS) is another technique that has been developed to evaluate *in vivo* the metabolic composition of the brain. Different compounds, including *N*-acetylaspartate (NAA), choline, creatine, and lactate, can be measured over the region of interest. Pathological cortex displays abnormal concentrations of these metabolites, and decreased NAA-containing ratios are found over the epileptogenic side in temporal and extratemporal epilepsies[66–6]; ^{1}H MRS abnormalities may help lateralize and predict seizure outcome after resective surgery.[69,70] The abnormal ratios seem to be the result of a metabolic more than an anatomical dysfunction; they have been shown to return to normal values after successful surgery.[71]

This technique still has, however, some limitations in clinical practice. Due to technical issues, it is not possible to scan extensive brain regions, and the region of interest has to be defined based on the results of other tests (MRI, EEG recordings, FDG PET, etc). At times, an accurate sampling of the region of interest is technically challenging (especially in extratemporal epilepsies) and the spectra obtained are of poor quality. Different centers currently use different imaging modalities (e.g., multivoxel versus single-voxel techniques), making the available data difficult to compare.

The information provided by ^{1}H MRS is at present considered only adjunctive to the data from EEG monitoring and anatomical neuroimaging during presurgical evaluation. However, it is likely that in the near future it may occupy a more important role in the presurgical evaluation of intractable epilepsy, when technical difficulties are solved and we are able to fully understand the meaning of the metabolic derangement.

Relationship of the functional deficit zone with the epileptogenic zone

The relationship between the functional deficit zone and the epileptogenic zone is complex and difficult to define even in individual cases. To start with, the functional deficit zone often varies in extension and boundaries depending on the technique (e.g., the areas that show hypometabolism in FDG PET may not overlap completely with the ones that show decreased blood flow in the interictal SPECT). As we have already mentioned, at times the information concerning memory is discrepant between the Wada test and neuropsychological evaluation tests.

The currently available techniques to define the functional deficit zone only measure global brain function (neurological exam, neuropsychological evaluation, Wada test to estimate memory), physiology (glucose uptake on FDG PET or blood flow on SPECT), or metabolic composition (^{1}H MRS); there are no tests available that estimate dysfunction directly related to epileptogenicity. As a result, the functional deficit zone is usually more extensive than the epileptogenic zone, and includes at times lesions not related to seizure generation or areas located at a significant distance from the seizure focus (diaschisis phenomenon). For example in patients with mesial temporal lobe epilepsy who become seizure free after selective resection of mesial structures, the presurgical PET usually shows an extensive area of hypometabolism involving also the lateral cortex. In patients with congenital hemiplegia and porencephaly on MRI, PET often shows extensive hypometabolism, even though some of these patients may become seizure free after limited resections, indicating that the epileptogenic zone is indeed more limited. In patients with tuberous sclerosis and infantile spasms, PET shows multiple patched areas of hypometabolism corresponding with the different cortical tubers; at times, these patients benefit from resection of individual tubers that correspond with the epileptogenic area. In addition, the spatial resolution of these functional neuroimaging techniques is poor compared to that of anatomical neuroimaging techniques such as high-resolution MRI.

At present, new techiques aimed at measuring cortical dysfunction more closely related to epileptogenicity are being developed. Some new functional neuroimaging techniques are able to

assess the distribution of certain neurotransmitters' receptors, which may be abnormal in the epileptogenic region. An example of these tests is the [^{11}C]-flumazenil PET study.[72–78]

Epileptogenic zone

The epileptogenic zone is the cortical area that is able to generate seizures, and whose complete removal is indispensable to make the patient seizure free. Of course, precise definition of the epileptogenic zone (location and boundaries) is essential for successful surgery of epilepsy. However, there is not a technique that precisely localizes the epileptogenic zone; we can only make an estimate through the information provided by the other five zones (symptomatogenic, irritative, ictal onset, functional deficit, and epileptogenic lesion), that are more or less precisely defined by the tests we have described above.

The evidence that the epileptogenic zone is a theoretical more than a practical concept is given by two facts:

1. The five areas described above never show complete overlap. The discrepancies are important in some patients and minor in others. If the discrepancies are significant and there is no plausible explanation for them, the patient is likely to have persistent seizures after surgery, and resection should be deferred until more precise testing (e.g., invasive EEG recording) is done. Another option is to consider the patient for alternative forms of treatment such as vagal nerve or deep brain stimulation. On the other hand, if the different zones show only minor discrepancies, it is generally assumed that the patient is an optimum surgical candidate and has good chances of becoming seizure free after removal of the area to which the different tests are pointing.
2. Even in the cases in which the different zones are similar, it is impossible to rule out the existence of a 'potential epileptogenic zone,' which remains silent in the presence of an epileptogenic zone with a lower threshold for seizure generation. However, this zone may become epileptogenic and generate seizures after the original epileptogenic zone is removed. This explains the occurrence of new seizure types in patients who have failed focal resections, suggesting different seizure origin and/or propagation pathways. At present it is impossible to localize this 'potential epileptogenic zone' that may be an important issue in some patients, especially those with extensive lesions and widespread epileptogenicity.

In view of all these limitations, it is obvious that we need to develop additional tests to define more directly the epileptogenic region. It is possible that tests that provide information about neurotransmitters directly involved in seizure generation may map the epileptogenic region more directly. Optimally, these tests should also be able to locate those regions with subtle abnormalities, corresponding to the 'potential epileptogenic zone.' Even when in these cases a complete resection involving the actual and potential epileptogenic zone is not possible, precise definition of the epileptogenic zone would permit a more accurate prognosis regarding seizure outcome after surgery. In addition, it is likely that the currently available techniques will significantly improve in sensitivity and specificity during the coming years, making determination of the different zones more precise and reliable. Simultaneous analysis of the information provided by the different tests will also increase their yield to estimate the epileptogenic region (e.g., computerized analysis of the superimposed MRI, ictal SPECT, and FDG PET images).[79, 80]

Case report

The case report presented below illustrates how we define the location and extent of the zones described above during the presurgical evaluation of a patient with intractable epilepsy. It also shows the complex relationship of the different zones with each other and with the epileptogenic zone.

I. G. is a 25-year-old right-handed woman who was the product of a normal pregnancy and delivery. She reached developmental milestones at appropriate intervals, finished high school, and attended college, although she did not complete a degree. She does not have any conventional risk factors for epilepsy (no history of febrile convulsions, central nervous system infections, or significant head trauma).

Her seizures started at the age of 10. They are described as involuntary contraction of the left side of her face that progresses to clonic activity of the left hand. At times this left face tonic phase may be preceded by ill-defined loss of sensation in the left leg or a sound similar to a helicopter in her head. Consciousness may or may not be affected during the seizures. Her seizures only occurred at night until she was 18, when they started to occur during the day also. Seizures happened around once or twice a month. The patient never had a generalized convulsion until her first noninvasive video-EEG monitoring, when medications were discontinued. The patient had failed a number of medications in the past, including phenytoin, valproate, phenobarbital, clonazepam, gabapentin, and lamotrigine.

Epileptogenic lesion (Figures 47.1 and 47.4D)

An MRI of the brain showed right frontoparietal atrophy. Volume loss was noticed along the right gyrus rectus, the adjacent orbital frontal gyri, the right superior frontal gyrus, the right insular cortex, the frontal operculum, and also, although to a lesser extent, the parietal operculum. The cerebral abnormality underlied a strip of focal atrophic scleroderma-like skin extending from the medial aspect of the right eyebrow to the vertex. The skin atrophy developed progressively at the age of 12 years, but had been stable approximately since the age of 22 years.

The patient had noninvasive video-EEG monitoring that showed continuous slowing in the right frontotemporal region with interictal sharp waves maximal at the F4 electrode. A single seizure was recorded; the clinical semiology was consistent with the history as described above. The EEG seizure arose from the right frontocentral region (max F4).

At this point, the family opted to proceed with medical therapy using a different drug regimen. However, seizures significantly increased in frequency over the next months, and the patient started to have one or two seizures a week. After the seizures the patient felt extremely tired and stayed in bed for one day. Seizures prevented the patient from participating in

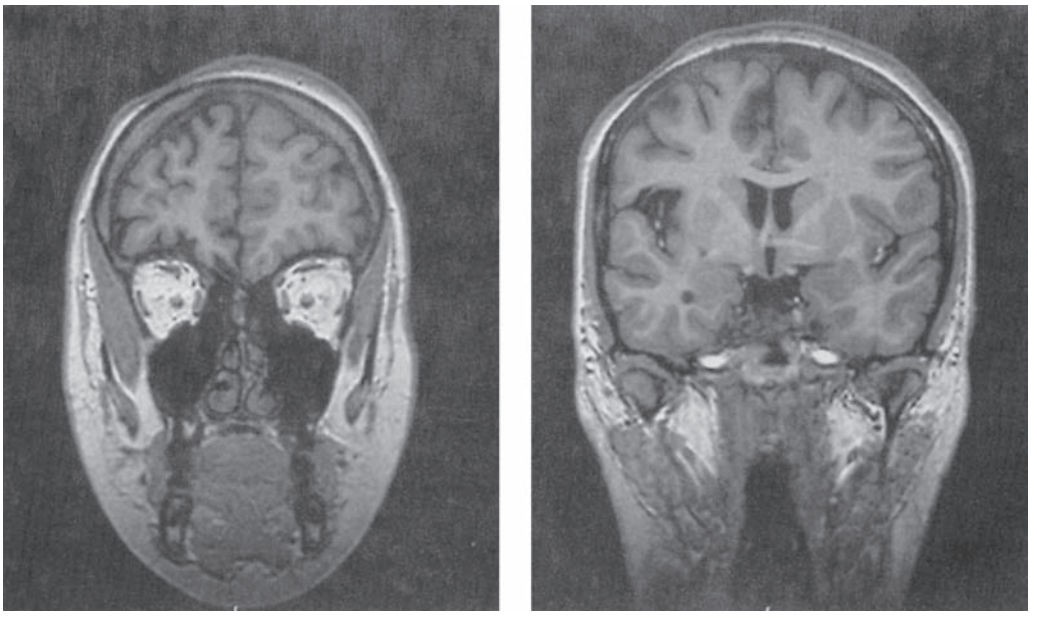

Figure 47.1 Preoperative MRIs (T1-weighted images, coronal cuts) showing the volume loss involving the frontal and part of the parietal lobes.

normal educational or social activities. The patient and her family decided to explore further the surgical options, and it was decided to proceed with invasive video-EEG monitoring for better delineation of the ictal onset zone and for mapping of eloquent cortex.

Four subdural electrode grids were placed over the right hemisphere. An 8 × 8 electrode grid (A plate) was located over the right frontal convexity with the posterior edge behind the central sulcus (Figure 47.2). A 4 × 4 electrode grid (B plate) was located over the basal frontal region. A 4 × 4 grid (C plate) was placed overlying the lateral aspect of the right temporal lobe, and a 1 × 6 strip (D strip) was placed over the mesial aspect of the right frontal lobe.

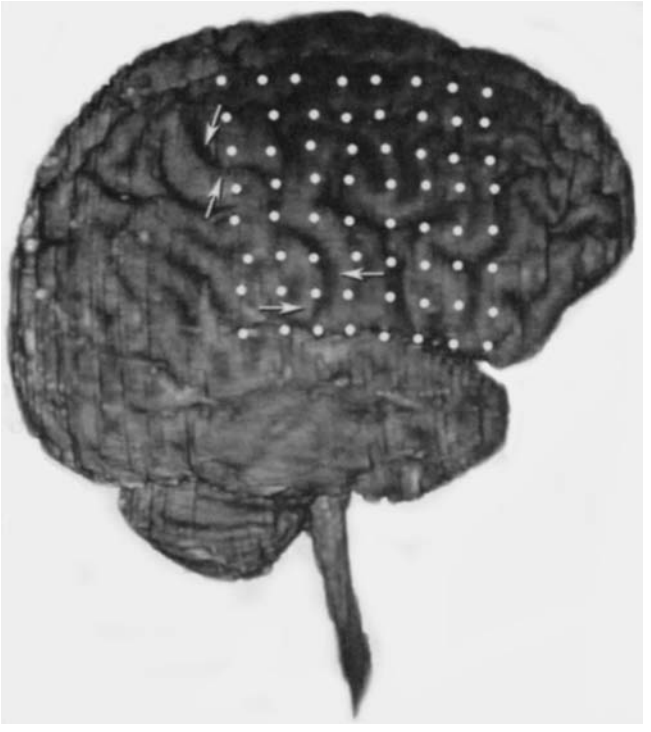

Figure 47.2 Three-dimensional MRI reconstruction showing the location of the A plate over the frontoparietal convexity. *Arrows* indicate central sulcus.

Symptomatogenic zone

The patient's seizures can be classified as aura→left face tonic →left arm clonic→generalized tonic-clonic seizures. The aura the patient describes has little localizing value as it varies from seizure to seizure and does not point to a specific brain region. However, the consistent left face tonic phase suggests early-spread of the discharges to the face region in the primary motor cortex of the right hemisphere, with later involvement of the arm area (manifested as clonic movements of the left arm). The EEG-recorded seizures support this conclusion.

Irritative zone (Figures 47.3A and 47.4A)

Interictal EEG showed prominent spiking mainly from two distinct regions in the A plate: the adjacent electrodes SA44, SA45, and SA52, near the base of the plate, and the electrodes SA3, SA4, and SA10, near the superior edge of the plate. Interictal spikes were seen frequently also in the electrodes SB2, SB6, SB10, and SB11 of the basal frontal B plate.

Ictal onset zone (Figures 47.3B, 47.3C, and 47.4B)

Several clinical seizures were recorded. Clinically the seizures consisted of left face tonic activity, evolving to left body clonic jerking and secondary generalization in five seizures. The patient was unable to speak during the motor phase, although in some cases she could prove that she was aware of her surroundings by mimicry in answer to questions. At times, repetitive mouth movements were seen

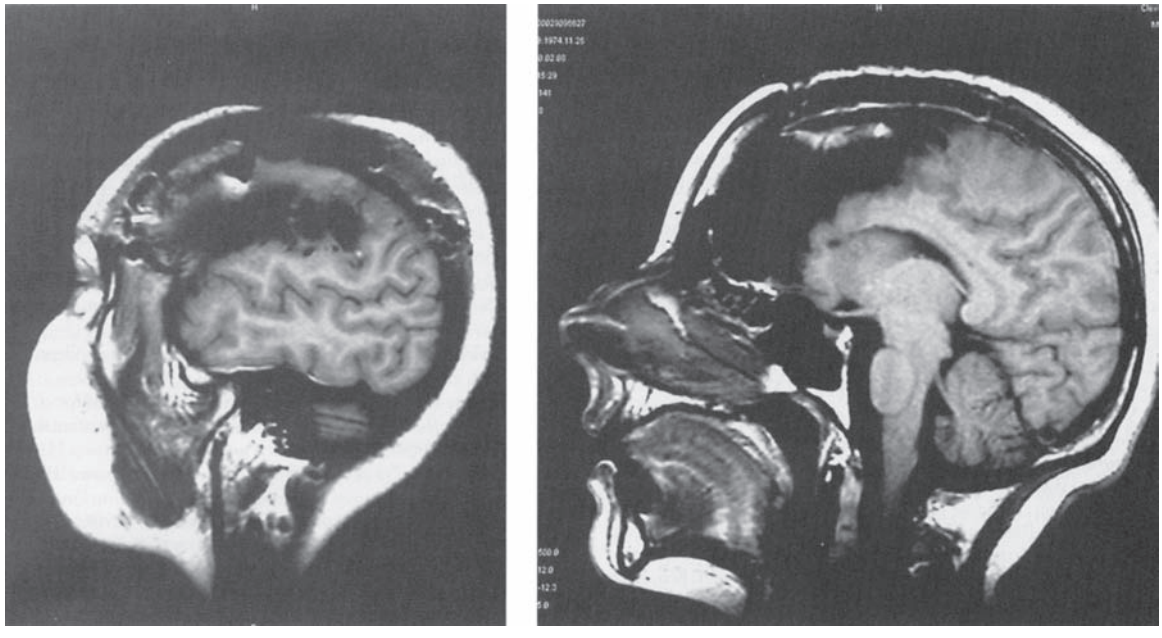
during the seizure. Three seizures came from a group of electrodes adjacent on the A plate (SA47, SA48, and SA55), located inferior to the central sulcus. One seizure arose from the electrodes SA16, SA24, and SA32, on the posterior edge of the plate, and one arose from the adjacent electrodes SA35 and SA44, in the inferior quadrant of the plate. In addition, several subclinical seizures, were recorded, arising at times from the same areas as the clinical seizures but also from the electrodes SA3 and SA20, SA19 and SA27, and finally SA25.

After video-EEG monitoring was completed, cortical stimulation was performed to map sensory and motor function. The results of the stimulation are shown in Figure 47.4C.

Functional deficit zone (Figure 47.4E)

A FDG PET scan showed moderate hypometabolism involving the right frontal lobe, specially pronounced at the junction of the anterior and middle thirds, and mild to moderate hypometabolism involving the right temporal cortex.



(a) (b)

Figure 47.5 Postoperative MRIs showing the extent of the resection (T1-weighted images, coronal cuts).

On the basis of the evaluation, it was decided to proceed with partial resection of the estimated epileptogenic zone in the frontal lobe and parietal operculum, including the primary face motor area but sparing the hand motor area (Figure 47.5). The extent of resection was further delineated by intraoperative cortical stimulation with the patient awake.

Functional outcome

After surgery, the patient had some weakness over the left extremities and difficulty in looking voluntarily to the left side. These deficits progressively resolved over a period of 10 days. A left facial droop was still present when the patient left the hospital 15 days after surgery. No sensory deficit over the left extremities was seen. Sensation over the left side of the face was also normal.

Seizure outcome

The patient remained seizure free for 20 days after the operation, and on day 21 she had a seizure consisting of clonic jerking of the left arm. This seizure most probably arose from the primary motor area of the hand, which was shown to be a part of the ictal onset zone but was not included in the resection to avoid the motor deficit.

SECTION 5

The symptomatogenic zone

48 The symptomatogenic zone – general principles

C Kellinghaus and HO Lüders

Introduction

The objective of the presurgical evaluation of patients with intractable focal epilepsy is to identify the epileptogenic zone, i.e., the cortical area(s) capable of generating epileptic seizures whose surgical removal or disconnection will result in seizure freedom. Unfortunately, there is no diagnostic method that is able to directly assess the exact location and extent of the epileptogenic zone. Even in patients who are seizure free after epilepsy surgery, we can only be certain that the epileptogenic zone was included in the resected area. However, it is impossible to know whether a smaller resection would have had the same result. Therefore, the location and extent of the epileptogenic zone has to be estimated using all available diagnostic methods that can help in this estimation. The different diagnostic methods are used to define several cortical zones (symptomatogenic zone, irritative zone, seizure onset zone, epileptogenic lesion, functional deficit zone), each of which helps us to estimate the location and extent of the epileptogenic zone.[1]

The symptomatogenic zone is defined as the cortical area generating the initial ictal symptomatology when activated by epileptic seizures. It is delineated by detailed analysis of the ictal signs and symptoms. It is essential to first obtain a thorough history of the seizures from the patient, caregivers, and witnesses to the seizures. These findings can be extended and verified by analysis of ictal video recordings using long-term video-EEG obtained in the setting of a diagnostic or presurgical epilepsy monitoring unit, during routine EEG or other recordings, or even using material recorded at home by family members. In this analysis, the emphasis should be placed on the initial symptoms of the seizures because they are generated by the cortex in close proximity to the epileptogenic zone.

Historical overview

Before the advent of EEG in the late 1920s, trying to locate the symptomatogenic zone and the functional deficit zone by examining the patient and analysing seizure symptoms were the only methods available to determine the epileptogenic zone. With his work in the mid 19th century, Hughlings Jackson pioneered the concept that the symptomatogenic zone is a useful approximation of the epileptogenic zone. Initially he believed that the generators of focal motor seizures were located in the basal ganglia.[2] In 1863, however, he published a case of a patient with syphilis and focal motor seizures stating that in many patients with convulsions of one side of the body, autopsy reveals brain pathology on the opposite side of the brain, 'frequently on the surface of the hemisphere'.[3] In the following years he discovered further clinical evidence supporting his view that the motor cortex plays an important role in motor function as well as epileptic seizures. Experimental studies by Fritsch and Hitzig confirmed Jackson's clinical view showing that electrical stimulation of a dog's frontal cortex could cause movement of contralateral body parts.[4] In 1873, Jackson put forward his definition of epilepsy that is still valid: 'Epilepsy is the name for occasional, sudden, excessive, rapid and local discharges of gray matter'.[5]

The work of Jackson and other pioneers of modern neuroscience like Gowers, Horsley and Ferrier led to the view that certain functions (e.g., motor control, sensation, language) were located in specific cortical brain areas. Using these principles for localisation of disease processes, they were able to correctly localize the epileptogenic zone and remove tumors or other lesions causing epilepsy.[6] One of the first cases of epilepsy surgery was published in 1879 by the Scottish neurosurgeon William MacEwen who successfully resected a frontal meningeoma rendering the patient seizure free and without deficits.[7] In 1884, Hughes Bennet and Rickman Godlee removed a cerebral tumor from the right frontal convexity near the primary motor area that had caused frequent focal and generalized motor seizures. While the operation stopped the seizures, the surgeons also documented well-known side-effects of epilepsy surgery like transient (worsening of the) hemiparesis and wound healing problems.[8]

Conditions necessary to produce ictal activation of cortical areas

Activation of cortical areas, either by ictal discharges or by electrical stimulation, is not an all-or-none phenomenon. This was elucidated by studying the effects of direct electrical stimulation using subdural or intracranial electrodes that closely resembles the effect of ictal activation.[9] There are several factors that determine whether a stimulus will be able to cause a clinical symptom.

Intensity, duration and polarity of the individual stimulation impulse

The response of neurons to an electrical field is related to the electrical potential distribution along each cell process.[10] Thus, the effect of an electrical impulse on neuronal tissue is strongly dependent of the amount of electrical charge (i.e., intensity multiplied with pulse duration) as well as the polarity of the impulse. Usually 'balanced-charge' bipolar square wave pulse forms are used.[11] Pulse duration usually is below 1 ms,[12,13] but longer pulses (up to 2.5 ms) have been used successfully.[14,15] Given a specific electrode geometry, electrode localization and pulse duration, the amount of electrical discharge applied to the cortex usually is modified by the chosen stimulus intensity (measured in voltage or amperage).

Stimulation frequency

It has turned out that the frequency that produces clinical effect with the lowest possible effective stimulus intensity is of approximately 20–80 Hz.[16] Most likely this is related to the duration of a single excitatory postsynaptic potential (15–50 ms), i.e., to achieve clinical signs the stimulus frequency should be high enough to produce temporal summation. Single stimuli, even when applied to eloquent cortex, are usually ineffective unless a very high intensity is used.

Duration of the stimulus train

In general, only trains of stimuli which permit temporal summation, are effective in eliciting clinical symptoms. Usually, train durations of 5–8 seconds are used,[12,16,17] and the symptoms tend to start after a delay of 1–3 seconds. In addition, the symptom or sign severity frequently increases during the stimulus train.[16]

Correlation of ictal cortical activation and the generation of ictal symptoms

Assuming that activation by ictal discharges follows the same basic neurophysiological principles as electrical stimulation, one can explain the not uncommon observation that epileptiform activity over eloquent cortical areas does not produce any symptoms. One of the best known examples is the absence of motor symptoms in patients with generalized spike-wave discharges in typical childhood absence epilepsy. Although the EEG clearly shows repetitive discharges over the primary motor area, no clonic motor activity may be seen. This is most probably because intensity or frequency (or both) of the discharge stimuli are not sufficient to elicit clinical symptoms. Therefore, the fact that ictal activation of a given cortical area does not produce any symptoms does not necessarily mean that this area is noneloquent. It may well be that the stimulus intensity, frequency and/or duration were not sufficient to elicit symptoms. These observations explain why studies trying to deduct the location and extent of the symptomatogenic zone solely by invasive ictal recordings are unreliable.

Spatial relationship of the symptomatogenic zone with the epileptogenic zone

The symptomatogenic zone and the epileptogenic zone frequently do not overlap. As stated above, the clinical effect of electrical stimulation is determined by multiple factors. However, even if we have epileptiform discharges of strength sufficient to activate eloquent cortex, very frequently the epileptiform discharge is not going to elicit symptoms or signs until it has spread outside the epileptogenic zone, i.e., in general, the epileptogenic and symptomatogenic zone does not overlap.[12] This has been demonstrated repeatedly during cortical stimulation when clinical symptoms only occurred when there were 'afterdischarges' (i.e., spontaneously ongoing and/or spreading epileptiform discharges after electrical cortical stimulation).[16] These symptoms, even if they resemble typical auras of the patient, frequently are elicited in proximity but not necessarily in the core of the epileptogenic zone, and they do not have additional value for defining resection boundaries.[18]

In addition, several symptomatogenic zones may be active at the same time, with one dominant symptom overshadowing others (e.g., focal clonic motor activity overshadowing focal sensory auras, loss of consciousness overshadowing auras.)[19] Thus, identification of the symptomatogenic area suggests that the epileptogenic zone is in the general neighbourhood, but it does not allow us to pinpoint the epileptogenic focus to a precise anatomic region.

Presurgical assessment of the symptomatogenic zone

Interview with the patient and family members

The first essential step in the assessment of the symptomatogenic zone is a careful interview of the patient, his family members or other witnesses about the seizure symptoms. The time course of the seizure symptomatology should be analysed placing special emphasis on the beginning. Some auras are generated by activation of a well-defined cortical area with relatively high degree of certainty. In these cases, the epileptogenic zone is usually also located in close proximity to the symptomatogenic zone responsible for the aura. This includes localized paresthesias in relatively restricted dermatomal distribution that are almost always generated by excitation of the primary somatosensory area of the contralateral hemisphere,[20] and visual auras with simple visual hallucinations that are usually the expression of activation of the primary visual cortex.[21] In both these cases, the epileptogenic zone tends to be in close proximity of the primary somatosensory area and the primary visual area, respectively. On the other hand, multisensorial hallucinations can be elicited by activation of several different cortical regions.[22] During the interview, particular care should be taken to be nonsuggestive, to use open questions where possible, or at least to give the patient several alternatives when focussing on a specific sign or symptom. This helps avoiding unnecessary bias and increases specifity and reliability of the data. Ideally, the

interviewer should have experience with a wide variety of different seizures and seizure symptoms.

Ictal video recordings

Although the first attempts to synchronously record EEG and epileptic seizures date back to the late 1930s,[23] ictal video recordings did not become widely available until the advent of modern communication and computing technology in the late 1970s.[24,25] Until then, analysis of ictal symptomatology was restricted to careful history-taking as well as systematic observation of seizures in epilepsy patients admitted to hospitals.

The introduction of closed-circuit video-EEG monitoring in dedicated wards has advanced our understanding of the relationship between the symptomatogenic zone and the epileptogenic zone considerably. Now it became possible to analyse and re-analyse the patient's seizures 'off-line' and without time constraints. In addition, the observer can now be blinded to other information relevant to the case, and different observers can analyze the same seizure independently. Thus, subtle but important signs can be noticed and evaluated regarding their localizing or lateralizing value. Video analysis alone, on the other hand, has some caveats. Ictal and postictal symptoms are not always easily distinguishable by semiology alone.[26] Conversely, the clinical onset of a seizure may become difficult to distinguish from normal nonictal behavior like daydreaming or fluctuation of attention. In addition, nonepileptic seizures may be only discerned from epileptic seizures by the concomitant EEG. As a consequence, video analysis of seizures has to be complemented by EEG recordings to determine the beginning and the end of a seizure as well as for ascertaining of the epileptic nature of the event.

Identification of established localizing and lateralizing signs

In patients in which postoperative seizure freedom indicates that the epileptogenic zone was at least included in the resected cortical area, the analysis of seizure symptoms can establish a correlation between a given symptom or evolution of symptoms and the location or laterality of the epileptogenic zone. In addition, the frequency of a symptom within a specific patient population, the predictive value for seizure freedom, the specifity for the hemisphere, lobe, or intralobar location of the epileptogenic zone, and the interrater reliability can be calculated.

Using these methods, several ictal symptoms and signs have been identified in the last decades that have a close correlation to the lateralisation of the epileptogenic zone[1,27] (see Table 48.1).

In addition, the localizing value of several symptoms has been established. For example, auditory and visual auras followed by immediate loss of consciousness seem to be typical for neocortical temporal epilepsy.[28] Early head version predicts extratemporal epilepsy,[29] and tonic posturing and cycling leg movements seems to be relatively specific for frontal lobe epilepsy.[30] The localizing value of auras arising from primary cortical areas (e.g., localized somatosensory or visual auras) has long been recognized (see above). Even in infants who cannot report auras, some of the main seizure symptoms occurring in this age group have important value in establishing the location of the epileptogenic zone: focal motor seizures and versive seizures indicate seizure onset in the contralateral hemisphere,[31] seizures featuring mainly behavioral arrest (hypomotor seizures) frequently are related to seizure onset in the posterior temporal regions.[32]

Electrical cortical stimulation

In a number of patients, particularly those who have no clear lesion in structural imaging studies, it becomes necessary to further delineate the seizure onset zone by electrocorticography, either intraoperatively or using chronically implanted subdural electrodes. In other patients, presurgical noninvasive studies permit relatively precise definition of the location and extent of the epileptogenic zone, but electrical cortical stimulation becomes necessary to determine its relationship to important adjacent eloquent cortical areas (Table 48.2).

Intraoperative stimulation, the method of choice for more than 100 years, because of its limitation, (anesthesia, time constraints), has been substituted by extraoperative stimulation in chronically implanted patients. Although the chronic implantation of intracranial and subdural electrodes carries the risk of complications like infection, bleeding or infarction, strict antiseptic precautions and restriction of the number of implanted electrodes to the necessary minimum can considerably lower the risk.[33,34]

The advances of the last decades relying mainly on detailed cortical stimulation using subdural grid electrodes in wake patients have resulted in the reliable definition of several different symptomatogenic zones (for details see the following chapters). These zones usually can be reproduced in any given patient. However, the interpretation of the results demands experience and care. Afterdischarges (i.e., epileptic discharges elicited by the stimulus) have to be taken into account. These discharges tend to spread to adjacent cortical areas and, therefore, elicit symptoms due to activation of extensive cortical areas located at a distance from the stimulated cortex. On the other hand, stimulation has to be strong enough to actually elicit the symptom corresponding to the region. Therefore, the best method to achieve reliable and valid results is to stimulate each electrode with stepwise increasing stimulus intensities until either symptoms are elicited, or afterdischarges are produced.[16,17,34] Moreover, individual activation thresholds vary over time[12] and depend on factors like anticonvulsant levels. To avoid false negative or false positive results, only those symptoms should be taken into account that are not associated with afterdischarges, and that are reproduced at different times.

Conclusion

Identifcation of symptomatogenic zones activated by the initial epileptic discharges is the oldest method used for determining the epileptogenic zone as well as the resection borders in epilepsy surgery. Although there is usually a stable and close spatial relationship between the symptomatogenic zone and the epileptogenic zone, frequently the two areas do not overlap. Careful analysis of the seizure symptoms using

Table 48.1 Lateralizing ictal and postictal symptoms with a specifity ≥ 75% (adapted from ref 1)

Symptom	Hemisphere of the epileptogenic zone	Specifity	Frequency	References
Localized somatosensory aura	Contralateral	89%	1–10% (epilepsy patients)	35,36
Hemifield visual aura	Contralateral	100%	29% occipital lobe epilepsy	37
Focal tonic/clonic activity	Contralateral	90%	45% frontal lobe epilepsy	38,39
Forced head version <10 sec before secondary generalization	Contralateral	>90%	35% temporal lobe epilepsy 45% extratemporal lobe epilepsy	29,38,39
'Figure-of-four' sign	Contralateral	90%	15% temporal lobe epilepsy 15% extratemporal lobe epilepsy	29,40
Unilateral dystonic posturing of the hand	Contralateral	>99%	45% temporal lobe epilepsy	41,42
Ictal automatisms with preserved consciousness	Nondominant	>99%	5% temporal lobe epilepsy	43,44
Ictal speech	Nondominant	80%	35% (epilepsy monitoring patients)	45
Ictal dysphasia and aphasia	Dominant	>99%	35% (epilepsy monitoring patients)	45
Ictal vomiting	Nondominant	80%	2% (epilepsy monitoring patients)	46
Ictal spitting	Nondominant	75%	0.5% (epilepsy monitoring patients)	47
Postictal palsy	Contralateral	>99%	0.5–15% (epilepsy monitoring patients, depends on testing)	48,49
Postictal dysphasia and aphasia	Dominant	80%	35% temporal lobe epilepsy	50
Postictal nosewiping	Ipsilateral	90%	55% temporal lobe epilepsy	51
Unilateral last clonic movement in secondary generalized seizure	Ipsilateral	80%	45–65% temporal lobe epilepsy	52,53

Table 48.2 Symptomatogenic zones as described by electrical cortical stimulation

Cortical area	Localization	Symptom
Primary motor area	Precentral gyrus	Tonic and/or clonic movement of a contralateral body part
Frontal eye field	Posterior and lateral part of superior frontal gyrus	Eye version to the contralateral side
Supplemental sensorimotor area (SSMA)	Medial aspect of the superior frontal gyrus, paracentral lobule, cingulated gyrus	Ipsilateral, contralateral or bilateral tonic and/or clonic movements, sensations
Negative motor area(s)	Inferior frontal gyrus, immediately in front of the primary motor area (1), mesial portion of the superior frontal gyrus (2)	Inability to move (ipsilateral and/or contralateral)
Anterior (Broca's) language area	Pars opercularis of the inferior frontal gyrus	Speech arrest, (motor) aphasia
Posterior (Wernicke's) language area	Posterior part of the first and second temporal gyri, supramarginal gyrus, angular gyrus	Comprehension deficits
Inferior temporal language area	Fusiform gyrus, inferior temporal gyrus, parahippocampal gyrus	Comprehension deficits, paraphasias
Visual areas	Occipital lobe (calcarine fissure)	Flashing lights, phosphenes (simple responses), geometric shapes (intermediate responses), images (complex responses)
Primary sensory area	Postcentral gyrus	Sensations (tingling etc.) of a contralateral bodypart
Secondary sensory area	Parietal operculum	Ipsilateral, contralateral or bilateral sensations
Auditory areas	Superior temporal gyrus (Heschl's transverse gyrus, planum temporale, middle and anterior part)	Simple (particularly Heschl's gyrus) or complex hallucinations
Olfactory areas	Insula, amygdala	Smells (frequently unpleasant)
Gustatory areas	Frontoparietal operculum, insula	Tastes

video-EEG reveal important information for the presurgical assessment of an epilepsy patient. This information can be used as an independent diagnostic tool to corroborate or refute hypotheses of the location of the epileptogenic zone generated on the basis of other diagnostic methods like imaging or EEG.

49 Auras: localizing and lateralizing value

S Rona

Introduction

Epileptic auras are seizures characterized by subjective sensations experienced by the patient, unaccompanied by any objective clinical manifestations. They are usually brief and often evolve into other seizure types. On occasion they may be prolonged, constituting a form of status epilepticus.

Auras can be characterized by positive or, more rarely, negative sensory phenomena. Paresthesias, visual or auditory hallucinations, a sensation of fear or a feeling of movement when none is occurring are positive phenomena. Numbness of a body part, blindness, deafness or a feeling of inability to move are negative phenomena. It is now widely accepted that negative as well as positive ictal phenomena are expression of an active seizure discharge.

John Hughlings Jackson[1] first established a correlation between ictal manifestations and the location of a structural lesion. Before the advent of modern imaging techniques, epilepsy surgeons had to rely on ictal symptomatology to deduce localizing information which could guide the surgical procedure,[2] and it became clear that the aura as the first symptom at the beginning of a seizure was an important localizing element. Initially, surgeons applied information obtained through cortical stimulation in animals to localize brain functions, but soon thereafter this was complemented by cortical maps obtained with intraoperative stimulation in humans. Based on pioneering work by Cushing[3] and Förster,[4] Penfield and his colleagues[5,6,7] provided a comprehensive account of signs and symptoms that could be evoked by electrical stimulation of different brain regions during epilepsy surgery.

The aura as expression of activation of the symptomatogenic zone

Already Penfield and Jasper[5] recognized that the aura was produced by an epileptic discharge in neuronal circuits devoted to the cerebral representation of the sensation the patient is experiencing. However, when attempting to localize seizures based on their semiology, it is important to bear in mind that this, is in most cases, not the region where the seizure originates. By definition, ictal discharges are generated in the epileptogenic zone.[8] Theoretically, this can be any cortical region, but seizures often originate in so-called silent areas of the cortex and only become clinically manifest when they spread into areas that are able to produce symptoms. Accordingly, these are called 'symptomatogenic zones' (for a more in-depth discussion of this concept see Chapter 48).

Since auras are partial seizures without impairment of consciousness and patients have to be awake and not amnesic in order to report them, it might be presumed that the epileptogenic zone and the symptomatogenic zone are not far apart. This is not necessarily true – within fractions of a second, seizure discharges can travel quite far across the brain. However, they tend to follow preferential pathways which have been described extensively in the literature, so knowledge of the usual propagation pathways can help to identify potential regions of origin. Depending on the road they take, ictal discharges can involve, sequentially or simultaneously, several potentially symptomatogenic areas. Therefore, additional localizing information can be derived from the clinical evolution of the aura and eventual associated symptoms. However, it has to be kept in mind that some symptoms may overshadow others, so the fact that the patient experiences only one symptom does not mean that only one symptomatogenic area is activated by the ictal discharge.

Another potential source of inaccuracy is related to the patient him- or herself. Since auras are subjective by definition, the localizing value of the reported symptoms critically relies on the ability and willingness of the patient to describe them, which again depends on the age, intellectual level, mood and mental state of the patient.

Identification of the symptomatogenic zone

Provided the symptomatogenic zone activated during the aura is accepted as useful for the definition of the epileptogenic zone, how can it be identified? Essentially there are two possible ways to accomplish this: either the spontaneously occurring symptom and the corresponding electrical discharge can be recorded with closed-circuit video-EEG, preferably with invasive electrodes, or the symptom can be elicited by electrical stimulation. Both methods have inherent limitations.

Partial seizures are characterized by alteration of function in a relatively limited cerebral area. What makes localization of spontaneous discharges recorde with scalp electrodes more difficult is the fact that surface EEG recordings detect only a portion of the underlying electrical brain activity.[9,10] Due to their limited extension, only 30–70% of simple partial seizures are accompanied by a discernible ictal discharge in surface recordings.[11,12] One possible solution is to implant electrodes directly into the brain in order to be closer to the discharging focus, but the positioning of the electrodes itself creates a selection bias: even with densely spaced depth or grid electrodes, only a limited area can be electrically observed, and

brain sites at a distance which can contribute to the ictal symptoms may not be covered.

Despite the advent of functional imaging, which has replaced invasive studies in many fields, electrical stimulation remains the 'gold standard' for the reproduction of the effect of cortical activation by an epileptiform discharge, and consistent reproduction of an ictal sign or symptom by stimulation of a given cortical area can provide reliable evidence of the location of a symptomatogenic zone.[13] However, the validity of the information obtained by electrical stimulation is influenced by a number of variables. In order to have an unequivocal reponse, it is important that the stimulus does not produce an afterdischarge activating additional areas, which may also be located at a distance and thereby escape observation. On the other hand, it has to be sufficiently intense to effectively produce a response. The effective stimulus intensity depends on the degree of cortical excitability at the moment of stimulation and may vary over time; it may also be different at different sites that can produce the same symptom.

Even when properly performed, cortical stimulation may activate not only the cortex underlying the stimulated electrodes, but eventually a whole neuronal network contributing to the elicited symptom. The more complex the symptom (or aura), usually the more complicated the network that needs to be activated for its expression. Fish and colleagues, reviewing the Montreal experience with electrical stimulation,[14] observed that a particular clinical phenomenon could often be elicited in the same individual from more than one area. These areas could be clustering in adjacent sites or involve widespread noncontiguous sites affecting one or more lobes, sometimes in both hemispheres, with a distribution specific for any one patient. Gloor[15] proposed that such responses, especially in the case of complex experiential phenomena, reflect the activation of a matrix of excitation in a widely distributed population of neurons, resulting from synaptic plastic changes in networks whose precise configuration is specific for a given experience. This concept has been elaborated in detail in more recent network models of cortical representation.[16,17]

Schulz and colleagues, in a recent study of 16 patients with stimulation-induced auras recorded with subdural grid electrodes,[18] also noticed that the area from which auras could be elicited by stimulation was larger than expected for a normal cortical representation and suggested that epileptogenicity may lead to abnormal facilitation of cortical pathways, resulting in the expansion of symptomatogenic cortical areas. The authors postulate that stimulation-induced auras are likely to result from facilitated pathways between the epileptogenic zone around the lesion, the stimulated cortex and the symptomatogenic zone.

Localizing value of spontaneous and stimulation-induced auras

When a typical aura happens to be elicited by electrical stimulation, how does its localization compare to the onset zone of spontaneous seizures? Bernier and colleagues[19] found a greater than 90% concordance between spontaneous and induced auras or seizures in patients with single unilateral foci but less with multiple foci. In their series of 126 patients, stimulation data reliably predicted the resection area in unilateral and bilateral temporal foci but less in other locations. Wieser and coworkers[20] reported a 77% concordance rate in patients with temporal lobe seizures. Schulz and colleagues[18] assessed the value of stimulation-induced auras (SIA) for defining the extent of the epileptogenic zone during epilepsy surgery. The SIA zone overlapped with the lesion in 75%, with the EEG seizure onset zone in 75% and with the irritative zone (or area of interictal spiking) in 50% of the patients. However, analysis of surgical outcome showed a significant correlation only with total removal of the epileptogenic lesion. Therefore, these numbers may be different in patients without a visible lesion.

With due consideration of the above-mentioned limitations, aura semiology can still be considered to provide essential clues for the localization and, to a certain extent, lateralization of epileptic seizures, as well as the prediction of surgical success. Palmini and Gloor[21] found that the localizing value of auras in indicating the most likely lobar origin of seizures was as good as EEG and modern imaging procedures, whereas Boesebeck and colleagues,[22] examining patients with epilepsy surgery in the posterior cortex, reported that patients with lateralizing auras had a significantly better outcome compared to those without lateralizing features.

In the following section, the localizing and lateralizing value of different aura types will be examined more closely. Auras are classified in accordance with the Semiological Seizure Classification),[23] developed at the Cleveland Clinic and used in major epilepsy centers around the world.

Aura types

Somatosensory auras

Somatosensory auras consist of abnormal sensations, involving one or more body parts. Just like focal motor seizures, they may migrate from one region to the next, following a somatotopic pattern ('Jacksonian march').[1] The most common epileptic somatosensory perceptions are paresthesias ('tingling'), pain and thermal sensations are less frequent.[24,25] Sensations referred to the viscera, for example the abdominal aura, and sensations involving the entire body are not classified as somatosensory auras.

The following cortical areas are involved in the generation of somatosensory phenomena:

Primary somatosensory area (SI)

The primary somatosensory area is located in the postcentral gyrus (Brodmann areas 1, 2, and especially 3b)[26] and contains a topographic representation of the different body parts, supramedially for the foot and leg and more laterally on the convexity for the arm, hand, and face.[4,5,27] However, recent studies[27,28] have indicated that the functional anatomy in this region can vary in individual patients, and that sensory function can also be represented anterior to the central sulcus (Brodmann area 4). This is especially true for patients with lesions in this area. The majority of the sensations elicited from SI affect the face, mouth, and hands, less frequently the feet, and they are usually limited to a relatively restricted distribution. Penfield and Jasper[5] were also able to elicit sensations in the head region between the arm and leg area. During stimulation of the

postcentral gyrus, Förster[4] occasionally observed sensations at ipsilateral homologous body parts. These were elicited most often in the areas of the face and mouth, bladder, colon and genitals, but never occurred when arm or leg areas were stimulated. Mazzola *et al*[29] also found that evoked responses affecting limbs were exclusively contralateral to stimulation in SI.

Second sensory area (SII) and insula

The second sensory area is located on the superior bank of the sylvian fissure, and has a representation of both sides of the body.[5] Lüders and co-workers[30] localized the second sensory area in the inferior frontal gyrus immediately anterior to the primary face and mouth motor area by both electrical stimulation and evoked cortical potentials in one patient. According to Penfield and Jasper,[5] the character of the sensory aura originating in the second sensory area does not differ from the primary sensory region, although they noticed that some patients described a cold sensation. Somatosensory and pain responses to direct intracerebral stimulations of somatosensory areas were obtained by Mazzola *et al.*[29] in 14 patients referred for epilepsy surgery. Stimulations were delivered using transopercular electrodes exploring the suprasylvian parietal cortex (SI area), the parietal opercular cortex (SII area), and the insular cortex. In all three areas, all types of somatosensory responses, including paresthesias, temperature and pain sensations could be elicited. The authors found distinct somatosensory maps in the suprasylvian, opercular and insular regions and separate pain representations in SII and insular cortex, with a spatial resolution of the somatotopic map in SII intermediate between those found in SI and insula. The sensations obtained through insular stimulation by Penfield and colleagues[5,6] most often involved the mouth or the upper extremities. Responses were primarily contralateral but sometimes ipsilateral or bilateral. In the study of Mazzola and colleagues,[29] the highest percentage of ipsilateral or bilateral responses was observed after SII stimulation. When the evoked sensations involved the midline part of the body (face or trunk), they were mostly bilateral regardless of the stimulated region. Response lateralization was similar for left and right stimulation. Various types of nonsomatosensory responses (auditory, vegetative, vestibular, olfacto-gustatory, etc.) could only be evoked by insular stimulation,[6,29] confirming that SII is mostly devoted to the processing of somatosensory inputs while the insular cortex is a polymodal area.

Supplementary sensorimotor area (SSMA)

Sensations produced by activation of the SSMA tend to be poorly localized and usually affect more proximal body parts. They are often bilateral and sometimes described by patients as a whole body aura.[5] Lim *et al.*,[31] with cortical stimulation through subdural electrodes, were able to elicit subjective sensory symptoms in the contralateral upper or lower extremities, bilateral lower extremities, or the head. Stimulation sites were the mesial aspect of the superior frontal gyrus, the cingulate gyrus and the precuneus.

Localizing value of somatosensory auras

In patients with somatotopically well-localized somatosensory auras, the epileptogenic zone frequently is in the perirolandic region, close to the location of the symptomatogenic zone. Since somatosensory auras rarely appear in isolation, the combination with other sensory or motor features and the evolution of subsequent motor patterns can be of help in localization. In a prospective analysis of clinical seizure patterns and their predictive localizing value in frontal and temporal lobe epilepsies, Manford and co-workers[32] performed a cluster analysis of 14 distinct clinical symptom groups, showing that sensorimotor symptoms correlated consistently with pathologic findings in the perirolandic area. Salanova *et al.*,[33] reviewing patients with parietal lobe epilepsy who underwent surgery, found that somatosensory auras were contralateral in 51 of 52 patients and bilateral in one. This confirms a previous study by Ajmone-Marsan and Goldhammer,[24] where contralateral somatosensory auras were found to be highly localizing in 96% of patients with central parietal lesional epilepsy. According to these authors, the presence of a Jacksonian march did not add localizing value.

Blume and colleagues[34] described five patients with seizures involving secondary sensory areas. Four of their patients experienced ictal numbness or tingling bilaterally and/or axially, the fifth patient experienced bilateral ictal pain. Associated ictal symptoms implicating adjacent regions appeared in all patients. The close proximity of second sensory area, insula and temporal lobe explains that sensations produced by activation of these areas are often associated and then progress to motor phenomena of the face or mouth produced by spread into the lower rolandic cortex. According to Isnard and colleagues,[35] the association of a sensation of laryngeal constriction with paresthesias affecting large cutaneous territories, eventually followed by dysarthric speech and focal motor symptoms, is highly suggestive of an insular seizure origin. Of note, in 10% of patients studied by Mazzola *et al.*,[29] SII stimulation directly produced an unpleasant pharyngo-laryngeal strangling sensation.

Somatosensory auras can also occur in temporal lobe epilepsy. In their series of 72 patients with somatosensory auras, Tuxhorn and colleagues[36] noted that four patients whose aura was ipsilateral to the lesion had temporal lobe epilepsy associated with hippocampal sclerosis. Erickson *et al.*[37] also reported nine patients with temporal lobe epilepsy and somatosensory auras. The most common manifestation was tingling, but sensory loss and pain also occurred. In their series, seizure origin was in the contralateral temporal lobe in four of five patients with unilateral somatosensory symptoms, including all patients with unilateral auras affecting a limb. In all except one patient, the symptoms could be explained by spread to the primary or second sensory area. However, somatosensory symptoms can also be produced by stimulation of different areas in the temporal lobe. Fish and co-workers[14] were able to elicit ipsilateral, contralateral and bilateral vague somatosensory feelings affecting one or more limbs from stimulation of amygdala, hippocampus or temporal isocortex. Interestingly, already Penfield and Jasper[5] pointed out that sensory phenomena could be elicited in regions of cortex that did not represent somatic sensory cortex. This may be due to abnormal facilitation of networks involving sensory symptomatogenic areas as suggested by a more recent study.[18]

Subtypes of somatosensory auras

Painful auras

In the series of Maugiere *et al.*,[25] pain was the second most common ictal sensation, occurring in 24% of patients with

somatosensory seizures. The nature of the pain was often described as unnatural, stabbing or cramp-like and overall quite severe. Several studies have shown that neurons in the primary somatosensory cortex can respond to painful stimuli.[29,36,38] Mazzola and colleagues,[29] stimulating somatosensory areas through depth electrodes, have demonstrated that painful sensations can also be elicited from SII and the insula. Out of 858 epileptic patients reviewed by Young and Blume,[39] ten had seizures characterized by unilateral pain in the face, arm, leg or trunk. Unilateral pain consistently implicated ictal involvement of the contralateral rolandic region. Siegel *et al.*[40] reported eight patients with painful auras involving head, face, limbs or abdomen (often in sequential order in the same patient), all originating from the parietal lobe. When the painful symptoms were lateralized, they were contralateral to the side of seizure origin. In the series of Nair and colleagues,[38] painful auras were contralateral to the epileptogenic zone in patients with perirolandic epilepsy. Lateralization was inconsistent in patients with temporal lobe epilepsy.

Thermal auras

Mauguière *et al.*[25] found a sensation of warmth or coldness in 11% of patients with somatosensory auras, and the thermal perception was always associated with either elemental paresthesias or pain. It was mostly described as unpleasant, often spreading from the initial site to involve a whole arm or leg or the ipsilateral face. Rarely, bilateral spread could occur. Electrical stimulation studies have demonstrated that most thermal sensations are obtained from the perisylvian region.[5,29] They do not provide reliable lateralizing information.

Somatosensory illusions

Somatosensory illusions, such as a sensation of swelling or shrinking of a body part, or a kinesthetic illusion (sensation of movement) have been found to occur in about 10% of patients with somatosensory epilepsy.[25,33] Similar to other disturbances of body image, somatosensory illusions can be obtained by stimulation of the postcentral gyrus, the inferior parietal lobule or the temporo-parieto-occipital junction, more often of the nondominant hemisphere.[41,42] Penfield and Jasper[5] were able to produce a sensation of movement of a body part by electrical stimulation anterior to the central fissure. Sensations of ocular movement without any objective evidence of movement have been observed in seizures of occipital lobe origin.[43]

Penfield and Jasper also described the feeling of inability to move a body part and attributed it to activation of precentral negative motor areas. Likewise, the feeling of inability to move has been related to discharges in the parietal lobe and around the sylvian fissure, involving the second sensory area.[41] These seizures have been reported to occur ipsi- and contralaterally to the discharging focus as well as bilaterally,[44] and therefore do not have lateralizing value.

Visual auras

Visual auras can manifest as simple hallucinations of static, flashing or moving lights in different shapes and colors, complex hallucinations of persons, scenes or objects, and illusions in the form of distortion of existing objects. They can involve the entire visual field or only a part, typically half. Negative phenomena (transient loss of vision, scotomata or visual agnosia) are also possible. Complex visual manifestations that are not the predominant symptom or accompanied by other alterations of perception are better classified as 'psychic'.

With electrical stimulation, most visual responses can be elicited from the visual areas in the occipital lobe and adjacent border zones with the parietal and temporal lobes. Simple visual hallucinations (flashes or static lights) are often produced by activation of the primary visual area (Brodmann area 17), which is located on the mesial surface of the occipital lobe and has a topographic representation of the visual fields. The surrounding visual association areas (Brodmann areas 18 and 19) are involved in the perception of color, movement and other more complex aspects of vision, including the integration with other sensory modalities.[5,45] Richer and colleagues,[46] stimulating the extrastriate mesial parieto-occipital cortex through intracerebral depth electrodes in 30 patients, found static visual hallucinations (white or colored flashes) at the cuneus near the calcarine fissure, and blurring of vision at the posterior cingulate and inferior precuneus. Visual motion perception was evoked in four patients, arising from the mesial parieto-occipital fissure in three and posterior cingulate in one patient. Laff and colleagues[47] report a patient in whom subdural EEG recordings of illusory motion perception revealed seizure onset in the right temporo-parieto-occipital junction.

However, this subdivision is not exclusive and visual responses can be obtained from many sites along the visual pathways.[48] In a few instances, visual hallucinations have even been evoked by stimulation of the frontal lobe. Blanke *et al.*[49] report two patients with complex visual hallucinations produced by stimulation of the left prefrontal cortex with different spatial organization: while visual hallucinations produced by stimulation of the inferior frontal gyrus were perceived in the whole visual field, complex visual responses evoked by stimulation of the middle frontal gyrus appeared in the contralateral hemifield. Beauvais and colleagues,[50] in a study with stereo-EEG recordings, were able to record spontaneous visual hallucinations originating from the superior frontal sulcus.

Blume and co-workers[51] assessed the localizing value of different semiological elements, including visual hallucinations, in 41 patients with occipital lobe epilepsy studied with invasive electrodes. Upon statistical analysis, no aspect of semiology distinguished lateral from mesial occipital seizures. Bien and colleagues[52] report 20 patients experiencing visual auras from a series of surgically treated patients with intractable focal seizures. Elementary visual hallucinations, illusions and visual loss were reported by patients with occipital lobe epilepsy, as well as by patients with occipitotemporal and anteromesial temporal seizure onset. Complex hallucinations and concentric restriction of the visual field (tunnel vision) occurred only in temporal or occipitotemporal seizures.

Simple visual hallucinations, when they are lateralized, always point to an origin in the contralateral hemisphere. To a certain extent, an origin above or below the calcarine fissure can be predicted in the case of hallucinations localized in the lower or upper quadrant of the contralateral visual field. Complex visual auras arising from the temporo-occipital junction or the basal temporal cortex have been reported to lateralize to the right hemisphere,[22,53] but not all authors have made this observation.

Subtypes of visual auras

Amaurosis

Ictal amaurosis has been observed in conjunction with unilateral or bilateral occipital lobe[41] or occipitotemporal[52] discharges. In post-traumatic epilepsy, it has been shown to occur more often with injury to visual association areas than to the calcarine cortex itself.[54] Lateralized visual loss is indicative of an ictal event in the contralateral hemisphere.

Visual illusions

Visual illusions are defined as misperceptions of real visual stimuli, such as changes of dimensions, perceptual intensity, motion, or speed. Visual distortions like macropsia, micropsia, and metamorphopsia most often occur with ictal discharges close to the geniculostriate radiation, such as the basal temporal cortex, or visual association areas.[52,54] There is some evidence that each hemisphere is involved in size processing for contralateral stimuli.[55] Another rare type of visual illusion is called palinopsia, defined as the persistence or recurrence of images in the visual field when the stimulus is no longer present. It has also been reported as an ictal manifestation, associated with an occipital seizure discharge.[56] When the phenomenon is lateralized, the eventual brain lesion is always contralateral to the perseveration and usually located in the occipital, parieto-occipital or temporo-occipital region of the right hemisphere.[56,57]

Auditory auras

Auditory auras can manifest as elementary hallucinations of simple sounds ('ringing', 'buzzing'), complex hallucinations like voices or melodies, or auditory illusions in the form of distortion of environmental sounds. Ictal deafness may also occur.[13] Complex auditory manifestations accompanied by other alterations of perception are better classified as 'psychic'.

Auditory phenomena can be produced by stimulation of the primary (Brodmann area 41) and association auditory cortices (Brodmann areas 42 and 22) within the temporal lobe. In the experience of Penfield and colleagues,[7,58] elementary auditory hallucinations could be evoked mainly by electrical stimulation of Heschl's transverse gyri in the first temporal convolution bordering the posterior third of the sylvian fissure. When stimulating the lateral and superior surface of the superior temporal gyrus, complex hallucinations were elicited. Stimulation of the superior temporal gyrus outside Heschl's gyri and the adjacent temporo-occipital neocortex (Brodmann areas 42 and 22) produced auditory illusions. According to evoked potential studies,[59] each cerebral hemisphere receives input from both ears, although stimulation from the contralateral ear appears to be better represented within the auditory cortex. This has also been confirmed by electrical stimulation. De Graaf and colleagues[60] studied 65 patients with intracranial depth electrodes placed at different sites of the superior temporal gyrus. Patients reported auditory hallucinations as well as illusions in response to electrical stimulation. Hallucinations could be contralaterally or binaurally perceived, but could also be very clearly located in extrapersonal space. This latter perception mostly occurred with intense noises and was often accompanied by a feeling of fear or unpleasantness. In the planum temporale, auditory illusions and hallucinations were observed with equal frequency. Stimulation of Brodmann's area 22 also provoked hallucinations as well as illusions. Hallucinations were mainly perceived binaurally, whereas illusions were more often contralateral. Therefore, it can be assumed that auditory auras, when they are lateralized, are indicative of a contralateral seizure origin.

In a series of surgical patients with auditory auras,[61] the epileptogenic zone was located in the temporal lobe (15 patients), frontal lobe (two patients) or the fronto-temporal region (one patient). Of the patients with temporal lobe seizures, five had mesial temporal and ten neocortical temporal lobe epilepsy as defined by EEG. In addition to auditory symptoms, half of the patients described other auras, including psychic, somatosensory, visual, abdominal, and gustatory phenomena.

Vertiginous auras

A variety of symptoms reflecting disturbance of vestibular function (sensation of rotation, sensation of movement in all planes) may occur during epileptic seizures. Typically, they are not accompanied by nystagmus. In a survey of 120 patients with epileptic vertiginous sensations, Smith[62] observed a strong association with visual and auditory symptoms, supporting the idea of a symptomatogenic zone close to visual and auditory association areas. In a functional MRI study with galvanic stimulation, Lobel and co-workers[63] found activation in the region of the temporo-parietal junction, the central sulcus and the intraparietal sulcus, in addition to frontal areas, presumably expression of a network subserving vestibular sensations. Kahane and colleagues[64] studied cortical areas with vestibular input by electrical stimulation through implanted depth electrodes in 28 patients from a larger surgical series. Most vestibular sites were located in the temporal or parietal lobe, but some also in the frontal, occipital, and insular region. The authors identified a lateral cortical temporoparietal area from which vestibular symptoms, and above all rotatory sensations, were particularly easily elicited. This area extended above and below the sylvian fissure, mainly inside Brodmann areas 40, 21, and 22.

Vestibular cortical areas have been said to exhibit a right-hemispheric dominance[65]; however, in the study of Kahane *et al.*,[64] almost 20% of vertiginous responses occurred after stimulation of left hemispheric sites. Kluge and colleagues[66] reported one patient with episodes of epileptic rotational vertigo accompanied by a left fronto-central seizure discharge, whose seizures were abolished by lesionectomy of a small tumor in the left middle frontal gyrus, providing additional evidence of the involvement of the (left) frontal lobe in the processing of vestibular sensations.

Olfactory auras

Olfactory epileptic auras are rare, constituting about 1% of all auras, and are typically described as unpleasant.[67] They are often associated with other sensory phenomena, such as olfactory, psychic, complex visual, abdominal or auditory auras, and patients sometimes find it difficult to distinguish between olfactory and gustatory auras. Tumors in the mesial temporal region are the most frequent cause of olfactory auras,[67] but they have been reported to occur also with hippocampal

sclerosis.[68] Manford and co-workers[32] found two patients with frontal lesions (one medial and one lateral prefrontal/premotor) with seizures characterized by a mixture of fear and olfactory and gustatory auras.

Olfactory sensations can be obtained through electrical stimulation, but only isolated cases have been reported in the literature. The most consistent location where they could be elicited is the amygdala.[5,69] Penfield and Jasper[5] were able to produce an olfactory sensation also after direct stimulation of the olfactory bulb in one patient, Jasper and Rasmussen[69] through stimulation of an insular site. In their review of patients with frontal lobe epilepsy studied stereo-electroencephalographically, Bancaud and Talairach[70] postulated an involvement of the posterior part of the orbitofrontal region in the production of olfactory illusions and hallucinations. However, is not clear whether the orbitofrontal region can be regarded as the symptomatogenic zone or whether seizure activity has to spread to mesial temporal areas or the insula before an olfactory or gustatory sensation appears. Munari and colleagues,[71] studying 105 patients with depth electrodes in the orbitofrontal region, found that discharges beginning in the orbital cortex became clearly symptomatic only when they spread to extraorbital regions.

Greenberg[72] suspects that an interaction of several areas is necessary to generate false perceptions of smell, but the precise mechanism by which this is achieved still remains unknown. The high frequency of gustatory and psychic auras and low frequency of abdominal auras in the series of Acharya and colleagues[67] suggests different pathways for the generation of olfactory, gustatory and psychic auras, probably more related to the amygdala, and abdominal auras, which appear to be more related to the hippocampus. Olfactory auras have no lateralizing value.

Gustatory auras

Although olfactory and gustatory auras are often associated, anatomic and physiologic data indicate a distinct cerebral representation of taste. Electrical stimulation studies have produced gustatory hallucinations mainly in two areas: the parietal operculum and the anterior mesiobasal part of the temporal lobe.[5,72] In a group of 20 patients with gustatory auras investigated with depth electrodes, Hausser-Hauw and Bancaud[73] were able to elicit gustatory hallucinations from either the parietal or rolandic operculum, in one patient each from the medial aspect of the right superior temporal gyrus and the anterior part of the right middle temporal gyrus. In addition, they electrically induced seizures with gustatory hallucinations by stimulation of the hippocampus and amygdala. Spontaneous seizures with gustatory hallucinations were arising from the temporal, parietal or parietotemporal region. The authors conclude that representation of taste is located in the frontoparietal operculum since gustatory sensations alone could be elicited only when this area was stimulated. Gustatory auras are usually not lateralized, but in the single case of Hausser-Hauw and Bancaud with a lateralized ictal taste sensation,[73] the discharge involved the contralateral hemisphere.

Autonomic auras

The term 'autonomic aura' refers to sensations suggesting an ictal activation of the autonomic nervous system (e.g., palpitations, difficulty breathing, urinary urge, feeling hot or cold) without objective evidence of altered nervous system function. The abdominal aura, which likely represents a subtype of autonomic aura, is classified separately because it is one of the most frequent types of aura and often associated with temporal lobe epilepsy.

Autonomic symptoms can be elicited by electrical stimulation of a number of cortical areas, namely the insula,[5,6,29,70] the anterior portion of the cingulate gyrus,[74] and the SSMA.[5] Structures within the mesial temporal lobe, in particular the amygdala, are also thought to be involved in autonomic function.[14] Van Buren and Ajmone-Marsan[75] have observed bradycardia, decreased skin resistance, increased esophageal peristalsis and apnea following amygdalar stimulation; thermoregulatory phenomena (feeling of warmth or coldness, shivering) have been elicited from the amygdala and the posterior hippocampus, as well as the mesial frontal region.[14,76] Already Penfield and Jasper[5] found that similar autonomic phenomena could be elicited from more than one area. One possible explanation is that autonomic responses originating from different cortical regions may be mediated through a common subcortical relay station such as the hypothalamus. Stimulation of the diencephalon has been shown to cause a variety of autonomic phenomena.[77]

Autonomic auras are frequently observed in seizures arising from the orbitofrontal region, most often due to seizure spread to the temporal lobe.[71] A sensation of laryngeal constriction has been reported to be typical for seizures arising from the insula,[35] especially if it is followed by diffuse and unpleasant paresthesias. Ictal SPECT obtained in two patients with ictal urinary urge[78] also showed a hyperperfusion of the insular cortex. Authors who studied this phenomenon agree that ictal urinary urge appears to be a lateralizing sign for non-dominant temporal lobe epilepsy.[78,79] Other types of autonomic auras do not provide lateralizing information.

Abdominal auras

Abdominal (or epigastric) auras are characterized by a sensation of nausea, pain or some kind of undescribable discomfort in the abdominal or periumbilical region. Most patients with ictal vomiting also experience a similar sensation. According to Van Buren,[80] this sensation is static in about half of the patients, in the other half it tends to rise from the epigastric region to the chest, throat or, more rarely, head or face. Discending abdominal auras have also been described.

Electrical stimulation studies suggest that the primary symptomatogenic zone for abdominal auras is located in the insula, even though other structures like the lower rolandic, the mesial temporal and the supplementary motor areas have been implicated.[5] While Penfield and Faulk[6] found gastrointestinal motility changes only with insular stimulation, Bartolomei and colleagues[81] induced viscero-sensitive phenomena including epigastric or throat sensations after either rhinal, amygdalar or hippocampal stimulation. Fish and coworkers[14] were also able to elicit an epigastric aura through mesial frontal stimulation. Stimulation-induced rising thoracic sensations were found to have the same anatomical distribution as static abdominal sensations.[5,6]

Abdominal auras are often thought to be characteristic for patients suffering from mesial temporal sclerosis, but several authors have reported abdominal auras as a manifestation of

seizures originating from other brain regions. In Van Buren's series,[80] only 69 of 100 patients with abdominal auras had temporal lobe epilepsy. Henkel *et al.*,[82] in a survey of 491 surgical patients, found that abdominal auras were more frequent in temporal than in extratemporal epilepsy, and more frequent in mesial than in neocortical temporal lobe epilepsy. According to these authors, an abdominal aura is associated with temporal lobe epilepsy with a probability of 74%, and the evolution of an abdominal aura into an automotor seizure increases the probability of temporal lobe origin to 98%. Most patients with extratemporal epilepsies had seizures arising from the frontal lobe. Three patients with parieto-occipital lobe epilepsy had abdominal auras associated with visual symptoms, providing an additional clue for localization.

Painful abdominal auras have been observed in patients with temporal and frontal lobe epilepsies. In three patients described by Young and Blume,[39] abdominal ictal pain reflected temporal lobe epileptic activity. Nair *et al.*[38] also found that the number of painful abdominal auras was highest in temporal lobe epilepsy. However, the relative frequency of painful abdominal auras was higher in patients with frontal lobe than in those with temporal lobe seizures.

There is no consensus with regard to lateralization of the abdominal aura. In Henkel's study,[82] no prevalence of one side existed. However, cluster analysis in another study of 31 surgically treated patients with temporal lobe epilepsy,[83] suggested that an abdominal aura combined with ictal vomiting lateralizes to the right hemisphere.

Psychic auras

Psychic auras include a variety of symptoms which can be generated by activation (and interaction) of different symptomatogenic areas, mostly located in the temporal lobe. In the past, psychic auras have also been labelled, 'experiential', since they often consist of multisensorial hallucinations or illusions reproducing an experience. For practical purposes they can be subdivided into three broad categories, although symptoms often overlap: emotional or affective manifestations (fear, anxiety or elation), distortions of familiarity such as the 'déjà vu' (i.e., the sensation of having previously lived through the same experience) or the 'jamais vu' phenomenon, and multisensorial hallucinations including the revocation of complex memories.

Penfield[5] found that most experiential reponses were elicited from the lateral temporal isocortex, or by mesial limbic stimulation in the region of the uncus. In later stereotactic investigations by the Montreal group,[15] virtually all psychic reponses were elicited by stimulations of the limbic structures of the temporal lobe. Halgren and co-workers,[76] in line with observations made by other authors, pointed out that mental phenomena evoked by mesial temporal lobe stimulation were variable and highly individual, related to the personality of the patient stimulated.

Forced thoughts, on the other hand, have been attributed to the frontal lobe. Mendez *et al.*[84] report three patients with left frontal lesions with auras consisting of forced thinking associated with speech arrest. The authors hypothesize that forced thinking is a manifestation of expressive language, distinct from experiential phenomena arising from the temporolimbic region.

Most psychic auras do not provide reliable lateralizing information. In Fish's series of patients with frontal and temporal lobe epilepsies studied with intracranial stimulation,[14] there was no consistent lateralization of psychic phenomena, with the exception of the déjà-vu illusion (see below).

Subtypes of psychic auras

Fear

The sensation of fear is said to be characteristic of activation of the amygdala. In Fish's series,[14] fear was indeed elicited most often from the amygdala, but also from the hippocampus, the temporal isocortex and, in two cases, by mesial frontal stimulation. Affective phenomena other than fear were also elicited mostly from the amygdala, in one case each from the hippocampus and the frontal lobe.

Pleasant auras

The localizing value of pleasant ictal sensations such as harmony, satisfaction, euphoria, or orgasm-like sensations, has been investigated by Stefan and colleagues.[85] In some patients, the happy feeling was associated with other sensory phenomena like an unpleasant smell, an epigastric or déjà-vu sensation or visual hallucinations; in one patient, the sensation could be triggered by eating spicy food. In eight of eleven patients, ictal happiness was associated with a discharge in temporal mesiobasal areas. Lateralization in this series was inconclusive. Janszky *et al.*[86] reported seven patients who experienced an orgasmic aura at the start of their seizures. All had temporal lobe epilepsy, and findings suggested a right-sided focus in six of these patients.

Distortions of familiarity

Distortions of familiarity like a feeling that a certain experience has occurred before ('déjà vu') or that a familiar context appears completely new ('jamais vu'), or a mixture of both, can also be generated by activation of the basal temporal region. In the series of Bartolomei and colleagues,[81] these phenomena were evoked much more frequently by stimulation of the rhinal cortex than by stimulation of other mesial temporal areas. In particular, déjà vu was associated with stimulation of the entorhinal cortex and reminiscence of memories with perirhinal stimulation. Some evidence suggests that déjà-vu sensations occur (or are reported) more commonly in seizures originating from the nondominant hemisphere. In Fish's series,[14] the déjà-vu illusion was elicited on the right side in four of five patients. A similar observation has been made by Weinand *et al.*,[87] who reported eight patients where déjà-vu auras lateralized to the nondominant hemisphere.

Multisensorial hallucinations and out-of-body experience

It is likely that the revocation of complex multisensorial experiences necessitates activation of a larger cortical network, important parts of which are the mesiobasal limbic cortex, the lateral temporal neocortex and the temporo-parieto-occipital junction.[15,16,17] The prevalent symptom of these hallucinations may provide some localizing information: Penfield and Perot[7] noted some degree of topographical segregation between auditory and visual experiential reponses on the lateral surface of the temporal lobe; while auditory reponses were clustered along the

first temporal convolution, visual reponses were evoked from more widespread regions of the temporal isocortex. Bancaud and co-workers[88] were able to elicit complex psychic symptoms ('dreamy states') by stimulation of either the amygdala, the anterior hippocampus or the lateral temporal neocortex (mainly the superior temporal gyrus). However, they found that spontaneous 'dreamy states' were always accompanied by simultaneous activation of all three structures.

Rare types of complex hallucinatory events which can be associated with vestibular sensations and other disturbances of body image are autoscopy and out-of-body experience. The electroclinical correlates of these phenomena were studied by Blanke and colleagues[89] in six patients, two of whom were investigated with subdural electrodes. In one patient, an out-of-body experience was induced through stimulation of the right parieto-temporal junction. At the same electrode site, vestibular sensations and visual body part illusions were produced. Overlap analysis found the angular gyrus to be involved in five patients in whom lesion analysis could be performed. The recorded seizures could originate from either hemisphere. The authors hypothesize that the experience of seeing one's body in a position that does not coincide with its felt position is due to faulty integration of input from proprioceptive tactile, visual and vestibular information systems with sensory information of extrapersonal space.

Nonspecific auras

This term refers to a variety of vague feelings that cannot be readily attributed to one of the previously described aura categories. Reasons why some auras appear nonspecific may be related to the varying ability of patients to describe their symptoms, their highly individual character which defies classification or further study, or their nondistinct localization.

Two subtypes of nonspecific auras, cephalic and whole-body auras, have been investigated more in detail:

Cephalic auras

Cephalic auras include sensations such as nonvertiginous 'dizziness', 'lightheadedness', an 'electric shock-like' feeling, 'numbness' or 'pressure'. Nair and Lüders[90] performed a retrospective review of video-EEG monitoring reports of 446 patients, about half of whom had temporal lobe epilepsies. In their series, cephalic auras were seen in patients with seizures originating from all lobes, but more commonly in lateral temporal lobe epilepsies. Palmini and Gloor[21] found that they occurred more often in patients with frontal lobe epilepsy.

Accordingly, different symptomatogenic areas for cephalic auras have been identified with intracranial recordings. Jobst *et al.*[91] found a cephalic aura in 24% of a series of 26 patients with frontal lobe epilepsy, 24 of whom were recorded with intracranial electrodes. Fish and co-authors,[14] using electrical stimulation of the temporal and frontal lobes, predominantly produced cephalic auras following amygdalar stimulation. In the series of Bartolomei and colleagues,[81] responses from rhinal stimulation also included headache and vague sensations of 'something happening in the head'. Penfield and Jasper[5] elicited cephalic auras from several noncontiguous areas of the temporal lobe, including the lateral temporal neocortex.

Some patients also report painful cephalic auras. Young and Blume[39] described 11 patients with ictal pain restricted to the head. Cephalic pain did not localize the site of seizure origin and was thought to reflect a vascular mechanism. In two patients with ictal headache recorded with depth electrodes, the epileptogenic focus was found in the right limbic system, and temporal lobectomy relieved the symptoms.[92] In the series of Nair *et al.*,[38] painful cephalic auras could be seen in patients with seizures originating from any lobe except the perirolandic region. In two patients with temporal lobe epilepsy where the cephalic pain was lateralized to one side, it was ipsilateral to the epileptogenic hemisphere. Bernasconi *et al.*,[93] reporting on 47 patients with periictal headache, also noted that the headache was more likely to be ipsilateral to the seizure onset focus in temporal lobe epilepsy (90% of cases), whereas headache in nontemporal lobe epilepsy was not lateralizing.

Whole-body auras

Penfield and Jasper[5] were able to elicit generalized body sensations from the second sensory area as well as the supplementary sensorimotor area. In the series of Nair and Lüders,[90] whole-body auras occurred in patients with frontal, temporal and multifocal epilepsies; the highest percentage (39%) was found in patients with seizures originating from the posterior temporal lobe. In these patients, the symptomatogenic area may have been the second somatosensory cortex. Whole body auras have no known lateralizing features.

Summary and conclusions

Since it is usually the first symptom to appear in the course of a seizure, the aura is still the best available clinical indicator of the possible location of an epileptogenic zone. However, when attempting to derive localizing information from aura semiology during the presurgical evaluation, it has to be kept in mind that the aura (like any other clinical symptom) is not produced by the epileptogenic zone itself, but is expression of activation of one or more symptomatogenic zones, which are not identical with but may actually lie at a distance from the epileptogenic zone.

The best experimental model to define the localization of the different symptomatogenic areas is to simulate the effect of a seizure discharge with electrical cortical stimulation. Over the years, extensive cortical maps of different brain functions have been developed which are widely used and reproduced yet present inherent limitations. For example, electrical discharges below an effective stimulus intensity do not produce symptoms. Also, identical symptoms can be elicited from several different areas which may not even be consistent in any one patient, and virtually no symptom can be considered pathognomonic for a specific brain region. In recent years, the modular approach to the localization of brain function has given way more and more to an integrated network approach that explains why symptoms due to activation of a network may be elicited at different points of the same circuit. Different symptomatogenic zones may therefore form symptomatogenic systems, just like the epileptogenic zone may actually be an epileptogenic system, different parts of which have different activation thresholds.

Nonetheless, there are different probabilities with which any given symptom can be elicited at different cortical sites,[94]

which can be used for localization. Known localizing and lateralizing features of different aura types are summarized in Table 49.1. In addition, auras are often associated with other symptoms forming symptom clusters which, in their unique association, can provide localizational clues or trace the propagation pathway the seizure takes in the brain. In the end, the localization of a presumed epileptogenic zone can only be accomplished through a combination of several semiological, morphological and electrographic pieces of information, of which aura semiology is just one, albeit important element.

Table 49.1 Localization and lateralization of epileptic auras

Aura type	Symptomatogenic zone (electrical stimulation)	Epileptogenic zone (lobe)	Lateralization
Somatosensory			
Pain, thermal sensations	SSI, SSII, insula	Parietal, temporal	Contralateral if from SS I; may be ipsilateral from SS II, insula, SSMA
Paresthesias	SS I/II, SSMA, insula, temporal	All lobes, more often parietal or temporal	
Limbs			
Head, trunk, genitals			No
Somatosensory illusions	SS I, inferior parietal lobule, TPO junction	Parietal, temporal	More often ND
Sensation of movement	SS I, SSMA, primary motor	Frontal, parietal	No
Eyes	Occipital lobe	Occipital	No
Visual			
Amaurosis	Occipital, temporo-occipital	Occipital, temporal	If lateralized, contralateral
Blurring of vision	Posterior cingulate, mesial > lateral parieto-occipital	Occipital, parietal, posterior temporal	
Simple and complex hallucinations	More likely occipital or temporal, but all lobes possible	All lobes	More often ND
Illusions	Basal temporal, TPO junction	Temporal, parietal, occipital	No
Tunnel vision	Basal temporal, occipito-temporal		
Auditory			
Simple hallucinations	More likely Heschl's gyrus	Temporal	If lateralized, contralateral
Complex hallucinations, illusions	More likely auditory association cortex	Frontal, temporal Temporal	
Vertiginous	All lobes, more frequently temporo-parietal	Parietal, temporal, frontal	More often ND
Olfactory	Amygdala, insula	Frontal, insular, mesial temporal	No
Gustatory	Insula, mesial temporal	Temporal, insular	If lateralized contralateral
Autonomic			
Throat constriction	Insula	Insular	No
Breathing difficulty, palpitations, thermodysregulation	Insula, anterior cingulate, SSMA, amygdala, hippocampus, hypothalamus	Temporal, (orbito-) frontal, insular	No
Urinary urge	Insula	Temporal, insular	More often ND
Abdominal epigastric	Insula, mesial temporal, mesial frontal	All lobes, most often temporal	Right, if associated with vomiting
Psychic			
Fear	Amygdala, hippocampus, mesial frontal	(Mesial) temporal or frontal	No
Happiness, ecstasy	Temporal	Temporal	More often ND
Déjàvu/jamaisvu	Mesial > lateral temporal	Temporal	More often ND
Multisensorial exp.	Lateral temporal, TPO junction	Temporal, parietal	No
Out-of-body experience	TPO junction	Temporal, parietal	No
Nonspecific			
Cephalic	More often frontal or temporal, but all lobes possible	All lobes	No
Whole-body	SS II, SSMA	More often mesial frontal or post. temp.	No

Abbreviations: SS I: primary somatosensory area, SS II: second somatosensory area, SSMA: supplementary sensorimotor area, TPO: temporo-parieto-occipital, ND: nondominant hemisphere

50 Autonomic seizures: localizing and lateralizing value

V Nagaraddi and HO Lüders

Summary

Autonomic symptoms are common during epileptic seizures, mainly in conjunction with other more prominent symptoms. However, in selected cases autonomic symptoms may also constitute the predominant ictal manifestation. Autonomic seizures are actually mediated by activation of the central autonomic network and are not an adjunct to motor and other manifestations of seizures. Autonomic seizures have been divided into cardiovascular, respiratory, gastrointestinal, cutaneous, papillary, and urogenital, depending upon the symptoms.[1]

Certain autonomic symptoms provide lateralizing and/or localizing information about the ictal onset zone, due to specific representation of the central autonomic network in the cortex. Autonomic symptoms range from subtle changes, which are apparent only with video-EEG monitoring, to severe, sometimes life-threatening events. When autonomic symptoms are the sole seizure manifestation, they can be difficult to differentiate from psychogenic non-epileptic seizures. Finally, autonomic symptoms during seizures provide a unique opportunity to study the functional organization of the central autonomic network.[1]

Introduction

Autonomic symptoms occurring during seizures have been recognized for more than 100 years. Changes in heart rate and respiration during a generalized tonic–clonic seizure are predictable and are obvious to an observer. Autonomic symptoms during focal seizures have long been observed as well, including goose bumps, flushing, pallor, sweating, sexual sensations, and pupillary changes.[2]

In 1981, the commission on classification and terminology of the International League against Epilepsy included autonomic seizures as a subdivision of simple partial seizures in the revised seizure classification. This subdivision included among others, epigastric sensations, pallor, sweating, flushing, piloerection and pupillary dilation.[3]

Autonomic symptoms can occur either during the ictus or postictally. They may also play a role in some interictal epileptic behaviors. Autonomic symptoms are being recognized with increasing frequency. Nevertheless, autonomic seizures are still frequently under- or misdiagnosed, resulting in expensive investigations and inappropriate therapies, leaving incapacitating and potentially fatal symptoms untreated.[4]

Both focal and generalized seizures alter the central autonomic functioning during ictal, postictal, and interictal states. All aspects of autonomic function can be affected, including the parasympathetic, sympathetic, and adrenal medullary systems. Focal and generalized seizures typically activate the sympathetic nervous system, increasing the heart rate and blood pressure, although parasympathetic activation or sympathetic inhibition may predominate during some focal seizures.[5]

Neuroanatomy of the autonomic system

The preganglionic sympathetic and parasympathetic efferent pathways are regulated by reciprocally interconnected cortical, subcortical, and brainstem regions. The components of the central autonomic network have been established by experimental methods, and include the insular cortex, the medial prefrontal cortex, the central nucleus of the amygdala, the nucleus of the stria terminalis, the hypothalamus, the midbrain periaqueductal gray matter, the pontine parabrachial region, the nucleus of the solitary tract and the intermediate reticular zone of the medulla.[6]

Anatomic and physiologic studies have defined a topographically organized visceral map in the insula, supporting the concept of the insula as a 'visceral sensory cortex', with localization of gustatory responsive neurons to the rostral agranular region and gastric mechanical responsive neurons to the caudal granular region. Electrical stimulation studies of the insular cortex have demonstrated heart rate, blood pressure, respiratory, piloerector, pupillary, gastrointestinal, salivatory, and adrenal responses. Intraoperative stimulation studies of the human insular cortex have suggested that tachycardia and pressor responses occur more commonly with right anterior insula stimulation, whereas bradycardia and depressor responses are more common with left anterior insular stimulation.[7,8]

Stimulation of the medial prefrontal cortex produces profound changes in blood pressure, heart rate, and gastrointestinal motility. A viscerotopic map of this region, which includes the anterior cingulate gyrus and the inferior and prelimbic cortices, supports the concept of the medial prefrontal cortex as a 'visceral motor cortex.' Intraoperative human stimulation studies of the cingulate gyrus have demonstrated changes in heart rate and blood pressure.[4,9]

Definition of autonomic seizures

Autonomic seizures have a measurable or visible autonomic symptom or manifestation, for example change in the heart rate or piloerection, which is also a prominent or predominant feature of the seizure. The symptom is usually verifiable by an observer, reproducible over several seizures and can be documented quantitatively or qualitatively. This is important in distinguishing autonomic seizures from autonomic auras, which are symptoms perceived by the patient, such as feeling hot, or cold and clammy etc., but there is no change that can be verified by observation or measurement, such as the temperature being assessed by touch or measured by a thermometer and sweating documented by either touch or observation. The limitation is that many of the autonomic symptoms in question, are not quantifiable in most routine settings, because there is no simple, practical means of measuring it, for example peristalsis, pupillary changes etc.

It should also be noted that almost all epileptic seizures have some autonomic symptoms, especially cardiac and respiratory changes. Most focal and generalized tonic-clonic seizures have changes in heart rate, as measured by the EKG. In most of these cases, there is sinus tachycardia at the onset of seizure and to a lesser extent sinus bradycardia. Similarly, there are changes in the respiratory pattern and rate, which could be either due to modulation of the respiratory centers in the cortex and brainstem due to the spread of the seizure or as a result of the tonic contraction and spasms of the diaphragm and intercostal muscles. In these seizures, the predominant feature is either the alteration in consciousness and or the motor manifestations accompanying it and therefore they are not classified as true 'autonomic seizures'.[4,5]

Cardiac manifestations

Cardiac manifestations are the most studied autonomic alterations, partly because of trying to elucidate the pathophysiology of SUDEP and also because most EEG recordings have an EKG channel that can be easily analyzed.

Ictal tachycardia

An increase in the heart rate is seen in the vast majority of all epileptic seizures, including subclinical electrographic seizures.[10–13] Depending upon the definition of tachycardia, usually >100 beats per minute, the incidence of ictal tachycardia varied from 33–87%.[14–18] Furthermore, there is a significant preponderance of ictal tachycardia in temporal lobe epilepsy versus extratemporal lobe epilepsy (62% versus 11%, $p < 0.0018$)[19] and in one study ictal tachycardia was seen in 98% of temporal lobe seizures.[16,20,21] Within the temporal lobe, ictal tachycardia was found to be more prevalent in seizures arising from the mesial temporal lobe.[15,21] The onset of tachycardia tended to precede the EEG seizure onset, more so in temporal lobe versus extratemporal lobe seizures and mesial temporal lobe versus lateral temporal lobe seizures.[13,17,21] Finally, ictal tachycardia has been lateralized to the right hemisphere in several studies.[17,22] This suggests that early and significant tachycardia was primarily associated with right mesial temporal lobe seizures.[20]

Ictal bradycardia

A decrease in the heart rate is a lot less common and varied from 0-5% of seizures reported in several studies.[14,16,17,20] There are mixed results to the localization and lateralization of ictal bradycardia. Most of the prior reports had shown a predilection of ictal bradycardia in left temporal lobe seizures.[23–25] However, a recent study and other reports dispute this finding and suggest that there is usually bilateral involvement in seizures causing ictal bradycardia.[24,26] The reason may be due to the fact that ictal bradycardia is relatively uncommon and the number of seizures with ictal bradycardia in all of the studies were small, which included several case reports.

Ictal asystole

The incidence of ictal asystole is extremely rare,[27,28] though it may be higher than previously estimated especially in focal intractable epilepsy.[29–31] It has been implicated as one of the causes of SUDEP. There are several anecdotal case reports of ictal asystole following ictal bradycardia in left hemispheric seizures, mainly left temporal and frontal lobe seizures.[28,32–35] Single cases of ictal asystole in seizures arising from the left cingulate gyrus[36] and right frontal lobe[37]have also been reported.

Ictal arrhythmia

High-risk or fatal cardiac arrhythmias during epileptic seizures are thought to be uncommon,[38,39] however the incidence of ictal arrhythmias appears to be more common in intractable and generalized seizures.[40] Various cardiac arrhythmias that have been reported during epileptic seizures include atrial fibrillation (AF), supraventricular tachycardia (SVT), premature ventricular contraction (PVC), premature atrial contraction (PAC), bundle branch block (BBB), ST depression and T-wave inversion.[39,40] None of these ictal cardiac arrhythmias seem to have any localizing or lateralizing value.

Respiratory manifestations

Respiratory manifestations are not as common as cardiac manifestations but is probably the second most common manifestation of autonomic seizures. Most of the studies have been done in pediatric patients as they appear to be more common in children

Ictal hyperventilation

Ictal hyperventilation, defined as a 10% increase in the respiratory rate from the pre-ictal baseline, was seen in 56% of focal seizures recorded from 37 children.[41] In another study, hyperventilation was seen in 18% of children with autonomic seizures and was more common in temporal lobe epilepsy compared to extra temporal lobe epilepsy, but this was not statistically significant.[42] A study in adults found hyperventilation in both temporal and frontal lobe epilepsies, but occurred more in mesial compared to lateral temporal lobe epilepsy.[43]

Ictal apnea

Ictal apnea is most commonly reported in neonates and infants, typically lasting 1–2 minutes.[44–51] It was seen in 20% of children,[42] 58% of adults[52] and 30% of focal epilepsies.[41] When localized, it was mostly seen in temporal lobe epilepsies,[44–48,51,53] with cases lateralizing to both the left[53] and right[47,51] temporal regions.

Ictal dyspnea and stridor

This is not a well defined entity in the available literature. It was seen in 15% of children and two-third were associated with the tonic phase of epileptic seizures.[42] A case report describes stereotypical episodes of dyspnea over 4 months which turned out to be due to a right mesial temporal lobe epilepsy.[54]

Postictal nose wiping/postictal coughing

These two manifestations are thought to be due to same mechanism, which is increased parasympathetic activity, resulting in increased nasal and/or pharyngeal secretions, which then cause the patient either to wipe the nose or induce coughing. These reflexive maneuvers are usually seen postictally because during the ictus, both reflexive maneuvers are inhibited. Postictal coughing is most commonly seen in temporal lobe epilepsies, but has not been consistently lateralized to either the right or left hemisphere.[42,55,56] However, the hand used in postictal nose wiping seems to lateralize and or localize to the ipsilateral temporal lobe.[57–60]

Gastrointestinal manifestations

Gastrointestinal manifestations are the earliest autonomic symptoms to be described and studied. These symptoms generally have good lateralizing and localizing value except for ictal defecation because it is relatively rare and probably under reported. Abdominal epilepsy has been included here, even though it actually constitutes several different autonomic symptoms, but they are primarily gastrointestinal manifestations.

Epigastric aura

Epigastric aura is the earliest autonomic manifestation to be described[61]and the most commonly reported aura,[62] it has significant localizing value, arising from the mesial temporal lobe structures and the insula primarily.[63,64] In terms of lateralizing value, some authors claim that it is more common in non-dominant hemispheric epilepsy,[65,66] but it has not been confirmed by others.[67–69]

Abdominal epilepsy

Abdominal epilepsy is the earliest autonomic seizure to be described, and was previously called visceral seizures.[9,70] It is more common in children[71,72] than adults.[73,74] It is characterized by recurrent paroxysmal abdominal pain, usually associated with nausea, vomiting, lethargy and confusion.[75–78] Abdominal epilepsy has not been consistently lateralized[73] but has been localized to the temporal lobe in several reports.[42,79–82] Most patients reported as abdominal epilepsy had paroxysmal autonomic symptoms but no objective proof that these symptoms actually were an expression of epileptic seizures.

Ictal vomiting (Ictus emeticus)

In contrast to abdominal epilepsy, in which vomiting usually accompanies the abdominal pain and the patient is aware of it, vomiting in ictus emeticus occurs as the sole manifestation[83,84] or may be associated with other symptomatology of temporal lobe seizures, but the patient is usually amnesic of the vomiting.[85–87] Ictal vomiting is a relatively rare manifestation of temporal lobe seizures in adults.[84,88] It has been postulated to arise mostly from the non-dominant temporal lobe[70,86–90] however there have been several reports of ictal vomiting with dominant temporal lobe epilepsy.[42,91–95] On the other hand, ictal vomiting is the predominant manifestation of the early onset benign childhood occipital lobe epilepsy, which affects 13% of children aged 3-6 years.[96–101] Ictal vomiting is also seen in extraoccipital benign childhood epilepsies and carries the same prognosis.[102,103] Ictal vomiting is thought to occur when the epileptic discharges involve the medial and lateral aspects of the temporal lobe and the adjacent insular cortex.[85–87,104,105] Even in extra-temporal lobe epilepsies, it has been shown that ictal vomiting occurs when the ictal discharge spreads to the temporal lobe from the extratemporal focus, which in most cases is the occipital lobe.[104,106]

Ictal spitting (Ictus exporatus)

Ictal spitting is a rare manifestation of epileptic seizures, with an incidence of 0.2 to 2.2% of patients in epilepsy monitoring units.[107–109] It has been lateralized and localized to the non-dominant temporal lobe in most of the studies,[42,108–112] but has been reported in dominant temporal lobe in a couple of studies.[107,113] Ictal spitting is also thought to arise from the insular cortex.[109]

Ictal defecation

Ictal defecation is the urge to defecate, associated with the onset of a focal seizure, which has been reported anecdotally by several authors.[64,70,114,115] A.L. Reeves mentioned several cases in a review article, of patients with the urge to defecate at the onset of a seizure. A recent case report describes a 47 year old right handed woman with the urge to defecate at the onset of a seizure and the EEG was lateralized to the right hemisphere during the seizure.[116]

Cutaneous manifestations

Cutaneous manifestations are rare autonomic expressions of focal epilepsy, that were first described by Penfield,[114] Mulder[70], Daly[115] and Van Buren.[64,64,64] They usually occur in conjunction with one another, in addition to other common manifestations of focal epilepsy. Other cutaneous manifestations, which have been cited in the literature include sweating, cyanosis and purpura, but will not be covered here because there have been no reported localizing or lateralizing value to any of these manifestations and most of these studies were case-reports.

Ictal piloerection (goose bumps)

Ictal piloerection was identified in only 0.4% of 3500 patients undergoing video-EEG monitoring in a single epilepsy center over a 7 year period.[117] It has been localized to the temporal lobe in the majority of the patients reported in the literature,[117–119] including confirmation with cortical stimulation.[117,120] The piloerection mostly tended to occur unilaterally and often had a 'Jacksonian march' and in most of the cases, it was ipsilateral to the onset of the focal epilepsy.[117–119,121] The etiology was diverse, and included tumors,[121,122] hippocampal sclerosis,[120,121,123,124] limbic encephalitis,[125] hyperosmolor non-ketotic hyperglycemia,[126] post-traumatic[127] and cryptogenic.[118,124] However, it has not been consistently lateralized to either hemisphere and with several case reports of left[118–120,124,128] and right[122,123,127,129] hemispheric onsets.

Ictal pallor

The only comprehensive study of ictal pallor was a recent study in 100 children, in whom 11 were found to have ictal pallor. In this study 11 children had left temporal lobe epilepsy.[130] This has not been replicated in adults with only a handful of reports and in most of these reports, ictal pallor was usually concomitantly associated with other cutaneous manifestation.

Ictal flushing

In contrast to ictal pallor, ictal flushing was observed in 19 out of 100 children undergoing video-EEG monitoring. Ictal flushing showed neither lateralizing nor localizing value. Flushing was mostly facial and happened not only during simple partial (motor) seizures but also during complex partial (temporal lobe) seizures, which suggests that flushing is due to both skin hyperperfusion during motor activities but also due to central autonomic involvement.[42]

Pupillary manifestations

Pupillary manifestations are rare autonomic manifestations, with only a handful of case reports in the literature and hence have limited localizing and lateralizing value.

Ictal mydriasis

Bilateral mydriasis is a common concomitant of generalized convulsive seizures, both primary and secondarily generalized, most probably due to the diffuse spread of the epileptic discharges, thus activating widespread subcortical midline structures and the central sympathetic nervous system.[1,4] Unilateral mydriasis is far less common and has been reported to be ipsilateral in focal occipito-temporal seizures[131] and contralateral in a young boy with a ' benign left frontal epileptic focus'.[132]

Ictal miosis

Bilateral miosis has been described in a case of generalized photosensitive epilepsy along with bilateral adduction as part of a near reflex accommodation spasm.[133] Bilateral miosis has also been described with bilateral internal ophthalmoplegia in a patient with left temporo-occipital epilepsy[134] and without internal ophthalmoplegia in a 3-year-old girl with right-sided mesiotemporal ganglioglioma.[42] Unilateral miosis associated with ptosis has been reported in two patients with temporal lobe epilepsy, with one case presumed to be ipsilateral and the other contralateral to the unilateral miosis.[135] Left miosis associated with left homonymous hemianopia and visual hallucinations has also been reported in a patient with right occipital lobe epilepsy due to a small cavernous hemangioma.[136]

Urogenital manifestations

Urine incontinence is the most common urogenital manifestation and is a common feature of generalized tonic-clonic seizures and usually occurs after the clonic jerking stops. It is not due to increased intravesicular pressure during the seizure, but rather depends on relaxation of the vesical sphincter during the phase of muscular recovery and occurs only if the bladder is full at the time of the attack. However, urine incontinence does not have any localizing or lateralizing value.

Ictal urinary urge

The aura of urinary urgency during seizures has been shown to be a lateralizing sign for non-dominant temporal lobe in two studies with a total of 12 adults undergoing video-EEG monitoring.[137,138] A single case of ictal urinary urge associated with confusion, oral and genital automatism has been reported in a 6-year-old boy with a left temporal lobe seizure.[139]

Sexual/orgasmic aura

Sexual auras refer to seizures that include erotic thoughts and feelings, sexual arousal, and orgasm. They may be accompanied by genital viscerosensory phenomena, vulvovaginal secretory activity, and olfactory hallucinations. Sexual auras are reported more frequently by women and may be associated more commonly with right temporal lobe epilepsy.[140–142] Orgasmic auras, a subset of sexual auras, have been lateralized to the right hemisphere in the majority of the cases reported in the literature.[143] In a case series of seven patients experiencing an orgasmic aura, six had right temporal lobe epilepsy confirmed by EEG, MRI, and ictal SPECT and the remaining patient who was left hemisphere dominant as confirmed by WADA, had left temporal lobe epilepsy.[144] There are, however, also isolated reports of orgasmic auras with seizures from the left hemisphere, as determined by EEG.[145]

Genital aura

Genital auras are characterized by unpleasant, sometimes painful, frightening, or emotionally neutral somatosensory sensations in the genitals and can be accompanied by ictal orgasm. Genital auras are localized to the parasagittal postcentral gyrus, where genital sensations are represented.

When these sensations are bilateral, then the secondary somatosensory area is also thought to be involved.[145–147]

Sexual automatisms

Sexual automatisms, characterized by hypermotor movements consisting of writhing, thrusting, and rhythmic movements of the pelvis, arms, and legs, sometimes associated with picking and rhythmic manipulation of the groin or genitalia, exhibitionism, and masturbation, are localized to seizures from the frontal lobe. In addition, sexual automatisms were seen from different subcompartments of the frontal lobe, including the frontal convexity, the orbitofrontal region, and the supplementary sensorimotor area.[148–151]

Genital automatisms

Genital automatisms, characterized by discrete genital automatisms such as grabbing or fondling the genitals, which can be accompanied by masturbatory activity and exhibitionistic behavior, were generally associated with temporal lobe seizures, but could not be lateralized.[141,142,152–154] Several recent studies in both adults and children have not shown any localizing or lateralizing value to genital automatisms. However, genital automatisms did localize to the temporal lobe when associated with ictal urinary urge or unilateral hand automatisms in adults. In children, the hand used for genital automatisms was more frequently ipsilateral to the seizure onset zone.[155,156]

51 Simple motor seizures: localizing and lateralizing value

S Noachtar and S Arnold

Definition of simple motor seizures

Simple motor seizures are characterized by unnatural, relatively simple movements that can be reproduced by electrical stimulation of the primary and supplementary sensorimotor areas.[1] Simple motor seizures can be divided into the following subtypes depending on the duration of the muscle contraction, the rhythmicity of movement repetition, and the muscles involved: myoclonic seizures (negative myoclonic seizure), clonic seizures, tonic seizures, epileptic spasms, versive seizures, and tonic-clonic seizures.[1–3]

In contrast to simple motor seizures, during complex motor seizures the patients perform movements that imitate natural movements, are relatively complex, and tend to involve different body segments moving in different planes. These movements have also been labeled automatisms.

If a given seizure cannot be classified into the following categories based on the available information the term simple motor seizure is recommended.[1–3]

Myoclonic seizures

Myoclonic seizures consist of sudden muscle jerks of short duration (less than 400 ms), which do not recur in a rhythmical fashion. They can be either bilateral (generalized) or unilateral (Figure 51.1–51.2). Generalized myoclonic seizures, which predominantly affect the shoulders and proximal arms, are typical for patients with juvenile myoclonic epilepsy[4] and have already been recognized in the mid-19th century.[5] Generalized myoclonic seizures are also frequently seen in patients with Lennox-Gastaut syndrome[6] and the rare MERRF syndrome (myopathy, encephalopathy, ragged red fibers) (Figure 51.1) or Unverricht-Lundborg-syndrome. Electroencephalographically, generalized myoclonic seizures are frequently associated with generalized polyspikes that have a fronto-central maximum. Bilateral myoclonic seizures are rarely observed in patients with focal epilepsies (Figure 51.2). The primary motor cortex or premotor areas are most likely involved in the generation of this seizure type.

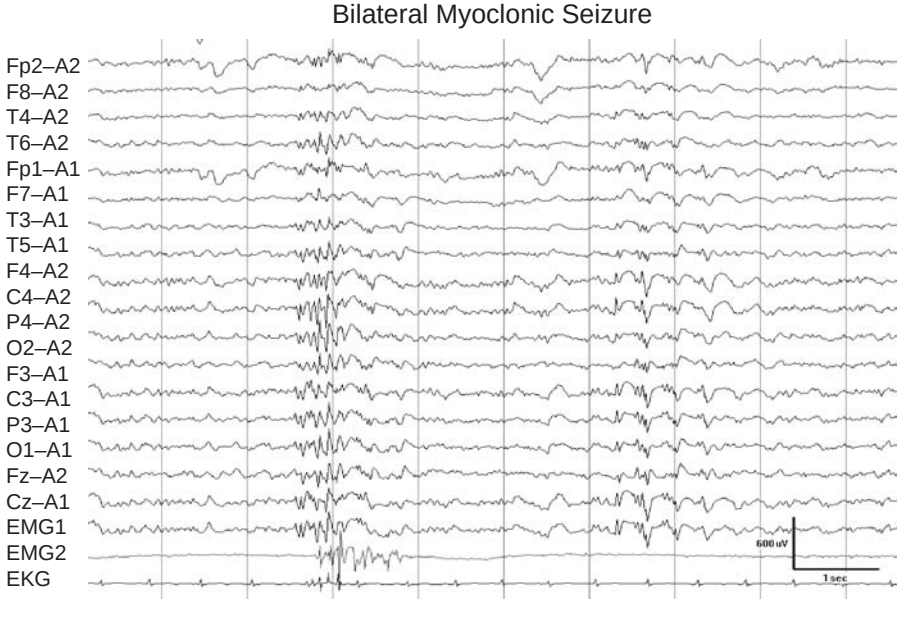

Figure 51.1. The generalized polyspikes in this 28-year old patient with MERFF syndrome are consistently associated with generalized myoclonic jerks of the trunk and proximal limbs, whereas single spikes, spike-wave complexes and less dense polyspikes were not. Longitudinal bipolar montage including EMG of both legs (EMG1=left anterior tibial muscle; EMG2= right anterior tibial muscle).

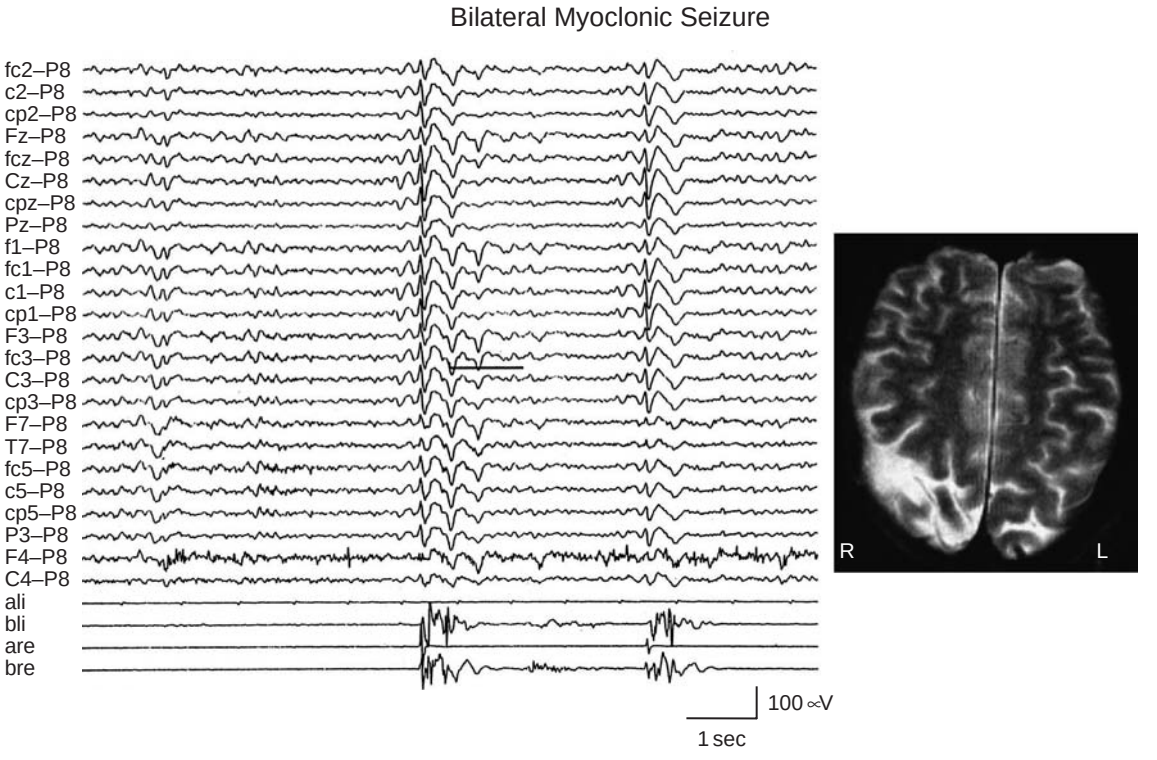

Figure 51.2. This 53-year-old patient has myoclonic seizures of both legs with a right zentral perinatal lesion. EEG is referenced to the electrode P8. ali= left brachioradial muscle EMG; bli=left anterior tibial muscle EMG; are=right brachioradial muscle EMG; bre=right anterior tibial muscle EMG.

Unilateral myoclonic seizures are very rare and occur contralateral or predominantly contralateral to the epileptogenic zone. Figure 51.2 shows the rare occasion that left central polyspikes in the EEG were consistently associated with myoclonic jerks of the both legs in a patient with a left central perinatal lesion. Some patients with juvenile myoclonic epilepsy report unilateral myoclonic jerks although video recording usually establishes the bilateral character of the myoclonic jerks. These patients typically favor the dominant arm.[7]

Negative myoclonic seizures

Negative myoclonus is a rare epileptic seizure type which is characterized by brief periods (20–400 ms) muscle atonia (Figure 51.3).[8] Negative myoclonus occurs only if muscle activity is exerted and the sujdden muscle atonia leads to the drop of the limb. Polygraphic recordings are helpful to document muscle atonia in the EMG associated with negative myoclonic seizures and epileptiform discharges in the EEG

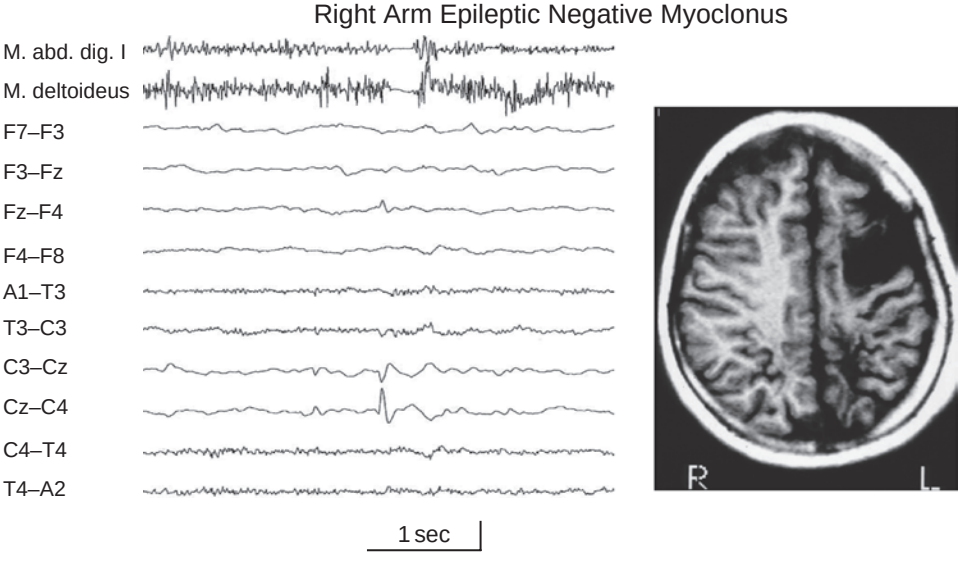

Figure 51.3. The transverse bipolar EEG montage shows that the left central sharp wave elicited a atonia of muscle activity in the right abductor digiti minimi and the right delta muscle, which documents an epileptic negative myoclonus. The MRI of this patient showed diffuse left hemisphere perinatal lesion and atrophy.

and distinguish negative myoclonus from myoclonic seizures, which may be difficult visually (Figure 51.3). Negative epileptic myoclonus has been described in patients with frontal and paracentral epilepsies.[9,10] Bilateral negative myoclonus also occurs in different encephalopathies.[8] In unilateral negative myoclonus, the epileptogenic region is contralateral to the affected limb. The central primary somatosensory cortex is considered responsible for the generation of negative myoclonus but there is very little data available.[11] The cortex in the postcentral gyrus has been shown to generate contralateral negative myoclonus.[10]

Clonic seizures

Clonic seizures consist of repeated, short contractions of various muscle groups (agonists and antagonists) usually characterized by jerking or twitching movements recurring at a regular interval between 0.2 and 5 per second (Figure 51.4). The jerks seen with myoclonic and clonic seizures are the same except that myoclonic seizures consist of single jerks which repeat in an irregular fashion whereas with clonic seizures the jerks have a regular rate. In other words, clonic seizures consist of 'myoclonic jerks' recurring at a regular repetition rate. The movements may affect any part of the body. Generally they are an expression of epileptic activation of the primary motor or the premotor areas.[12] Focal clonic seizures mostly affect the distal segments of the extremities, e.g., the hand or the face. Clonic activity may show a 'march' from the distal to the proximal parts of the extremities, reflecting the spreading activation of the primary motor cortex. Electrical stimulation of the supplementary sensorimotor area can elicit distal clonic movements, but only very rarely.[13] Typically clonic seizures start with a tonic phase, which frequently is not clinically detected unless polygraphic recordings reveal that the frequency of muscle contraction is higher in the beginning of the seizure and gets gradually slower, thus leading to recognizable clonic jerks.[14] Unilateral clonic seizures typically involve the face or hand area and less frequently the leg or trunk[15–17].

Clonic seizures were first systematically described in 1827 by Bravais[18] who distinguished facial, brachial, and crural onset clonic seizures and described the typical unilateral march of the convulsion which was later associated with Hughlings Jackson's name. In a large series of 8938 epileptic patients clonic seizures have been found to be rare occurring in only 2.2% of the patients.[19] However, clonic seizures were relatively frequent in those 127 patients who had somatosensory auras. One third (34.3%) of these patients had clonic seizures.[19] Of 52 patients reported by Hallen in 1952, clonic seizures started in the hand in 16, in the face in 14, in the foot in ten, in the shoulder in four, in the leg in four, in the head in two, in the thorax in one and in the neck in another patient.

The seizures types preceding and following clonic seizures are very variable. We analyzed all patients in whom clonic seizures were recorded at the Epilepsy Monitoring Units of the Bethel Epilepsy Center from 1991–1994 and the University of Munich Epilepsy Program from 1994–1995. We identified 127 patients with clonic seizures occurring in 162 different seizure evolutions from the data bases (Figure 51.5). Thus, some patients had more than one seizure evolution. Clonic seizures were the initial seizures in 33 patients. In the remaining 129 seizure sequences usually automotor (n=45) and tonic (n=45) seizures preceded the clonic seizures. The different seizure types preceding clonic seizures are listed in Figure 51.5. The clonic seizures evolved typically into generalized tonic-clonic seizures (n=58) and less frequently into other seizure types such as tonic or versive seizures (Figure 51.5). No following seizure types were observed in 42 patients.

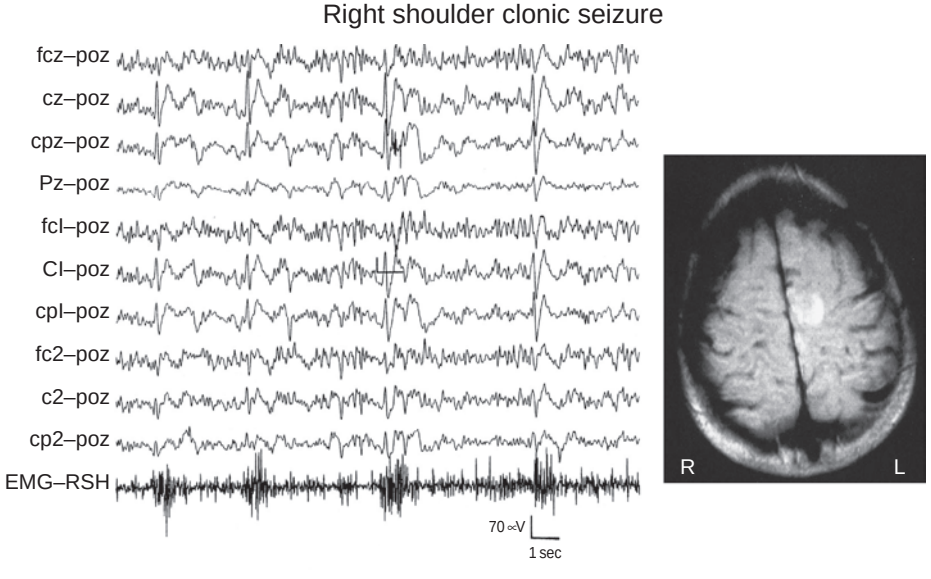

Figure 51.4. This 14-year-old boy had clonic seizures of the right shoulder secondary to a low-grade glioma, which were consistently associated with left central spikes in the surface EEG. Selection of ten EEG channels in a referential montage to the electrode POZ. EMG-RSH=EMG of the left delta muscle.

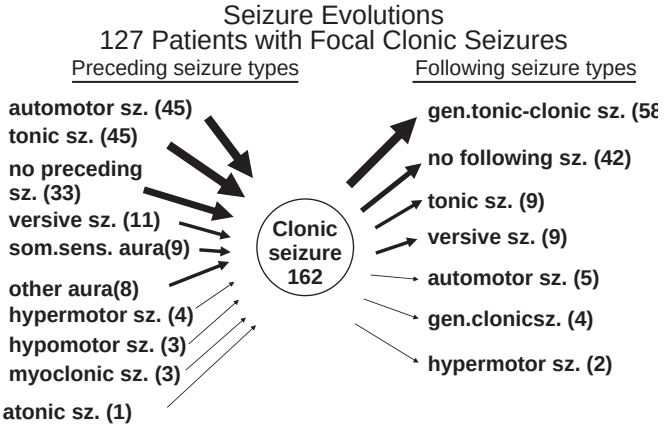

Figure 51.5. Seizure types preceding and following clonic seizures in 162 seizure evolutions of 127 patients who underwent EEG-video monitoring. Clonic seizures were the initial seizure manifestation in 33 seizure evolutions. The frequency of preceding and following seizure types are given in parenthesis. Clonic seizures were preceded by other seizure types in 129 seizure evolutions.

Clonic seizures may represent the initial seizure symptomatology but may be preceded by other seizure types such as auras, automotor or tonic seizures (Figure 51.5). Clonic seizures can evolve into other seizure types most commonly into generalized tonic clonic seizures (Figure 51.5–6). Unilateral clonic seizures are present in several focal epilepsies. In patients with frontal lobe epilepsy, clonic seizures tend to occur early in the seizure evolution and the patient is usually conscious at the time the clonic activity begins (Figure 51.6).[12,20] When clonic seizures are the result of spread of epileptiform activity into the frontal lobe from the occipital or temporal lobe, consciousness is usually altered at the onset of unilateral clonic seizures. Generalized clonic seizures only very rarely occur with preserved consciousness.[21]

Fincher and Dowman[22] reported on a series of 130 patients with 'Jacksonian' seizures. Eighty-four patients had 'purely motor' seizures. In 20 patients somatosensory auras were followed by motor seizures and in nine patients motor features immediately preceded sensory 'attacks'. In 17 instances there were sensory and motor 'attacks' occurring simultaneously. The authors mention two patients, in whom generalized jerkings were not associated with loss of consciousness. Consciousness is usually preserved if unilateral clonic activity is the initial seizure manifestation. If an automotor seizure precedes a clonic seizure, which we observed only in temporal lobe epilepsy and not in frontal lobe epilepsy consciousness will typically be disturbed during the clonic seizure.[23]

A series of 'pure' frontal lobe epilepsies of the Montreal Neurological Institute showed focal 'sensorimotor seizures' in 27% of the patients.[24] Automotor seizures were as common in this series (30%). Geier *et al.*[25] found 'clonic and/or tonic seizures' which were not further specified in 77.3% of 22 patients with frontal lobe epilepsies. Disturbance of consciousness (100%), deviation of head and eyes (86.4%), vocalisation (86.4%), and falling (81.8%) were more common in this study than clonic seizures. In a recent study of 252 patients with focal epilepsies 14 patients had clonic seizures.[20] In the 14 patients with clonic seizures a structural lesion could be demonstrated in the primary motor cortex in seven patients, in the premotor region in one patient and in the parietal cortex in another patient. Clonic seizures occurred both in temporal and frontal lobe epilepsies but the seizure evolution was different: if the clonic seizures occurred early in the seizure evolution there was a significant association with frontal lobe epilepsy.[20]

In a series of 40 patients with frontal lobe epilepsies who underwent selective epilepsy surgery of the parasagittal convexity of the frontal lobes (PSC) or anterolaterodorsal convexity (ALDC) and remained seizure free, seizure onset in the PSC (eight of ten patients) was more frequently associated

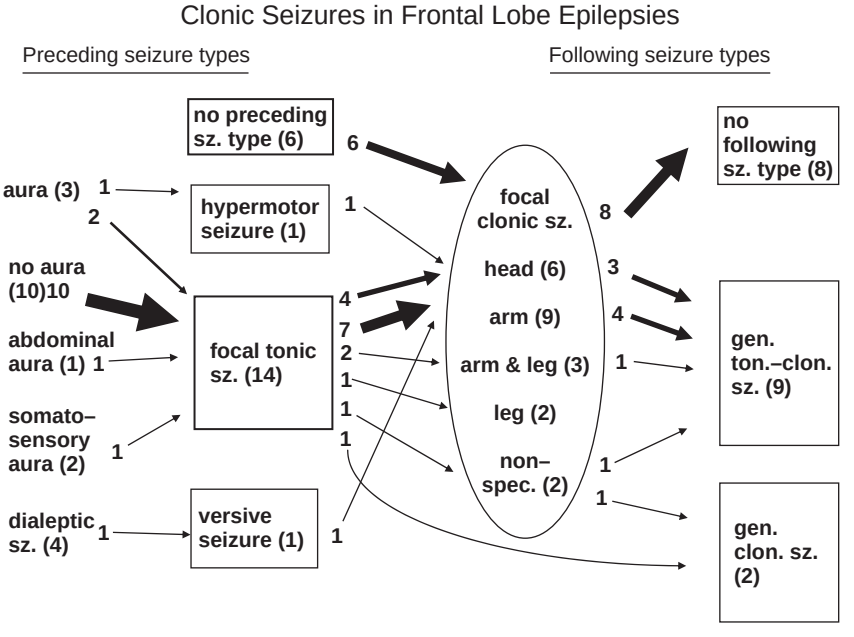

Figure 51.6. Seizure types preceding and following clonic seizures as documented by EEG-video monitoring in 19 patients with frontal lobe epilepsies. Clonic seizures were the initial seizure manifestation in seven seizure evolutions. Focal clonic seizures evolved further either into generalized tonic-clonic or generalized clonic seizures.

with focal motor seizures than seizure onset in the ALDC (15 of 30 patients).[26] In a later report of the same group 29% to 60% of the patients with 'dorsolateral frontal lobe epilepsies' had clonic seizures.[27] The authors concluded that clonic seizures occur in patients with epilepsy of different frontal compartments and are not a reliable indicator of seizure onset location.[27] A neuroimaging study using FDG-PET in patients with probable frontal lobe epilepsy reported clonic seizures in nine of 22 patients. In six patients clonic activity was the initial seizure symptom. Precentral seizure onset was assumed in three, premotor onset also in three, and mesial onset in another three patients.[28] A study of ten patients with medial frontal or orbitofrontal seizure onset did not describe clonic seizures.[29] These patients had seizures characterized by complex motor automatisms with kicking and trashing movements and a bizarre appearance frequently leading to erroneous diagnosis of non-epileptic psychogenic seizures.

Data about seizure evolution of focal clonic seizures is sparse. Thirty percent of 24 patients with frontal lobe epilepsy have been described to have clonic seizures.[30] In three of these patients the clonic seizures were preceded by conscious contralateral version. The clonic seizures were followed by tonic seizures consisting of tonic posturing of all extremities in three patients. Harvey *et al.*[31] reported clinical seizures characteristics in 22 children with frontal lobe epilepsies who underwent ictal SPECT studies. Ten children had clonic seizures. Seizure evolution commenced most frequently with behavioral arrest (n=13) or auras (n=6) which evolved into tonic seizures (n=11), hypermotor (n=6), or automotor seizures (n=2). The clonic seizures were preceded by tonic seizures in seven patients, by an aura in one patient, by behavioral arrest in one patient, and by an automotor seizure in another patient. Only one patient had clonic seizures as the inital seizure manifestation. In one child the clonic seizures further evolved into generalized tonic-clonic seizures.

We identified 19 patients of the above mentioned series of 129 patients with clonic seizures who had a frontal lobe epilepsy. The seizure evolutions in these cases are shown in Figure 51.6. Only in six patients the seizures started with clonic activity. More commonly, the clonic seizures were preceded by one or two other seizure types such as auras and tonic seizures.

In conclusion, the occurrence and frequency of clonic seizures in frontal lobe epilepsy varies considerably between studies. It seems that the occurrence of clonic seizures depends on different locations of seizure onset in the frontal lobe and individually different seizure spread patterns. In our series, tonic seizures typically preceded clonic seizures and only a minority of the patients had clonic seizures as the initial seizure type.

In temporal lobe epilepsy, complex motor activity like oral automatisms was seen most frequently (10%) whereas simple motor activity like facial and brachial twitching without Jacksonian march occurred 'less commonly' (4%).[32] Another study only mentions automatisms as the ictal symptomatology of seizures in patients with temporal lobe epilepsies.[33]

In a cluster analysis of 59 patients of 'primary psychomotor epilepsy' unilateral and bilateral tonic, clonic, and versive activity was described.[34] Most commonly the face area was involved unilaterally (about 30–50% of the seizures), followed by the hand (20%) and the leg (7%). In this report tonic, clonic, and versive seizures were all lumped together.[34]

A recent study of seizures in 31 patients with temporal lobe epilepsy who underwent epilepsy surgery and were seizure free reported unilateral clonic activity in the face in eight and in the arm in three patients.[35] Bilateral clonic activity of the arms was observed in 14 patients and of the legs in one patient.[35] These findings are in agreement with the study of Abou-Khalil *et al.*[36] who observed focal clonic activity in eight of their 32 patients with unilateral temporal lobe epilepsies documented by EEG-video recordings. In three of these patients the clonic activity was concomitant with head turning to one side. However, the study did not distinguish between head turning that looks like a normal movement and the forceful 'version' frequently associated with unilateral clonic movements which is almost pathognomonic of regional contralateral epilepsy.[37] The study of Manford *et al.*[20] reported on clonic movements in 17 of 58 'temporal seizures' in 42 patients with temporal lobe lesions. Clonic movements were observed more frequently in patients with frontal lobe lesions (35 of 61 seizures of 49 patients). However, clonic movements are only suggestive of frontal lobe epilepsy when they occur early in the evolution of a seizure.[20]

We evaluated the seizure sequences in our series of 24 patients with temporal lobe epilepsies who demonstrated clonic seizures during EEG-video recordings (Figure 51.7). All 24 patients had automotor seizure preceding the clonic seizures and in no case did the clonic seizures involve primarily the leg. In three patients, automotor seizures first evolved into versive seizures and then eventually into clonic seizures. All patients had generalized tonic-clonic seizures following the clonic seizures. We recently found statistically significant differences in the seizure evolutions of mesial and neocortical temporal lobe epilepsy.[38] Abdominal auras and contralateral dystonic posturing were more frequent in patients with mesial temporal lobe epilepsy whereas early clonic seizures occurred more frequently in patients with neocortical temporal lobe epilepsy. This might reflect different cortical spread of seizure activity.[38]

In conclusion, clonic seizures are usually preceded by automotor and followed by generalized tonic-clonic seizures in temporal lobe epilepsy. Thus, the seizure sequences of clonic seizures in temporal lobe epilepsy is clearly different from the seizure sequences in frontal lobe epilepsy (Figure 51.6–7).

It is well known that tumors in the paracentral (perirolandic) region are frequently associated with epilepsy.[39] Most studies about focal epilepsy syndromes distinguish frontal and parietal lobe epilepsies. However, in a considerable number of patients the seizure anatomically involves both, the frontal and the parietal lobe. The observation that seizures arising from the frontal and parietal lobes outside the perirolandic region behave differently both, clinically and pathophysiologically to seizures arising from the perirolandic (paracentral) region has been recognized for decades and is reflected in the studies of the Montreal school.[30, 40]

About one third (34.3%) of 127 patients who had somatosensory auras had also had clonic seizures.[19] Fifty percent of the lesions of these patients were located in the contralateral central region.[19] In a series of 28 patients in whom extratemporal seizure onset had been documented by means of invasive EEG recordings, nine patients had clonic seizures and two of them had epilepsia partialis continua.[41] The seizure onset

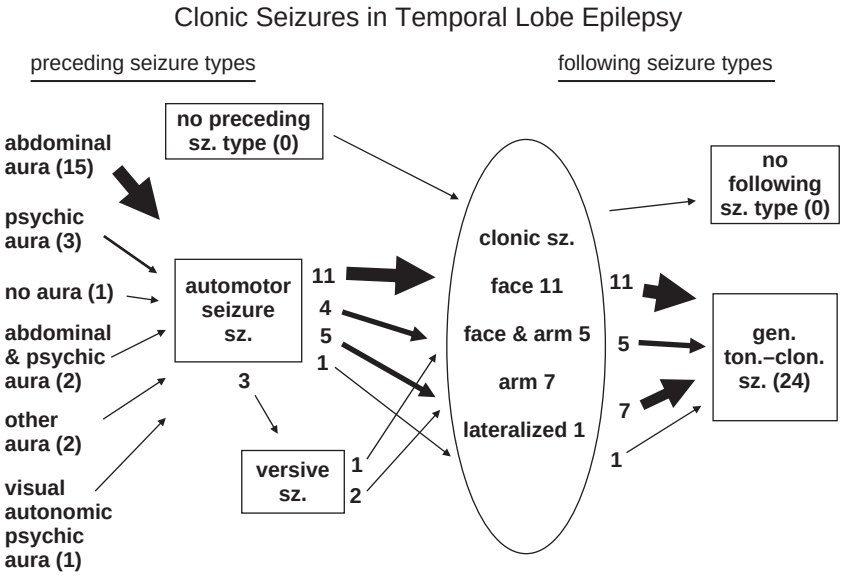

Figure 51.7. Seizure types preceding and following clonic seizures as documented by EEG-video monitoring in 24 patients with temporal lobe epilepsies. All clonic seizures of this series were preceded by other seizure types. Most commonly clonic seizures involved the face and were preceded by automotor seizures. All patients showed an evolution to generalized tonic-clonic seizures.

was perirolandic in six of these nine cases and six patients had auras preceding the clonic seizures. Of 34 patients with parietal lobe tumors who underwent surgical resection at the Montreal Neurological Institute between 1934 and 1988, 82% had focal clonic activity in the course of their seizures.[42] In a greater series of 82 patients with parietal lobe epilepsy of the same institution 57% had clonic seizures.[40] However, as mentioned above, in the MNI series parietal lobe epilepsy usually refers to the parietal lobe posterior to the postcentral sulcus and does not include the postcentral gyrus.[40] In another series, clonic seizures occurred in three of ten patients with lesions in the parietal lobe (including the postcentral gyrus).[43] One patient had 'focal motor seizures' which were preceded by a somatosensory aura of the right hand. In two patients somatosensory auras preceded the clonic seizures, in one patient clonic seizures were the initial seizure manifestation. In another study of 11 patients with parietal lesions most probably also involving the postcentral gyrus, clonic seizures were reported in 4 patients.[44] Somatosensory auras were present in 7 patients of this series.

In a recent report of 11 patients with seizures involving the supplementary sensorimotor area, all patients showed clonic movements present in one or more extremities following tonic posturing which usually lasted 10–30 seconds.[45] The clonic movements and the tonic posturing are usually bilateral, but unilateral clonic activity is an excellent lateralizing sign.[26,46] Seizures involving the supplementary sensorimotor area are typically either tonic or less frequently hypermotor seizures,[23] e.g., consisting of bizarre and violent movements predominantly of the trunk and the proximal extremities.[45,47–49]

Tonic and clonic seizures have been described in patients with occipital lobe epilepsy.[50,51] The initial seizure symptomatology most frequently includes visual auras and other signs such as eye blinking or eye deviation. Spread to the frontal lobes is usually associated with tonic and/or clonic activity. This has been reported in three of 25 patients as the only spread pattern. In another 11 patients of this series, a combination of 'frontal' and 'temporal lobe type' seizure was observed.[51] However, no data were available in this study regarding the exact seizure semiology and frequency of tonic or clonic seizures.[51] In another study of eight patients in whom occipitotemporal seizure onset was documented by invasive EEG studies, no patient had clonic seizures of the extremities.[52] One patient had jerking eye movements to the right. In the series of 42 patients with occipital lobe epilepsies of the MNI treated between 1930 and 1991, 13 patients had unilateral clonic seizures of the arm or face.[50] In ten patients versive head and/or eye deviation preceded the clonic seizures.[50] The detailed evolution of the clonic seizures is not mentioned.

Since the early reports it has been recognized that children with benign focal epilepsy of childhood frequently have clonic seizures.[53] Characteristic seizures consist of tonic, tonic-clonic, or clonic seizures involving the face area. Usually this is preceded by an unilateral somatosensory aura of the face.[54] Spreading of the clonic activity to the ipsilateral hand or arm ('Jacksonian march') occurs only infrequently. Usually the seizures occur during sleep and evolve into generalized tonic-clonic seizures. In these cases a focal seizure onset may be overlooked.

Rasmussen's encephalitis almost invariably is associated with clonic status which usually is restricted to the arm and less frequently to the face and leg of one side.[55] Clonic status usually occurs with the progression of this syndrome which typically includes hemiparesis of the affected limbs (Figure 51.8).

Generalized clonic seizures are frequently seen following generalized tonic seizures in grand mal epilepsy. This type of seizures (generalized tonic-clonic seizures) will be discussed in detail in another chapter. Isolated generalized clonic seizures are rare in adults but may, for instance, occur in patients with progressive myoclonic epilepsies.[7] These patients typically have generalized myoclonic seizures which are not as repetitive and rhythmic as clonic seizures. In newborns, generalized clonic seizures are more frequently observed but may still have a focal seizure onset in the EEG.[56] We identified two patients who had generalized clonic seizures in our series of frontal

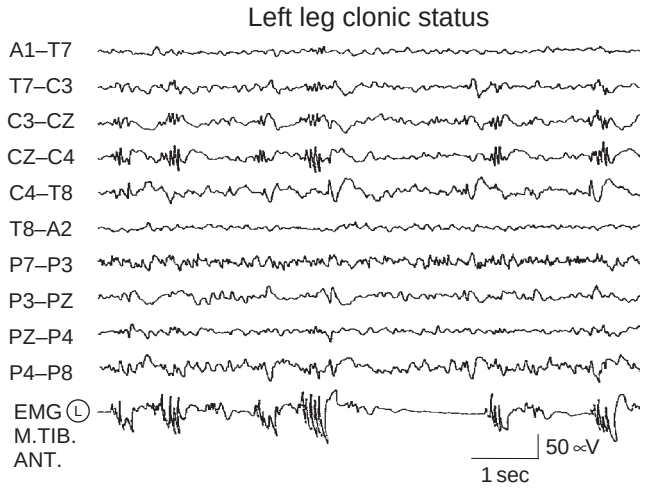

Figure 51.8. Sixty-nine-year old man with continual jerking of the left foot and leg for several weeks, without loss of consciousness. Electromyography from the left anterior tibial muscle showed that jerks occurred synchronously with each burst of polyspikes on EEG. Polyspikes were maximum at left vertex electrodes, presumably as a result of paradoxical lateralization of the discharge from the right interhemispheric region.

lobe epilepsies. Both patients had focal tonic seizures preceding the generalized clonic seizures.

Jackson's clinico-pathological observations showed that motor seizures are associated with lesions of the motor cortex.[57] Electrical stimulation of the primary motor area (Brodmann's area 4) or the premotor areas (area 6) can elicit clonic movements.[58–60] It is therefore reasonable to conclude that clonic seizures are an expression of epileptic activation of the motor cortex. Electrical stimulation of the supplementary sensorimotor area can elicit clonic movements, but this occurs only very rarely and typically not at seizure onset but later in the seizure evolution.[13,62]

The fact that the hand and face area are most commonly involved in clonic seizures is usually attributed to the large cortical representation of these parts of the body. In contrast, the rare occurrence of clonic seizures limited to the trunk reflects its small cortical representation.[17] Spread of clonic seizures may reflect the cortical representation of the body in the motor cortex. It has been speculated that the variability of the observed spread patterns may reflect interindividual variability of the cortical representation.[15] It is important to remember also that clonic seizures can only be elicited when the epileptic discharge is strong enough to produce suprathreshold activation of a given region of motor cortex. Experimental studies have shown that different regions of the motor cortex have also different thresholds to electrical stimulation.[63]

It is important to point out that high-frequency electrical stimulation (50–60 Hz) of the primary motor area in wake humans ictally causes tonic contractions, which evolve into clonic twitching of the affected muscles at a frequency of ca. 1–2 Hz.[14] The epileptic clonus consists of simultaneous contractions of agonistic and antagonistic muscles at regular intervals and is separated by periods of complete muscle relaxation. Epileptic clonic muscle contractions are generated by localized polyspike-wave activity in cortical primary motor areas. The periods of muscle relaxation occur during the EEG slow waves. The study of Hamer *et al.*[14] suggests that focal clonic seizures are focal tonic-clonic seizures. It is known that single or short series of electrical stimuli only elicit muscle responses if relatively high intensities are used.[60,64] Temporal and spatial summation of the stimuli were needed for clonus generation.[65] This principle is illustrated in the patient with the left calf clonic status shown in Figure 51.8. This explains why single spikes or slow, repetitive spikes frequently do not elicit muscle twitching, whereas polyspikes or runs of paroxysmal fast activity are usually associated with muscle responses. Most probably temporal facilitation elicited by repetitive stimulation is necessary to exceed the threshold of the motor cortex. Jerking of the left calf was always accompanied by polyspikes in the EEG (Figure 51.8), whose potential field extended from the vertex to the left central region. Conversely, individual spikes that did not correlate with jerking of the foot had a slightly different potential field extending to the right centroparietal area. The polyspikes in this case have a maximum ipsilateral to the affected leg. This is an example of paradoxical lateralization.[66–68]

The EEG of generalized clonic seizures shows generalized epileptiform discharges. There is typically a 1:1 relationship between muscle twitch and epileptic discharge, and the background activity between the discharges is generally suppressed. Generalized fast activity usually leads to tonic 'posturing seizures' and only exceptionally to clonic movements. Generalized clonic seizures are assumed to be the result of intermittent generalized epileptic activation of the motor region of the cortex (Brodman areas 4 and 6). We have also observed cases in which epileptic seizures originating in the supplementary sensorimotor area led to bilateral clonic movements of the upper extremities without any clouding of consciousness. In these cases no generalized spike-and-wave discharges occurred. It is quite probable that the generalized clonic seizures in these cases are caused by restricted activation of one or both of the supplementary sensorimotor areas.

Tonic seizures

Tonic seizures consist of a sustained contraction of one or more muscle groups usually lasting at least 3 sec leading to posturing of the limbs or whole body.[3,23,69] Tonic seizures in patients with focal epilepsy preferentially affect proximal muscle groups on both sides of the body. However, they predominate most often in the contralateral body, leading to an asymmetric posture.[70] In most patients with focal epilepsy, consciousness is unclouded, at least at the onset of such unilateral or asymmetric seizures.[25,71,72] If clearly unilateral, tonic seizures have a high lateralizing significance, pointing to a contralateral seizure onset. Ictal EEG in frontal epilepsies shows a low-amplitude high-frequency pattern ('recruitment pattern') (Figure 51.9). Consciousness is disturbed from the beginning of generalized tonic seizures, which are common in patients with Lennox-Gastaut syndrome.[6] Generalized tonic seizures usually last from 3–10 sec. The ictal EEG of generalized tonic seizures in patients with Lennox-Gastaut syndrome is similar to the ictal EEG in frontal lobe epilepsies showing a diffuse low-amplitude high-frequency recruiment pattern (Figure 51.9). Tonic seizures in focal epilepsies are more commonly bilateral (76%) than unilateral (24%).[73] The majority of bilateral tonic seizures involve the whole body (both arms

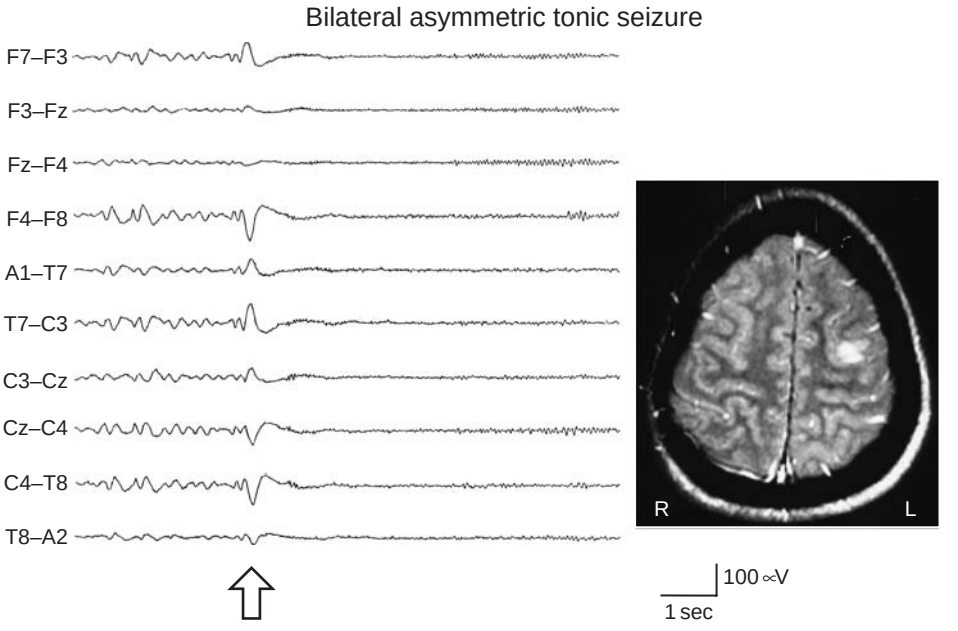

Figure 51.9. This transverse bipolar EEG montage of a 17-year old female with a low grade glioma in the medium frontal gyrus shows a typical EEG seizure pattern during a bilateral asymmetrical tonic seizure. After a high amplitude midline sharp wave the EEG shows low amplitude high frequency activity with a midline frontocentral maximum (recruitment pattern). The arrow marks the clinical seizure onset.

and legs and trunk).[73] Unilateral tonic seizures affected most commonly one arm (56%) or one side of the body (20%).[73]

Tonic seizures occur most commonly in frontal lobe epilepsy (62.2%) and very rarely in temporal lobe epilepsy (1.7%). In the latter only unilateral tonic seizures occurred, whereas 32% of the tonic seizures in frontal lobe epilepsies were bilateral.[73]

Focal tonic seizures most probably originate in the cortical motor areas, i.e., the primary motor and the supplementary sensorimotor areas. However, the reticular formation of the brain stem and the thalamus were reported to be involved in the generation of tonic seizures in patients with Lennox-Gastaut syndrome.[74]

Phonatory seizures could be considered tonic seizures of the phonatory muscle system. They result from activation by the ictal discharge of the primary motor cortex or the SMA.[75] Phonatory movements have been elicited on stimulation of the SMA or the primary motor cortex below the tongue or lip area. Vocalization in SMA seizures is more often sustained than interrupted, whereas seizures involving the primary motor area tend to produce interrupted sounds.

Paroxysmal dystonia resulting from subcortical pathology such as brainstem dysfunction or multiple sclerosis has to be considered in the differentialdiagnosis of focal tonic seizures.

Epileptic spasms

Epileptic spasms typically occur between 3–12 months of age. They are a frequent seizure type in children with West syndrome and in this context have also been called 'infantile spasms'.[76] Epileptic spasms consist of relatively symmetric tonic and myoclonic features, which may vary in the same patient from one seizure to another. The muscle contractions predominantly affect the proximal and axial muscles and typically lead to flexion of the neck (and legs) and abduction of both arms. Less frequently myoclonic or tonic extension may lead to an opisthotonic posture. Epileptic spasms usually last 2–10 seconds and frequently occur in clusters. Short myoclonic contractions may mix with tonic contractions in one cluster. The ictal EEG of patients with West syndrome during epileptic spasms typically shows an attenuation of the background activity and depending on the resolution of the EEG system a low-amplitude high-frequency pattern (Figure 51.10).

This seizure type is age specific and also occurs in focal epilepsies with different epileptogenic zones. Well established examples have been published like for instance an 11-month-old with epileptic spasms secondary to a right temporal hamartoma which was seizure free postoperatively.[23] Consequently,

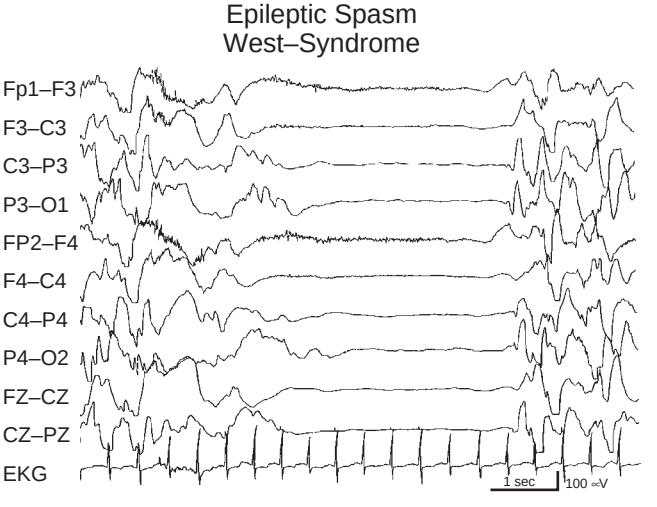

Figure 51.10. The epileptic spasm of this 8-month-old child with West syndrome is electroencephalographically associated with a diffuse attenuation of the hypsarrhythmia during the seizure.

epileptic spasms do not allow localization. Children with epileptic spasms typically develop other seizure types after the age of 3–5 years[77] as in the above-mentioned case, in whom at the age of 2 1/2 years mild automatisms occurred.[23]

Versive seizures

Versive seizures consist of a sustained, unnatural turning of the eyes and head to one side.[37] The version usually consists of a smooth, tonic lateral deviation of the eyes with, not infrequently, a clonic superimposed component. Often the angle of the mouth is also deviated to the same side and the neck is extended. These seizures are the expression of epileptic activation of the frontal eye field (inferior/medial frontal gyrus) that is contralateral to the side to which the eyes turn.[60,78] Epileptic activation from the temporal lobe or other structures distant from the frontal eye fields may spread into the frontal eye field, giving rise to versive seizures.[37] In temporal lobe epilepsy, version occurs when the patient has already lost consciousness and the version is frequently preceded by oral and maunal automatisms (automotor seizure). A study of patients with extratemporal and temporal epilepsies showed that version occurred earlier than 18 seconds in seizures with an extratemporal onset and later than 18 seconds in the vast majority of temporal lobe epilepsies,[79] which reflects faster spread to the frontal eye fields from extratemporal particularly frontal lobe regions than from the temporal lobes. Patients may be unconscious (n=16) or conscious (n=7) depending from which region of the cortex the seizures originated in 222 patients considered for epilepsy surgery at the Montreal Neurological Institute.[80]

The early 1980s witnessed a controversy surrounding the lateralizing value of versive seizures in temporal epilepsy.[81,82] Then Wyllie *et al.* defined version as a forced, sustained, and unnatural movement. On the basis of this definition, versive seizures have a high lateralizing significance to seizure onset in the contralateral hemisphere, particularly when they occur immediately before a generalized tonic-clonic seizure.[46] The mechanisms involved in the contralateral head version is not well understood considering that for a version of the head to the contralateral side the ipsilateral sternocleidomastoid muscle needs to be activated.[83] Quantitative movement analysis was able to demonstrate that in temporal lobe epilepsy there is a initial ipsilateral head turning followed by a contralateral head version which last longer and occurs prior to secondary generalization.[78]

Tonic-clonic seizures

Tonic-clonic seizures are characterized by a typical sequence of a generalized tonic contraction followed by clonic contractions. Grand mal (= 'the great evil') is a synonym for generalized

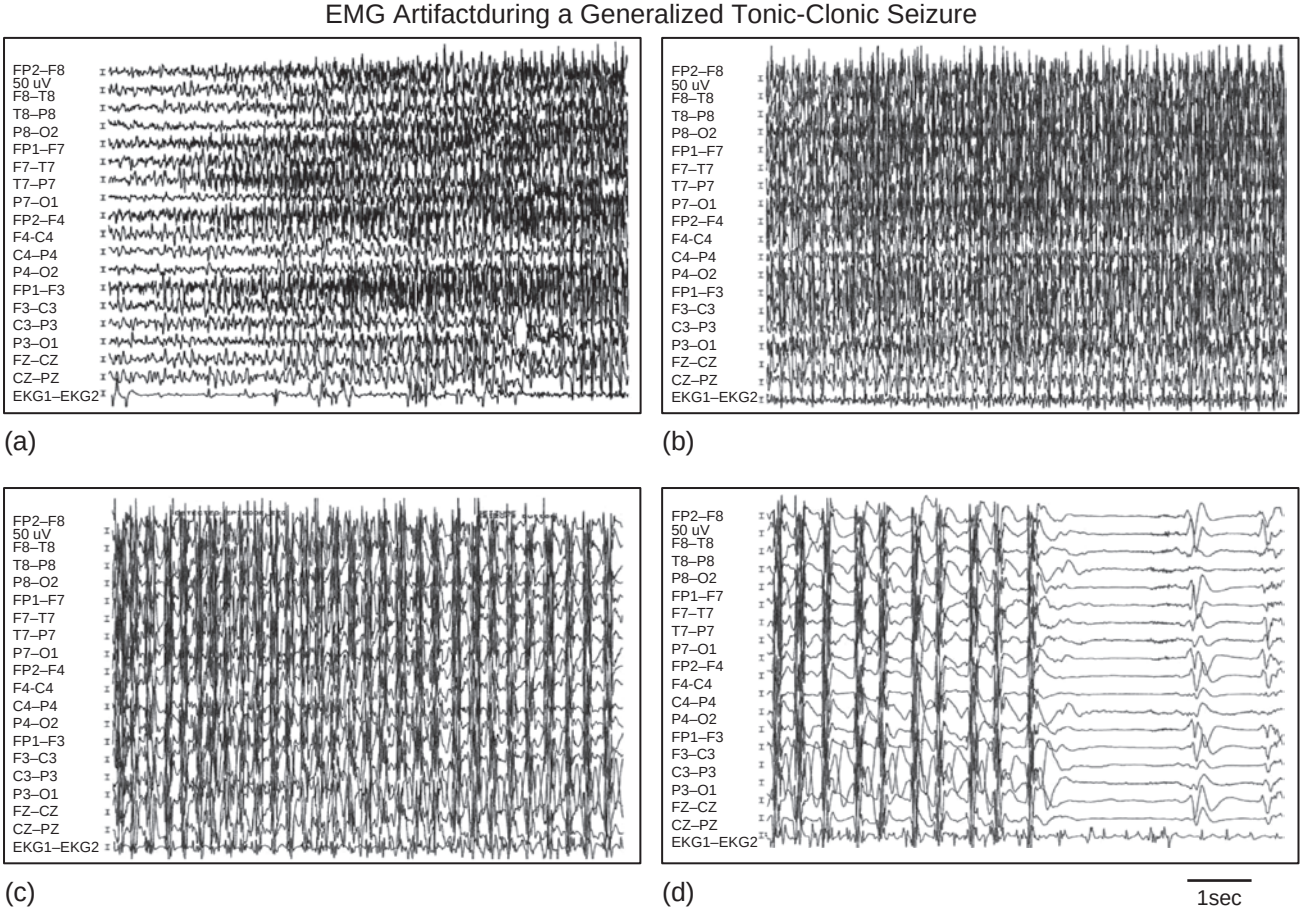

Figure 51.11. Typical EMG artifact illustrating the course of a generalized tonic-clonic seizure. Initially the tonic activity increases in amplitude (a–b) followed by gradually increasing clonic activity with periods of reduced EMG artifact (c–d). The duration of the pauses inbetween the clonic activity increases towards the end of the clonic activity. This EMG artifact is very typical for generalized tonic-clonic seizures and may even help to distinguish them from non-epileptic pseudoseizures.

Figure 51.12. The increased intrathoracal pressure during the tonic phase may lead to subcutan petechial bleeding, which can be seen in the periorbital region of this 16-year-old male. He had his first generalized tonic-clonic seizure the day before. This phenomenon is typical for generalized tonic-clonic seizures.

tonic-clonic seizure, which is the only seizure type in grand mal epilepsies (Epilepsy with grand mal [generalized tonic-clonic] seizures on awakening) (Commission on Classification and Terminology of the International League Against Epilepsy.[84] The seizures have a typical evolution, initially occurring with tonic posturing, adduction with extension of all four extremities, and flexion of the wrist and fingers. This phase lasts for approximately 5 (to 12) seconds and then evolves into a 'tremor-like' twitching.[85] The ictal EEG shows a typical EMG artifact (Figure 51.11). The repetition rate of the twitches gradually becomes slower and the amplitude increases, giving rise to the clonic phase (Figure 51.12). The clonic phase consists predominantly of flexion myoclonic jerks of the elbow, hip, and knee. The duration of the tonic-clonic seizures varies between 1–2 minutes.[85]

Consciousness is always disturbed with the beginning of the tonic phase. Generalized tonic-clonic seizures are followed by a prolonged postictal coma and confusion. During the tonic phase increased intrathoracal pressure may lead to petechial subcutan bleeding in the periorbital region (Figure 51.12).

Generalized tonic-clonic seizures may occur in generalized and focal epilepsy syndromes. Occasionally other generalized seizure types may evolve into generalized tonic-clonic seizures (i.e., generalized myoclonic seizure → generalized tonic-clonic seizure or dialeptic seizure → generalized tonic-clonic seizure). The evolution of generalized myoclonic seizures into generalized tonic-clonic seizures is typical for juvenile myoclonic epilepsy. In focal epilepsies, generalized tonic-clonic seizures usually constitute the end of a seizure evolution. The focal seizure types preceding a generalized tonic-clonic seizure depend on the cortical region, which gives rise to the seizure.

Secondarily generalized tonic-clonic seizures may infrequently evolve into a short (2–10 sec) focal motor seizure that may be generated by persisting epileptiform discharges in the hemisphere of origin or may involve the contralateral hemsiphere (paradoxical version).[86,87] The clonic phase of generalized tonic-clonic seizures may end asymmetrically, showing clonic jerks persisting in the limbs ipislateral to the hemisphere of seizure onset.[85] It is speculated that this seizure evolution reflects earlier seizure cessation in the hemisphere of seizure onset, whereas the contralateral hemisphere still continues to seize. Patients with juvenile myoclonic epilepsy may have generalized myoclonic seizure preceding the generalized tonic-clonic seizures, particularly after sleep deprivation. Clinical experience shows that there are some patients with clonic-tonic-clonic seizures but there are only anecdotal reports on this observation.[7]

The pathophysiological considerations on the origin of generalized tonic-clonic seizures are the same as discussed above for generalized tonic and generalized clonic seizures.

52 Complex motor seizures: localizing and lateralizing value

MM Bianchin and AC Sakamoto

Introduction

Clinical signs and symptoms expressed during epileptic seizures are thought to be generated by widespread neuronal matrices, linked together by anatomic connections, and further strengthened through repeated use.[1–4] Although presenting great interindividual variability such neural networks share similarities among different patients, permitting the expression of stereotyped ictal behaviors that might indicate the underlying neural substrates. When motor networks are activated during seizures, patients may exhibit motor behaviors that can be classified as simple motor seizures (reproducible by direct stimulation of the primary motor cortex) or complex motor seizures.[5,6] Classifying seizures according to semiological ictal findings, and particularly according to motor behavior is especially useful during presurgical video-EEG evaluations. This semiological-oriented classification was first proposed by Lüders and colleagues as an alternative classification to that of ILAE.[5,6] Semiologic Seizure Classification (SSC) might provide a more comprehensive picture of epileptic seizures, notably in patients with focal epilepsy, being very useful for both, everyday clinical practice and more specialized evaluations in epilepsy centers.[7–9] The relevance of this semiological-based approach is well demonstrated by Chee and colleagues[10] who reported that the epileptogenic region can be correctly lateralized by semiological analysis in 78% of patients, with positive predictive value of 94%, and very good interobserver reliability. When combined with video-EEG analysis, semiological findings might allow lateralization and/or localization of epileptogenic and symptomatogenic zone in most patients.[11–13]

According to the SSC complex motor seizures encompass three main seizure types: (1) automotor seizures; (2) hipermotor seizures; and (3) gelastic seizures. Automotor and hypermotor seizures are more frequently associated to temporal or frontal lobe epilepsies, respectively,[5] while gelastic seizures are usually related to hypothalamic hamartoma.[5,14] Complex motor behaviors may also be observed in the late course of posterior cortex seizures, once these might propagate to more anterior regions.[15–18]

The reader must observe four important points regarding this classification. First, the complex motor behaviors observed during seizures are usually similar to complex movements executed during common life diary activities (e.g., coughing, swallowing, lip smacking, clapping hands, among many others), or alternatively, can resemble motor behaviors observed in movement disorders (e.g., limb dystonic posturing), suggesting they share common functional anatomic substrates.[5] Second, the ictal motor behavior can be qualified as ipsi- or contralateral, according to the lateralization of the epileptogenic zone. Third, distinct from ILAE's classification,[19] in the SSC the term 'complex' refers to the complexity of the movement, and not to the patients' state of consciousness.[5] Forth, classifying seizures according to ictal motor behavior is a purely semiological concept, and therefore, based exclusively on clinical manifestations observed during seizures.[5] When these ictal signs and symptoms are sequentially considered, they may additionally indicate specific propagation patterns and reflect the anatomical sites involved during seizure propagation, the sequences of these involvements, and some mechanisms of ictal spreading. The assessment of symptomatogenic motor regions and networks through ictal semiology is of paramount importance for the process of epileptogenic and symptomatogenic zone localization. In addition, ictal semiology might also hold postsurgical prognostic significance.

In this chapter we will address the complex motor seizures, mainly emphasizing motor components and localizing and/or lateralizing features. Periictal complex motor phenomena, when common, stereotyped, and consistently associated with complex motor seizures will also be described, since they might also carry valuable localizing and lateralizing information. In addition, we will briefly review the existing evidences on the mechanisms and anatomic areas possibly involved in the production of complex motor seizures and associated common behaviors. Table 52.1 summarizes existing data on complex motor seizures. Preliminarily, however, a brief consideration about auras will be presented, once auras antecede complex motor behaviors in most patients.

Auras

Auras are reported by most patients with automotor or hypermotor seizures. Automotor seizures are more frequently associated to temporal lobe epilepsy, and by far epigastric aura with raising sensation is the most common type of aura anteceding these seizures. Epigastric aura might also occur in association with frontal lobe epilepsy, although much less frequently.[20–26] Also common in automotor seizures are auras of fear, anxiety, or other related symptoms.[20,24–26] Other types of auras common to automotor seizures but less frequently

Table 52.1 Selected motor behaviors observed in association with complex motor seizures

Motor characteristics findings	Frequency	Lateralizing value	Epileptogenic zone	Simptomatogenic zone	Observation
Limb automatisms	Most patients.	Usually ipsilateral in MTLE, contralateral in NTLE, and nonlateralizing in frontal lobe seizures.	Highly suggestive of MTLE when associated with contralateral dystonic posturing.	Variable. Frontal or temporal activation. May correspond to releasing phenomena.	When automotor and associated with preserved responsiveness suggest nondominant temporal lobe (6% of TLE).
Oral automatism	Very common.	Nonlateralizing.	Suggests temporal lobe. May be observed in seizures originating in frontal lobe.	Limbic system.	Positive ictal activation or releasing phenomena.
Genital and sexual automatisms	10% of patients with FLE or TLE.	Poor. Lateralizatory value on depending other signs.	Frontal or temporal.	Unknown.	In hypermotor seizures, suggest frontal lobe. In automotor seizures, suggest temporal lobe.
Unilateral dystonic limb posturing	15–70% of patients with TLE or FLE.	Contralateral in more than 90% of patients.	Temporal or frontal.	Temporal, frontal, parietal and basal ganglia (Putamen).	When associated with unilateral automatisms suggests mesial temporal epilepsy.
Unilateral tonic posturing	50% of FLE patients. 15–20% of TLE patients.	Contralateral in 40–90% of patients.	Temporal or frontal.	Supplementary motor area, basal ganglia, other frontal areas cannot be excluded.	May be differentiated from dystonic posturing by absence of rotational components.
Unilateral immobile limb	5–28% of patients with TLE.	Contralateral in most patients with automotor seizures.	Temporal.	Contralateral frontal lobe.	Probably a negative motor phenomenon.
Postictal palsy	Less than 1% of patients.	Contralateral in all patients.	Frontal or temporal.	Possible exhaustion or inhibition of Brodmann area 4 and 6.	Should be differentiated from ictal unilateral immobile limb.
Pelvic thrusting	24% of FLE patients. 6% of TLE patients.	None.	Usually frontal, may be temporal.	Unknown.	May be observed in pseudoseizures (17% of patients).
Non-versive head turning	75% of TLE patients. 50% of FLE patients.	Usually ipsilateral (see text for details).	Not determined. Basal ganglia (striatum) might be involved.	Unknown.	Lateralizatory value is controversial.
Head version	35% of TLE patients. 20–60% of FLE patients.	Contralateral in more than 90% of patients.	Frontal or temporal.	Broadmann's area 6 and 8.	Associated with conjugate eye versions to the same side and preceding (10 seconds or less) secondary generalizations.
Head and eye ipsiversion at the end of generalized seizure	15–20% of secondary generalized seizures.	Ipsilateral if initial head version vanish during generalization.	Frontal or temporal.	Cotralateral Boardman's area 6 and 8.	If initial head version is maintained during seizure, late head version still contralateral to epileptogenic zone.
Unilateral eye blinking	0.8–1.5% of patients.	Ipsialateral in 80% of patients.	Mostly temporal in automotor seizures.	Not determined.	Involvement of inferior post-central area has been suggested.

Continued

Table 52.1 cont'd

Motor characteristics findings	Frequency	Lateralizing value	Epileptogenic zone	Simptomatogenic zone	Observation
Nosewiping	50–85% of MTLE patients. 10–33% of extratempor al patients.	Ipsilateral to temporal lobe epileptogenic zone in 70–90%. Nonlateralizing in frontal lobe seizures.	Suggest mesial temporal epileptogenic zone. Might be extratemporal.	Unknow. Might reflect olfactory hallucinations, nasal secretion or abnormal amygdalar network functioning.	May reflect contralateral postictal movement abnormalities or neglect.
Ictal vomiting	2% of TLE patients.	Suggests nondominant epileptogenic zone.	Suggests nondominant temporal lobe.	Activation of limbic structures, insula, and mesial frontal regions.	Unknown mechanisms.
Ictal spitting	Less then 1% of patients.	Suggests nondominant epileptogenic zone.	Suggests nondominant temporal lobe or hemisphere.	Cortical activation or releasing phenomena of unknown networks.	It is not due to bad mouth sensation, excessive salivation, or drooling.
Ictal urinary urge	2.5% of TLE patients. are in other Epilepsies.	Suggests nondominat epileptogenic zone.	Suggests nondominant temporal lobe.	Insular cortex, mesial frontal region, medial temporal gyrus, and operculum.	Suggests activation of specific nondominant hemispheric bladder control centers.
Periictal water drinking	15% of TLE patients.	Suggest nondominant epileptogenic zone.	Suggests nondominant temporal lobe.	Amigdala, hippocampus, and parahippocampal gyrus. Hypothalamus?	Unknow. Propagation of ictal activity to hypothalamus has been suggested.
Periictal cough	9–40% of patients.	Nonlateralizing.	Suggests temporal lobe.	Unknown. Might be due to activation of central autonomic pathway.	Multiple mechanisms. Increased respiratory secretion might have a role.
Unilateral ear-plugging	Rare.	Suggests contralateral epileptogeni c zone.	Suggests neocortical temporal cortex.	Auditory cortex, on superior temporal gyrus.	Probably a stereotyped response to annoying auditory phenomena.
Complex hypermotor ictal behaviors	More then 50% of FLE patients. 2–3% of TLE patients.	Nonlateralizing.	Highly suggestive of frontal lobe. Might be observed in seizures from other regions due to ictal propagation.	Frontal lobe.	There is no consensus on the specific localization of epileptogenic or symptomatogenic zones in frontal lobes.
Gelastic seizures	Rare	Nonlateralizing.	Highly suggesive of hypothalamic hamartomas. Other lesions also possible, mostly frontal or temporal.	Anterior cingulated regions inolved in motor aspects of laughter. Temporal lobes involved in mirth.	Mirth is only possible with conscience preservation during at least part of the seizure.

Observations: Data regarding adult patients. Motor symptoms might be observed in posterior cortex epilepsy due to seizure propagation. The general predominance of central autonomic networks in nondominant or right hemisphere might account for nondominant (right) periictal-related behaviors. Frequencies are taken from reports on different series of video-EEG monitoring. For references, consult text. Ipsilateral or contralateral refers to the epileptogenic zone.
Legends: FLE = frontal lobe epilepsy; **TLE** = temporal lobe epilepsy, **MTLE** = mesial temporal lobe epilepsy; **NTLE** = neocortical temporal lobe epilepsy. **ETLE** = extra-temporal lobe epilepsy.

observed are *déjà vu, jamais vu*, olfactory auras, feelings of depersonalization.[20,24] Some auras preceding automotor seizures are difficult to be characterized by patients and neurologists because they consist of complex subjective symptoms exclusively felt during seizures, and not usually experienced in other contexts. It is not uncommon that patients with automotor seizures and mesial temporal lobe epilepsy have history of auras in the past that no longer exist. This should be specifically asked to patients, once past or present history of auras is an important aspect of automotor seizures.

Depending on the series, 15–69% of patients have auras preceding complex motor seizures of frontal lobe origin, a region more often associated with hypermotor seizures. [21,23,27–29] These auras consist of feelings of tightness or tingling of certain body parts, auras of whole body sensation, cephalic sensation, and other nonspecific feelings.[21,23,27–31] Palpitations, fear, anxiety, and even panic have also been reported, although much less frequently.[21,23,27–29,32,33] When comparing seizures of temporal lobe origin with those emanating from frontal lobes, psychic, gustatory, olfactory, fear, auditory, visual, or experiential auras suggest temporal lobe seizure onset and therefore are more frequently associated with automotor seizures.[24] A nonspecific general body sensation is much more suggestive of frontal lobe epilepsy, frequently preceding hypermotor seizures.[23,33] Cephalic sensations or other vague complaints are nonspecific and might occur in both, automotor and hypermotor seizures. Because auras are among the first clinical seizure symptoms, they might reflect initial and more circumscribe regional alterations, having diagnostic and prognostic significances.[31,34] For these reasons, detailed evaluation of auras should not be forgotten during complex motor seizures evaluations. The reader should review the chapter about auras for a more detailed discussion.

Automotor seizures

Automotor seizures (SSC) or complex partial seizures (ILAE's classification) are by far the commonest type of complex motor seizures observed in video-EEG units. Automotor seizures are more commonly observed in association with temporal lobe epilepsy. These seizures are usually preceded by auras and their most remarkable characteristics are the impairment of consciousness and the presence of automatisms (e.g., oral automatisms, and limb automatism) and/or stereotyped motor behaviors (e.g., dystonic posturing), involving mainly hands, mouth, or tongue.[5] The lateralizing and localizing semiological findings in automotor seizures are rich, especially when observed in association with temporal lobe epilepsy, where the number of clinical symptoms per seizures and duration of the seizures are usually higher than in other complex motor seizures.[23] Consciousness is affected, but can be preserved in variable degrees, especially when seizures originate and remain restricted to the nondominant hemisphere.[10,12,35–37] In the following sections we will review in detail these automatisms and most common associated periictal motor behaviors. A short discussion about mechanisms of all these ictal or periictal motor behaviors is also presented.

Automatisms

Oral or alimentary automatisms and automatisms of limbs usually more exuberant in the upper limbs are commonly observed in automotor seizures. These automatisms are significantly more observed in temporal lobe epilepsy but can be also seen in extratemporal seizures.[16,23,33,38,39] Typical automatisms observed in automotor seizures can be discrete, consisting of repetitive and stereotyped involuntary actions as is the case of oral automatisms,[10,40,41] or more complex, characterized by involuntary, learned and semipurposeful complex motor acts, like fumbling, picking, or gesticulating movements.[24,40,42–45] By comparing automatisms between patients with 'pure culture' of temporal and frontal lobe epilepsies, Kotagal and colleagues[23] observed that alimentary automatisms, repetitive upper limb automatisms, perseverative automatisms, looking around and complex gestures were much more commonly seen in temporal lobe epilepsy, while hypermotor seizures were much more frequent in frontal lobe epilepsy. Indeed, although in surgical series of frontal lobe epilepsies up to 77% of patients might present some type of automatism during seizures, they are usually hyperkinetic and qualitatively distinct from automotor automatisms. These aspects will be discussed further in hypermotor seizures.[21,23]

Automatisms in automotor seizures may be interpreted as release phenomenon and/or the result of activation or disruptions caused by seizure propagation to limbic system, subcortical structures, and/or other cortical regions.[40,45–47] In the following sections we will better characterize the most common types of automatisms associated with automotor seizures, namely, oral and gestural automatisms, and discuss their underlying mechanisms.

Oral automatisms

Automatisms involving the oral region including masticator movements, swallowing, lip smacking, kissing or other tongue movements are classically observed in automotor seizures from temporal lobe origin.[33,40,48] However, they can also occur in extratemporal seizures, especially when ictal discharges spread and secondarily involve the temporal lobes.[16,18,21,38,39,49,50] When occurring in frontal lobe epilepsy, these automatisms are more common in association with orbito-frontal seizures.[21] Precise mechanisms of oral automatisms are still poorly elucidated. They may represent release phenomenon or positive activation of the limbic system.[40] Electrical stimulation of limbic structures, and particularly of amygdala, can induce oral automatisms, but only when associated to clinical seizures or widespread afterdischarges.[2] In line with this observation, Maillard and colleagues[45] observed that oral automatisms occur relatively early during seizures initiated in medial-lateral temporal structures, but only late in medial temporal seizures, suggesting that oral automatisms require widespread dysfunction of medial and neocortical temporal lobe structures for their expression.[45,51]

Gestural automatisms

Gestural automatisms observed in automotor seizures are far more prominent in upper limbs and face. Lower limb automatisms although less frequent and more discrete share similar mechanisms and significances.[52] In unilateral temporal lobe automotor seizures, while the contralateral limb is usually tonic, dystonic, or immobile, the ipsilateral limb may present

several different patterns of gestural automatisms.[10,40,41,53–57] Depending on the series, limb automatisms are reported in more than 80% of temporal lobe epilepsy patients,[10,57,58] being exclusively unilateral in more than 50% of the patients.[58] Gestural automatisms are usually observed after the initial instants of the seizure, which seems to be the time necessary for the ictal spread to limbic-neocortical structures.[45] During video-EEG it is useful to observe that limb automatisms are predominantly ipsilateral to the epileptogenic zone in patients with mesial temporal lobe epilepsy, but contralateral in patients with neocortical temporal lobe epilepsy.[57,59] In mesial temporal lobe epilepsy, automatisms occur just before or simultaneously to dystonic posturing. This pattern suggests that ictal activity spreads from mesial temporal lobe structures sequentially to medial frontal cortex and then to striatopallidal complex, or that it spreads to medial frontal cortex and basal ganglia simultaneously.[57] Unilateral ictal automatisms associated with contralateral dystonic posturing are highly suggestive of mesial temporal lobe epilepsy.[58,60] However, the lateralizing value of unilateral automatisms not associated with dystonic posture has limited lateralizing value.[58] When occurring isolated and left-sided, they might indicate ipsilateral epileptogenic zone. When observed right-sided, without contralateral dystonia, they have no lateralizing value.[58] It is interesting to note that unilateral automatisms in automotor seizures of mesial temporal lobe origin might correspond in fact to bilateral automatisms, being the automatisms contralateral to the epileptogenic zone overridden by dystonic or tonic posture, or by ictal paresis.[58,60] With very rare exceptions, automatisms observed in automotor seizures with preserved responsiveness are characteristic of epileptogenic zone in the nondominant temporal lobe.[35–37,61] Gestural automatisms have complex mechanisms, most of them not elucidated yet. By stimulating the anterior gyrus cinguli and mesiotemporal structures, oral and hand automatisms can be evoked,[62–64] thus suggesting that these automatisms can be caused by ictal spreading activity. However, other authors have suggested also that at least some automatisms may correspond to releasing phenomenon, not being caused by direct ictal activation.[35,58,65]

Genital and sexual automatisms

Genital automatisms are defined as repeated ictal fondling, grabbing, scratching or other genital manipulations. They must be differentiated from other genital or seizure manifestations, like sexual or orgasmic auras, genital sensory phenomena, or hypermotor sexual automatisms.[66–70] Genital and sexual automatisms are observed in about 10% of the patients referred for epilepsy surgery.[71] While orgasmic auras originate from the nondominant temporal lobe,[70,72,73] genital and sexual automatisms are essentially nonlateralizing, and may be seen in seizures originating from frontal as well as temporal lobes.[69,71,72,74–76] According to Leutmezer and colleagues,[76] the term 'sexual' refers to symptoms or signs with erotic components while the term 'genital' refers to symptoms or signs involving the genitalia but without erotic components. The quality of genital or sexual automatisms might indicate the lobe of seizure origin. Aggressive sexual pelvic or truncal movements are usually automatisms appearing in the context of hypermotor seizures associated with frontal lobe epilepsy,[71,75,76] while subtle genital automatisms like fondling or grabbing the genitals are more commonly observed in temporal lobe seizures.[69,71,76] The latter occur more frequently in men and may localize the seizure onset to the ipsilateral temporal lobe only when associated to unilateral hand automatisms (70% of patients), or to the nondominant temporal lobe when associated with periictal urinary urge (in 22% of patients).[69]

Pelvic thrusting is a complex motor behavior that needs some consideration because it might be observed in a moderate number of patients, with different meanings. Geyer and colleagues reported that pelvic thrusting is more commonly observed in frontal lobe seizures (24% of the patients) or in pseudoseizures (17% of the patients),[77] but it can be also observed in temporal lobe seizures, in a smaller percentage of cases (6% of the patients). It does not have any lateralizing value.[77]

The mechanisms underlying sexual and genital automatisms are also not well understood. A transitory Klüver and Bucy syndrome-like phenomenon caused by bi-temporal lobe dysfunction, a nonspecific behavioral pattern, or even a specific behavior related to limbic activation, or a reaction to other internal stimuli were all hypothesized mechanisms, but so far not corroborated by electro-clinical supportive data.[69,78]

Stereotyped ictal or periictal motor behaviors

Prominent stereotyped motor behaviors are integrant components of complex motor seizures, mainly automotor seizures. The assessment of their semiological characteristics is of diagnostic importance since they frequently carry useful and reliable information for the localization of the epileptogenic zone. The main clinical features of the most common types of ictal stereotyped motor behaviors are described in the following sections.

Dystonic limb posturing

Dystonic limb posturing consists of a sustained limb posturing similar to that observed in movement disorders, very often occurring in the course of automotor seizures. Unilateral or predominantly unilateral dystonic posturing of the upper limb is perhaps the most reliable lateralizing sign in temporal lobe automotor seizures.[10,54,55,57,79–84] Although less frequently it can also occur in frontal lobe epilepsy, where it might be observed latter in the course of the seizures. Depending on the series and on the clinical criteria of inclusion, dystonic posturing can be observed in 15–70% of the patients.[10,40,55,57,81,82,84–86] When present, unilateral dystonic posturing is usually observed several seconds after seizure onset, suggesting that seizure propagation is necessary for producing it.[87] Dystonic posturing occurs contralateral to the epileptogenic zone in more than 90% of the patients with temporal or extratemporal seizures.[54,82,84,88] Contralateral dystonic posturing associated with head turning and automatisms ipsilateral to the epileptogenic zone are findings highly suggestive of mesial temporal lobe epilepsy.[55,57,79,81,89] Rusu and colleagues also associated dystonic posturing with hypersalivation, somatomotor manifestations, secondary generalization, profound clouding of conscience, and prolongued postictal confusion to mesial temporal lobe epilepsy.[84] Dystonic posturing may occur in different degrees of complexity and duration, and has been correlated with different seizure patterns of propagation to temporal, frontal, and parietal lobes.[84,87,90,91] However, most

authors agree that direct or indirect basal ganglia activation,[87,90,91] and more specifically, the putamen seems to be necessary for ictal dystonic posturing.[87,92,93] PET and SPECT findings are in line with these evidences,[94] and additionally revealed alterations in insula, inferior and superior frontal gyri, cingulated gyri, as well as in parietal areas.[84,94] Taken together, these findings suggest that dystonic posturing results from widespread subcortical and cortical involvement of different neural networks. This observation agrees with those suggesting that dystonic posturing might be a negative predictor for good surgical outcome in mesial temporal lobe epilepsy,[84,95] once broad spread of ictal activity has been previously reported to be accompanied by worse post-surgical outcome.[96]

Unilateral tonic posturing

Contralateral tonic limb posturing, although less frequent and less specific, is also considered an important lateralizing sign in temporal lobe automotor seizures. It is observed in about 17% of temporal lobe epilepsy patients, being contralateral to the epileptogenic zone in 40 to 86% of them.[54,82] Unilateral tonic limb posturing may be also observed in up to 15% of extratemporal seizures,[54] being contralateral to the seizure focus in 67–89% of these patients.[54,85] Tonic posturing has been differentiated from dystonic posturing by the absence of rotational or torsion components. However, it can be observed co-occurring with dystonic posturing and it has been considered as a muted expression of more classical dystonic posturing by some authors.[54,84] Unilateral tonic posturing are most likely due to the activation of the supplementary motor area (SMA), although basal ganglia, cingulate gyrus, and primary motor area cannot be ruled out in the generation of tonic posturing.[65,97]

Unilateral immobile limb

Unilateral immobile limb or unilateral ictal akinesia was initially described as 'ictal paresis' or 'ictal paralysis' and can be defined as a sudden loss of tone in one upper limb while the opposite side expresses automatisms. It is often observed during temporal lobe seizures, being considered as highly specific for lateralizing the epileptogenic zone.[54] Ictal immobile limb is reported in about 5–28% of the patients, being contralateral to the epileptic focus in virtually all patients.[54,98,99] It is frequently associated to ipsilateral limb automatisms, usually occurring immediately after the initial symptoms.[99] In some seizures it occurs after patients had already initiated bilateral automatisms, while in others it may appear concomitantly with the onset of the ipsilateral automatisms. In about 70% of the seizures, unilateral immobile limb may precede typical ictal dystonia. In the other 30%, it may be followed by more complex automatisms, other signs of frontal lobe involvement, or secondary generalization. Authors have excluded tonic posturing as cause of upper limb immobility, despite the fact that muscle tonus had been tested in only few patients.[98] Ictal paresis should be differentiated from postictal paresis or Todd's palsy, a transient focal motor deficit that might occur after a seizure in 0.5–13.4% of the patients, depending on the series.[100,101] It lasts about 3 minutes, ranging from 11 seconds to 22 minutes, usually being unilateral and contralateral to the seizure focus.[101] Bilateral postictal paresis has also been described.[101,102] Postictal limb paresis might be associated with ictal unilateral clonic activity (55.6% of seizures), dystonic posturing (47.9% of seizures), and ictal limb paresis (24.6% of seizures).[100] The mechanisms underlying ictal unilateral immobile limb are not completely elucidated, corresponding probably to a negative motor sign. Ictal invasive recordings performed in few patients suggested epileptic activation of the contralateral premotor cortex, prefrontal cortex, anterior cingulate gyrus and orbitofrontal cortex as the neural substrates involved in this motor behavior.[99] Congruent with these findings, negative motor responses can be elicited by stimulation of mesial and lateral frontal lobe regions.[103–105]

Eyes motor behaviors

Conjugated and sustained tonic versive eye movement occurring shortly before generalization is the most reliable ocular sign for seizure lateralization. It usually occurs associated to head version. Both, head and eyes version, frequently appear contralaterally to the epileptogenic zone,[106,106,107] due to seizure propagation to Broadman's area 8. Although they are simple motor phenomena, they were included here because head and eyes version may be observed in the context of complex motor seizures. Unilateral eye blinking is rare and may be observed in about 0.8 to 1.5% of seizures from patients referred to video-EEG, being ipsilateral to the epileptogenic area in about 80% of the patients.[65,108,109] The mechanisms underlying ipsilateral ictal eye blinking are still unclear.

Nistagmus is another eye motor sign, observed in less then 1% of patients during video-EEG and reviewed here because it is a motor sign with lateralizing properties. Nistagmus is usually observed in association with posterior cortex epilepsy, the fast phase being contralateral to the epileptogenic zone in all well-documented cases.[110–117] Mechanisms of ictal nistagmus are complex and still not elucidated. Intermitent, but periodic activation of cortical saccade areas by ictal activity, activation of slow ipsiversive smooth pursuit region, or even activation of cortical optokinetic regions and subsequently subcortical structures were all mechanism hypothesized.[117]

Head turning and head version

Versive and nonversive head turnings are common signs of automotor seizures. Version classically defines a tonic, unnatural, and forced lateral gyratory movement while head deviation or head turning refers to other head gyratory movements with more natural and unforced components. While some controversy exists about the significance and reliability of ictal nonversive head turning as a lateralizing sign, authors agree that forced versive head movements are contralateral to the epileptogenic zone in more then 90% of cases, especially when associated to conjugated eyes version and occurring shortly (usually 10 seconds or less) before secondary generalization.[10,21,43,81,85,106,107,118–121] When contralateral to epileptogenic zone, head versions are sometimes referred as adversion or contraversion. Depending on the series, head version is observed in approximately 35% of patients with temporal lobe epilepsy and in 20–60% of patients with extratemporal epilepsies, mainly frontal lobe epilepsies.[10,21,43,81,85,106,107,118–121]

Nonversive head turning occurs in up to 73% of the temporal lobe seizures, but its value as a lateralizing sign has been controversial.[120] In focal seizures without generalization, when a single head turning occur, it is ipsilateral to the epileptogenic

focus in up to 94% of the seizures.[120] When two head turnings occur to the same direction (19% of the seizures), they are usually ipsilateral to the seizure focus. However, in focal seizures with secondary generalization, when two head turnings occur, the first is usually ipsilateral to the seizure onset and the second is contralateral to the epileptogenic zone, usually appearing shortly before generalization.[81,120] Head turning or deviation can be observed in about 50% of patients with frontal lobe seizures, being also ipsilateral to the epileptogenic zone in most cases. When patients show both sides head gyratory movements, ipsilateral head turning usually occurs earlier and precedes contralateral head turning.

Late ipsiversion of head and eye at the end of a generalized tonic-clonic seizure might be observed in 15–20% of patients. When initial contraversion persists during the generalization phase, late head deviation is usually contralateral. When initial contraversion vanish during the generalized phase, late version is usually ipsilateral.[10,106] Head version can be elicted by direct electric stimulation of the premotor areas (Broadman's areas 6 and 8). Thus, propagation of seizures to these areas might underlie this behavior shortly before generalization. This seems to be also the mechanism of late ipsiversion, when activation of contralateral nonepileptogenic hemisphere predominates, after the initial ictal activity in the epileptogenic hemisphere is already exhausted or inhibited.[10,106,117] The mechanisms of other nonversive head turning are less well understood. The association of ipsilateral head turning with contralateral dystonic limb posturing has led some authors to associate ipsilateral head turning with seizure spreading to the basal ganglia, and more specifically to the striatum.[81,120,121] However, other authors have suggested neglect of the contralateral space as the possible mechanism involved in ipsilateral head turning.[107,121]

Facial alterations

Facial expression changes occur in virtually all types of complex motor seizures. In automotor seizures, most patients exhibit neutral facial expression and staring, but emotional facial changes (e.g., disgust, happiness, and sadness) may also be observed.[122–124] Expressions of anger, surprise, or fear are not commonly seen in automotor seizures, but frequently occur in hypermotor seizures.[122,124–126] Although emotional facial asymmetry is not a specific ictal motor abnormality, it deserves a brief mention here because it might help in lateralizing the epileptogenic zone. Observed in about 70% of temporal lobe epilepsy patients, inferior facial weakness is usually, but not always, contralateral to the epileptogenic zone.[127–130] Ictal smile was reported in children, occurring in 11% of frontal lobe seizures, in 3% of temporal lobe seizures, and in 26% of posterior cortex seizures, where it is significantly more common. This finding might lateralize the epileptogenic zone to the nondominant hemisphere.[131] Rarely, ictal cry may be observed in patients with temporal or medial frontal lobe epilepsy.[132,133]

Mechanisms involved in ictal facial expression changes are multiple and complex. Facial alterations might be caused by direct seizure activation or disconnections of cortical or subcortical motor areas involved in facial muscle control,[122,134–139] or be provoked by ictal alterations in emotion-regulation networks. Seizures originating from or involving limbic and related structures may also activate or disrupt regions involved in the modulation of emotional responses, provoking emotional facial alterations that can appear associated to complex motor behaviors, like fear or anger, sometimes being quite dramatic and resembling panic attacks.[124,126,140] Associated emotional behavior may be observed in temporal lobe epilepsy, but extreme emotional ictal behaviors (usually intense agitation, screaming, facial expression of rage, fear, or anger) are more commonly observed in frontal lobe seizures.[125,126] The analysis of the neural substrates underlying emotional responses is particularly complex, once emotions and related behaviors are difficult to be reproduced and studied under controlled situations. Nevertheless, an increasing body of evidence has pointed amygdala, prefrontal cortex, hypothalamus, cingulate cortex, orbitofrontal cortex, insular cortex, and the ventral striatum as components of a complex neural emotional network.[141–144] More complex emotional motor behaviors might be related to seizure propagation to rostral cingulate (M3) or caudal cingulate areas (M4), regions that might be responsible for 'emotional facial movements'.[46,136,139]

Nosewiping or nose-rubbing

Many epileptic patients wipe or rub their nose during or shortly after ictal period (less then 60 secounds) and this motor behavior appears to have localizatory and lateralizing value.[117,145,146] Nosewiping is significantly more frequent in mesial temporal lobe seizures than in other temporal lobe or extratemporal lobe seizures.[147,148] In temporal lobe epilepsy, ictal or postictal nosewiping might be observed in 50–85% of the patients and in 43% of the seizures, while it might be observed in only 10–33% of all patients with extratemporal epilepsy.[145,148,149] In automotor temporal lobe seizures, nosewiping has lateralizing properties, being performed with the hand ipsilateral to the epileptogenic zone in about 75–90% of patients.[145,146,148,149] In extratemporal epilepsies nosewiping might be observed in about 50% of the patients.[149] Nosewiping is uncommon in patients with generalized epilepsy, after secoundarily generalized seizures or during nonepileptic events.[146] Nose wiping is hardly lateralizatory in frontal lobe epilepsy.[150]

The pathophysiology of ictal and postictal nose wiping remains uncertain but it might reflect ictal olfactory hallucinations or increased nasal secretions.[148] Earlier ictal amygdala involvement is more common in nosewiping. This finding together with observations that amygdala has a particular role in the olfactory system[2,148] might suggest that direct amygdala ictal activation or disorganization of amygdale-related neural network might play an important role in the genesis of ictal or postictal nosewiping.[2,148] The use of the ipsilateral hand may be related to contralateral postictal movement abnormalities or neglect.[151–153]

Other stereotyped motor behaviors

Some ictal or periictal complex motor behaviors may be determined by special and well-characterized physiological states that can cause stereotyped and well-defined clinical situations such as cough, urinary urgency, thirst, vomiting, spitting, orgasmic related behaviors, among others. These periictal complex motor behaviors possibly have some common points that might allow them to be grouped together. In this venue, it is interesting to note that many of these behaviors are more

commonly observed in patients with nondominant temporal lobe epilepsy. Although several mechanisms could be involved, it is tempting to hypothesize that some of these abnormal behaviors can only be observed because patients keep some degree of awareness about their own feelings, about themselves, and about the surrounding ambient during seizures. Moreover, some of these behaviors correspond to autonomic responses, and the predominance of autonomic functions in the nondominant temporal lobe has also been advocated.[154]

Ictal vomiting

Ictal vomiting is an unusual manifestation, observed in about 2% of patients submitted to video-EEG.[89,155,156] Frequently associated with nondominant temporal lobe epilepsy, it might be also observed in language-dominant temporal lobe epilepsy.[155,157–163] The mechanisms of ictal vomiting are not yet completely elucidated. However, seizure activity in mesial temporal structures, other limbic structures, insula, and mesial frontal regions seems to be necessary. This association is supported by several clinical-electrografic correlations,[155,158–163] direct electrical stimulation[157] and evidences obtained from SPECT studies.[159]

Ictal spitting

Ictal spitting is another uncommon ictal behavior, occurring in less than 1% of the patients referred for video-EEG monitoring.[164,165] It is usually observed in seizures involving nondominant temporal lobe epilepsy,[164,165] but seizures of language-dominant temporal lobe and extratemporal lobes were also reported.[166] The mechanisms underlying ictal spitting remain largely unknown. Increased salivation, a rare finding also associated with nondominant temporal lobe epilepsy has not been associated with spitting in most patients.[167] It appears that spitting corresponds to complex automatisms similar to other oroalimentary automatisms. The association of ictal spitting with nondominant hemisphere further suggests involvement of autonomic mechanisms. However, ictal spiting is hardly explained by bad mouth sensations, excessive salivation or drooling, as one could intuitively suppose.[166,167]

Ictal urinary urge

Ictal urinary urge provokes characteristic motor behavior in association with seizures,[168,169] usually with epileptic focus located in the nondominant hemisphere.[168,169] It might be observed in 0.2–2.5% of patients during video-EEG, being more common in temporal lobe epilepsy.[65,168,169] The lateralizing significance of this sign can be explained by a hemispheric specific representation of central bladder control. PET studies on brain activation during micturition in normal subjects suggested a predominance of the right hemisphere in central bladder control.[170,171] The symptomatogenic zone probably involves the insular cortex, mesial frontal region or the medial temporal gyrus and operculum.[168–172]

Periictal water drinking

Water drinking is also a characteristic behavior occasionally observed during or up to 2 minutes after an automotor seizure.[154,173,174] It occurs in about 15% of patients and it is usually associated with nondominant temporal lobe epileptogenic zone. Depth electrodes recordings have evidenced seizures starting in the amygdala, hippocampus, and parahippocampal gyrus.[153,154,174] Propagation of seizures from these structures to hypothalamus was suggested as the cause for water drinking.[154] As in other nondominant temporal lobe seizures, the general predominance of central autonomic networks functioning in the nondominant hemisphere has been also advocated,[154] but more specific mechanisms remain uncertain.

Ictal or periictal cough

Cough is a relatively common ictal or periictal finding in epilepsy, being observed in 9–40% of patients during video-EEG.[175–177] Coughing may be observed in temporal lobe seizures as well as in extratemporal seizures, but it is rare in pseudoseizures. Some authors have suggested that periictal coughing is more often observed in temporal lobe epilepsy, although without lateralising properties.[175–177] Mechanisms of periictal cough are complex and might differ between temporal and extratemporal lobe seizures.[176,177] Nevertheless, pericital coughing is thought to be consequence of increased respiratory secretion or provoked by direct activation of the central autonomic pathways.[177]

Unilateral ear plugging

Ear plugging may be observed in some epileptic patients, probably representing a stereotyped response to an annoying auditory phenomenon. It is usually observed in children with epilepsy and learning disabilities or poor communication skills.[178] Similar to nose rubbing, ear plugging is not a primary motor seizure, but a motor behavior probably performed in response to an auditory hallucination provoked by seizures involving the contralateral superior temporal gyrus.[178] Thus, this behavior may occasionally be helpful in indicating the localization of the epileptogenic zone in the contralateral auditory cortex, on the superior temporal gyrus.[178]

Hypermotor seizures

Hypermotor (Semiological Classification) or hyperkinetic seizures (ILAE Classification) were first defined as hypermotoric turning movements and postures,[42] and further detailed by Lüders and colleagues as seizures in which the main clinical manifestations consist of complex movements involving the proximal segments of limbs and trunk. These characteristics result in large movements that might appear violent when occurring in high speed.[5] These seizures are commonly refereed as complex gestural automatisms, gestural motor symptoms, hyperkinetic or hypermotoric behavior.[166] Motor activity includes axial motor components like trashing, jumping, or body rocking. It might involve lower or upper extremities like thrashing of the extremities, bicycling leg movements, stepping, pedaling, hand flapping, clapping, slamming, pounding, fist clenching, grasping, shaking or playing with objects. Sexual automatisms are common and characterized mainly by pelvic thrusting and aggressive genital manipulations. Vocalization, laughing, shouting, or crying are frequently associated, but considered not specific findings of hypermotor seizures.[21,23,32,75,179–181] Not only the pattern of motor behavior, but also its quality, i.e., agitated, frenetic, and hyperkinetic, characterizes seizures as hypermotor seizures.

Although movements might seems violent, emotional or affective signs are reported as minimal and rare.[126,182] Nevertheless some patients might exhibit emotional components associated with hypermotor seizures,[126] but these aspects cannot be easily characterized and as a consequence, they are far less studied. The combination of all these components results in the large clinical variability of hypermotor seizures and unique and very bizarre-appearing seizures, sometimes suggesting pseudoseizures for those not habituated with video-EEG. For those habituated, hypermotor seizures are perhaps too bizarre for pseudoseizures.[181,183] Hypermotor seizures usually originate in the frontal lobes,[42,184] but it may also begin in the temporal lobes, posterior cortex, and insula.[18,39,185,186] In the next sessions we discuss hypermotor seizures and other complex motor ictal behaviors related with frontal, temporal, and insular regions, pointing some important clinical differences of these seizures.

Hypermotor seizures and frontal lobe

Frontal lobe seizures express one of its main function: triggering, organizing, and performing most diverse motor activity. Except for 'frontal lobe absences' where little or no motor activity is observed, some form of motor activity is observed in virtually all patients with frontal lobe epilepsy and more complex motor ictal behaviors are very common.[21–23,32,33,38,97,166,179,181,187–192] However, it is important to remember that these seizures are not exclusively characterized by motor activity. In fact, many patients may have auras preceding complex motor ictal behaviors of frontal lobe origin.[21,23,28,166,183,193] Moreover, in spite of being much less evident, motor behavior is preceded or followed by tonic muscle activity of limbs. Mainly due to the exuberance of the hypermotoric behaviors and short duration of episodes, auras and other periictal subtle muscle activities are usually underestimated, and specific efforts in their identification may be necessary. During hypermotor seizures, conscience may be preserved to some degree in many patients and this aspect, associated with the brevity of seizures might account for minimal postictal confusion.[179] Considering all types of automatisms observed in surgical series of frontal lobe epilepsy, hyperkinetic automatisms seems to be the most common type of automatisms, occurring in more than 50% of these patients.[21] They are usually observed early (first half) in the seizure.[184] When paroxysmal dystonic movements are observed in association with nocturnal hypermotor seizures, autosomal dominant nocturnal frontal lobe epilepsy should be suspected.[194–196]

When associated with hyperkinetic automatisms, some other clinical characteristics classically suggest seizures originating in frontal lobe. These findings are brief seizures, seizures of sudden onset and termination, early motor signs, minimal post ictal confusion, seizures that occur in cluster, seizures occurring during sleep, and seizure with tendency to rapid generalization, although not as frequent as previously suggested.[21,23,32,179–181] More recently, authors have been observing that some of these associations might be clinically nonelevant or even controversial.[21,181,184,197] Nevertheless, some of these characteristics seem to be a direct consequence of seizure spreading properties in the frontal lobe. Indeed, it is interesting to note that in spite of the intense interconnections of frontal lobes with other brain regions, ictal activity of complex motor seizures remains restricted to the frontal lobe where it originates. When propagating outside the frontal lobe of origin, it usually spreads to the contralateral frontal lobe. Because of the limited ictal spreading for an appreciable period of time, some authors were able to lateralize clinical seizure findings in up to 75% of patients with frontal lobe epilepsy.[198,199] However, it is also interesting to note that the variable and often bilateral limb motor phenomena observed in hypermotor seizures of frontal lobe origin may reflect prominent multiple target corticofugal projections from the epileptogenic zone and significant projections to proximal limbs.[199,200] Thus, bilaterality of clinical expression of motor components observed in hypermotor seizures from frontal lobe origin does not necessarily reflect bilateral cortical spread. When seizures spread to other brain regions outside frontal lobes, ictal activity frequently invades the temporal lobes, leading to false impression of temporal lobe seizures.[181,192,201–203] Differences between complex ictal motor behaviors in frontal lobe epilepsy and temporal lobe epilepsy have been observed since Penfield and Jasper.[23] Even when limited to the frontal lobe of origin, hypermotor seizures are characterized by involvement of all limbs, being bilateral, like thrashing or hitting, and include the lower limbs in movements resembling running, kicking, crossing and uncrossing the legs, or pedaling movements. They might be frenetic and bizarre, and patient may vigorously rock to and from, pound the bed or other objects with their hands, and jump or scramble about. It might be associated with pelvic trust and aggressive genital manipulation.[23,75,180,204] It is not uncommon that patients yell, growl, shout expletives, bark, laugh, whistle, or hum. Head and eyes deviation are frequently observed during hypermotor seizures but are of lesser lateralizing or localizatory value, except when versive, sustained and occurring late in seizures, shortly before generalization, being in this case contralateral to the epileptogenic zone. These patients might have poor surgical prognostic.[21,85,205] Conscience might be preserved during episodes, in spite of patients not being able to cooperate with test performed during the ictal period. Depending on the authors, some complex motoric behaviors observed in frontal lobe epilepsy may be seen as adapted behaviors to the environment or active interactions with surrounding objects, an observation in line with findings of some conscience maintenance during hypermotor seizures.[179] When frontal lobe and temporal lobe ictal automatisms are compared, differences are indeed quite evident and should be stressed here. Perseverative automatisms and complex gestures occurring in more homogeneous and stereotyped clinical patterns are usually observed in association with temporal lobe seizures. Upper extremities automatism observed in MTLE involve the distal segments of the fingers and hands and are discrete, repetitive and stereotyped, characterizing automotor seizures.[184] By contrast, upper extremity automatisms observed in most frontal lobe seizures present great clinical variability, being coarse, irregular, complex, semi-purposive, and involving more proximal muscles of shoulder, elbows, as well the hands, characterizing hypermotor seizures.[184,206] Alimentary automatisms might occur in both type of epilepsy, but are more frequent and occur early in temporal lobe epilepsy.[33,184] When observed in frontal lobe seizures, 'automotor-type' automatisms have been associated with seizure origin in orbito-frontal regions and as stated before, it might

reflect seizure propagation from frontal to temporal lobe, leading to false localization of the epileptogenic zone localizing in the temporal lobe.[202,203,206] This situation might be particularly tricky in presurgical evaluation of patients with normal neuroimaging findings, where extra-caution is necessary. When multiple motor symptoms are considered together, complex motor seizures might be better characterized and understood. Differences between complex motor seizures of frontal and temporal lobe origin might be also better appreciated. In this venue, Kotagal and colleagues[23] demonstrated that complex motor seizures of frontal lobe origin are characterized by a cluster of repetitive proximal upper extremity movements, complex motor activity, and hypermotor activity. In contrast, complex motor seizures of temporal lobe origin are better characterized by a cluster of oroalimentar automatisms and repetitive distal upper extremity movements. Usually but not always, alteration of conscience is associated with both seizure patterns.[23] Although infrequent, mixed semiology might suggest propagation from one lobe to another. In these situations, a very careful analysis of initial symptoms and the sequence of appearance of ictal motor findings are particularly important. Such approach might indicate more precisely the initial symptomatogenic zone and the patterns of seizure propagation. When clustered together, some clinical seizure patterns may indicate the ictal activation of functionally and/or anatomically related areas, an observation that might help during clinical evaluation of patients, especially in those with normal neuroimaging findings.[23]

Origin of hypermotor seizures in frontal lobe

Although the association between hypermotor seizures and frontal lobes overall is well accepted, there is no consensus on the specific localization of the symptomatogenic zone responsible for complex motor behavior observed in frontal lobe seizures. This fact reflects mainly the relative few studies on 'pure culture' frontal lobe epilepsy and series with limited number of patients included. Also account for these difficulties, the intrinsic proprieties of frontal lobe, such as its large volume as well as the complexity of connections of its neural networks, leading to rapid seizure propagation in variable spreading patterns within the frontal lobes.

According to Bancaud and Tailarach, there are five different frontal regions from which complex motor seizures might originate: anterior cingulated gyrus, frontopolar cortex, orbito-frontal cortex, opercular-insular cortex, and medial-intermediate region.[207] More recently, hypermotor seizures have been associated with seizures originating from medial or orbitofrontal regions,[206] an association further confirmed by SPECT findings in few patients.[208,209] Also in hypermotor seizures, PET revealed interictal hypometabolism involving frontomesial, anterior cingulate, perirolandic, and anterior insular/frontal opercular areas.[210] However, none of ictal complex motor behavioral patterns were observed to be exclusive from these regions, once there are well-documented examples of such seizures initiating in other frontal lobe regions as well.[21,181,188,208] Other authors have further differentiating prefrontal seizures in ventro-medial prefrontal seizures or dorsolateral prefrontal seizures. Seizures arising from ventral or ventro-medial regions appear to correspond to those initially described as 'complex partial seizures of frontal origin'. [179,180] Some of these patients exhibit hypermotor seizures resembling intense and dramatic behavioral reaction to fear, with semi-purposeful gesticulation, like kicking or punching, bipedal cycling movements or attempts to escape. On its turns, seizure originating in dorso-lateral prefrontal regions might be characterized by tonic eye deviation preceding head version and complex semi-purposeful gestural automatisms that might be directed toward the same location as the gaze.[179] However, as stated before, the origin of hypermotor complex behaviors within the frontal lobe is a matter of ongoing research. In spite of some seizure patterns being associated with specific frontal lobe regions by some authors, others could not observe such associations. On the contrary, they simply concluded that hyperactive seizures with frenetic automatisms, characteristic of hypermotor frontal lobe epilepsy, do not seem to be associated with any specific sublobar region within the frontal lobes.[181,206] In line with this last hypothesis, a mechanism proposed for complex ictal motor behaviors observed in frontal lobe epilepsy is that epileptic activity may simply disrupt the control normally exerted by higher brain centers over other regions, allowing release phenomena or disinhibition of more primitive and stereotyped behaviors.[179] It is possible that frontal lobe seizures might leads to an imbalance between internally generated control of movement and response to environmental cues.[179] This phenomenon would be the basis of the complex motor behaviors observed in frontal lobe epilepsy. Nevertheless, frontal lobe epilepsy remains the next frontier.[191] Whether hypermotor seizure or complex ictal motor phenomena have origin in specific subregions within the frontal lobe or not is still unknown. Studies with larger groups of patients with pure frontal lobe epilepsy, evaluated with modern neuroimaging appropriately combined with electrophysiological techniques and proven seizure free after surgery, are necessary to solve this problem.

Hypermotor seizures in temporal lobe epilepsy

Much less frequently, hypermotor seizures are observed in seizures originating in the temporal lobes, even if sleep-related.[185,197] This should not be a surprise if one considers that temporal and frontal structures are highly interconnected and under certain aspects, some of these regions might be considered as a physiological continuum, as is the case of limbic and para-limbic structures. In this venue, Carreno and colleagues,[185] analyzing a series of 502 patients with temporal lobe epilepsy identified only 12 individuals (2.4%) with seizures originating from mesial or neocortical temporal lobes, who exhibited complex motor behaviors similar to those observed during frontal lobe seizures. Large amplitude movements mainly involving the proximal segments of the limbs were observed in six of these patients, four other patients presented unilateral hemiballismus-like movements and the remaining two had movements affecting all four members, resembling rowing or bicycling (one patient) and violent and disorganized thrashing (the other patient). As observed by those authors, these patients might present 'temporal lobe' auras preceding the hypermotor phase, a finding that although far from being specific, might help differentiate hypermotor temporal lobe seizures from frontal lobe seizures. It is also possible that careful evaluation of the very early symptoms in these patients might provide additional clues for temporal lobe seizure onset, with rapid, but latter propagation

to frontal lobes. Indeed, although the epileptogenic zone in those cases is located in the temporal lobe, there are growing evidences suggesting that the symptomatogenic zones are in fact located in the anterior cingulated cortex and/or the orbitofrontal cortex.[125,126,211] This pattern of propagation with ictal discharges spreading to frontal lobe structures would explain the frontal-like symptomatology presented by this particular group of temporal lobe epilepsy patients. Surgical results in these patients are mainly dependent on the etiology of the epilepsy (mesial temporal sclerosis, malformations of cortical development, tumors, among others), being similar to those observed in patients with typical temporal lobe seizure semiology.[185]

Hypermotor seizures in insular lobe

Ryvlin and colleges[186] recently reported on three patients with medically intractable nocturnal hypermotor seizures whose depth electrodes investigation had demonstrated non-equivocal insular origin, more specifically in its anterosuperior portion. This observation was further corroborated by additional findings, with patient's habitual seizures being triggered by electrical stimulation in one patient, and interictal spikes over the insular region in the other two patients (suggesting its involvement in the origin of the hypermotor seizures). Thus, as in the case of seizures emanating from temporal lobes, seizures originating in insular regions might be associated with hypermotor behaviors as well.

Epileptogenic zone in bimanual-bipedal automatisms

Bimanual-bipedal automatisms are one of many automatisms observed during hypermotor seizures. However, because it is frequent, better characterized in literature, stereotyped, and easily recognizable during video-EEG, it deserves additional comments. Although usually seen as a frontal lobe clinical finding, it might be observed in few patients with seizures originating in temporal lobes as well.[212,213] Swartz[212] reported that bimanual-bipedal automatisms occur in 27% of patients with frontal lobe seizure onset and in 7% of patients with temporal lobe epilepsy. Disputing this, other authors report these behaviors as being exclusive of frontal lobe epilepsy semiology.[23] According to Swartz mesio and/or latero-temporal plus orbital areas seem to be activated in seizures originating from temporal lobes, while dorsolateral and mesiofrontal areas were more commonly activated in seizures originating from the frontal lobes.[212] Thus, although symptomatic areas of bipedal-bimanual automatisms are frontal lobes, epileptogenic areas might be frontal or temporal.

Gyratory ictal behavior

Gyratory ictal behavior, commonly refereed as gyratory seizures, is characterized by ictal rotation usually around the body axis for at least 180 degrees.[214] It was included here because gyratory ictal behaviors might be observed as integrant components of complex motor seizures. It is a non usual ictal clinical finding, observed in about 4% of patients referred to epilepsy surgery and hardly observed in pseudoseizures.[183] Gyratory ictal behaviors are more commonly observed in seizures originating from frontal lobes, but it might be also observed in seizures originating from the temporal lobes.[214] Gyratory ictal behaviors might have localizatory and lateralizing value. When following a forced head version, the rotation side is usually contralateral to the epileptogenic zone. Conversely, when not preceded by a forced head version, the direction of rotation is usually toward the side of seizure onset.[214] The mechanisms involved in the genesis of these behaviors are unknown.

Gelastic seizures

Gelastic seizures are seizures whose main characteristics are brief periods of laughter or grimaces, accompanied or not by subjective feelings of mirth. The term 'gelastic' is originated from the Greek word *gelos* which means joy, an expression referring to the observation of laughter during seizures.[14,215–219] Gelastic seizures are uncommon type of seizures, better classified apart from other complex motor seizures due to their peculiar characteristics. Although this semiological finding strongly suggests hypothalamic hamartoma as the cause of the seizures, rare patients might experience gelastic seizures due to other types of brain lesions, located in diverse brain areas.[14,14,215–224]

Hypothalamic hamartomas are rare but well-recognized developmental malformations of the tuber cinereum, associated with precocious puberty and gelastic seizures. Although there is a spectrum of epilepsy severity associated with hypothalamic hamartomas, patients with hypothalamic hamartomas who present the classical form of the disease develop gelastic seizures during infancy or early childhood, followed by appearance of generalized seizures associated with broad cognitive and behavioral deterioration. Endocrine disorders are also observed, leading to precocious puberty.[14,14,215–219] Rare patients might experience milder forms of the disease, with seizures only characterized by pressure to laugh.[225] Typically, gelastic seizures might be difficult to recognize as epileptic events until an average of 4 years. These patients are poorly responsive to pharmachological treatments. Alternatives therapies, such as vagal nerve stimulation and the ketogenic diet have not shown clear benefits. However, because gelastic seizures originate and propagate from hypothalamic hamartomas, surgical seizure control is possible. Advances in surgical techniques have allowed safe resections of hypothalamic hamartomas, leading to drastic improvements in seizure control.[14,220–223,226–231] Surgical treatment is also possible in refractory cases associated with lesions other than hypothalamic hamartoma.[215,217,224,232–235] In these cases the prognosis is mainly dependent on the local and extension of the lesion. As is the rule in epilepsy surgery, small epileptogenic lesions located outside the eloquent cortical areas, and whose epileptogenic zone can be completely excised, carry good surgical prognosis.

The pathophysiology of gelastic seizures remains undefined but it is mainly dependent on the lesion from where seizures emanate. In the case of hypothalamic hamartomas, investigations involving ictal recordings from implanted electrodes, including electrode contacts placed directly into the hypothalamic hamartoma, suggested that gelastic seizures arise directly form these lesions.[14,236] Recently, Wu and collegues[237]

have demonstrated that hypothalamic hamartoma cells exhibit intrinsic pacemaker-like activity, a finding suggesting these cells might underlay the genesis of epileptic activity. Although this finding might provide evidences for seizure generation, less is known about the microcellular network associated with these cells or the hypothalamic hamartoma neural network involved in seizure spreading.[237–244] Although seizures seem to originate in the hypothalamic hamartoma itself, the neural networks and pathways which are activated during seizure propagation seem to be directly responsible for promoting the laughter or joy and different patterns of propagation might account for some clinical variability of gelastic seizures. These circuits are still not completely defined. Circuits involved in physiological laughter and/or mirth seem to be activated during seizure propagation in these patients, resulting in the gelastic seizures. The same brain networks might be activated during gelastic seizures originated from other brain lesions that not hypothalamic hamartomas. Although various anatomical regions may elicit laughter, it seems that the anterior cingulate regions are involved in the motor aspects of laughter, while temporal lobes, and particularly its basal regions, seem to be mainly involved in the processing of mirth.[217,233,238,245] Although laughter is quite evident in these patients, mirth is a subjective sensation and patients need to keep some degree of awareness of the seizures in order to be able to report it.

Complex motor seizures in children

Clinical features of complex motor seizures are distinct in children. Not only the etiological profile and associated pathologies are diverse[246–249] but differences in brain maturation also seem to influence seizure semiology.[41,42,246–248,250–256] Adapting Gloor's concepts,[1] it is probably appropriate to consider that clinical phenomenology of seizures in children is generated by widespread immature neuronal matrices, not fully specialized, linked together by still in-development anatomical connections that are just beginning to become strengthened through repeated use.[1,2] Indeed, it is during brain maturation that neuronal matrices are formed and wired together, creating the organized and specific neuronal networks characteristic of adult life. In immature neural matrices, the epileptic electrical activity seems to evolve according to patterns of propagation distinct from those observed during adulthood.[251,257] Differences in propagation patterns seem to be influential to the clinical course of complex motor seizures in children. These theoretical considerations are important once they might help to explain the occurrence of a certain gradient of motor findings between childhood and adulthood, evolving from more simple, prominent and broader, to more elaborate, discrete, and focal complex motor patterns.

In children under 3–4 years old with temporal lobe epilepsy, seizures tend to manifest with prominent tonic, clonic, or myoclonic patterns that are sometimes bilateral and symmetrical, with ictal characteristics closer to seizures from generalized epilepsy syndromes. Although lateralising signs might be observed with very good interobserver agreement in up to 75% of children under 13 years old, the lack of specific clinical lateralizing signs, especially unilateral automatisms, dystonic posturing, version, postictal dysphasia, and postictal facial wiping is not unusual in young children.[256] Postictal nose wiping, unilateral tonic seizures, Todd's paralysis, unilateral clonic seizures, and ictal nistagmus are among lateralising signs observed earlier.[42,246,248,251,258–262] When automatisms are observed, they tend to be less elaborated and are usually restricted to oroalimentar automatisms.[251] These features may be also seen in focal epilepsies originating in other brain areas.[249,258–261] As the child grows, the motor manifestations become more elaborated. These modifications seem to become clinically evident after 3.5–4 years of life, probably coinciding with more advanced stages of brain maturation.[251] At these later stages, motor signs become progressively less prominent, giving room to more complex automatisms that increases in complexity as the child grows. At this age, many children might also show dystonic posture or versive movements.[42,246] After six years of age, motor phenomenology of temporal lobe seizures become similar to that observed in adults.[42,246,248,256]

As can be concluded from above, complex motor seizure analysis is particularly challenging in young children, once they present less frequently lateralizing and localizing signs, and they are usually unable to give reliable information about auras or other subjective symptoms. Oller-Daurella and Oller,[263] studying focal seizures in 154 children during the first 3 years of life observed that only 23% of them had focal ictal signs suggestive of focal pathologies. All the others had nonfocal seizures. In a postsurgical retrospective analysis, Loddenkemper and colleges[262] studied ictal lateralizing findings in infants from 1 to 32 months of age with focal epilepsy. They observed reliable lateralizing motor signs in only 58% of the seizures, in 63% of the children, mostly consisting of lateralized simple motor seizures. Complex motor behaviors were not observed or were not reliable for focus localization.[262] Head and eye version were common, but shifted laterality, consequently being nonreliable as lateralizing signs.[262]

In young children, temporal, temporo-parietal, or occipital lobe seizures are more commonly characterized by impaired responsiveness and awareness (difficult to evaluate in very young children) and decreased motor activity. This pattern is usually referred as hypomotor seizures. Hypermotor seizures might occur, but it is sporadic.[56,252,264] These seizures are clearly distinct from seizures initiating in frontal, central, fronto-central or fronto-parietal regions, that are characterized by motor alterations consisting of tonic, atonic, or clonic movements.[56,264] Pediatric frontal lobe epilepsy might be especially challenging for epilepsy surgery. When compared with those children with temporal lobe epilepsy, children with frontal lobe epilepsy had more frequent seizures, seizures of brief duration, and seizures occurring more often during sleep. Other characteristics of pediatric frontal lobe epilepsy are seizures of explosive onset with scream or cry, marked agitation during seizures, stiffening, kicking, or bicycling of legs, incontinence, and rapid recovery, with only brief postictal phase.[265,266] In older children, seizures assume patters of adulthood epilepsy. In mesial temporal lobe epilepsy seizures are usually of automotor type while in patients with frontal lobe epilepsy seizures might be complex hypermotor seizures or simple motor seizures, like asymmetric tonic seizures or focal clonic signs.[265] Epileptic spasms are nonspecific findings

regarding lateralization, once it can be observed in association with focal lesions in all regions cited above.[264]

Final comments

The reader must keep in mind that, although several aspects of complex motor seizures might help in localize and lateralize the seizure onset zone, semiological findings cannot be 100% accurate. Some discrepancy should always be expected between the epileptogenic and symptomatogenic zone once these zones are conceptually distinct, and although overlapping is common, there exist considerable intra- and interpatient variability. Also because of this variability, exceptions in the lateralizing and localizatory value of many signs may be expected. Nevertheless, careful descriptions of the complex motor findings observed during ictal periods are accurate enough for correct semiological seizure classification, frequently providing useful evidences supporting surgical decisions.[7–9] In this venue, besides studying isolated clinical signs and describing them in detail, epileptologists should also concentrate research efforts in specifying common patterns of composed motor behaviors, as well as in the establishment of common patterns of temporal and sequential evolution of these behaviors. Although not practical during actual routine presurgical evaluation, it is however possible that such analysis might be particularly relevant in near future. For example, combining two motor signs might improve the diagnostic power of the epileptogenic zone, as is the case of ipsilateral automatism associated with contralateral dystonic posturing in automotor seizures. Also, some patterns might have prognostic significances, as is the case of patients that evolve to generalization during ictal spreading of mesial temporal lobe seizures.[95] For these matters, cluster analysis,[184,267] neuroetholgy,[268] or other techniques developed in order to group common events together and establish time-related sequences of behaviors might add further insights to clinical analysis of isolated signs. We believe such approaches might help planning more tailored surgical resections in future.

53 Dialeptic seizures: localizing and lateralizing value

S Noachtar

Definition

Definition of dialeptic seizure

The term dialeptic seizure has been introduced by us to allow for a seizure classification which is purely based on ictal seizure semiology.[1,2] Dialeptic seizure refers to a seizure whose predominant ictal features are alteration of consciousness, staring and loss, or minimal motor activity. The term absence seizures, on the other hand, describes a subgroup of dialeptic seizures but also includes EEG findings in the seizure classification.[3] It was the pioneering work of Gibbs and co-workers who demonstrated that in patients with absence epilepsies dialeptic seizures were associated with generalized 3 Hz spike-wave complexes in the EEG.[4] Ever since the term absence has been defined as an electroclinical syndrome consisting of loss of consciousness, arrest of activity *and* an EEG showing generalized spike-wave complexes. It seems therefore appropriate to introduce a new term which describes the ictal loss of consciousness and the arrest of motor activity emphazising a purely clinical seizure classification independent of associated EEG findings. The verb διαλειπειν is old Greek and means to interrupt, stand still, or pass out.

Definitions of consciousness are subject to controversy.[5,6] A clinically applicable definition of consciousness has to be restricted to awareness and responsiveness which is actually included in the proposal of the International Classification of Epileptic Seizures (ICES).[3] However, there are not infrequently limitations and exceptions to this concept. Patients may not infrequently recall the command to push a button during a seizure but may have been unable to do so.[7,8] Awareness and responsiveness may be disturbed differently. It has been shown recently, that patients may be fully responsive during focal seizures associated with automatisms and yet not be able to recall the events during the seizure. We could observe this phenomenon prospectively in 10% of the patients with right temporal lobe epilepsies.[9] Even with simultaneous Video-EEG recordings it may be impossible to exclude that the patients failure to respond was not caused by an arrest of activity due to epileptic activation of the speech areas. Thus, assessment of consciousness during an epileptic seizure may well not be trivial and remains conceptually difficult.[5]

For the purpose of the present chapter we will consider that an impairment of consciousness occurred during a dialeptic seizure if either responsiveness or recall were disturbed. Clinically, dialeptic seizures frequently are associated with minimal motor activity such as eyelid myoclonia and upward eye movements. To classify seizures in children or mentally retarded adults in whom it is sometimes impossible to assess ictal consciousness the term hypomotor seizure has been introduced.[10,11] Loss of voluntary tonic motor activity may be present during dialeptic seizures and is clearly distinct from atonia of postural tone leading to drop or fall. If the predominant feature of a seizure is an inability to follow a motor command such as pressing a button with full recall of the event, the seizure should be classified as an akinetic seizure (see Chapter 54a). If motor activity is present during a dialeptic seizure it is usually restricted to some minor motor movements like eye blinking. If motor activity predominates the seizure semiology the seizure will be classified according to the specific motor activity (e.g., automotor seizure, if automatisms occur or clonic seizure left arm, if the left arm is jerking).

Subgroups of dialeptic seizures

A subclassification of dialeptic seizures seems justified since the above mentioned definition is quite broad. Some patients have very brief dialeptic seizures characterized by an abrupt onset and offset. These seizures when associated with bursts of generalized 3 Hz spike-wave complexes have been classified as typical absences and are usually seen in patients with absence epilepsies.[3] On the other hand, the ICES identifies as atypical absences dialeptic seizures in which changes in muscle tone are more pronounced and which usually do not begin and end abruptly and are accompanied by generalized irregular slow spike-wave complexes with a repetition rate of 2.5 Hz or less.[3] It has also been proposed to distinguish between 'simple' absences and 'complex' absences basically depending on the degree of motor activity associated.[12,13] Clinically, this subclassification overlaps somewhat with the distinction between 'typical' and 'atypical' absences which has been proposed by the ICES.[3] However, there is evidence to suggest that the distinction between typical and atypical absences depends mainly on the EEG abnormalities associated with the dialeptic seizures.[14] Holmes *et al.*[14] analyzed a total of 926 dialeptic seizures in 54 patients with generalized epilepsies and found automatisms more frequently in 'typical absences' and more loss of muscle tone in 'atypical absences'. Both subtypes of dialeptic seizures usually had a sudden onset and end. The authors concluded that typical and atypical 'absence' seizures are not discrete entities but rather form a continuum.[14] Based on the associated motor or automotor activity dialeptic seizures occurring in patients with generalized epilepsies

(absences) have been subdivided in six subtypes by Penry and co-workers.[15] Only about 10% of all absence seizures are characterized by lapse of consciousness usually associated with a change in facial expression (staring) and cessation of motor activity, according to Penry *et al.*[15]

Of the patients with absence seizures, 71% showed at least some clonic components.[15] Dialeptic seizures with tonic components are rare (3%),[15] and show an increase of muscle tone which may cause a backward movement of the head and trunk ('retropulsiv petit mal').[16] The tonic postural movements usually include both flexor and extensor muscles of the trunk or head, but extensors typically dominate. They can be asymmetric, leading to brief versive movements. Atonic components during dialeptic seizures are usually gradual causing the head to drop slightly or objects fall of the hands. An asymmetry of the decrease of muscle tone may occur. Myoclonic jerks may intermix leading to a rhythmic appearance of a head drop. Rarely the atonia is as severe and lasts long enough to cause the patient fall. Seizures in which the loss of tone is the predominant feature should be classified as atonic seizures or astatic seizures when the patients actually falls. An atonic component occurred in about half of the patients in at least one absence seizure.[15]

Most patients with dialeptic seizures present some mild automatisms in at least some of their seizures. The automatisms may reflect a continuation of what the patient was doing prior to the seizure onset. The patient may, for instance, continue moving the fork or spoon or chewing if a seizure occurs while eating or continue to walk if a seizure commences while walking. However, the movements will usually be slower and not as elaborate. De novo automatisms typically include simple movements such as lip licking, grimacing, yawning, swallowing, scratching or fumbling. About 88% of the patients of Penry *et al.* showed some kind of automatisms during their dialeptic seizures,[15] and 28% of all dialeptic seizures were subclassified as dialeptic seizures with automatisms. The occurrence of automatisms increases with seizure duration and usually oral automatisms occur first followed by manual automatisms.[17] At a seizure duration of 3 seconds in 22% of the seizures automatisms were present, whereas at a seizure duration of 18 seconds in 95% of the seizures automatisms occurred.[15] Seizures in which the automatisms constitute a prominent part of the seizure should be classified as automotor seizures. Some dialeptic seizures are accompanied with autonomic components such as pallor of the face, flushing, mydriasis, salivation, tachycardia, piloerection and rarely urinary incontinence.

It is important to notice that in 40% of the dialeptic seizures of patients with generalized epilepsies several of the above-mentioned features occurred.[15] There was a considerable overlap of the subtypes from one seizure to another in the same individual.[15] Fifty percent of the patients evaluated have had only one of the above-mentioned subtypes of absence seizures.[15]

There are reports which will be discussed later that describe dialeptic seizures in patients with focal epilepsies. However, subtypes of dialeptic seizures are not systematically studied in these patients.[18–21] Further studies are currently being undertaken to gain more insight into the semiology of dialeptic seizures in focal epilepsies.[22]

Relationship of dialeptic seizures with 'absence seizures' and 'complex-partial' seizures

As mentioned above the term dialeptic seizure exclusively refers to an ictal seizure semiology. The ICES, however, is based on both, clinical symptomatology and EEG.[3] Therefore, a seizure consisting of lapse of consciousness and minimum of motor activity, i.e., would be classified as 'complex-partial' seizure according to the ICES if the EEG reveals focal epileptiform activity.[23–24] A seizure with essentially identical seizure semiology would be classified as an absence seizure in ICES, if the EEG showed generalized spike-wave complexes. Thus, absence seizures define an electroclinical syndrome consisting of dialeptic seizures, and less frequently other semiological seizure types like automotor seizures or akinetic seizures, occurring in association with generalized spike-wave-complexes. Complex partial seizures of the ICES define any seizure occurring in association with an alteration of consciousness and focal epileptiform EEG discharges (or normal EEG) and clinical or imaging features suggesting a focal epilepsy. Dialeptic seizures associated with a focal EEG pattern are actually one type of complex partial seizures of the ICES. The main difference between these terms is that dialeptic seizures refer exclusively to the clinical semiology of the seizures whereas absence seizures and complex partial seizures define electroclinical complexes, i.e., the definition of the terms includes clinical semiology and a specific EEG seizure pattern.

In this chapter we will use the above-mentioned clinical definition of dialeptic seizures. This will allow us to use the term dialeptic seizure independently of the EEG. Such an approach may enable us to better assess the mode of appearance and frequency of dialeptic seizures in different epilepsy syndromes and allow us to better investigate the evolution and spread of epileptic seizures.[24]

Relationship of dialeptic seizures with epilepsy syndromes

Dialeptic seizures can occur in different epilepsy syndromes (Figure 53.1). Most patients with dialeptic seizures have generalized epilepsies such as absence epilepsy and Lennox-Gastaut syndrome. Dialeptic seizures also occur even if less frequently in other generalized epilepsies such as generalized myoclonic epilepsy and probably even less frequently in focal epilepsies.[18,25–28] We recently reviewed the electronic data files of the Epilepsy Program of the Cleveland Clinic Foundation and identified 34 patients with unequivocal EEG-video documented dialeptic seizures in patients with focal epilepsies (Figure 53. 2).

Clinical characteristics of dialeptic seizures

Clinical symptomatology

Dialeptic seizures are seen in different epileptic syndromes and tend to vary considerably in their clinical semiology. In the literature there is no good semiological study studying systematically the differences of dialeptic seizures in different epileptic syndromes. Particularly, there is little data on dialeptic seizures in focal epilepsies. Because of this limitation it is necessary to describe the characteristics of dialeptic seizures independently for each epileptic syndrome.

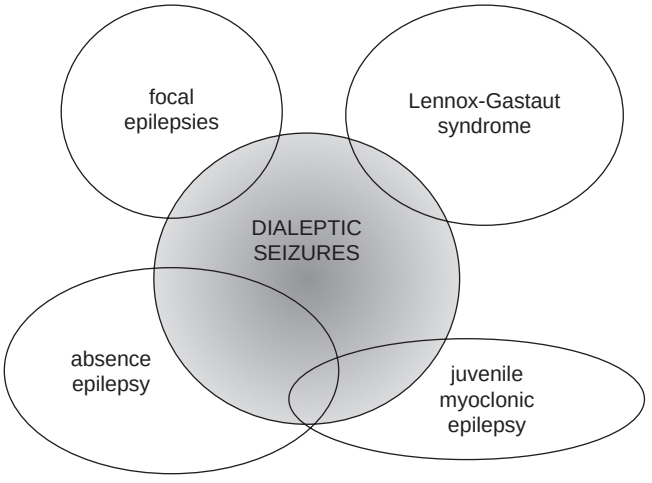

Figure 53.1 Dialeptic seizures occur in absence epilepsy, juvenile myoclonic epilepsy, Lennox-Gastaut syndrome and in focal epilepsies.

Dialeptic seizures in patients with absence epilepsy

The hallmark of dialeptic seizures in these patients is a sudden lapse of consciousness with amnesia and an arrest of volitional movements. Usually the seizures are brief, lasting about 4–10 seconds.[29] Rarely (3%), dialeptic seizures last up to one minute.[15–17,30] The seizures may be subtle and go unnoticed by the surrounding. The patient will typically show an arrest of whatever they were doing at the onset of the seizure. A pre-existing movement like walking may however sometimes be continued for some time. If a dialeptic seizure occurs while talking, the patient may realize an interruption of the conversation but may otherwise be unaware of having had a seizure. During an dialeptic seizure the patient is unresponsive, but may grunt in reply to a question or verbal commands. Reactivity is frequently disturbed at the beginning of the seizure and is less pronounced after a few seconds.[7] Browne *et al.*[7] could demonstrate, that 4 seconds after onset of the spike-wave discharges, 52% of their patients with generalized epilepsies had normal reaction time. This can be nicely documented when asking the patient to press a button using the 'clicker test'. The patients are usually unable to follow the command to press the button but some may recall the command later[8].

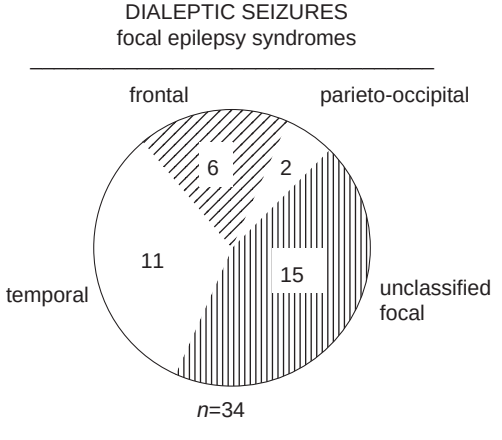

Figure 53.2 Focal epilepsies in which video-EEG documented dialeptic seizures were seen in 34 patients recorded at the Cleveland Clinic Foundation.

During a dialeptic seizure motor activity is normally reduced to a minimum, although some minor movements may be present the longer the seizure lasts.[17] These typically include clonic or versive upward eye movements, blinking or mild clonic jerks of the face or the extremities. The muscle tone may change during such attacks either presenting an increase of tone such as in a 'retropulsiv' movement of the trunk [16] or rarely a decrease of tone leading to dropping of the head or slumping of the trunk. The face usually gives the impression of atonic stare. The eyes become vacant giving a trance like expression. Subtle automatisms like lip smacking, swallowing, or fumbling may also occur but should not predominate otherwise the seizure would be classified as automotor seizure. Polygraphic video-EEG studies have shown that 1.2 seconds after onset ocular movements occur followed by oral automatisms about 4 seconds later and 1 second later manual automatisms develop.[17] Dialeptic seizures usually end abruptly, and the patient may commence his previous activities being amnestic for the time of the seizure. Detailed video-EEG analysis supported the clinical experience that most patients demonstrate some mild motor activity during their dialeptic seizures and only rarely lapse of consciousness and arrest of motor activity are the only ictal features.[15–17]

Dialeptic seizure is the predominant seizure type in absence epilepsies and best described in this epilepsy syndrome. These patients account for 10–15% of epilepsy patients in the pediatric age range.[31] The dialeptic seizures in these patients usually last 3 to 10 seconds, occur daily and very frequently ('pyknolepsy').[32] The age of onset ranges from 3 to 12 years of age and girls account for approximately two-thirds of the affected.[16,30] Later in life, patients with absence epilepsies frequently suffer also from generalized tonic-clonic seizures.[16,29,33]

In long-term follow-up studies, the proportion of patients entering remission varied between 19% to 90%.[34–42] Favorable prognostic factors include normal intelligence, lack of additional generalized tonic-clonic seizures, typical 3 Hz Spike-wave-complexes and initial response to medical treatment. Generalized tonic-clonic seizures occur in 35–60% of these patients.[35,37,38,41]

The longer the follow-up period, the poorer seems the remission rate. However, even if the dialeptic seizures have a good prognosis, generalized tonic-clonic seizures may ensue in adulthood.[43] In a long-term follow-up study over 20 to 37 years, 92% of the patients, in whom the dialeptic seizures persisted beyond the age of 30 to 61 years, eventually developed generalized tonic-clonic seizures.[44]

Some authors subdivide absence epilepsies into childhood absence epilepsy and juvenile absence epilepsy according to the age of onset and clinical course.[16,45] The patients with juvenile absence epilepsy are reported to have less frequent dialeptic seizures ('spanioleptic'), generalized tonic-clonic seizures may precede the dialeptic seizures more frequently and the EEG shows more irregular and fast spike-wave-complexes and a higher rate of photoparoxysmal responses [46] as compared to the childhood absence epilepsy group. These differences are considered to reflect genetically different traits.[47] Others have questioned the clinical significance of this subdivision of absence epilepsies and propose a continuum of idiopathic generalized epilepsies with a great deal of overlap.[48–51] The issue is at present not resolved, but subclassification of the absence epilepsies may be justified in the light of further

genetic studies[47] and possible different prognosis.[42,51] Childhood absence epilepsy showed less seizure relapse after discontinuation of antiepileptic medication (19%) than juvenile absence epilepsy (33%),[42] but this observation was not supported by others.[51]

The ictal EEG usually reveals regular spike-wave-complexes which show a repetition rate of 3 Hz. The spikes may be more blunt and the repetition rate will drop the longer the dialeptic seizures last.

Patients with absence epilepsies are particularly sensitive to hyperventilation and/or photic stimulation.[34,52–54] Of the 374 dialeptic seizures in the 48 patients evaluated by Penry *et al.*, 29% occurred spontaneously. Hyperventilation which is the most potent activator in these patients, provoked 53% and photic stimulation another 18% of the dialeptic seizures.[15] Both methods also activate interictal generalized spike-wave-complexes in the EEG.

The evolution of dialeptic seizures depends on the epilepsy syndrome. In generalized epilepsy syndromes the typical evolution of an dialeptic seizure is into a generalized tonic-clonic seizure.[16,24]

Dialeptic seizures in patients with Lennox-Gastaut syndrome

It was already noticed in the early days of EEG that a slow repetition rate of generalized spike-wave-complexes at 2 Hz ('petit mal variant') correlates with a milder impairment of consciousness during dialeptic seizures as compared to the 3 Hz spike-wave pattern.[54–55] The syndrome has been delineated later referring to patients with frequent tonic-, atonic-, myoclonic- and dialeptic seizures commencing early in childhood and being poorly responsive to medication. The patients usually have or develop mental impairment.[56,57] The ICES lists these dialeptic seizures as 'atypical' absences (see above).[3] In a pediatric age group Lennox-Gastaut syndrome accounted for 1–2%, whereas childhood absence epilepsy for 10–15% and juvenile absence epilepsy for 5%.[31] In patients with Lennox-Gastaut syndrome the onset and end of dialeptic seizures was reported to be more gradual and not as abrupt as in the absence epilepsy patients and the attacks usually last longer. However, the video-EEG study of Holmes *et al.*,[14] on 926 dialeptic seizures in 54 patients did not show any significant difference in the seizure onset and end between typical and atypical absence seizures. Some tonic, atonic and/or clonic movements particularly concerning the eyes and the perioral muscles and automatisms may occur.

Dialeptic seizures in these patients are not precipitated by hyperventilation and photic stimulation. Hyperventilation rarely facilitates the occurrence of slow-spikes-wave complexes and photic stimulation does not have any effect.[58]

The evolution of dialeptic seizures in these patients has not yet been systematically evaluated but they can also evolve into generalized tonic-clonic seizures.

Dialeptic seizures in patients with other generalized epilepsies

Dialeptic seizures are not infrequently seen in patients with other generalized epilepsies.[16,59] Juvenile myoclonic epilepsy occurs in 5% of a pediatric population.[31] The frequency of dialeptic seizures in patients with juvenile myoclonic epilepsy varies between 15–40% of the patients in different studies.[16,61–63] Clinically, the dialeptic seizures in this patients group do not differ from those seen in patients with absence epilepsies. However, the ictal EEG in this older age group is not as regular as in the children with absence epilepsies and shows typically irregular spike-wave complexes with a repetition rate faster than 3 Hz.

Photic stimulation seems to be particularly useful in patients with juvenile myoclonic epilepsy and elicits epileptiform activity in the EEG of 30% of these patients,[46] although dialeptic are rarely provoked. Rarely, other mechanisms such as reading-induced or video-game-induced dialeptic seizures have been reported.[64,65]

Some authors proposed the classification of an 'epilepsy with myoclonic absences' describing an epilepsy syndrome with patients who they felt are inbetween the idiopathic absence epilepsies and the Lennox-Gastaut syndrome.[35,66–68] 'Myoclonic absence seizures' represent the only or predominant seizure type in these sometimes mentally retarded patients and the myoclonic components are described to be massive as compared to the mild clonic movements recognized in typical dialeptic seizures. These seizures are refractory to medication in about 50% of these patients. This syndrome has been included in the International Classification of Epileptic Syndromes.[69] However, a distinction by seizure type alone appears unjustified.

Patients with neurological diseases such as Batten disease, Lafora disease, or subacute sclerotic panencephalitis are rarely reported to suffer from dialeptic seizures.[70–72]

Dialeptic seizures in focal epilepsies

Janz[73] already pointed out that dialeptic seizures consisting of pure brief lapse of consciousness may occur in epilepsy syndromes other than generalized epilepsies as well and therefore proposed the term 'pyknoleptic petit mal' for dialeptic seizures in patients with childhood absence epilepsy. Although several textbooks on epilepsy mention that dialeptic seizures may also occur in focal epilepsies, our knowledge at present is very limited.[16,73] Only few data and scattered reports are available which mainly deal, although not exclusively, with patients with frontal lobe epilepsies.[25,28]

An abrupt ictal onset and end which is a typical feature of dialeptic seizures in childhood absence epilepsies seems also to occur in patients with frontal lobe epilepsies. This observation prompted the French school to coin the term 'frontal absence'.[27,74] Fronto-mesial and fronto-orbital seizure onset has been associated with this kind of seizure.[27,74] 'Complex partial seizures' including dialeptic seizures (frontal absences) have been reported to occur in 161 seizures of medial intermediate frontal onset of 39 patients.[27,74] However, the relative frequency of dialeptic seizures (frontal absences) was not specified. The symptoms observed during these 'frontal absences' include disturbance of consciousness (loss of contact), speech arrest, arrest of movements, simple gestures (automatisms), conjugate deviation of the eyes and head, and immediate recovery of consciousness.[27,74]

Patients with temporal lobe epilepsies not infrequently also have seizures consisting of an arrest of movement and lapse of consciousness without automatisms or other

motor movements.[21,78] Because these seizures resemble the dialeptic seizures ('absences') seen in patients with generalized epilepsies the term 'pseudoabsence' has been proposed.[26,78,79] Karbowski *et al.* described this phenomenon in 5 of 12 children evaluated.[80] Wieser *et al.* reported that 'pseudoabsence' seizures have been the predominant seizure type in 2 out of 25 patients evaluated.[79] Shimizu *et al.* reported that the interictal PET regional hypometabolism was identical in 18 temporal lobe patients regardless whether they had seizures characterized by automatisms ('automotor seizure') or motionless staring ('dialeptic seizures').[81] Wieser subclassified focal seizures arising from frontal and temporal lobe according to seizure onset as documented by depth recordings.[82] However, no clear clinical distinction was made with regard to dialeptic seizures. Recently, a study using cluster analysis in seizures of patients with frontal and temporal lobe epilepsies concluded that dialeptic seizures may occur in both syndromes and cannot be distinguished on clinical grounds only.

The distinction of dialeptic seizures consisting of an arrest of movement and lapse of consciousness arising from the temporal lobes and dialeptic seizures particularly in patients with Lennox-Gastaut syndrome ('atypical' absences) is sometimes impossible based on clinical semiology.[83]

We reviewed the database at the Epilepsy Monitoring Unit of the Cleveland Clinic Foundation from 1991 to 1995 looking for patients who underwent prolonged video-EEG Monitoring and in whom at least one unequivocal dialeptic seizure was recorded. Dialeptic seizures were defined purely on clinical grounds as seizures in which arrest of activity and lapse of consciousness were the predominant ictal features, and other features such as automatisms are not as prominent. We identified 34 patients with focal epilepsies in whom dialeptic seizures were documented by EEG and video. Fifteen of these 34 patients had focal epilepsies of one hemisphere but the epileptogenic zone could not be localized further. Eleven patients had temporal, six patients frontal and another two had parieto-occipital lobe epilepsies (Figure 53.2). The proportion of patients with temporal lobe epilepsy may be biased because these patients tend to be over-represented in epilepsy surgery centers.

In focal epilepsies hyperventilation may provoke focal epileptiform discharges in up to 10% of the patients, but it is not known whether this activates dialeptic seizures. Photic stimulation is not an activator of focal seizures except rarely in parieto-occipital epilepsies. It is not known if dialeptic seizures can be triggered by photic stimulation.

The semiology of the dialeptic seizures was similar independent of the lobe of seizure origin. Thus, analysis of the dialeptic seizure itself did not allow differentiation of the epileptogenic zone. However, the evolution of dialeptic seizures may provide lateralizing or localizing information (see below). Dialeptic seizures may be preceded by other seizure types such as auras[24,25] (see below). In focal epilepsies the evolutions are more variable: an aura may precede a dialeptic seizure and the dialeptic seizure itself may evolve into other focal seizures such as for instance into a versive seizure. At present no representative data is available as to the evolution of dialeptic seizures. There are two main reasons for this: the term 'absence' is by definition of ICES a generalized seizure, and ICES does not allow for classification of seizure evolution in generalized epilepsies. Recently, a study analyzed seizure patterns in patients with frontal and temporal lobe epilepsies and used a purely clinically-based definition of the seizure types.[84] Most dialeptic seizures (identified as 'absence' seizures in this study) commenced without warning, but in 13 of 57 cases auras preceded the dialeptic seizures and further evolved into versive or automotor seizures.[84]

Pathophysiology

Generalized epilepsies

The advent of electroencephalography proved the epileptic origin of dialeptic seizures in generalized epilepsies. Gibbs *et al.* described first that 'absence' seizures are associated with a generalized 3 Hz spike-wave pattern in the EEG.[4] Since several experimental animal models have been established which served for both the search of the underlying mechanisms of the absence epilepsies and the development of drugs against human dialeptic seizures. Examples include, amongst others, the systemic pentylenetetrazol model,[85] the feline generalized penicillin model,[86] the rat ICV enkephaline model,[87] the systemic gamma-hydroxybutyrate model,[88] the tetrahydroxyisoxosolopyridine (THIP) model,[89] and genetic models such as the photosensitive Senegalese baboon (papio papio)[90] or the tottering mouse.[91]

The concepts proposed for the generation of dialeptic seizures occurring in generalized epilepsies have been subject to much controversy. Two contrary hypotheses have been debated for decades.[92] The centrencephalic theory (Montreal school) proposed that a thalamocortical mechanisms capable of inducing spindles and recruiting responses were involved in the production of generalized spike-wave discharges and typical dialeptic seizures.[93,94] It has been postulated that brain stem structures as also the thalamus may play an essential role in the pathogenesis of dialeptic seizures. A recent study using functional MRI supported this view and showed that, during absence seizures of a patient with absence epilepsy, the BOLD effect in the frontal cortex was reduced whereas it was increased in the thalamus.[95] In contrast to this concept it has been stated that generalized spike-wave discharges are a cortical phenomenon.[96,97] Both concepts were based on the results of experimental studies in animals. In an attempt to reconcile these apparently conflicting views, the corticoreticular hypothesis has been put forward. It postulated that generalized spike-wave discharges result from an abnormal interaction of cortical and diffusely projecting subcortical thalamic and midbrain reticular mechanisms.[98,99] Based on this theory, the cortex is the primary generator of spike-wave discharges.[100] It could be demonstrated that electrical stimulation of the thalamus which elicited spindles and recruiting responses in control animals elicited spike-wave complexes in cats given penicillin intramuscularly.[101] On the other hand, injection of penicillin in the thalamus did not elicit spike-wave discharges, whereas diffuse application on the cortex did. Additional studies could also demonstrate a facilitating effect on spike-wave discharges through a depression of desynchronizing effects of the reticular formation.[102]

Several further mechanisms, such as altered properties of T-type calcium channels, increased numbers of GABA-B receptors, and changes in the subunit composition of GABA-A receptors have been postulated to be involved in the generation of dialeptic seizures in generalized epilepsies.[103] Since the

predominant clinical feature of dialeptic seizures is an inhibition of motor and cognitive function, it has been suggested that the underlying mechanisms may involve synaptic inhibition.[104] It could be demonstrated in the feline generalized penicillin model, that the slow-waves of the spike-wave complexes are associated with GABA-mediated chloride-sensitive IPSPs in cortical neurons.[105] Furthermore, GABA agonists like THIP can elicit 'absence like seizures' suggesting an effect of synaptic inhibition.[89]

Focal epilepsies

The term 'frontal absence' has been coined by the French school referring to brief seizures which are clinically not distinguishable from dialeptic seizures of the generalized epilepsies. Invasive EEG recordings in these patients frequently revealed a frontal seizure onset.[13,106,107] It has been suggested that epileptic discharges arising from several areas of the frontal lobe, such as intermediate frontal region, orbitofrontal region, and cingulate gyrus may elicit dialeptic seizures.[20,74,79,108,109] It is intriguing that a seizure symptomatology which conceptually is so strongly associated with generalized epilepsy can have a focal seizure onset. The concept of 'frontal absence' was further supported by studies showing that electrical stimulation of the mesial frontal lobe can give rise to dialeptic seizures as well as to generalized spike-wave discharges at the scalp.[18,26] This finding is in correspondence with the EEG observation of secondary bilateral synchrony arising from the mesial frontal lobe.[28] Systematic electrical stimulation of the frontal lobe disclosed regions from which an arrest of motor activity could be elicited.[110–112] Close connections between the prefrontal cortex and the nonspecific thalamic nucleus and the midline region of the intralaminar thalamic complex are known to exist.[113] Seizures may arise from prefrontal cortex rapidly spread to the reticular formation causing an alteration of consciousness and generalization. Epileptic activation of the negative motor regions or the disturbance of consciousness itself may lead to an arrest of motor activity. It is not yet clear whether the frontal cortex or subcortical structures are the pacemaker of these ictal discharges, which usually involves both of them during the course of a seizure.[74]

Arrest of motor activity and blank staring with loss of consciousness have also been described in patients with temporal lobe epilepsies,[19,80] which makes it most unlikely to be specific to a particular cortex region. Epileptic activation of limbic structures has been proposed as the pathogenesis for these dialeptic seizures but this has not yet been proven.[73] Invasive recordings have shown that ictal discharges in the mesial temporal lobes may be associated with this symptomatology.[82] Ictal SPECT studies in patients with temporal lobe epilepsies have shown that loss of consciousness was associated with hyperperfusion of brainstem structures as a result of spread of epileptic activity.[114] Although some invasive recordings can reveal highly localized seizure onset zones, it has to be kept in mind that invasive studies only record from a very limited region of the brain.

Theoretically, the degree of arrest of motor activity and loss of consciousness may be a reflection of the volume of cortex involved in the seizure discharge. It is conceivable that motor activity may be inhibited either by epileptic activity excerting an interference on the function of primary motor cortex or epileptic activation of negative motor areas which both lie within the frontal lobe. Source analysis of generalized spike-wave complexes seen with dialeptic seizures in patients with generalized epilepsies points to the frontal lobes.[115] Alternatively, arrest of motor activity could be an expression of the loss of consciousness. However, as mentioned before, preserved perception associated with inhibited motor activity has been documented.[116] On the other hand disturbed perception with preservation of some automatic motor activity has also been observed. It therefore seems unlikely that consciousness and motor activity are disturbed by the same mechanisms.

Illustrative patient

This 16-year-old girl has had epilepsy since the age of 14 years. The seizures were characterized by loss of responsiveness and arrest of behavior. Sometimes, her dialeptic seizures were heralded by an aura sensation of vague strangeness or familiarity (psychic aura). Postictally, she had difficulty naming objects but she could describe the use of the objects. The postictal aphasia points to seizure onset in the dominant hemisphere. Ictal EEG showed left temporal seizure pattern. Interictally, the EEG showed spikes and continuous slowing in the left temporal region. MRI showed a low grade astrocytoma in the anterior part of the left inferior temporal gyrus and ipsilateral mesial temporal sclerosis. The patient underwent a left anterior temporal resection including the tumor and remained seizure free for 5 years' follow-up.

Localizing and lateralizing significance

The above-mentioned semiological features of dialeptic seizures allow to some extent to identify the epilepsy syndrome and thus the epileptogenic zone. The semiology of dialeptic seizures may provide some clues as to the epilepsy syndrome: shorter duration (< 20 s) is more likely to occur in generalized epilepsy as compared to focal epilepsy.[22] Typically additional clinical factors are helpful like for instance the pyknoleptic occurrence of brief dialeptic seizures in a neurological normal child of school age which is highly suggestive of absence epilepsy. Pyknoleptic appearance was extremely rare in focal epilepsy.[22] Since, by definition, little additional clinical features are associated with dialeptic seizure it is not surprising that the analysis of these phenomena provides few criteria for differentiation between different epilepsy syndromes. Blinking seems to be significantly more frequent in generalized epilepsy than focal epilepsy.[22] The evolution of dialeptic seizures is important for localization and lateralization. If dialeptic seizures are preceded by an aura this fact clearly points to a focal epilepsy and the characteristics of the aura are crucial for further localization. There is scant data on which and how often lateralizing features occur during dialeptic seizures. Somatosensory auras would favor a seizure onset in the paracentral region, or abdominal auras a temporal seizure onset.[117] Unilateral clonic seizures which evolved into dialeptic seizure have been reported, but the epileptogenic zone in this patient was most likely rather diffuse as documented by EEG and multiple other seizure types.[24]

The seizure evolution following a dialeptic seizure is also important: dialeptic seizures which evolve into hypermotor or tonic seizures are highly suggestive of a frontal seizure onset. Automotor seizures of patients with temporal lobe epilepsy frequently show some motionless stare at seizure onset.[21] This evolution is typical for automotor seizures and should not be classified as dialeptic seizure→ automotor.[2,118]

Postictal phenomena, such as postictal aphasia, point to a seizure onset in the dominant hemisphere as shown in the illustrative patient. We observed a few versive seizures following dialeptic seizures which arose contralateral to the direction of the version.[119] Other lateralizing phenomena, such as postictal coughing,[120] ipsilateral nose wiping,[121] sign of four,[122] ictal vomiting,[123] and unilateral blinking [124,125] occur probably rarely, if at all, during dialeptic seizures but no data is available of the frequency and lateralizing significance in the setting of dialeptic seizures.

54a Special seizures: localizing and lateralizing value

SR Benbadis

Introduction

'Special seizures' are, in the semiologic seizure classification, those that cannot be classified in any of the other broad categories[1] (see Chapter 34 in this volume). Thus, by definition, these seizures do not meet criteria for *auras*, *autonomic seizures*, *dialeptic seizures*, or *motor seizures*. In general, special seizures represent *negative* phenomena, which makes them unusual or 'special' among epileptic seizures. Special seizures include atonic seizures, astatic seizures, hypomotor seizures, akinetic seizures, negative myoclonic seizures, and aphasic seizures (see Chapter 32 in this book).

Astatic and hypomotor seizures

These two categories of special seizures, like others in the semiologic classification, are defined by the predominant phenomenology. What they have in common is that they are also defined by the *inability to characterize the mechanism of the symptoms due to lack of information*. Thus, they do not represent unique or specific seizure types and do not have a clear localizing value.

- *Astatic seizures* are seizures whose salient feature is a fall, but in which the mechanism of the fall cannot be further categorized. Thus, this category is most useful when there are incomplete data, e.g., history only or infants. If the predominant historical feature is a fall and there is no further useful information, this category (astatic seizure) is used. When more data are available, especially video-EEG recordings, more a specific seizure type should be identified in most cases. Seizure types that can result in a fall include tonic, atonic, GTC, and (more rarely) myoclonic seizures. Again, these are usually relatively easily identified with video-EEG monitoring. In occasional situations where the seizure cannot be more precisely classified even on video-EEG it is usually because they represent a 'mixture' of myoclonic, tonic, and atonic features[2]. These are usually seen in patients with symptomatic generalized epilepsies of the Lennox-Gastaut type (see tonic seizures in Chapter 53 and atonic seizures below), and in myoclonic astatic epilepsy of early childhood (Doose syndrome).[2]
- *Hypomotor seizures* are those whose salient feature is immobility or a reduction in movements. As for astatic seizures, this category is most useful when there is incomplete data, e.g., history only. If the predominant historical feature is immobility and there is no further useful information, this category (hypomotor seizure) is used. More specific seizure types that can result in a hypomotor behavior include auras (by way of distress or distractibility), dialeptic seizures (where the predominant manifestation is an alteration of consciousness), and negative myoclonic or akinetic seizures (see below), and these can be identified more precisely with video-EEG recordings. Probably the common justified use of this category is in infants and young children where consciousness cannot be assessed. In fact, in this age group hypomotor seizures are likely a bland form of 'complex partial' seizures with no or minimal automatisms.[3]

Atonic seizures

Atonic seizures are defined by loss of postural tone. This is usually abrupt and results in a fall, complete or incomplete depending on severity and the patient's position. They frequently result in injuries.

Atonic seizures are seen almost exclusively in patients with symptomatic generalized epilepsies of the Lennox-Gastaut type, so their 'localizating value' is that they are usually... generalized. Atonic seizures are, in fact, a type of generalized seizures in the ILAE seizure classification,[4] and are typically accompanied, ictally, by generalized seizure patterns such as electrodecrement, paroxysmal fast activity, or spike-wave complexes. There is some evidence for a symptomatogenic zone in deep (nonrespectable) structures such as the brainstem reticular formation[5,6] or the thalamus.[7] Atonic seizures are considered relatively common in the symptomatic generalized epilepsies of the Lennox-Gastaut type because seizures that cause falls are often assumed to be atonic. However, careful video analysis shows that the majority of epileptic falls are tonic rather than atonic.[6, 8] Often it is not completely clear that it is 'atonia' that is causing the fall, and it is instead a mixture (or sequence) of myoclonic, tonic and atonic phenomena.

Atonic seizures can, rarely, be seen in focal epilepsy but this has not been clearly documented.[9] However, even in patients with focal epilepsy (e.g., secondary to a focal cortical dysplasia), ictal SPECT recordings point to a strong inhibition in the *bilateral* motor cortexes.[10] From a practical point of view,

atonic seizures do not a have a reliable localizing value for purposes of resective surgery, and their presence should, generally, argue against pursuing resective surgery.

Akinetic seizures and negative myoclonic seizures (epileptic negative myoclonus)

That electrical stimulation of the cortex can inhibit movements has been known since the seminal work of Penfield and Jasper.[11] More recent studies showed that electrical stimulation of two regions in the frontal lobe elicit inability to initiate or maintain voluntary movements.[12–15] The *primary negative motor area* lies in the inferior frontal gyrus, immediately anterior to the motor face area, close to (and often overlapping with) Broca's area on the dominant side. The *supplementary negative motor area* is anterior to the face region of the supplementary sensorimotor area. Electrical activation of these negative motor areas may produce focal as well as bilateral inability to perform voluntary movements.[12,13] The fact that responses to electrical stimulation are often bilateral makes these seizures difficult to lateralize on clinical (semiologic) grounds. Studies in primates support observations documenting two similar negative motor areas in the frontal lobe.[12] Premotor and primary somatosensory cortex xan also produce (contralateral) negative motor responses.[16,17] Epileptic myoclonus is referred to as 'pure' when it is not immediately preceded by positive myoclonus, enhancement of EMG, or a motor evoked potential.[16] There is good evidence that the presence or absence of an antecedent positive motor phenomenon depends partly on stimulus intensity, except for the SMA where pure silent periods are obtained regardless of stimulus intensity.[16]

Akinetic seizures

Akinetic seizures are defined, in the semiologic classification, by the inability to perform voluntary movements, not due to loss of consciousness (which would make it a dialeptic seizure), or loss of muscle tone (which would make it an atonic seizure). It should be pointed out that the term 'akinetic seizures' has different meanings outside of the semiologic classification. A longer duration (several seconds) differentiates it from negative myoclonic seizures, which are much briefer (see below). Akinetic seizures have been reported under other names such as ictal paresis[18] and hemiparetic seizures.[19]

The symptomatogenic zone for akinetic seizures is most likely the primary or supplementary negative motor areas, as can be demonstrated by video-EEG recordings[20] and confirmed by electrical cortical stimulation.[12–15] Akinetic seizures most often affect distal (hand) muscles. Because of their proximity, the primary motor area are often simultaneously activated, producing clonic jerking of the face or tongue at the same time.

Negative myoclonic seizures (epileptic negative myoclonus)

Negative myoclonic seizures are *brief* (often 30–50 msec but by definition < 500 msec) episodes of muscle atonia, and can be viewed as the brief (sporadic) version of akinetic seizures. They can in fact be elicited by electrical stimulation using single or low frequency (1 Hz) stimulation.[16] This is analogous, on the 'positive' side, to myoclonic seizures being the brief (sporadic) version of clonic seizures. They are only clinically apparent if the muscles in question are tonically used at the time (for example, outstretched hands). The muscle atonia can be documented by a silent period on EMG, which is identical whether the negative myoclonus is epileptic or nonepileptic such as asterixis.

The epileptic nature of a negative myoclonus, and its symptomatogenic zone, can be documented by its time-locked association to an epileptiform EEG discharge (spike or sharp wave), which typically occurs 15–50 msec prior to the EMG inhibition.[21–25] Since negative myoclonic seizures are essentially the brief (sporadic) version of akinetic seizures, their localizing value (or lack thereof) is similar, pointing to the negative motor areas mentioned above: premotor cortex[16] post-central primary somatosensory,[16] primary[2,23] and supplementary negative motor area (dorsolateral frontal).[26,27] In keeping with this, when epileptic negative myoclonus is seen in association with clear surface EEG abnormalities, the phenotype resembles benign childhood epilepsy with Rolandic spikes.[28]

Aphasic seizures

Various speech disturbances can occur during seizures.[29–31] Ictal aphasia (or dysphasia) is found in about 30% of patients with temporal lobe epilepsy.[29,32] However, the term 'aphasic seizures' should be reserved for seizures in which aphasia is the *predominant* ictal symptom, and such seizures are relatively rare (the vast majority of aphasias are caused by head injury, stroke and dementia). In the International Classification of Epileptic Seizures, 'dysphasic seizures' are found under 'simple partial' seizures (with psychic symptoms), which is appropriate, since by definition aphasia requires intact consciousness. Confusingly, however, it is also stated that these seizures more commonly occur as 'complex partial' seizures.[4]

Studies of electrical cortical stimulation have identified four language areas: Broca's, Wernicke's and supplementary motor areas have been known since the work of Penfield and associates,[33,11] while the basal temporal language area was described more recently.[34–36] Identifying a language disturbance during electrical cortical stimulation requires a meticulous methodology to exclude speech impairment caused by nonspecific motor phenomena (positive, negative or apraxic).[34,35] Identifying aphasia during seizures is fraught with the same difficulties, as it requires a *selective* impairment of language. Consciousness and awareness should be intact. If a patient has a more global impairment or is mute, aphasia may well be present but cannot be identified. As pointed out above, ictal aphasia may be difficult to elicit and diagnose in typical short-lived seizures. Thus, while some reports on ictal aphasia include cases of sporadic seizures,[37–42] the majority describe cases of status epilepticus.[43–51]

Types of aphasia include Wernicke, conduction, anomic, and isolation (transcortical) aphasia.[52] However, due to short seizure duration and concomitant symptoms, such complex classification is not possible for ictal aphasia. From a practical

point of view, ascertaining the presence of a true language disturbances, rather than a nonspecific motor phenomenon (e.g., speech arrest) or a more global alteration in consciousness, is the crucial step. The basic dichotomy (i.e., anterior/Broca/expressive/nonfluent vs. posterior/Wernicke/receptive/fluent) is realistically practical for seizures, and consistent with the early reports of ictal dysphasia.[32] The easiest type to identify ictally is the anterior type (Broca, nonfluent, expressive,). The posterior type (Wernicke, receptive, fluent) is more difficult to distinguish from less specific alteration of awareness. Further subtypes cannot realistically be identified ictally, which is unimportant since the type of aphasia does not reliably predict the lobe or region of seizure onset.[30] The fact that *subtypes* of aphasia have no specific localizing value is quite consistent with the findings of cortical stimulations, where the type of aphasia may change with the stimulus intensity, and where stimulation of Broca, Wernicke, and basal temporal language areas produces relatively similar deficits.[35]

Localizing value

Most patients with documented aphasic seizures have temporal lobe epilepsy, but this most likely reflects the predominance of such patients in monitoring units. In the only sizeable series of patients with ictal aphasia,[32] 30 of 34 patients (88%) had left temporal lobe epilepsy (defined preoperatively). Of 17 patients with definite localization (i.e., became seizurefree after temporal lobectomy) and ictal aphasia, 16 (94%) had left temporal lobe seizures. Ictal aphasia can occur in seizures arising from almost any lobe, including frontal, fronto-temporal, centro-parietal, parietal, temporo-parietal, posterior lateral temporal, and temporo-occipital.[37,40,45,47,50,51,49,53,55] This is not surprising if one considers the four language areas defined by electrical stimulations. Furthermore, the presence of ictal aphasia in seizures of various origin is also in keeping with the important concept that distinguishes between epileptogenic zone and symptomatogenic zone[56]; in brief, epileptogenic zones in various locations may be in silent cortex but produce discharges which spread to one or more language areas. In additional to the 'classical' language areas, there is also convincing evidence incriminating the basal temporal language area.[30,37,38,43]

Ictal aphasia as a lateralizing sign

By contrast, regardless of the lobe, the *lateralizing* value of ictal aphasia is excellent, with nondominant seizures being exceptional. Ictal aphasia was seen in two seizures arising from the nondominant hemisphere (in one patient) in the series of Gabr *et al.*,[29] and in that patient aphasia was limited to paraphasia. One similar exception was reported in the series by Serafetinides and Falconer[32]; although the patient had ictal aphasia and proven right temporal lobe epilepsy (by seizure-freedom after temporal lobectomy), language dominance had not been determined by Wada testing, and the patient may have been right-hemisphere dominant. Thus, when present, the lateralizing value of ictal aphasia is high, and seems to be comparable to that of postictal aphasia, which is 92–100%.[29,57]

54b Secondary generalized tonic-clonic seizures

SD Lhatoo and HO Lüders

Introduction

Secondary generalized tonic-clonic seizures (SGTCS) are a common occurrence in the video-monitoring phase of the presurgical assessment of focal epilepsies, although in contrast to primary generalized tonic clonic seizures (PGTCS), the rather scanty literature available on their semiology and pathophysiology belies this. To date, the most authoritative work on generalized tonic clonic seizures (GTCS) has been the description provided by Gastaut and Broughton in their influential monograph *Epileptic Seizures: Clinical and Electrographic Features, Diagnosis and Treatment*. Modern epilepsy semiology literature is reliant on their observations and the few contemporary analyses that exist use their description as a benchmark. Gastaut and Broughton acknowledged the difficulty in distinguishing PGTCS from SGTCS when seizures were clinically generalized at onset, a conundrum that has not completely diminished since then, and thus their classical account of the generalized tonic-clonic seizure appears to present a composite of mainly 'grand mal' primary but also secondary generalized tonic-clonic seizures. However, certain semiological features often differ and may be of critical value in the distinction of one from another. Furthermore, these features may have a lateralizing value that complements the other facets of presurgical assessment.

Semiology of the SGTCS

Gastaut and Broughton's work provides exquisite detail on the semiology and pathophysiology of GTCS with detailed descriptions of electroencephalography, electrocardiography, electrodermography, sphygmomanometry, pupillary measurement, intravesical pressure measurements, and audiometry and spirometry. They divided the various phases of the GTCS into:

1. preictal manifestations
2. the ictal phase
   a. the tonic phase (including an 'intermediate vibratory period')
   b. the clonic phase
   c. (concurrent) Autonomic changes
3. immediate postictal features
4. late postictal features

It is the first two phases–the preictal phase and the ictal phase, that are of greatest semiological interest, mainly because of the clinical information that they provide as an aid to seizure localization and lateralization. The later phases of the SGTCS are less likely to yield significant information.

The preictal 'myoclonic' phase (such as occurs in juvenile myoclonic epilepsy (JME)) was thought to occur in the majority and constituted a 'succession of brief, bilateral and massive muscle contractions which usually last a total of several seconds ... frequently accompanied by a spasmodic cry'. The tonic phase, accompanied by loss of consciousness, was characterized by a brief phase in flexion followed by a longer one in extension, in all lasting ten to twenty seconds. A typical flexion was described as one similar to the response to the command 'Put up your hands!' with shoulder elevation, arm elevation and the elbow semiflexion. The lower limbs were described as being less involved but often with flexion, abduction and external rotation of the thighs and legs, completing an emprosthotonic posture (Figure 54b.1).

This tonic flexion was followed by tonic extension into an opisthotonic position (Figure 54b.2). Contraction of the thoraco-abdominal musculature produced the 'tonic epileptic cry'. The arms became semiflexed in front of the chest but also at times became extended, with forearm pronation and either wrist flexion and finger extension or wrist extension and fist clenching. The legs went into forced extension, adduction and external rotation along with extension of the feet and toes into a Babinski-like posture. This 'tetanic' phase subsequently became less complete and the rigidity was replaced by a fine tremor that grew in amplitude and slowed in frequency from 8 per second to 4 per second because of recurrent decreases in muscle tone–a so-called 'intermediate vibratory period'.

The clonic phase lasted about 30 seconds and was said to occur when each of the recurrent muscular contractions responsible for the vibratory phase became sufficiently prolonged to completely interrupt the tonic contraction, the resultant flexor spasms of the entire body appearing to resemble an 'an epileptic form of bilateral myoclonus'. This myoclonus progressively slowed until seizure cessation. Variations to this entire theme were considered occasional and unusual. Asynchrony between two sides during the tonic or clonic phases was one such deviation. This asynchrony could be clinical or only evident on EMG recordings when clinically unnoticed.

Lateralization in the initial phase of the SGTCS

Two important studies have addressed the issue of the importance of two semiological features at the onset of secondary

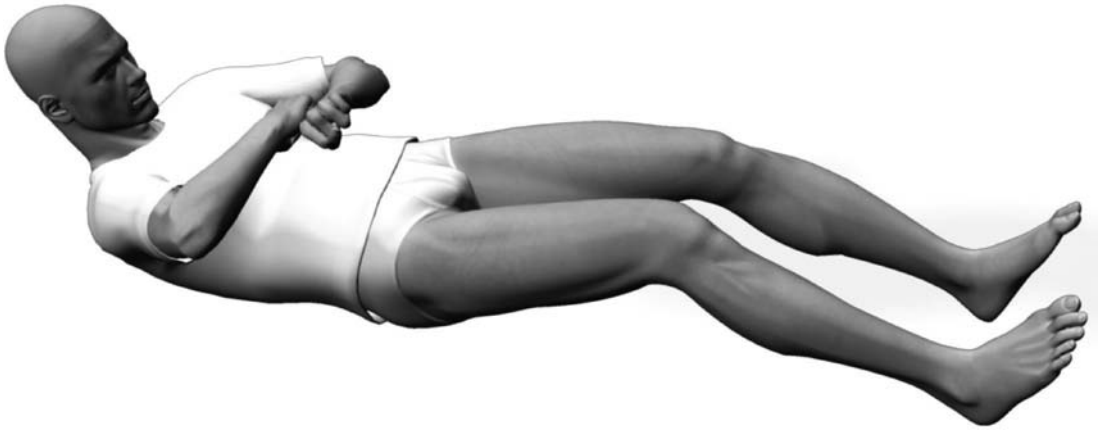

Figure 54b.1 The flexion or 'emprosthotonic' posture.

generalization in focal epilepsies that can be an invaluable aid to lateralization. Wyllie *et al.*[2] studied head version in 61 seizures in 27 patients and reported that this occurred contralateral to the hemisphere of seizure onset in all patients. It is important to emphasize here that the definition of head version is crucial to correct lateralization. Only forced and prolonged head turning, usually in a clonic motion with the chin pointing upwards, with eye version to the same side as head version allows precise lateralization (Figure 54b.3). Very frequently, such a version is also accompanied by pulling of the face towards the contralateral, clonic, twitching side.

Kotagal *et al.*[3] reported the 'sign of 4' or the 'figure 4 sign' where the elbow contralateral to the hemisphere of seizure onset extends and the ipsilateral elbow flexes over the chest to produce an upper limbs posture that resembles a figure 4. (Figure 54b.1). In a study that looked at 39 patients with focal epilepsy, correct lateralization with this sign was seen in 90%. Other studies have subsequently confirmed the clinical utility of this sign.

However, both head version and the sign of 4 are unreliable signs once the seizure is well established and their main value is derived at the onset of generalization when they are less likely to represent symptomatology remote from the ictal onset zone.

Lateralization in the SGTCS and seizure progression

A few studies have since examined the progression of the SGTCS (Table 54b.1). A study from Bethesda, Maryland in 1994[4] presented a videotape analysis of 120 SGTCS in 47 patients with focal epilepsy with an age range between 11 and 56 years. Seizure semiology analysis was carried out jointly by three observers and the generalized phase was divided into five phases that constituted onset of generalization, pretonic clonic, tonic, tremulousness and clonic phases. Eighty-four percent of the seizures had the 'onset' phase characterized by vocalization, head version or some form of movement, 48% had a pretonic clonic phase where patients had irregular and asymmetric jerking, 95% a tonic phase and 98% a clonic phase. Only 27% of these seizures exhibited all five phases. The authors noted that generalization was not uniform or symmetric and noted the marked heterogeneity in GTCS phenomenology. Another study that examined SGTCS progression in temporal lobe epilepsy patients in 2001[5] found the classically described sequence of progression in only half their patients and in a third, a clonic phase preceded the tonic and in a quarter, the progression was one of tonic to clonic to tonic. Asynchrony in the clonic phase was noted in only two patients.

An unblinded videotape analysis from Nashville, Tennessee in 1999[6] compared ten GTCS in nine patients with idiopathic generalized epilepsy and ten GTCS in ten patients with temporal lobe epilepsy. Interestingly, (and this has been noted by subsequent studies), focal features were seen before generalization in seven idiopathic generalized seizures, most commonly comprising head turning, in one patient occurring in different directions in two different seizures. The authors noted that the tonic phase was always symmetric but that in the last generalized

Figure 54b.2 The extension or (opisthotonic) posture.

Figure 54b.3 The sign of 4 with right elbow extension indicating left hemisphere seizure onset. Also notice version of the head to the right.

clonic phase, asymmetry or asynchrony of motor activity was seen transiently in three seizures. In contrast, in the temporal lobe epilepsy patients, focal tonic activity occurred in four seizures, with variable lateralization and there was asymmetric or asynchronous activity in the clonic phase in eight seizures. Seizure progression in these patients was tonic to clonic in eight, clonic to tonic to clonic in one and only clonic in one.

A 2003 study from Calgary[7] attempted to distinguish primary from SGTCS in children aged 18 months to 17 years by examining 64 GTCS in 13 children with medically refractory epilepsy. The study highlighted mouth movements and motor activity following clinical and EEG seizure end as distinctive features of the SGTCS, although these conclusions and their value in clinical practice is debatable. However, these authors also noted the asymmetry in arm movements in seven out of 12 children and in leg movements in nine out of 12 children during secondary generalization. In five patients, seizure activity continued on one side, with varying lateralization.

Thus, no reliable clinical features appear to lateralize the hemisphere of seizure onset once the seizure is well under way. This is not surprising, given that the seizure has propagated to areas distant from the ictal onset zone.

Lateralization in the latter phase of the SGTCS

Two studies have examined lateralization during seizure termination in temporal lobe epilepsy. They found that in 80–83% of seizures that ended in an asynchronous fashion, the final clonic movements occurred on the side ipsilateral to the hemisphere of seizure onset.[8,9] This may reflect on earlier seizure cessation in the hemisphere of seizure onset due to factors such as neuronal fatigue, an exhaustion of excitatory processes, or a predominance of inhibitory processes. The marked slowing usually seen on scalp-EEG during this phase in the hemisphere ipsilateral to the paradoxical movements lends support to this. Paradoxical movements are most likely to be generated in the contralateral cortex and propagated by the pyramidal tract, rather than originating in the brainstem, not least because there is a clear relationship between ipsilateral cortical discharges and strictly contralateral clonic signs. There appears to be some lateralizing value to this sign although it is important to emphasize that the seizure should always be viewed in its entirety and the value of lateralizing signs at seizure onset outweigh the importance of phenomena that occur during or towards the end of seizures.

Two common themes emerge from these studies. Firstly, that there is considerable heterogeneity in seizure progression during the phase of secondary generalization as compared to Gastaut's classical description and secondly, there is asynchrony (disparity of rhythm between the two sides) and/or asymmetry (disparity in amplitude of limb movement between the two sides) during the seizure in a substantial proportion of patients. Contrary to the caution required in interpreting late ictal phenomena, forced head version immediately prior to the onset of secondary generalization and the asymmetric 'sign of 4' tonic posturing at the onset of the SGTCS are known to be useful lateralizing features where head version or elbow extension in the sign of 4 occur contralateral to the hemisphere of seizure onset.[3] However, there is literature to suggest that focal features also arise in the GTCS of idiopathic generalized epilepsy, although definitions of head version for example, may differ in their interpretation.[10]

The Cleveland Clinic experience

In our own semiological analysis of 24 SGTCS in 14 patients (12 male, two female) aged 9–39 years who underwent

MCD – malformation of clinical development; DNET – dysembryoplastic neuroepithelial tumor.

video-EEG monitoring as part of their presurgical investigation for medically refractory focal epilepsy, we found confirmation of some of the clinical features described in the literature. All 14 patients had invasive evaluations with subdural grid electrodes and/or depth electrodes. The duration of epilepsy ranged from 1–22 years. Clinical details are provided in Table 54b.2. In each case, the epilepsy diagnosis was made with on the basis of semiology, MR as well as functional imaging, interictal and ictal EEG findings.

Seizure semiology was studied from the point of onset of secondary generalization. We employed a practical definition for generalization as that clinical stage where there was clear evidence of bilateral motor arm and/or leg involvement along with complete loss of consciousness. Thus, we did not include head or eye version in this definition. Mode of onset, progression of generalization, duration of various motor stages, symmetry of seizures, synchrony of the clonic phase, and the presence or absence of paradoxical lateralization were all studied. Asymmetry was defined as a greater than 50% difference in amplitude of movement between the two sides of the body. Asynchrony was defined as a clear difference in the rhythm of movement between the two sides of the body. Table 54b.3 summarizes these findings.

14.	AST	A	No	A	Yes	Yes

AST – asymmetric tonic; ST – symmetric tonic; S – symmetric; A – asymmetric.

Seizure onset

The sign of 4 was seen in eight (seven patients) of 24 (33%) seizures. In seven of these seizures (87.5%), it predicted the side of seizure onset correctly, with arm extension contralateral to the side of seizure onset. In one patient, two further seizures occurred without a sign of 4, suggesting that this does not consistently occur in all seizures in the same patients. In 6/24 (25%) seizures, there was an asymmetric tonic onset to the seizures that did not amount to a sign of 4. In 6/24 (25%), there was a symmetric tonic onset to the generalization. In 4/24 (17%) there was a clonic onset that was asymmetric in all.

Seizure progression

Progression of generalization through various phases also varied. In 13/24 seizures (54%), there was a tonic phase followed by the vibratory phase, followed by a clonic phase. In 6/24 seizures (25%), there was no intervening vibratory phase. In one patient, there was progression from a tonic to a focal arm clonic phase. The clonic to tonic to clonic progression noted by Gastaut was seen in only 3/24 (13%) of seizures and in one patient, the seizure remained clonic throughout. All seizures had a clonic phase.

The tonic phase

During the tonic phase, the dominant posture varied with different patients and with different seizures in the same patients. These postures could be categorized into the following types:

1. Type 1 (35%) The upper limbs were held in a position of shoulder adduction, elbow flexion, wrist flexion and finger flexion or extension. The lower limbs were held extended with plantar flexion. The neck was flexed (Figure 54b.4a).
2. Type 2 (26%) The body was held in the same position as in Type 1 but with persistent elbow extension rather than flexion (Figure 54b.4b).
3. Type 3 (9%) The body was held in the same position as in Type 1 but with hip and knee flexion rather than extension (Figure 54b.4c).
4. Type 4 (30%) The body was held in a position of bilateral asymmetric tonicity with upper and/or lower limb flexion on one side and upper and/or lower limb extension on the other (Figure 54b.4d).

The clonic phase and paradoxical lateralization

During the clonic phase, there were asymmetric movements in 13/24 seizures (54%) and asynchrony of limb movements in 15/24 of seizures (62%) (Video.1). During both the tonic phase as well as the clonic phase, asymmetry and/or asynchrony had no lateralizing value.

Focal clonic limb movements occurred at the end of the bilateral motor seizure in 8/24 seizures (33%) in seven patients. These comprised strictly unilateral arm clonic movements in seven and clonic movements of the face, arm and leg in one patient. In six (75%), these lateralizing movements occurred paradoxically ipsilateral to the side of seizure onset, a figure that is keeping with similar observations made by previous studies that have examined seizure termination in temporal lobe epilepsy.[8,9]

Thus, asymmetry and asynchrony at any stage of the secondary GTCS seems a common phenomenon. This is at variance with the primary GTCS, where symmetry and synchrony are more often found.[6] However, there are an increasing number of studies that report clinical as well as electroencephalographic focality in patients with primary GTCS. Usui *et al*[11] reported 26 patients with JME, only two of whom had both JME and a focal epilepsy. Of these patients, 46% had focal semiological features that included focal

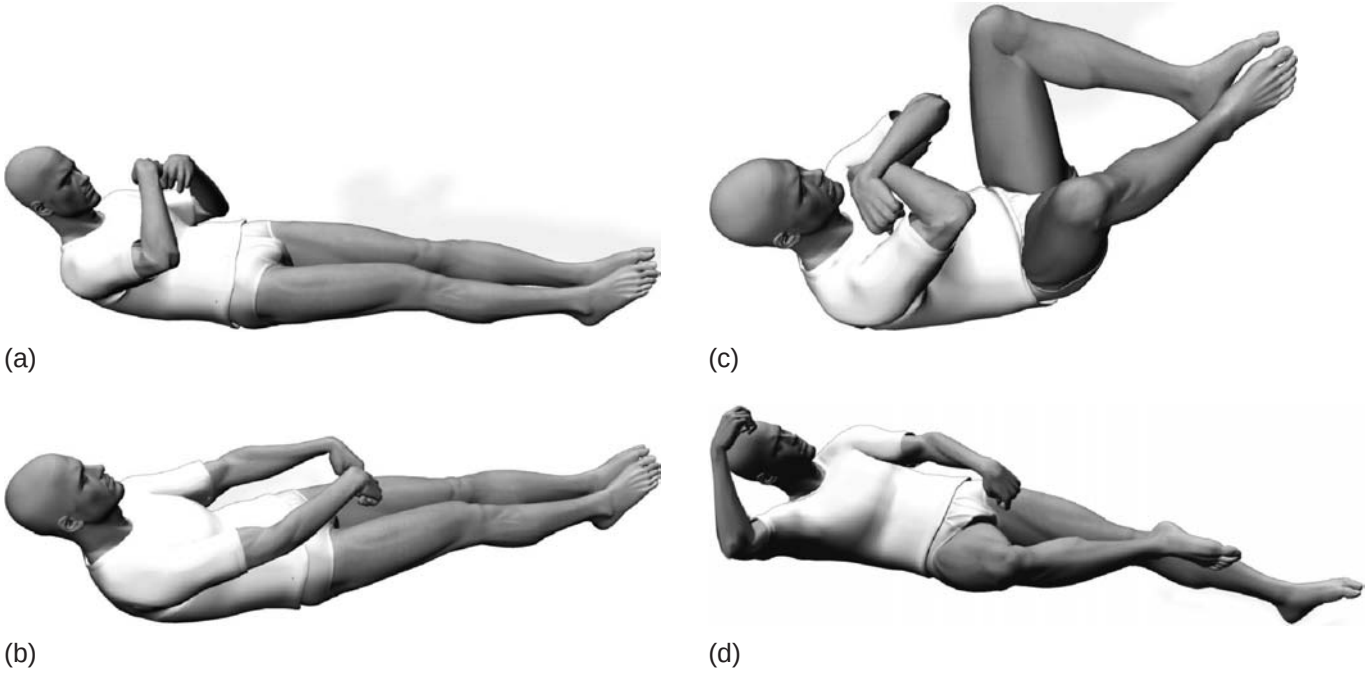

Figure 54b.4 (a–d) Dominant body postures during the tonic phase of the SGTCS.

myoclonus, sign of 4 tonic posturing, forced head version and left arm clonic movements. EEG seizures in these patients were all generalized at the onset, although in two patients with left head version at onset, the EEG lateralized to the right side during the seizure. It is likely, therefore, that primary and secondary GTCS represent a semiological spectrum where symmetry and synchrony are seen most often in primary GTCS, with increasing asymmetry and asynchrony across the continuum towards a typical secondary GTCS. (Figure 54b.5).

Pathophysiology of the secondary GTCS

Gastaut, commenting on asynchronous generalized seizures, speculated on the possibility of two independent unilateral seizures occurring, one in each hemisphere. The traditionally held view of ictal cortical activity during a generalized seizure is one of complete synchronization of widespread brain activity. Recently, there has been some debate whether this is true. Investigators have attempted to address these questions with human EEG analyses, both scalp as well as invasive, and with magnetoencephalography (MEG).[12–15]

Synchronization implies the agreement in time of a particular property of two dynamical systems, usually in the time and frequency domains, and biological synchronization (particularly phase synchronization) has been studied in various ways.[16] In the context of epilepsy, nearest-neighbor phase synchronization (NNPS) has been used in scalp EEGs as a means to more sensitive seizure detection.[15] Whilst synchronization of adjacent brain areas is a not a biologically counter-intuitive premise and the results are therefore not surprising, this method does not address the issue of distant brain synchronization during seizures. Furthermore, scalp EEG studies are subject to reference contamination and volume conduction artifacts, issues that may be particularly prominent during generalized seizures.

Le Van Quyen[13] used the Hilbert transform method and wavelet methods to analyze neural synchrony in a patient with mesial temporal lobe epilepsy undergoing a depth electrode evaluation. A contact each in the ipsilateral amygdala and hippocampus was used against an ear (scalp) electrode that was thought to be quiet. The raw data was digitized at 200 Hz and passed to a 32-channel amplifier system with band-pass filter settings of 0.5–99 Hz. Preseizure recordings showed phase relationship of neuronal activity in the 30–80 Hz range. At seizure onset, (presumably with a seizure that remained focal) there was a transition to synchrony in the 12–15 Hz and 3 Hz range. As the seizure progressed, there was synchrony in the 3 Hz range that persisted but there was strong desynchronization in the high frequency range. Following the seizure, there was synchrony again in the 30–80 Hz range. Thus, despite the relative proximity of the electrodes studied, there was some evidence of asynchrony. Another patient with orbitofrontal epilepsy was studied with subdural grids. Here, seizure onset was characterized by abrupt synchrony at 8–10 Hz followed by synchronies at 25–90 Hz. As the seizure progressed, there was a progressive decline in synchronization frequency. However, it is not clear if this patient had secondary generalization to the seizure and what precise electrodes, near or distant, showed asynchrony. Gotman in 1987[17] described interhemispheric interactions in focal seizures after examining the intracranial recordings of eight patients with epilepsy. They compared, where possible, homologous brain regions in each hemisphere and found that interhemispheric coherence or broadly, phase synchrony, was surprisingly low. However, sampling of brain areas was limited to a few depth electrodes and no data on the clinical semiology was presented. Other observers have made observations on pathological synchrony in epileptogenic brain in focal epilepsy through invasive recordings although again, conclusions are restricted by the limited areas covered by the electrode contacts.[14]

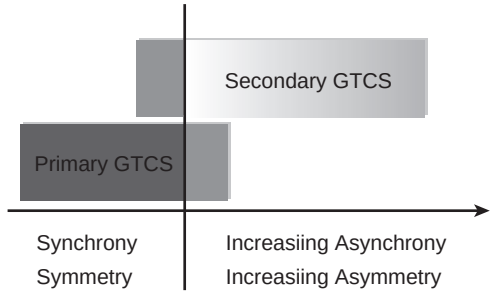

Figure 54b.5 The semiological spectrum of primary and secondary generalized tonic-clonic seizures.

A magneto-encephalographic study with scalp-EEG examined local and distant phase synchronization in generalized seizures.[12] Interestingly, distant synchronization was observed to be better in primary generalized absence seizures compared with secondarily generalized motor seizures in focal epilepsy, although in the latter, there was evidence of strong local synchrony in keeping with the scalp EEG data presented by van Putten.[15]

Thus, although it makes intuitive sense that there should be generalized synchrony in extended brain regions during generalized seizures, the true picture is less clear and there is evidence in the literature that significant asynchrony may occur in SGTCS. Patients undergoing invasive monitoring with subdural grids and/or depth electrodes provide an opportunity to examine these issues.

Brain synchrony in SGTCS and the concept of multiple simultaneous seizures

We analyzed the SGTCS of nine seizures in nine of the above patients who underwent an invasive presurgical evaluation for medically refractory epilepsy. Electrodes of seizure onset were screened and referenced to an uninvolved/artifact free intracranial electrode. Pre- and postoperative 3D MRI reconstruction was used with data from somatosensory evoked potentials and cortical electrical stimulation to determine the position of the central sulcus in order to locate electrodes over the motor strip. These were screened and referenced to an uninvolved/artifact free intracranial electrode. The seizure patterns at onset and during each phase of the secondary

GTCS were analyzed with particular emphasis on synchrony of EEG rhythms. Synchrony was not defined quantitatively but in practical terms as the consistent agreement in time and/or frequency between the electrical activities of one brain region with another.

Results of the analysis of synchrony are detailed in Table 54b.4. Synchrony between the motor strip and the brain region of seizure onset was seen only in three patients (33%), one during the tonic phase only and too during the clonic phase only. Thus, in the majority of patients, there was a clear asynchrony with very different seizure rhythms occurring in the two hemispheres or even within one hemisphere. This appeared to confirm Gastaut's suspicion that there is indeed more than one seizure occurring in the brain during a generalized seizure. In patient 1 for example (Figures 54b.6–8), where there is coverage of both motor strips as well as of the region of seizure onset. A clear difference in seizure rhythms can be visualized between the frontal lobes on either side and between the frontal lobe and temporal lobe in the hemisphere of seizure onset.

Thus, synchronization of brain regions does not appear to be necessary during SGTCS. Indeed, different seizures appear to occur simultaneously in different brain regions during the same clinical seizure.

Seizure generation and seizure modulation; the roles of cortex and brainstem

As is evident from discussions elsewhere in this book, there is robust animal evidence of brainstem seizure generation. However, it is far from clear that the same is true in humans. It appears likely however, that involvement of the cortex is critical to seizure generation. In all our patients, clinical seizure end always preceded EEG seizure end, suggesting that for the production of clinical seizure symptoms, a cortical discharge is always necessary, unlike the situation with brainstem seizure generation for example, where clinical symptoms could be expected to occur in the absence of cortical discharge. However, it is extremely likely that the brainstem plays an important part in the modulation of the secondary GTCS. Whilst it is easy to visualize the corticospinal tract as the main pathway for the clinical motor expression of the cortical seizure discharge, there are several other pathways that originate in the frontal cortex that relay in the human brainstem. These include projections to the brainstem reticular nuclei, the vestibular nuclei, the superior colliculus, the red nucleus, and the olivary nuclei, amongst others. There are interneuronal connections between these structures in the

brainstem that probably form networks as part of central pattern generators. From here, the vestibulospinal and reticulospinal tracts project downwards into the spinal cord and are likely candidates for the structures that subserve the variability in tonic posturing that is seen with the secondary GTCS. The vestibulospinal tract for example, produces upper limb flexion and lower limb extension whereas the reticulospinal tract produces the converse.

Patients who have undergone anatomical hemispherectomies may provide the best human evidence of brainstem seizure modulation. Video 2 demonstrates a generalized tonic-clonic seizure in a 3½-year-old posthemispherectomy patient who has no residual cortex on the right side. The patient first presented with infantile spasms from birth due to an extensive right hemispheric malformation of cortical development. A right functional hemispherectomy was carried out with removal of the pericentral and temporal cortices. Following this, the patient continued to have medically refractory seizures although these were now left arm tonic seizures evolving into bilateral asymmetric tonic seizures and generalized clonic seizures, indicating a right frontal lobe onset. An anatomical hemispherectomy was then carried out with complete removal of all cortical structures. Following this surgery, the patient continued to have seizures that now originated from the left frontal region as shown in Figure 54b.9.

As evidenced from the video, the tonic and clonic manifestations of the seizure are very symmetric in their expression, rendering it unlikely that the uncrossed ipsilateral corticospinal tract or the ipsilateral supplementary motor cortex have a role in their generation. Both these pathways have a clear predominance of contralateral projections and therefore tend to produce either strictly or predominantly contralateral motor seizures. Therefore, it is more probable that the ipsilateral cortical seizure discharge is being modulated in the brainstem to produce bilateral motor phenomena expressed through the vestibulospinal and/or reticulospinal tracts.

Conclusions

In summary, the semiology of the secondary GTCS is phenomenologically heterogeneous, with asynchrony and asymmetry displayed prominently in a substantial proportion of seizures, unlike the GTCS of primary generalized epilepsy where seizures are mostly synchronous and symmetric. Clinical asynchrony and asymmetry are accompanied by electrical asynchrony in the majority of patients as evidenced by the study of seizure rhythms in patients with secondary GTCS

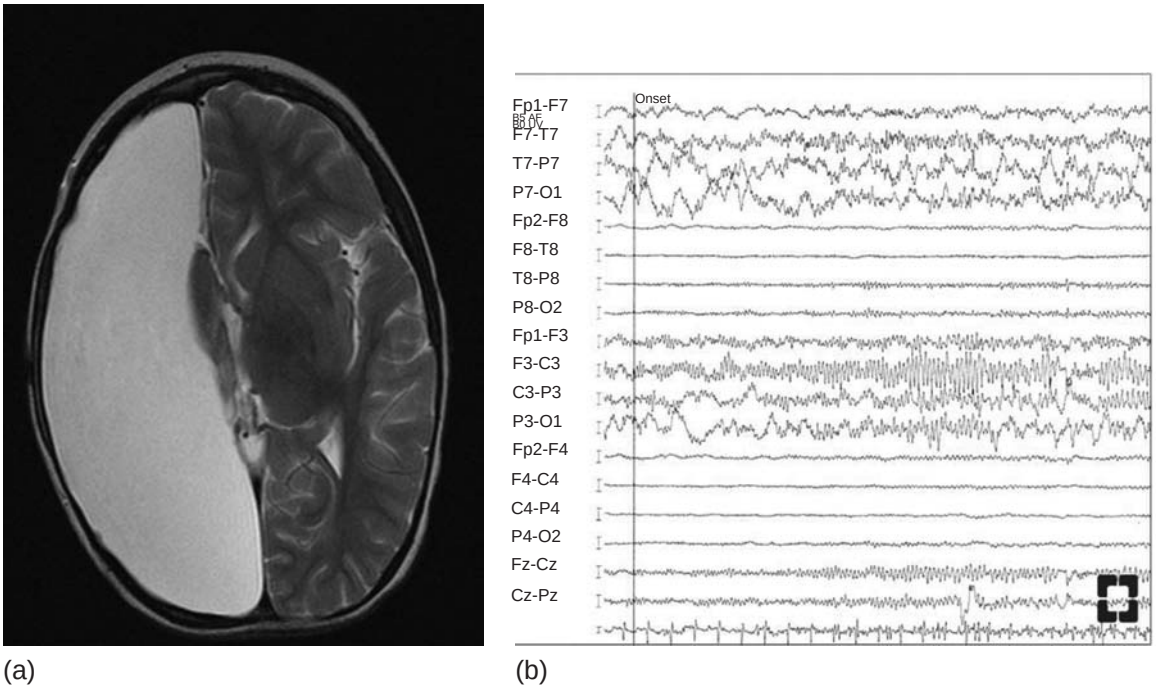

Figure 54b.9 MRI Brain image of patient with right anatomical hemispherectomy. EEG showing seizure onset in the left frontal region.

undergoing invasive evaluations. Electrical synchronization of brain activity does not appear necessary in secondary GTCS and indeed, there may be more than one seizure occurring in different brain regions at the same time. In humans, seizure generation is most likely to occur only in the cortex, although evidence from patients who have undergone anatomical hemispherectomies strongly suggests that significant seizure modulation takes place in the brainstem. Thus, both areas of the brain (cortex and brainstem) are important in the shaping of the semiology of the secondary GTCS.

SECTION 6

The irritative zone

55 The irritative zone: general principles

M Eccher and D Nair

Introduction

There are various cortical zones in epilepsy that have been defined in order to service as tools to aid in the presurgical evaluation for epilepsy surgery. One of these zones is the irritative zone which has been defined as that region of cortex which generates interictal epileptiform discharges. The presence of interictal spikes is a hallmark of epilepsy and often used in corroborating the diagnosis.[1,2] In addition, the characteristics of the interictal epileptiform activity can also aid in defining the epilepsy syndrome, such as differentiating focal from generalized epilepsy. in some situations. The irritative zone can be measured by a variety of means: surface and invasive EEG with visual analysis or dipole source modeling of EEG, magnetoencephalography (MEG), and EEG spike triggered functional magnetic resonance imaging (fMRI). The reason to pursue accurate measurement of these cortical zones including the irritative zone is to define the epileptogenic zone in a particular patient. The epileptogenic zone is a theoretical concept but its estimation is a prerequisite in planning of successful resective epilepsy surgery.

Factors affecting the irritative zone

The irritative zones can be affected by a number of factors: the type epilepsy syndrome, the conscious state of the patient, changes in temperature, age, presence of anesthesia, and use of anticonvulsants etc. One of the clearest examples of the variance of epileptiform activity based on a change in the state in a pediatric patient is electrical status epilepticus during slow wave sleep[3] which demonstrates a dramatic change of spikes frequency from the awake to a sleep state. In many focal epilepsy syndromes NREM sleep may increase the frequency of interictal epileptiform activity in both adult as well as pediatric age groups. In some children with focal epilepsy there may be a presence of nearly continuous production of interictal epileptiform discharges during sleep. The mechanisms for this activation is not yet clear but may involve the activating and synchronizing properties of oscillations generated between cortical and thalamic structures which may lead to the development of paroxysmal synchronization. Focal cerebral cooling has been shown to reduce epileptiform activity in animals as well as reports of cold saline irrigation has been shown to result in transient or complete cessation of spiking.[4] There is also reports that dendate spike activity recorded in urethanized infant rats increase severalfold when cooled from 32–27° C.[5] This raises the possibility that variation of body temperature may have an effect on frequency of epileptiform spikes. How significant this effect is unclear and is not well studied in the human brain. The effect of anesthetics on interictal spikes has been discussed in some detail in the chapter on intraoperative cortical mapping and electrocorticography. The presence of interictal epileptiform activity can be influenced also by antiepileptic medications. Intravenous benzodiapezines results in both acute seizure control and suppression of interictal epileptiform activity. For epilepsies other than absence, antiepileptic medications given over a medium and long term range has no clear correlation between seizure control and frequency of interictal epileptiform activity.[6] In patients whose epilepsy is in remission the persistence of interictal epileptiform discharges has been associated with a higher risk for seizure recurrence upon discontinuation of antiepileptic medications.[8,9]

Special features influencing the irritative zone

There are some interesting features of the irritative zone that are of particular interest. One in particular is that around 10% of patients with epilepsy never show any interictal epileptiform discharges. This is in part due to several limitations inherent to EEG. One main problem is the difficulty with temporal sampling. This is particularly problematic with the short-time sampling that occurs during a routine EEG. Even with long-term monitoring in a video-EEG unit, the time restriction is limited to a few weeks at most. On the other hand, the presence of interictal epileptiform discharges does not always indicate the presence of epilepsy, as a small percentage of normal subjects who never develop epilepsy may still have interictal epileptiform discharges. Another issue affecting EEG interpretation is that the cortical generators of many normal as well as abnormal waveforms recorded on the EEG are not well known, particularly when looking with invasive EEG. This goes hand-in-hand with the notion that all spikes might not be similar. To begin with, the ability to record spikes at the scalp in patients with temporal lobe epilepsy usually involves synchronous or temporally overalapping activation of 10–20 cm^2 of gyral cortex.[10] So there are many spikes that are seen on intracranial-EEG and not seen at the scalp at all. The significance of these spikes is not known. Additionally, due to the limitations involved with intracranial-EEG, what constitutes an epileptiform spike from a nonepileptiform transient is not clear, as mentioned earlier.

There are a number of normal patterns that are sharply contoured seen on the scalp-EEG which have been shown to be normal variants due the ability to study healthy volunteers with scalp-EEG. Similar investigations of identifying normal patterns are not feasible for intracranial-EEG. Some spikes may have particular characteristics that make them perhaps more significant than other spikes. For example, there may be forms of interictal epileptiform activity seen with such frequency or regularity that they may represent a transitional state from interictal to ictal EEG activity. This was suggested in a study of cortical dysplasia in which continuous epileptiform discharges had a high intrinsic epileptogenic property, so much so that if regions harboring these spikes were left behind during epilepsy surgery those patients uniformly faired poorly from a standpoint of seizure freedom after surgery.[11] In contrast to this phenomenon, patients with mesial temporal lobe epilepsy can often have an irritative zone that extends to the opposite hemisphere, as with the case of bitemporal spikes. However, these patients have a very high success rate with unitemporal resection which leaves intact the opposite temporal structures.

In generalized epilepsy such as absence, the frequency of 3 Hz-spike and wave has a close correlation with the frequency of detected seizures. In focal epilepsy the correlation is substantially weaker. However, it has been shown in one study of nonlesional intractable temporal lobe epilepsy, patients with few or no interictal epileptiform activity had a later age of seizure onset, less frequent and less severe seizures, and a lower incidence of hippocampal atrophy to suggest that a rarity of spikes could reflect a disease state that is not less severe.[12] However, in most cases of focal epilepsy there is very little evidence to suggest that there is a direct correlation between spikes and seizures. Since there is no clear increase in the frequency of spikes before seizures or an increase in spike frequency with a decrease in antiepileptic medications, the mechanisms for interictal and ictal phenomenon may be different.[13]

The presence of spikes is not usually associated with any clinical manifestation as compared with epileptiform activity consisting of ictal epileptiform activity. However, if epileptiform spikes are of 'sufficient intensity' and are being generated in a region within the eloquent cortex, then they may result in symptoms. A clear example is focal myoclonic jerks associated with spikes in the primary motor cortex. This type of myoclonus can be of positive or negative motor activity (Figure 55.1). Some more sensitive measures of clinical observation such as continuous psychological testing can show brief episodes of impaired cognitive function at the time of epileptiform discharges. There also evidence that the localization of the interictal spike activity would predict the impairment seen with such testing.[14,15] There is some suggestion that suppression of interictal discharges with antiepileptic medications could improve psychosocial function.[16]

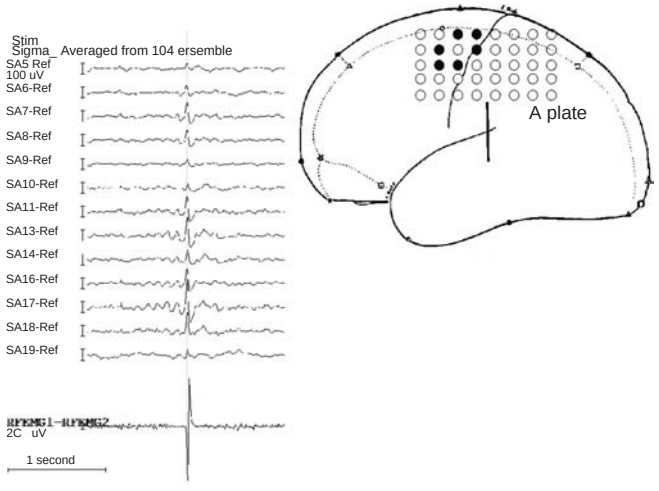

Figure 55.1 Patient with a history of medically intractable epilepsy who presents with positive and negative myoclonus undergoing an invasive evaluation for epilepsy surgery. Shown on the illustration is a map of the patient's 'A plate' subdural grid, in which spikes are shown maximum at electrodes 7, 8, 11, 13, 16, 17 (marked by the solid circles). Also shown is the EMG activity monitored during the patients spiking activity. The EEG shows 104 averaged spikes. Note the time display is shortened to show the relationship of the spike to the EMG activity. Just prior to the spike there is a marked decrease in EMG activity followed by a myoclonic jerk from the right finger that is time-locked to the interictal spike.

The relationship of the irritative zone to other cortical zones in epilepsy

The irritative zone stands in contrast to other defined zones of the epileptic brain (see Table 55.1). The delineation of these individual cortical zones is essential to the process of determining whether a patient with medically refractory focal epilepsy can be offered resection with reasonable chances of seizure freedom or substantial improvement without unacceptable postoperative deficits. It is our contention that the differentiations set forth in this set of definitions is implicit in any evaluation for epilepsy surgery; making them explicit allows for clarity in decision making, and must therefore optimize patient care. Complexities involved in studying these concepts include the current limitations in studying cortical

Table 55.1 Zone-wise definitions of the epileptic brain[32]

Epileptogenic zone	Region of cortex that can generate epileptic seizures, the total removal or disconnection of which is necessary and sufficient for seizure freedom
Irritative zone	Region of cortex that generates interictal epileptiform discharges in the EEG or MEG
Seizure-onset zone	Region of cortex from which clinical seizures originate
Ictal symptomatogenic zone	Region of cortex that generates the initial seizure symptomatology
Functional-deficit zone	Region of cortex that in the interictal period is functionally abnormal

neuronal function in health and pathology. There are various permutations that one can see with the relationship of various cortical zones of epilepsy based on different epilepsy syndromes. Two such examples are illustrated in Figure 55.2. However, the relationships can be even more complex in that even within an epilepsy syndrome such as temporal lobe epilepsy, the relationship of the different cortical zones can be slightly different. For example, in Figure 55.2A, which illustrates a case of temporal lobe epilepsy, bitemporal spikes are depicted. Other cases of temporal lobe epilepsy may have no interictal epileptiform discharges or may have a wider population of spikes. The ability to measure the functional deficit zone might be influenced by the frequency of spikes and/or seizures, so that regions of hypermetabolims may be depicted by a PET scan with an active epileptogenicity. The measurement of these different zones helps in the formulation of a hypothesis of the location of the epileptogenic zone in a particular patient. This concept is the crux of planning resective epilepsy surgery or planning an invasive evaluation for epilepsy surgery.

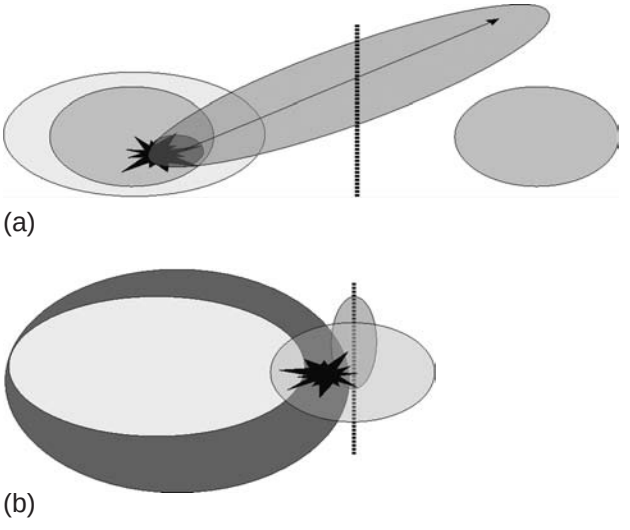

Figure 55.2 The relationship between the different cortical zones is graphically displayed in two examples. The yellow sphere represents the functional deficit zone; the light green sphere represents the irritative zone; the light orange sphere represents the symptomatogenic zone; the red sphere represents the ictal onset zone; and the black star represents the epileptogenic zone; the hashed line represents the division between the two hemispheres. Example a might represent a case of temporal lobe epilepsy in which there might be bitemporal spikes, unitemporal ictal onset, seizure semiology with lateralizing and localizing signs (direction of arrow indicates onset to progression of the semiological signs), and hypometabolism on a PET scan involving the temporal lobe ipsilateral to the ictal onset. In this example, seizure freedom could be achieved with a mesial temporal resection, and one can assume that the epileptogenic zone would have encompassed mesial temporal structures and perhaps the portions of the parahippocampal gyrus (extending just beyond the ictal onset perhaps recorded on depth electrodes as one example). Another situation is shown in Figure 55.2b which might represent a case of supplementary sensorimotor area epilepsy. In this case the irritative zone might be represented by spikes at the midline, ictal onset is lateralized to one hemisphere; there is PET hypometabolism of frontal and temporal lobes ipsilateral to the ictal onset, seizure semiology might imply SSMA onset. The epileptogenic zone is localized to a portion of the SSMA. (See Color plates.)

EEG recordings of the irritative zone

The first, and for decades the only, means by which to delineate brain regions giving rise to interictal paroxysmal activity was EEG. EEG enjoys several advantages over other means by which to define the irritative zone. It is of relative technological simplicity in the age of microcomputing, and can be utilized by a single clinician working alone or with the aid of a small number of well trained technologists. It is commonly available, well established in the clinical arena, and well studied in the scientific literature.

The irritative zone is localized on scalp-EEG by mapping of the potential differences recorded at the surface.[17] Epileptiform potentials are recognized as sharply contoured transients, nearly always of negative polarity, which disturb the background cerebral rhythms. When they are focal in nature, their localization is recognized in a referential montage as the electrode(s) of maximal voltage amplitude, and in a bipolar montage as the electrode(s) across which a phase reversal can be seen. The irritative zone is then concluded to reside in that region of the cerebral cortex underlying the electrodes at which these potentials are recorded.

The limitations of scalp EEG in the localization of the irritative zone include the region of cortex required to be recruited in the epileptiform activity before being seen at the scalp. At least 6 cm^3 of cortex,[18] possibly as much as 20 cm^2,[10] must be involved if a cortical transient potential is to propagate to the scalp surface. The cortical surface is highly convoluted and spatially complex, and the relationship of the scalp localization to the cortical area of origin is approximate at best

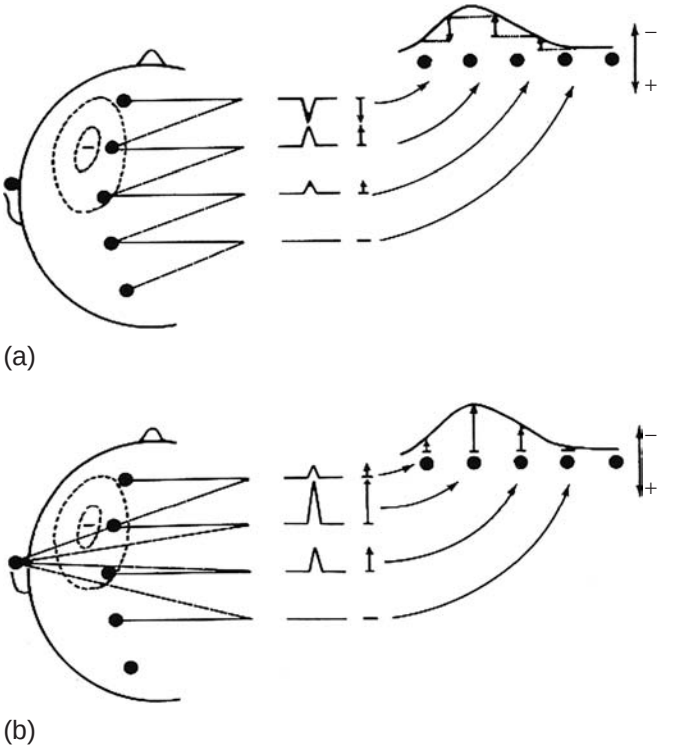

Figure 55.3 A schematic illustration of electrical potential analysis in clinical EEG. Using either bipolar (a) or referential (b) analysis, the voltage maximum of a transient recorded on clinical EEG can be plotted out; the generator is assumed to underlie the electrode at which the voltage maximum is recorded (used with permission from Fisch.)[49]

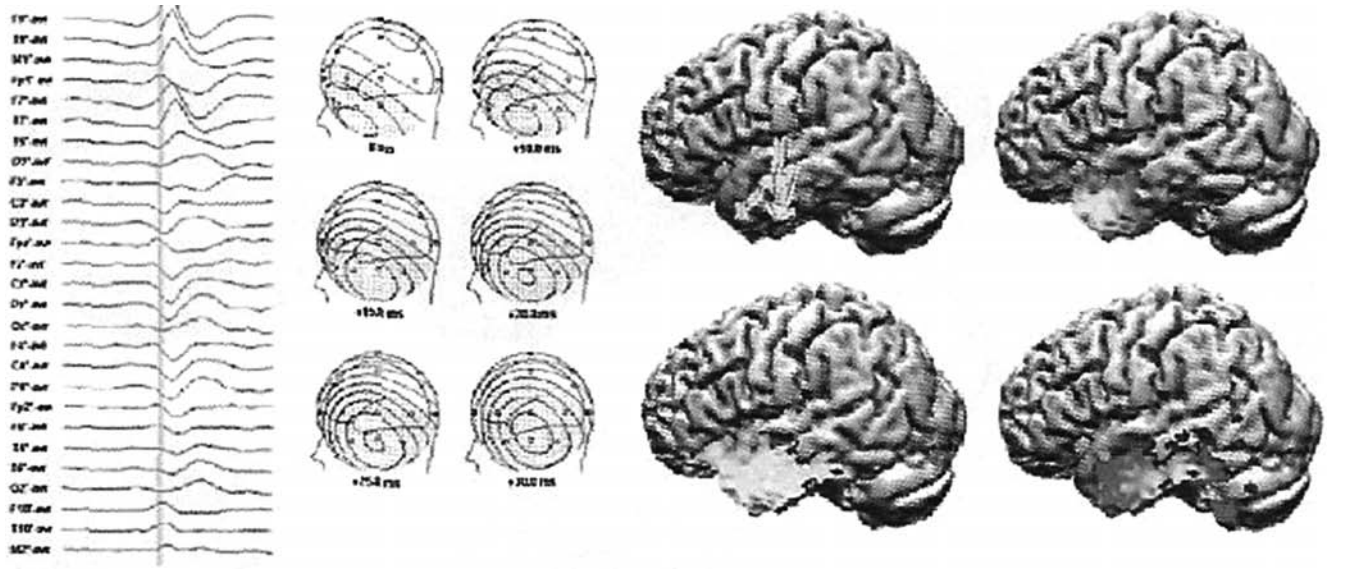

Figure 55.4 Dipole modeling from EEG. Raw EEG waveform on the left, with cursor at the point of initial deflection, defined as time 0 ms. In the middle, derived surface isopotential lines at 5 ms intervals from 5–30 ms. On the right, four brain models with superimposed dipole model solutions: on the upper left, three single dipole solutions at 0, 15, and 30 msec, and in the other three, current source density solutions, separately for each time point – 0ms upper right, 15 ms lower left, and 30 ms lower right. Single dipole solutions have less visual appeal, but less manipulation and abstraction. Current source density maps could be considered a representation of the irritative zone, but their abstraction from the original dipole must be borne in mind. (Used by permission from Ebersole.)[50]

and misleading at worst: potentials from the superficial midline cortex can appear to localize opposite the midline from their origin, and potentials from deep midline cortex, orbitofrontal cortex, insular cortex, supratentorial occipitotemporal cortex, and the mesial temporal structures may propagate to the surface poorly or not at all.[19]

The least invasive means of supplementing scalp-EEG is with the addition of sphenoidal electrodes. These can be performed when a mesial temporal focus is suspected. Placed by needle under the zygomatic arch and over the mandibular ramus, sphenoidal electrodes are intended to reside near the vicinity of the foramen ovale making them more effective in recording potentials of mesial temporal origin as compared with scalp electrodes.[20–22] They are generally well tolerated by patients, especially when placed under light sedation, and are of low morbidity in experienced hands. The chief arguments against their use are that they add insufficiently to the overall evaluation of such patients, when other sources of lateralizing information such as imaging and semiology are considered, to justify their modest risk and discomfort (Blume).[23]

Another, noninvasive, technique developed to augment the localizing potential of surface EEG is electrical dipole source modeling. This technique aims to solve the 'inverse problem' of clinical EEG and deduce the cerebral electrical potential giving rise to the electrical potential differences recorded on the surface. The laws of physics dictate that there are infinite possible solutions to any inverse problem, however, and the source can therefore only be modeled as an abstracted single dipole or set of dipoles. Optimizal accuracy requires modeling conductance of electrical signals through four 'spheres' of different physical properties–brain, cerebrospinal fluid, skull, and scalp.[24]

Recent studies indicate that dipole analysis has the potential to provide a reasonable spatial estimate of the source of surface EEG potentials. Comparison of surface recorded potentials to invasively recorded EEG has suggested that the modeled dipole sources are in fact within several millimeters of the cortex generating subdural EEG discharges. While initially studied in temporal lobe epilepsy, this modality appears to have potential applicability to all forms of localization-related epilepsy.[25]

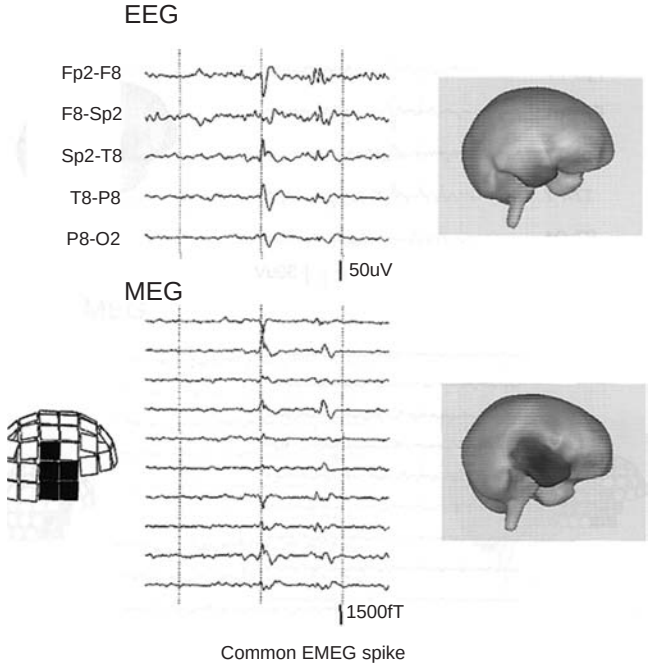

Figure 55.5 Dipole source modeling, with a current density representation, of the same epileptiform transient in simultaneously recorded EEG and MEG. (Used with permission from Iwasaki *et al.*)[51]

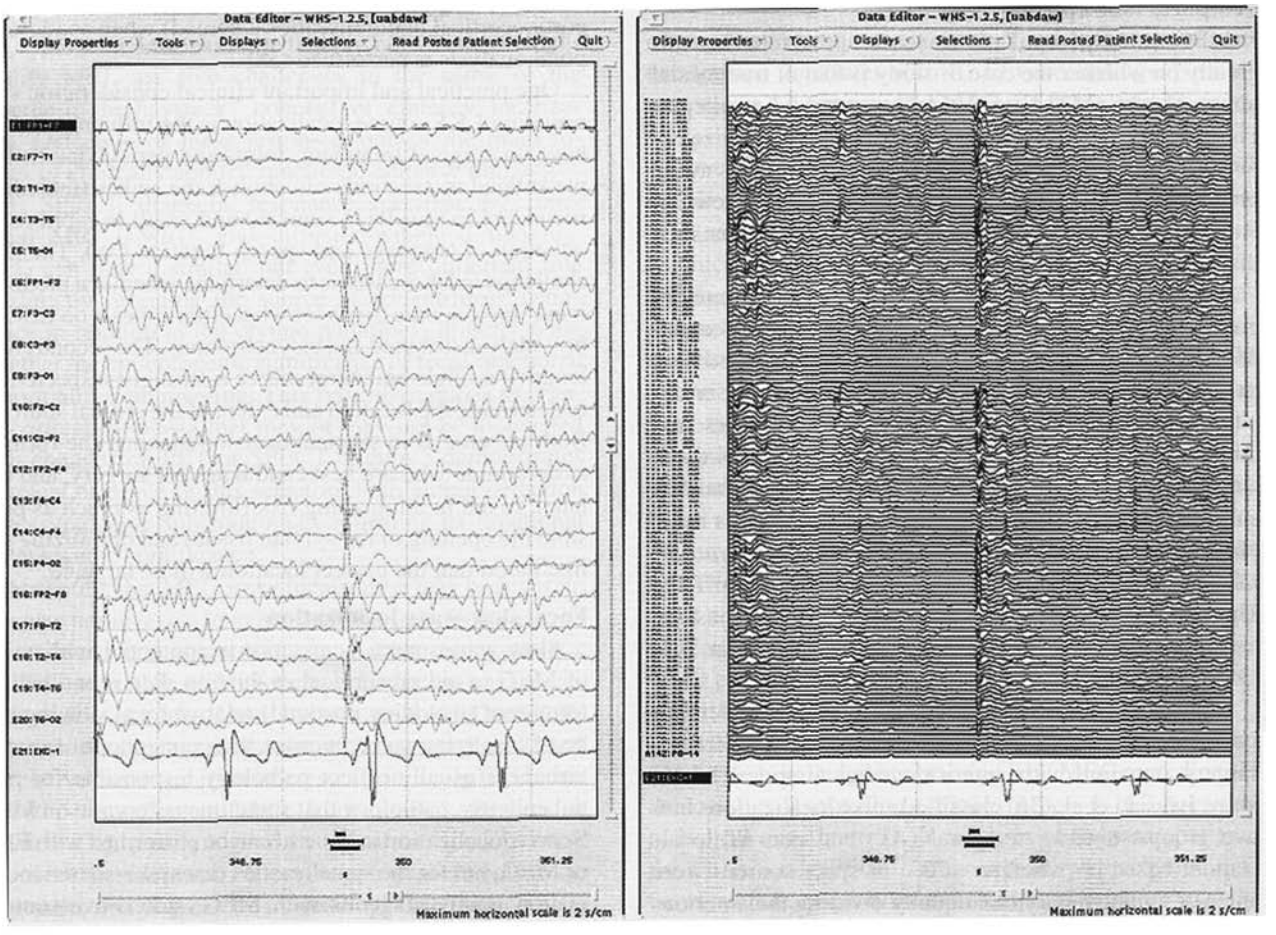


(a)

Figure 55.6a Left: 23-channel EEG of frontally maximal discharge with secondary bilateral synchrony. Right: 128-channel MEG of spike corresponding to that on EEG. (Modified with permission from Knowlton and Shih.)[52]

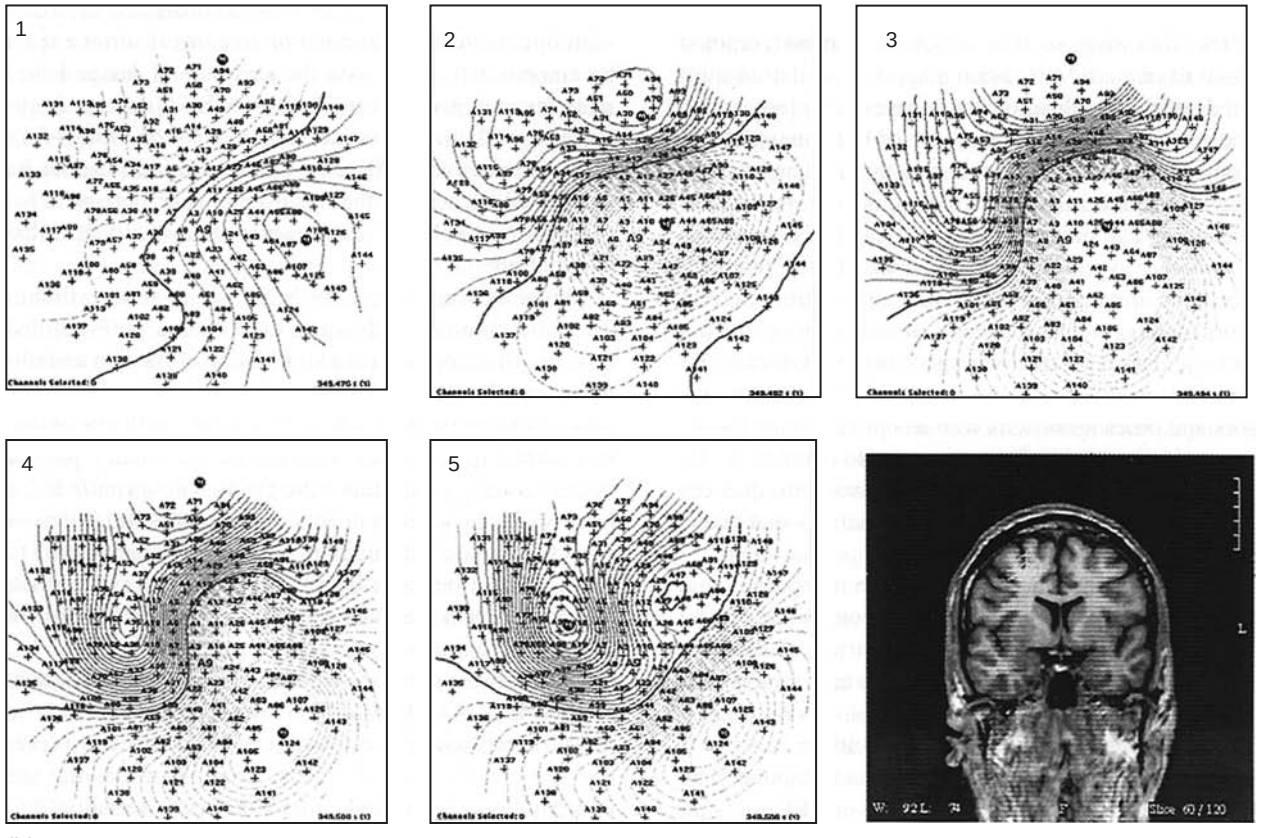
Dipole source analysis, until fairly recently an investigational tool, is now available as software extensions for many EEG systems, either commercially (e.g., BESA (www.besa.de) or Curry (www.neuroscan.com)) or as somewhat less comprehensive freeware (LORETA (www.unizh.ch/keyinst/ loreta.htm)). This approach can produce graphical representations of the spatial region putatively responsible for the observed surface potantials. These representations can be quite visually appealing, essentially appearing to highlight the area of cortex giving rise to a spike – in short, providing an outline of the irritative zone.

Current models, however, have weaknesses inherent in their structure. Optimal dipole modeling requires using not an average head model, but a 3D reconstruction of the patient's own head.[24] Which exact point of the interictal EEG spike is chosen for the model can produce substantial variation in the resulting modeled locus. The best available evidence suggests that the errors introduced by such issues are in the order of a few millimeters, but comparatively few patients have been formally studied versus the gold standard of invasively recorded EEG. In some, the error may approach a magnitude of centimeters.[25] Until there is greater confidence regarding in which patients dipole source modeling is essentially 100% accurate, this modality will not achieve replacement of intracranial-EEG. For the near future, it will likely represent merely a complement to such invasive recording, however, with accruing experience at major centers, such modeling stands poised to spare some patients this step.

Invasive EEG recordings of the irritative zone

Until recent years, direct EEG recording from the brain was the only neurophysiological means of characterizing the irritative zone more finely than could surface EEG, and experience with invasive EEG is vast. New utilizations of invasive monitoring have been devised in recent years.

Foramen ovale recording, which has fallen out of favor in the U.S. has never been abandoned in many centers, especially in Europe, and studies regarding its use continue.[26–28] Placed under fluoroscopy by an anterior approach through the cheek and then the foramen ovale into the subarachnoid space between the mesial temporal lobe and the pons, they are limited to evaluation of patients with mesial temporal lobe epilepsy. These electrodes do not require craniotomy, and can provide semi-invasive lateralization of interictal spikes and ictal onsets when that information is essential and sphenoidal electrode-supplemented surface EEG is insufficient. Foramen ovale electrodes cannot be utilized for functional stimulation mapping, unlike all other intracerebral electrodes, and they can only be utilized in relatively confirmed temporal lobe epilepsy



(b)

Figure 55.6b 1–5: Surface magnetic flux contour plots at 0 ms, 12 ms, 24 ms, 30 ms, and 36 ms of the MEG discharge in Figure 55.6a. Frames 2 and 3 show a lateralized contour pattern potentially attributable to a single dipole, modeled in the lower right; by frame 4, the singularity of the dipole is lost. (Modified with permission from Knowlton and Shih.)[52]

in which the only question is lateralization. Their proponents tout their high patient tolerability and the fact that they do not require general anesthesia and craniotomy. Whether they are safer than craniotomy and invasive electrode placement unfortunately has not been subjected to rigorous study.

Direct invasive EEG is the gold standard for delineation of the irritative zone. It was the first technique introduced for increasing the spatial resolution of surface EEG,[29–31] was the basis of the original definition of the irritative zone,[32] and remains the gold standard against which all other current techniques are compared (e.g., reference 10). Depth electrodes, subdural electrode strips or grids, or any combination of these can be utilized. Subdural electrodes record from the cortical surface. Depth electrodes have been used in years past to record from various subcortical structures; their most universally accepted use, particularly in the U.S., has been in recording from the amygdala and hippocampus.[33] In some centers, particularly in Europe, depth electrodes have been used to the relative exclusion of subdural electrodes in the evaluation of malformations of cortical development and other epileptogenic lesions,[34] including even in the sylvian fissure.[35] They are placed under fluoroscopic or stereotactic guidance to avoid pial vessels. This approach, termed stereoelectroencephalography, aims to place electrodes on all sides of, and within, the epileptogenic lesion and thereby localize the region of interictal spiking and ictal onset.[36]

In all approaches, the irritative zone is considered to comprise all tissue from which interictal spikes are recorded. This delineation of the irritative zone is conceptually straightforward, and does not required computational abstraction or processing. The clinical neurophysiologist evaluating a patient for epilepsy surgery need not have significant additional skills beyond those utilized in surface EEG. It is for these practical reasons, as well as historical ones, that invasive EEG remains the gold standard against which all other techniques are measured. Unfortunately, only tissue upon or into which electrodes have been placed can be evaluated. A firm presurgical hypothesis must have been developed on the basis of imaging, surface EEG, seizure semiology, and the other modalities discussed in this chapter, and invasive electrodes are placed in a specific locale on the basis of this hypothesis.[36] Unless electrodes are placed outside the hypothesized irritative zone, invasive EEG cannot provide evidence of a more widespread irritative zone than suspected – this is the chief limitation of invasive EEG in defining the irritative zone.

MEG recordings of the irritative zone

Previously an investigational modality, MEG is now making the transition to routine clinical use in some centers. Based on essentially the same physics as EEG, MEG records the magnetic fields generated by neuroglial ion shifts, instead of the electrical fields recorded by EEG. MEG requires superconducting detectors at 4 K (superconducting quantum interference devices, or SQUIDs) – a clinical MEG machine is comprised of several SQUIDs in a large flask of liquid helium. Brain signals are several orders of magnitude weaker than common modern environmental electronic noise, so a MEG machine must be

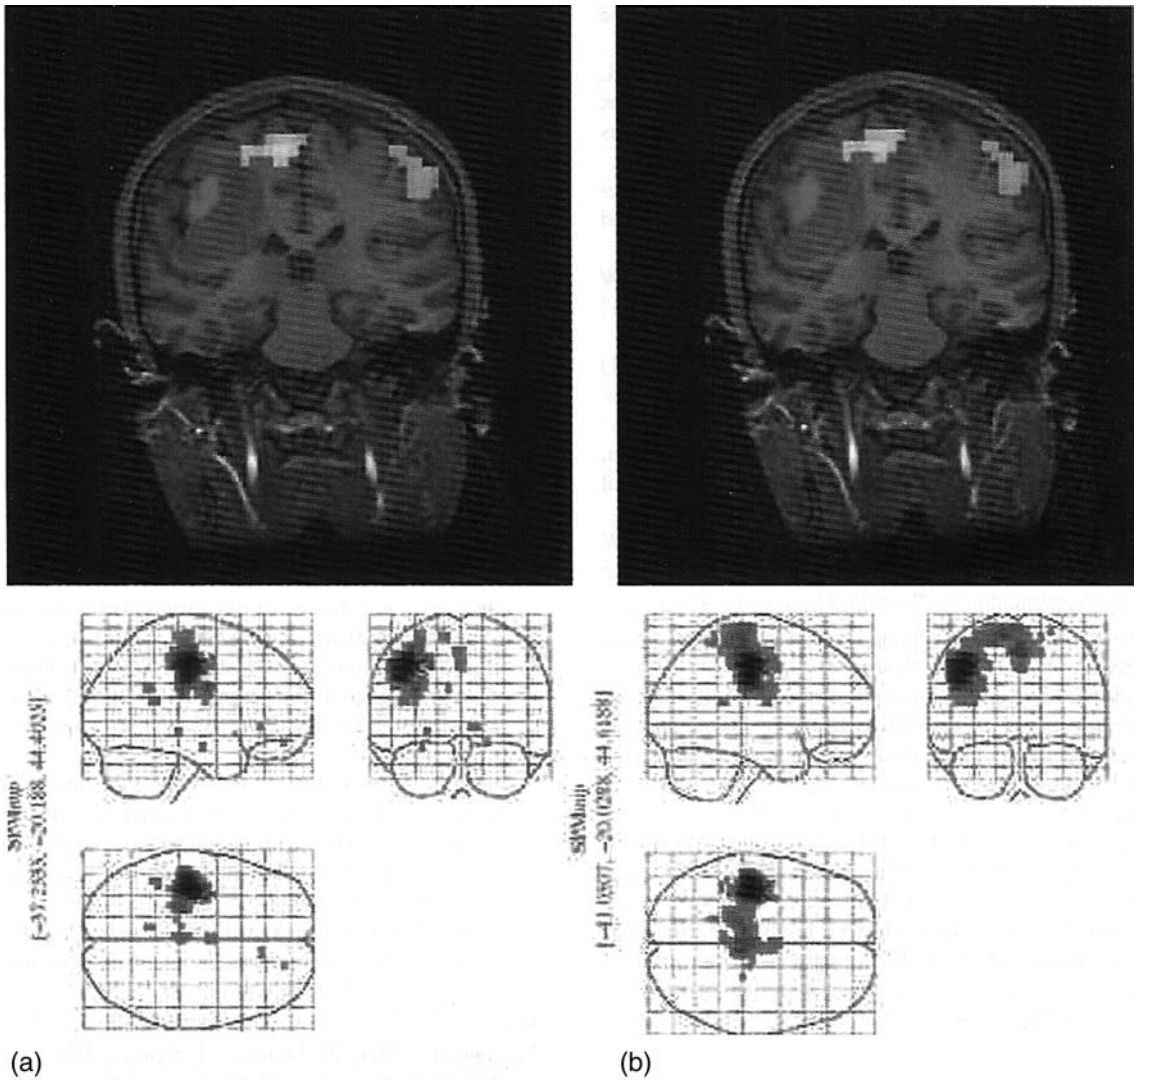


Figure 55.7 fMRI of a patient with right central malformation of cortical development and intractable epilepsy. On the left, activation associated with right finger-tapping in blue, left finger-tapping in yellow, and interictal surface EEG spikes in red; on the right, the same motor mapping tasks with activation associated with EEG spikes *and* slow waves in red. (Modified with permission from Diehl *et al.*)[53] (See Color plates.)

placed in a very carefully magnetically shielded (Faraday cage) room. Obviously, unlike EEG, MEG will remain limited to highly industrialized countries for some years to come.

The advantages of MEG over EEG are debated,[37–39] but potentially substantial. MEG assesses the strength and orientation of magnetic field, not electrical potential difference – it is therefore reference free, unlike EEG. The orientation of the magnetic field in the tissue is orthogonal to that of the electrical dipole – MEG therefore essentially records dipoles oriented parallel to the scalp, where EEG records those oriented perpendicular to it, so the two are theoretically complementary.[40] Without question, MEG can record spikes that are not apparent on EEG, and vice versa.[41] MEG therefore offers a complementary means of mapping the irritative zone by exactly the same two means as does EEG – visual analysis and dipole source modeling. Dipole modeling is much more straightforward than with EEG, because the magnetic permitivity of all layers of cerebral tissue, fluid and bone is identical, and the model therefore need not include multiple spheres. As with EEG dipole modeling, a highly visually appealing map of the interictal irritative zone can be produced (see, e.g., Ko *et al.*, Figure 2).[42] Unfortunately, to this point, the published case series comparing MEG to surface and invasive EEG are small. The relative value of the irritative zone map produced by MEG dipole modeling remains to be rigorously validated (the same could be justly said, however, for the irritative zone as mapped by invasive EEG). With further study, MEG stands to become a vitally useful tool in presurgical epilepsy evaluation.

MRI recordings of the irritative zone

Also now technically feasible, though less clearly poised to transition from investigation to clinical use, is functional magnetic resonance imaging (fMRI) of the irritative zone. The engineering hurdles associated with recording EEG in the inhospitable environment of the MRI machine have been successfully addressed.[43,44] Series are now available that demonstrate that an MRI signal can be acquired in the time window immediately following an interictal spike recorded on concurrent EEG. Contrast of the T2* image in this time window to the average acquired in the comparative resting state permits

identification of that region of tissue in which a blood–oxygen label-dependent (BOLD) change occurs. The tissue that has a detectable metabolic response concurrent with an EEG spike could be construed to be a better representation of that body of physiologically activated brain tissue than the volume across which the electrical potential is distributed. As with all fMRI assessments, the region of T2* change can be represented graphically, producing a visually appealing representation of, putatively, the irritative zone. There are conceptual problems with this leap, however. It is well known that the BOLD effect on which fMRI is based is spatially skewed towards draining cortical veins.[45,46] Also, inherent in the technique is the utilization of a mathematical model of the hemodynamic response; manipulations of the exact time-to-peak-response in the model can profoundly affect the volume of tissue concluded to be 'involved'.[47] Finally, as EEG-spike-triggered fMRI utilizes surface EEG, its resolution is limited to those interictal paroxysms that activate enough tissue that the dipole propagates to the surface. Clarification of the utility of the fMRI-mapped region of BOLD change concurrent with interictal surface EEG spikes must await future studies.

Conclusions

Clearly, multiple physiologically-based techniques are now available for evaluating the volume of brain tissue giving rise to paroxysmal bursts of activity between epileptic seizures. The role that delineation of this zone plays in the presurgical evaluation of each individual patient depends upon the patient's specific localization-related syndrome. As has long been appreciated,[48] the interictal irritative zone may not overlap well, or even at all, with the ictal onset zone, and the relationship of these two cortical areas to the epileptogenic zone as we define it is highly variable between syndromes. Much work remains to be done to clarify which of these techniques, or which combination of these techniques, will best permit us to offer curative surgeries to our patients.

56 Noninvasive electroencephalography evaluation of the irritative zone

HM Hamer

General concepts

The main goal of the presurgical evaluation in patients with medically intractable epilepsy is the identification of the cortical area capable of generating seizures, and whose removal or disconnection will result in seizure freedom. This area is called the epileptogenic zone.[1] The irritative zone is the area of cortex capable of generating interictal epileptiform discharges (IED). It does not coincide but frequently overlaps with the usually smaller epileptogenic zone. Extensive experience with routine extracranial EEG shows that in general the location of IED is a good indicator of the area of cortex from which seizures are originating.[1,2] The methodology of many studies on this topic, however, is biased towards patients with medically refractory epilepsies.[3,4]

The term interictal epileptiform discharge (IED) comprises spikes and sharp waves which usually break background activity. Both, spikes with a duration of less than 70 ms and sharp waves with a duration of 70–200 ms, have a pointed peak and are of negative polarity in most cases because they are generated by depolarization of vertically oriented neurons.[3,5,6] Positive IED can be seen in electrocorticography and infrequently in patients with a breach rhythm, head trauma or cortical dysplasia.[3,7] Spikes and sharp waves convey an increased risk of epilepsy and must be differentiated from benign variants resembling IED.[2,3] Some reports suggest that spike suppression and not an increase of IED frequency heralds seizures which proposes that a strong after-inhibition produced by IED protects against the occurrence of ictal discharges by maintaining a low level of excitation in a general condition of hyperexcitability.[2,8] This finding, however, remains controversial.[9,10]

There is evidence that the interictal epileptiform discharges in focal and generalized epilepsies, though not accompanied by obvious clinical events, can induce brief episodes of impaired cognitive function if tested with sensitive methods.[11,12] In focal epilepsy, the type of deficit may depend on where in the cortex the IED arises.[13] Suppressing interictal discharges could improve behavior in children particularly with focal epilepsy.[14] Auditory reaction times was found normal before IED in absence epilepsy but decreased in many patients at the onset and after a delay of 0.5 seconds of IED.[12,15] Moreover, chronic and frequent IED on the left may induce a reorganization of speech lateralization.[16]

EEG recorded by scalp and sphenoidal electrodes compared to intracranial electrodes and Magnetoencephalography

In general, surface EEG provides a good overview because it samples from a large portion of the brain. However, several square centimeters of synchronously discharging cortex are necessary to be detected by overlying scalp electrodes.[17–19] Cerebral activity is attenuated by the impedance of the cerebrospinal fluid, meninges, skull and scalp. Therefore, scalp-EEG fails to show a great number of IED recorded by depth or subdural electrodes (Figure 56.1) and interictal activity arising from deep or midline structures is usually not reflected in surface EEG.[1] The distribution of IED on the scalp depends on the conductive properties of the surrounding tissue, the spatial characteristics of the generator, propagation pathways and on the spatial resolution of the surface EEG. Consequently, the distribution of interictal epileptic discharges in the scalp EEG can fail to localize or even mislocalize the region or hemisphere of seizure origin.[3] Patients with an epileptogenic zone in the frontal, occipital, insular-opercular and orbitofrontal regions may show falsely localizing temporal IED.[20–22] Closely spaced scalp electrodes can improve the yield of spike detection and localization over the standard 10–20 system.[23,24]

It remains controversial whether or not sphenoidal electrodes placed close to the foramen ovale increase the sensitivity of IED detection. While several studies found that in a minority of patients, especially with temporal lobe epilepsies sphenoidal electrodes can record epileptiform activity which does not appear in anterior temporal electrodes (Figure 56.2),[25–29] others could not verify this observation.[30] Sharp waves with the maximal amplitude at the sphenoidal electrodes can arise from the mesial or lateral temporal lobe or from an orbito-frontal focus.[27] Sphenoidal electrodes can register higher amplitudes of IED as compared to scalp electrodes.[3,31,32] However, sphenoidal electrodes still fail to detect a large proportion of IED recorded by foramen ovale electrodes (Figure 56.1).[30]

Multichannel whole-head MEG has a similar sensitivity to detect IED as compared to noninvasive EEG[19,33,34] and the combination of both provide complementary and confirmatory information for the localization IED which cannot be obtained with either technique alone. In a study on 70 surgical candidates, MEG identified IED in one-third of EEG negative patients, especially in cases of lateral neocortical epilepsies and epilepsies due to cortical dysplasia.[19,35] Conversely, IED were seen only in the EEG in a subset of patients with mesial frontal lobe epilepsy.[35]

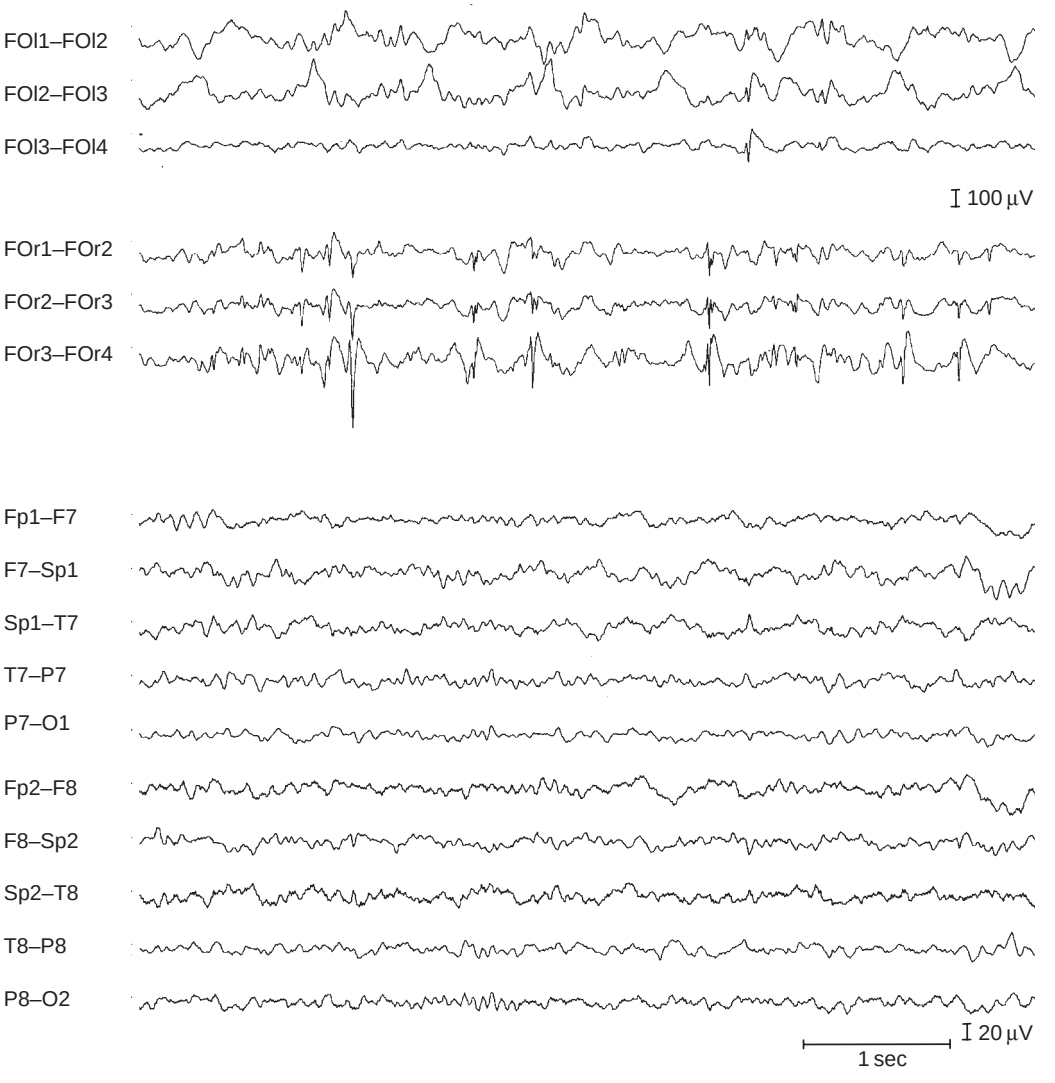

Figure 56.1 Invasive Video-EEG monitoring with bilateral foramen ovale electrodes of a 38-year-old patient with bitemporal epilepsy. In addition, scalp electrodes were attached according to the International 10–20 system and sphenoidal electrodes were bilaterally inserted. Note the interictal epileptiform discharges (IED) recorded maximally at the fourth contact of the right foramen ovale electrode while the scalp and sphenoidal electrodes fail to detect these IED. FOr1, FOr2, FOr3, FOr4: four contacts of the right foramen ovale electrode; FOl1, FOl2, FOl3, FOl4: four contacts of the left foramen ovale electrode; Sp1: left sphenoidal electrode; Sp2: right sphenoidal electrode.

Yield of scalp EEG

The first EEG will uncover IED in about 30–50% of the patients with epilepsy and the yield increases to 60–90% by the fourth EEG.[2,36–38] This contrasts with the frequency of IED in nonepileptic patients ranging from 0.5% in healthy young men[39] to 12% in a study including all age groups and patients with progressive cerebral disorders.[40] Specificity is probably lower and sensitivity higher in children as compared to adults, but reliable estimates are not available.[2] The frequency of IED in elderly patients with epilepsy is substantially lower than that reported in epileptic populations as a whole.[36,41] The majority of reports could not establish a correlation between the levels of anticonvulsants and the frequency of focal interictal spiking, although this issue remains controversial.[9,36,42–45] Overall, it can be expected that around 10% of the patients with epilepsy (more with extratemporal than with temporal epilepsy) will show no IED in scalp EEG during wakefulness or sleep in spite of prolonged or repeated recordings.[2,46,47] The yield from a single EEG is substantially increased in patients investigated within one or two days after a seizure, and is greater in patients with monthly seizures than in those who had been seizurefree for a year.[36,45,48] The duration of recording may also affect the detection rate of interictal spiking.[9]

Moreover, the yield can be significantly increased and new abnormalities found, if the EEG includes sleep recordings.[2,48,49] IED are seen more commonly during sleep, with the greatest activation during non-REM sleep.[1,50–53] Increased neuronal synchronization within thalamocortical projection neurons during non-REM sleep may contribute to the activation process in epileptic cortex.[46] The predictive accuracy in lateralization of epileptogenesis is improved during non-REM sleep in patients who showed bilateral or no discharges in wakefulness because unilateral discharges arising de novo in sleep were always correctly lateralizing.[46] In patients who had unilateral discharges in the awake state whether ipsilateral or contralateral to the epileptogenic zone, the findings were generally unchanged during sleep although sleep may alter IED morphology and distribution.[52] Spikes can be more

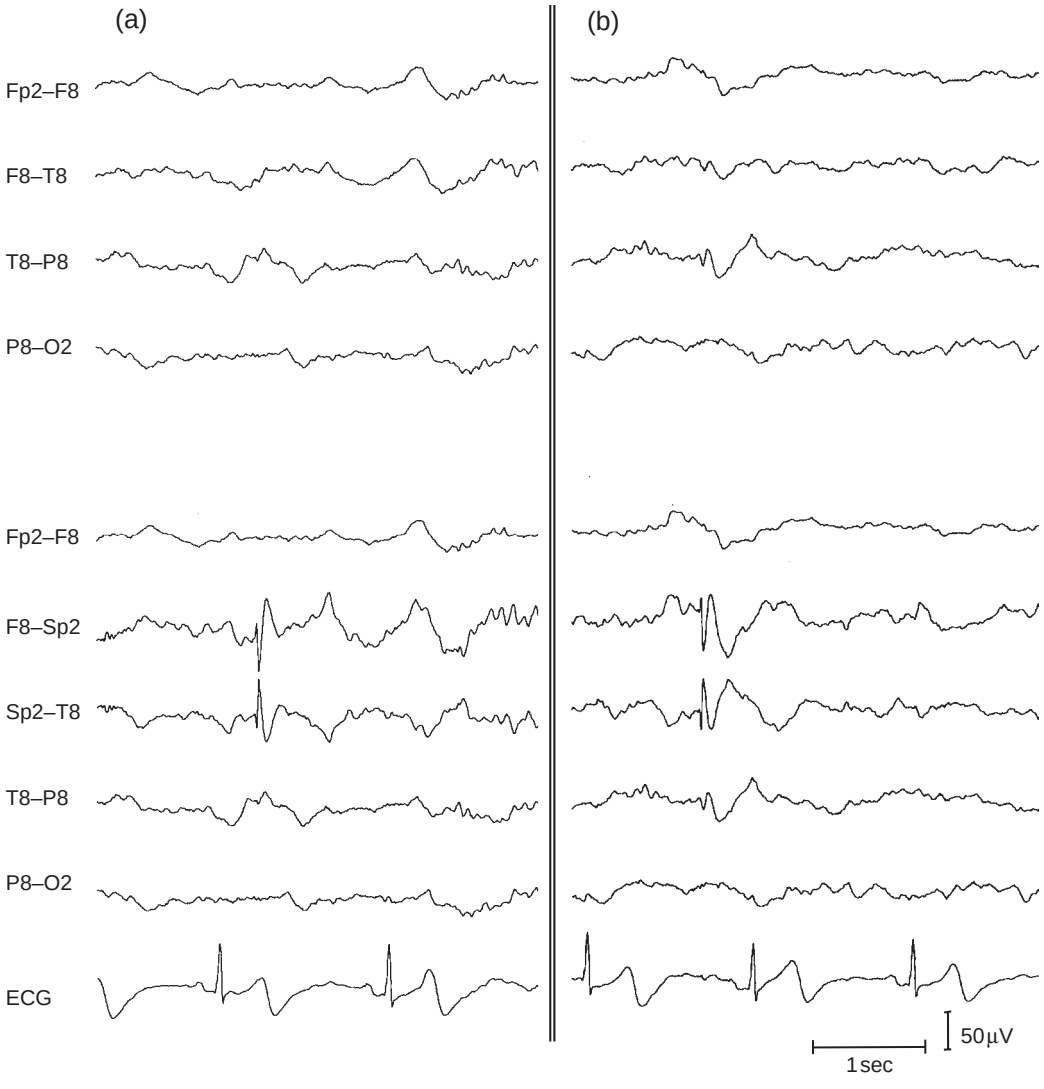

Figure 56.2 Two examples of interictal epileptiform discharges (IED) of a 39-year-old patient with right mesial temporal epilepsy due to hippocampal sclerosis. Scalp electrodes were attached according to the International 10–20 system and additional sphenoidal electrodes were bilaterally inserted (Sp2: right sphenoidal electrode). The first four channels represent a longitudinal bipolar montage of scalp electrodes over the right temporal area. In the following five channels, the right sphenoidal electrode is included between F8 and T8 in a bipolar fashion. Note the sharp waves recorded by the sphenoidal electrode and missed by the scalp electrodes. ECG: electrocardiogram.

widespread during non-REM sleep than during wakefulness or REM sleep suggesting that the localization of interictal discharges in REM sleep may be a better indicator of the epileptogenic zone than in non-REM sleep.[53] Hyperventilation or photic stimulation rarely activate IED in patients with focal epilepsies.[54,54–57]

Specificity of interictal scalp EEG

In general, the frequency, repetition rate, morphologic characteristics and state dependence of interictal epileptiform activity cannot be used to predict the etiology or severity of the disorder.[3] However, rhythmic spiking on a slow background activity and not associated with behavioral changes has been found to be characteristic for focal cortical dysplastic lesions.[58–60] Tumors tended to cause wider distributed IED as compared to developmental abnormalities or hippocampal sclerosis,[21,24,61] which was also true for seizure patterns.[62] This may be caused by local neuronal injury, edema, ischemia or other electrical and/or biochemical effects of the structural lesion on susceptible neighboring brain tissue or homologous contralateral areas.[63,64]

Prognostic relevance of postoperative IED

In both, temporal and extratemporal epilepsy, absence of IED in the 6-month or 1-year postoperative scalp-EEG was associated with good postoperative outcome.[65–69] The prognostic value of a 3-month postoperative EEG remains controversial.[25,70–72] The presence of IED in the early extracranial postoperative EEG (within 1 or 2 weeks) were not found to be of prognostic value in most of the studies.[71,73–76] There are conflicting results on the prognostic value of IED in the postresection electrocorticography (ECoG). Several studies found an association between postresection IED in this test and less favorable outcome [74,77–80] while others did not.[25,67,71,73,81–83] The lack of agreement of these studies may be due to differences in the patient populations (e.g. lesional versus nonlesional cases), the recording

techniques and in the anesthetic agents used during surgery. Even in the studies confirming the association of postresection IED and seizure continuation, the percentage of patients with postresection persistence of IED but still favorable outcome varied from 25–47%[69,74,78,79] which can make it difficult to estimate the prognosis in individual cases.

Temporal lobe epilepsy (TLE)

As mentioned above, several studies indicated that the majority of mesial and neocortical temporal IED fails to be recorded by surface electrodes.[4,18,84] The IED which are recorded in the extracranial EEG, however, may show a better correlation with the seizure origin as compared to IED recorded by depth electrodes.[85] This suggests that widely synchronous interictal spikes more likely rise from the epileptogenic area than spikes with smaller fields.

In addition to IED, temporal intermittent rhythmic delta activity (TIRDA) was also strongly correlated with a clinical diagnosis of TLE[85–87] (Figure 56.3). TIRDA was seen in 0.3% of all recordings obtained in a general EEG laboratory [88] but in as many as 28% of patients being evaluated for temporal lobe resection.[89] A significant association was found between a mesial temporal epileptogenic zone and TIRDA.[90] On the other hand, temporal intermittent polymorphic delta activity was recorded in patients with temporal and extratemporal epilepsies.[89]

Distribution of IED in TLE

In TLE, IED tend to produce a stereotyped pattern on the scalp with highest amplitudes at the anterior temporal electrodes. This may be due to the location of the neuronal generators within the temporal lobe and anatomical characteristics of the brain coverings, such as skull discontinuities.[17] Children may have a more widespread irritative zone which may be caused by a high frequency of dual pathology.[91] Most[78,82,92–95] but not all studies[47,96] confirmed the finding that IED confined to the anterior temporal region are predictive of good postoperative outcome after TLE surgery.

Lateralizing value of IED

The incidence of bilateral IED in TLE is estimated to lie between 20 and 44% and may be higher when investigated with invasive EEG.[4] The probability of bilateral IED was positively correlated with the duration of the EEG monitoring.[96,97] Bitemporal IED increase the likelihood that seizures are arising independently from both sides[98] and can reflect bilateral damage, dysfunction at a distance, or secondary epileptogenesis.[21,99,100]

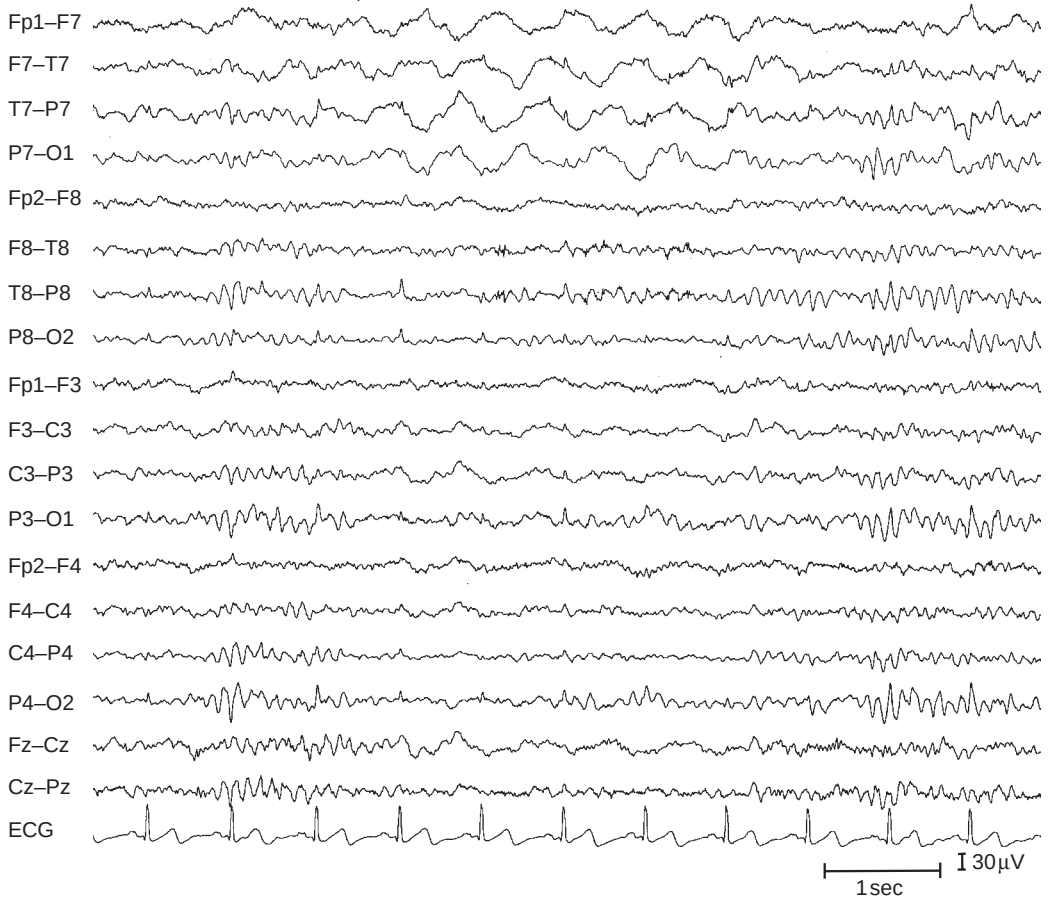

Figure 56.3 Interictal EEG of a 21-year-old patient with left temporal lobe epilepsy due to hippocampal sclerosis. Scalp electrodes are attached according to the International 10–20 system. Note the temporal intermittent rhythmic delta activity (TIRDA) in the left temporal region. ECG: electrocardiogram.

In extracranial EEG recordings, interictal discharges can have a more reliable lateralizing value than ictal changes in temporal lobe epilepsy,[100] and they almost always predict seizure origin in TLE and good postoperative outcome if they are exclusive or clearly preponderant on the side of surgery.[4,37,71,78,82,85,98,101–108] In a study of 59 candidates for temporal lobectomy, 92% of patents with >90% lateralization of the IEDs had a good surgical outcome, whereas only 50% with <90% had a favorable outcome.[47] Preoperative IED frequency was not associated with postoperative outcome.[109,110] In addition to IED, lateralization of delta activity also indicated the side of temporal seizure origin in a high proportion of patients.[58,85] These findings may not fully be applicable for tumor patients who can show a wide irritative zone[24] and whose postoperative seizure outcome was not affected by bilateral IED.[65]

Mesial temporal lobe epilepsy (mTLE)

The IED in hippocampal sclerosis (HS) have a very localized field which is frequently missed by scalp electrodes.[4] If IED are recorded in the extracranial EEG, they are highly restricted to anterior temporal electrodes.[24,111,112] Using three-dimensional multiple dipole modeling, two possible sources of interictal spikes in HS patients could be identified.[113] The first source involved the mesio-basal aspect of the temporal lobe (hippocampus and parahippocampal gyrus) and was followed within 40 msec by activation of the anterior temporal lobe neocortex. Extracranially recorded IED in mesial and not in lateral TLE frequently show a negative pole in the anterior temporal region or at the sphenoidal electrode and a widespread positive pole over the vertex.[114] As a rule, patients with HS have greater than 90% of their interictal epileptiform discharges in the anterior temporal region. Therefore, frequent posterior or extra-temporal sharp waves may decrease the certainty of the diagnosis of HS.[24] The rare occurrence of lateral temporal and frontal spikes/sharp waves in patients with HS may be due to spread of epileptic discharges to the temporal neocortex or to the (orbito-)frontal cortex via the limbic system.[114]

In patients with a history and ictal symptoms and signs suggestive of mTLE, interictal epileptiform discharges recorded during serial routine EEGs can reliably lateralize the seizure focus if they are consistently lateralized to one temporal lobe and are concordant with MRI-identified unilateral hippocampal atrophy.[96,102,104] This supports the view that seizure recordings may not be necessary in this situation.[115] In mTLE, concordance of structural MRI and interictal EEG was more closely associated with good surgical outcome than concordance of MRI and ictal EEG findings with nonlateralizing interictal EEG.[116] Although bilateral IED decrease substantially the chances of a favorable postoperative outcome,[117] subjects with bitemporal IED but MRI hippocampal abnormalities concordant with the ictal-onset region still can have a good to excellent surgical outcome.[24,94,103,112,118]

Frontal lobe epilepsy (FLE)

The value of noninvasive EEG is more limited in extratemporal epilepsy than in TLE. More than a third of patients with frontal lobe epilepsy may not show any IED in extracranial EEG[26,119] so that absence of interictal spikes with documented seizures suggests extratemporal epilepsy.[120] If IED are recorded in extratemporal epilepsy, especially in FLE, they tend to be less welllocalized, multifocal, generalized, or even mislateralized.[22,26,119,121–125] The poor localization of IED in FLE is due to the anatomy of the frontal lobe with inaccessibility of much of the frontal lobe to surface electrodes and the network of projection pathways that allow the rapid spread of epileptiform activity within and outside the frontal lobes. The rates of bilateral IED were significantly higher in patients with FLE than with TLE.[123,126,127] Mesial frontal lesions facilitate secondary bilateral synchrony (Figure 56.4)[128,129] which is the phenomenon of seemingly generalized IED which can be observed in up to 40% of these patients.[129,130] The presence of unilateral focal discharges that initiate the generalized IED and additional focal or at least lateralized epileptiform or nonepileptiform abnormalities seen strictly on the same side differentiate secondary bilateral synchrony from generalized IED observed in idiopathic generalized epilepsy.[131] Nonepileptiform EEG abnormalities, such as focal or lateralized slowing or an asymmetry of background activity, may give a clue to the abnormal side in the situation of independent bilateral IED. Patients whose seizures originated from the dorsolateral frontal convexity frequently had focal interictal epileptiform abnormalities that localized to the region of seizure onset while patients whose seizures began in the mesial frontal region had either no interictal epileptiform activity or had multifocal epileptiform discharges.[132,133]

Generalized IED in FLE were associated with poor postoperative outcome[134] while unifocal IED were highly predictive of successful outcome.[121]

Parietal lobe epilepsy (PLE)

The relative frequency of parietal lobe epilepsy is generally considered low and the data concerning this patient group are limited.[135] The majority of patients with PLE shows IED. The IED are usually widespread and multifocal and can be bilateral suggesting an extent of the irritative zone far beyond the epileptogenic zone.[62,135–138] Secondary bilateral synchrony can be recorded in up to 30% of the cases especially with parasagittal lesions.[62,137] In general, extracranial interictal EEG findings are an unreliable indicator of parietal lobe epilepsy.[138,139] Electrophysiologic studies should be carefully addressed if there is disagreement between scalp-recorded EEG and neuroimaging.

Occipital lobe epilepsy (OLE)

A great majority of patients with OLE have abnormal interictal or ictal EEG findings but scalp EEG may fail to detect epileptiform activity generated by an irritative zone on the inferior and mesial occipital surfaces. Nonepileptiform abnormalities, such as decreased alpha activity or focal slowing, may then help to detect occipital dysfunction. The most frequent IED in OLE are spikes and sharp waves in temporal or temporo-occipital regions with shifting maximums in some patients.[21,135,140,141] Widespread and bilateral IED are common and isolated epileptiform activity restricted to the occipital

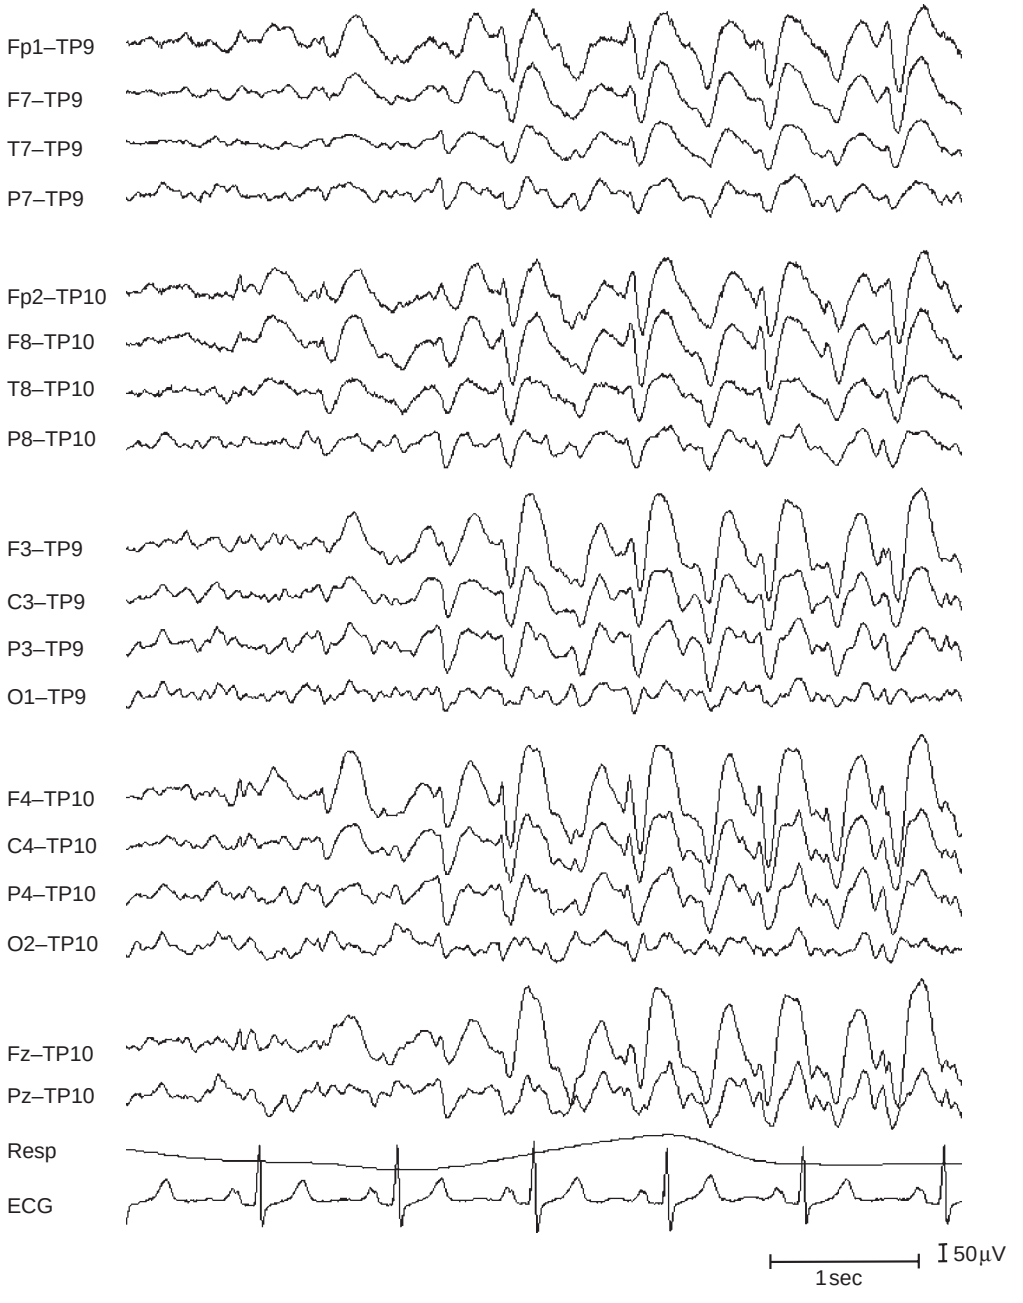

Figure 56.4 Interictal EEG of a 21-year-old patient with right frontal epilepsy. Referential montage with the ipsilateral TP9 (resp. TP10) electrode as reference electrode. Note the secondary bilateral synchrony consisting of generalized spike-wave-complexes preceded by right frontal discharges. ECG: electrocardiogram; Resp: respiration.

lobe is infrequent.[21,75,140,142] Rarely, IED can be recorded with highest amplitudes in the contralateral occipital region in the sense of a paradoxical lateralization if the dipole is oriented in such a way that contralateral occipital electrodes best detect it. This can be suspected if IED appear ipsilateral to more normal background activity.[143] A preponderance of focal IED may reflect the underlying pathology because the incidence of focal occipital IED was much higher in occipital epilepsies caused by malformations than in those due to tumors.[21] Patients with focal epilepsies generally have a low incidence of photosensitivity of 0.7–3.0%.[56,57,144] Among these patients, however, patients with OLE have the highest incidence ranging from 6–13%.[57,141,145]

In contrast to temporal lobe epilepsies, where the lack of contralateral IED is predictive for a seizure-free postoperative outcome,[117] this correlation could not be shown in posterior epilepsies.[62] Moreover, location of IED in any cortical region was not associated with the outcome in 42 surgical candidates suffering from occipital or parietal lobe epilepsy.[62] Similarly in another study of 35 patients who underwent surgery for intractable OLE, there was no relation between occipital and extraoccipital interictal surface EEG findings and seizure characteristics, postoperative outcome, or lesion location on MRI.[21]

Conclusions

Interictal EEG alone cannot exclude or establish the diagnosis of epilepsy and the amount of IED does not provide a guide to

seizure frequency. Negative findings from a single waking EEG are to be expected in many patients and contribute little to the diagnostic assessment, whereas the absence of IED in serial EEG both in waking and sleep significantly reduces the probability of epilepsy. The finding of epileptiform EEG activity plays an important role in classification of epilepsies and epilepsy syndromes especially in the absence of other evidence of cerebral disease. Tumorous epilepsies appear to generate wider irritative zones as compared to other etiologies.

The great value of IED in localizing temporal epileptogenesis and predicting postoperative outcome in TLE has been increasingly recognized in recent years although scalp EEG fails to detect most of the epileptiform activity recorded by intracranial electrodes. In the vast majority of patients with mesial temporal lobe epilepsy, interictal epileptiform activity is highly restricted to anterior temporal electrodes including sphenoidal electrodes. Bilateral IED can be generated by unilateral TLE but decrease the chances of postoperative seizure freedom.

The value of interictal epileptiform activity in the scalp-recorded EEG is more limited in extratemporal epilepsy as compared to temporal lobe epilepsy. Many of the patients with extratemporal epilepsy show either no or widespread and multifocal discharges. Mesial frontal and parietal lesions facilitate secondary bilateral synchrony. In contrast to temporal lobe epilepsy, no association could be found between poor postoperative outcome and preoperatively recorded multifocal or bilateral IED in occipital or parietal lobe epilepsies.In general, the absence of IED in the 6-month or 1-year postoperative scalp-EEG is associated with good postoperative outcome.

57 The irritative zone evaluated with invasive recordings

A Palmini

Introduction

Epilepsy surgery offers the perspective for a definitive treatment, notably in those patients in whom antiepileptic drugs prove insufficient to control seizures. A treatment intended to eradicate epilepsy should aim at removing all relevant epileptogenic brain tissue, sparing eloquent cortex. Of course, an a priori step, and thus a major issue, is to determine what exactly means relevant epileptogenic brain tissue.

Prior to this era of major conceptual and practical advances in the identification of tissue that should be removed to control seizures surgically,[1,2] a great deal of attention was given to cortical regions displaying interictal spikes. Indeed, the identification of these regions via extra- or intra-operative electroencephalography was the cornerstone for the early development of epilepsy surgery.[3–6] Interestingly, the importance attached to interictal spikes have diminished in the last two decades, *pari pasu* with major developments in neuroimaging and the greater feasibility of ictal recordings. Furthermore, something close to a *coup de grace* on interictal spikes was perpetrated by a major conceptual advance, namely, the understanding of the role of structural lesions, ictal recordings, ictal semiology, and dysfunctional cortex in seizure generation.[1,2] In other words, different methodologies and more data have progressively taken the place of interictal spikes and have done so by refining (or 'redefining') the concept of epileptogenic brain tissue, replacing it by this more pragmatic concept of *relevant* epileptogenic brain tissue. Thus, in this introduction of a chapter where we review the methods and objectives of localizing interictal spikes by directly recording from the cortical tissue of epileptic patients, we need to acknowledge that such localization is currently not at the top of the hierarchical listing of the most useful tools to delineate the epileptogenic zone (EZ; ie, the 'relevant' epileptogenic brain tissue).

Nevertheless, as many have correctly said and I have stated recently,[7] experienced epileptologists would not dispense with a full analysis of the interictal spikes. If this holds true for the analysis of scalp recordings, let alone for the opportunity to analyze interictal spikes recorded directly from the brain. With these preliminary considerations in mind, this chapter will try to reconcile two truisms about interictal spikes: the fact that they may often not be a major player in the delineation of the EZ while, at the same time, and in specific circumstances, their careful analysis through invasive recordings may provide invaluable and *unique* data for such delineation.

We will start by reviewing the spatial relations between interictal spikes, ictal recordings, and structural lesions, as observed through distinct modes of invasive neurophysiological evaluation. We will then move on to those 'specific circumstances' where interictal spikes may be crucial in the delineation of the EZ.

The irritative zone localized by invasive recordings and the relevant epileptogenic brain tissue

How different methods of invasive recordings evaluate the irritative zone

Acute electrocorticography

Invasive recordings of interictal spikes are almost as old as scalp EEG itself. From the inception of electroencephalography, this method was applied to record directly from the brain surface. Indeed, Penfield and Jasper at the Montreal Neurological Institute (MNI) used acute intraoperative electrocorticography (ECoG) to advance the field of epilepsy surgery in the 1940s and 1950s.[3–5] The strong impact imparted by this and other traditional schools of thought in the epilepsy surgery field have led to the continued use of acute ECoG by many epilepsy Centers around the world.[8–11]

Like all recording methods, the use of acute ECoG to analyze the irritative zone has advantages and disadvantages. The risks, costs, and technology involved in acute ECoG recordings are much less impressive in comparison with other invasive methods. In addition, the surgeon and the neurophysiologist can explore various subregions within a given exposed cortical area, by freely moving the cortically-applied carbon ball or strips/grids electrodes. Furthermore, as will be reviewed below, there are some patterns in the acute ECoG that may be more or less specific for certain types of underlying pathologies and which may have a major impact in the final delineation of the EZ.[8–10]

Finally, there are two peculiar additional advantages of the use of acute ECoG, and both pertain to the possibility of additional recordings *after* tissue resection. One is that carbon ball electrodes can record from the depth of gyri, after an initial resection was performed (Figure 57.1). This is important because some epileptogenic pathologies, particularly focal cortical dysplasias (FCD), may extend to or involve only these deeper cortical areas (Figure 57.2).[12] Despite the high degree of epileptogenicity of these lesions, very active epileptogenic

activity originating in these deep seated lesions (or parts thereof) (Figures 57.1 and 57.2) may defy recordings purely from the cortical surface – such as the type of probing provided by subdural grid electrodes.

The other related advantage is that acute ECoG allows an 'electrical revision' of the exposed cortical surface after initial resection. Epileptogenic abnormalities encountered in these acute post resection recordings may or may not be relevant for prognosis or as an indication of the need for additional tissue resection. As will be reviewed below, such variability is related to the underlying pathology. In those scenarios where additional resection may have an impact on the final outcome, acute ECoG stands as the only method allowing such tailoring.

On the other hand, although it provides relative gains in the spatial domain, acute ECoG is potentially less effective than chronic invasive recordings in the time domain. In other words, while acute ECoG allows free movement of electrode contacts within a given area, the time allotted to record – and thus determine the irritative zone – is limited to something around 20–60 minutes. In contrast, other methods allow recordings for days or weeks. Another disadvantage of acute ECoG is that recording electrodes usually cover only a given surface of the cortex. Other methods may allow the implantation of electrode contacts in different regions of one, or even the two hemispheres, and thus the chronic recording is not only longer, but also may encompass more cortical regions. This may be an apparent paradox with what was mentioned above, about the spatial advantages of the acute ECoG. This apparent paradox is reconciled by the 'golf player' approach to the localization of the EZ, which is a metaphor for the sequential steps taken to progressively circumscribe the cortical area in which the EZ is contained, resembling the approach of a golf player to progressively approximate the ball to hole. The first shot usually approximates the ball, the second aims at better positioning the ball as close as possible to the hole, and the third shot will eventually try to succeed in putting the ball in. The approach to the localization of the EZ also begins with semiology and scalp EEG, both providing a first step toward localization, which is refined by further 'shots', such as structural and functional imaging and, occasionally, invasive EEG recordings. Before we are close enough to the EZ, the cortical coverage provided by acute ECoG is usually smaller than other methods of recording, which can sample (interictal and ictal activity) from different areas of both hemispheres. However, once the cortical region containing the EZ is fairly circumscribed within the limits of a craniotomy, then the acute ECoG recording electrodes provide a better and flexible coverage of all cortical regions exposed by the craniotomy. This resolves the spatial resolution paradox.

Chronic recording with subdural grids and strips

Interictal spikes can also be probed through chronic invasive recordings with subdural grids and strips. These subdural

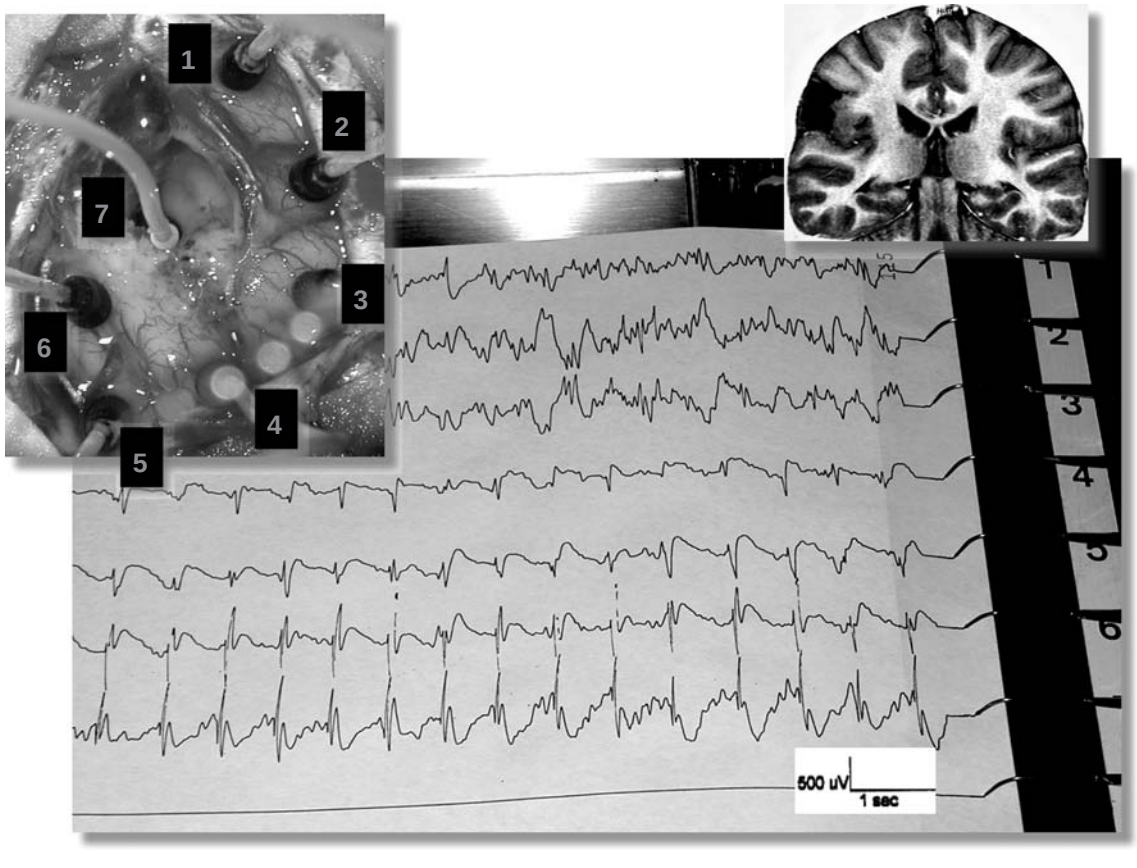

Figure 57.1 Composite picture of acute ECoG recording with carbon ball electrodes and histopathological H-E section showing type II focal cortical dysplasia. The recording was obtained during reoperation. Note that electrode 7 records from deeper regions on the bottom of the previous resection. The portion of the ECoG included in the picture is restricted to the recording of the electrodes shown on the left side. The ECoG montage is circular, starting with 1–2 and finishing with 7–1. Continuous, repetitive spikes very typical of type II focal cortical dysplasia are recorded phase-reversing at electrode position 7, with some adjacent volume conduction. The MRI picture of this patient is shown in Figure 57.2.

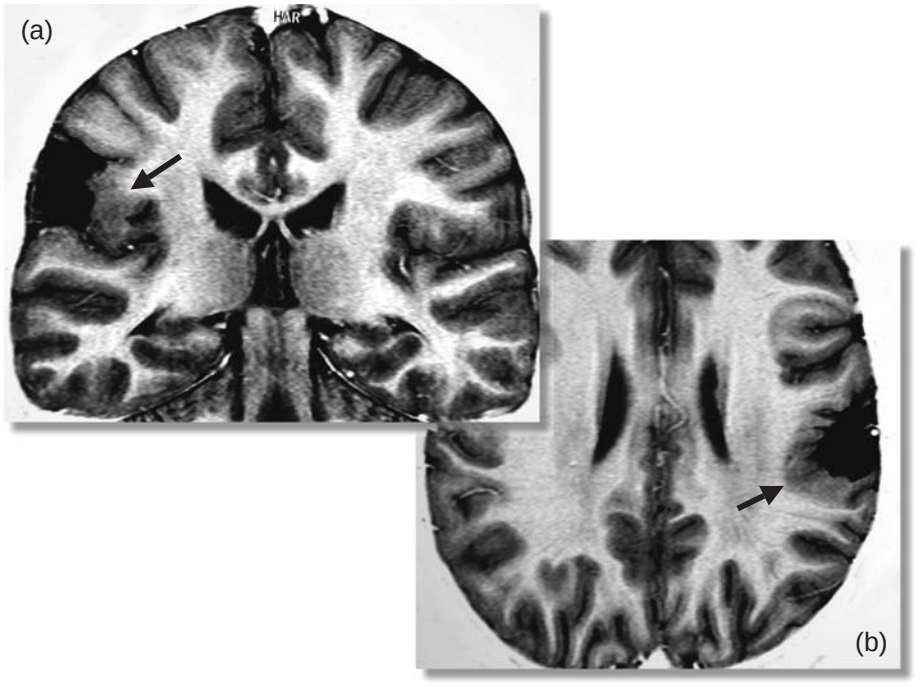

Figure 57.2 Postoperative coronal (a) and axial (b) MRI sections acquired on inversion recovery showing dysplastic tissue in the peri-insular 'deep' cortex (arrows). Previous resection was restricted to more superficial cortical regions and this deeper abnormality remained and led to seizure recurrence.

electrodes sample electrical activity from variable extensions of cortical tissue, within which the EZ is believed to be contained. The first main difference between chronic subdural recording versus acute ECoG is that whereas the latter specifically aims at interictal recording (that is, to pigeonhole the irritative zone as much as possible), the former is primarily intended to record seizures, that is, to localize the *ictal onset zone*. Theoretically, chronic subdural recordings with grids provide an almost ideal situation, in which both the ictal onset zone and the (more or less) adjacent irritative zone would be localized.[13] Several factors, however, mitigate against this very desirable scenario. First and foremost, is the need for a dedicated surgical procedure to implant the electrodes, with the attending risks of infection, edema, and hemorrhage.[14,15] In addition, grids cover only a portion of the exposed surface of the cortex, and it is not uncommon that parts of the irritative zone extend beyond (anterior, posterior, superior, or inferior to) the electrode coverage.[16] Because these electrodes are fixed, they cannot be moved after implantation. Another caveat, which chronic grids share with acute ECoG, is that both are incapable of recording fully (ECoG) or partially (grids) from inferior and medial surfaces of the cortex. Of course, grids can and often are implanted in areas inaccessible to carbon ball ECoG electrodes, such as the inferior temporal, the orbital, and the medial frontal cortices. However, the coverage is incomplete. Finally, one other important disadvantage of chronic subdural grids recording in comparison to acute ECoG is the fact that the latter can provide postresection recordings to verify the extent of resection of the part of the irritative zone exposed by the craniotomy. This often leads to tailoring of the extent of resection, which is important in many situations, particularly when the underlying pathology involves cortical regions in the deeper parts of the gyri (see above). Carbon ball electrodes can be used to probe from these deeper cortical regions after initial resection, which is not the case with grid and strip electrodes.

Intracerebral depth electrodes

The irritative zone can also be examined through intracranial EEG using stereotactically implanted depth electrodes. This is the only method allowing chronic recording of deeply situated cortical targets. At the outset it is important to mention that even more than the recording with subdural electrodes, the use of depth electrodes is fully intended to record ictal activity. Indeed, the very decision process of where to implant these electrodes is driven by the most likely ictal onset and early propagation regions, in what is known as the anatomofunctional 3D view of the EZ.[12,17] In other words, depth electrodes are implanted in the regions most likely to be involved at seizure onset and early propagation, providing a dynamic, electrical picture of seizure onset and progression.[18] The cortical volume sampled by depth electrode contacts is small, and thus a hypothesis-driven choice of targets is key to a successful investigation. Accordingly, this inherently limited sampling allows only an equally limited view of the irritative zone. However, the sampling provided, albeit limited, may be of relevance for the understanding of the relations between spikes, structural lesions, and ictal onset zones in selected cases. Examples include the interictal spikes recorded from within focal dysplastic lesions[12,19,20] adjacent from dysembryoplastic neuroepithelial tumors[21] and from mesial temporal regions[22] in patients with indication for bitemporal implantation. Nevertheless, it is to be understood that the indications for depth electrode implantation are virtually never related to the mapping of interictal spikes. In addition to the sampling limitations, depth electrode implantation is an invasive and costly

procedure whose indications – even to explore ictal onset zones – are often debatable.

The irritative zone (usually) contains the ictal onset zone: understanding the actual and potential relations

If the interictal spike is a signature of epileptogenicity, it is then to be expected that the region of seizure onset is to be found within the (usually larger) area from where spikes are recorded. Spikes can be generated by genuinely pathologic cortical regions but also by nonpathologic cortical areas whose epileptogenic threshold was lowered due to synaptic (or ephatic) connections with the primarily pathologic cortex. In other words, the irritative zone includes both pathologic and non pathologic tissue. Although the differentiation of where the former ends and latter begins is often blurred, it is accepted that the ictal onset zone is usually linked to pathologic tissue. This is an old concept, actually. In the 1940s, Penfield used the term 'epileptogenic lesion' to describe not necessarily a visible structural lesion, but rather a surrounding, partially damaged, cortical area in which a critical mass of preserved neuronal activity did generate spikes thought to be relevant for seizure generation.[4,5]

Taking from the discussion above, the identification of the irritative zone by whatever method is a 'first filtering' of electrical brain activity, useful to circumscribe the much valued ictal onset zone. This usefulness, of course, is constrained by the sampling issue. The more accurate the sampling, that is, the more accurate the determination of the irritative zone, the higher the chances of localizing the ictal onset zone. The use of invasive recordings in this regard is then to be critically appraised.

On the one hand, by recording directly from cortical generators, intracranial electrodes may refine the mapping of the irritative zone, adding dimensions unavailable or inconsistently available from scalp recordings, such as variable spike amplitude, sharpness, frequency, and rhythmicity. Within a larger cortical area, those regions displaying higher amplitude, sharper, very frequent and/or rhythmic spikes are usually closer to or colocalize with the ictal onset zone.[23] On the other hand, direct cortical recording by whatever invasive method often depicts a more extensive irritative zone than scalp recordings,[24,25] and this may be a confounding factor in the localization of the EZ. A notable example are the very frequent bitemporal independent spikes recorded through depth or subdural electrodes almost in every instance these electrodes probe both temporal lobes.[22] As shown in studies from the pre-MRI era, temporal lobes displaying frequent spiking in depth electrode recordings may *not* be associated with seizure generation in patients with temporal lobe epilepsy and bitemporal interictal spikes.[22] Thus, interpretation of the extent and significance of the irritative zone as recorded through invasive electrodes cannot be dissociated from the other findings obtained through semiology, imaging and scalp recordings.

In the section above I analyzed the different types of invasive methods which can be used in the presurgical evaluation and which can record the irritative zone. At this point it should be said that each method will provide somewhat different relations between the irritative and the ictal onset zone. For instance, acute ECoG usually does not allow a correlation between these two anatomo-functional zones, and thus will rely on the data derived from imaging, semiology, and scalp recordings as well as on spike morphology, frequency and rhythmicity to adequately interpret the relevance of acutely recorded spikes. In contrast, one of the major advantages of invasive recordings with subdural grid and strip electrodes is to allow a spatial relation between a larger cortical region displaying spikes and (usually) a more limited region involved at seizure onset. Nevertheless, as will be seen below, even with the advantage of ictal electrographic recordings it is often difficult to assign 'values' or 'weights' to regions more or less adjacent to the ictal onset zone which display interictal spikes. Not unexpectedly, therefore, some studies have shown that the best surgical results are obtained with resection of both the ictal onset and the irritative zones, at least the irritative zone within the recording limits of subdural grids.[26,27] How much these findings should impact on the very indication of grid implantation (versus, for instance, acute ECoG recording) is not known. As will be seen later, the type and extent of the associated structural lesion (when present) or the presumed underlying etiology will be important to decide on how much of the irritative zone should be included in the final resection (as part of the EZ or 'relevant' epileptogenic brain tissue).

An additional point of practical relevance concerns the not uncommon observation that seizures may recur despite apparently complete resection of the ictal onset zone. The logical way to approach this phenomenon is through the conceptual understandings that the (i) ictal onset zone is not synonymous with the EZ, and (ii) that despite the best possible localization of the actual EZ at one point in time, there may be latent cortical regions that may take over as a previously unsuspected epileptogenic zone in the future. This latter possibility was conceptually advanced by Rosenow and Ludders by coining the terminology 'potential epileptogenic zone'.[28] The reason I mention this here is that the irritative zone – or the correct appraisal of the significance of the different types of interictal epileptic activity – may prove useful to anticipate the possibility that some cortical region may eventually harbor a 'potential EZ'. Notwithstanding the elegant conceptualization recently proposed by Rosenow and Ludders, the idea of a potential EZ was already present in some of Penfield's writings, where he proposed that within an area of epileptogenic cortex identified by ECoG, seizures could originate in more than one subregion and propagate through facilitated pathways.[4,5] These pathways could thus be conceived as a common denominator for electrical seizures originating in different subregions of a larger area of epileptogenic cortex. This, in turn, would lead to similar semiology, irrespective of the exact subregion of seizure origin. These are scenarios in which the EZ (or the 'potential' EZ) is more extensive than the (any single) seizure onset zone, justifying the individualization of these concepts. It is to be expected that incomplete resections of this 'potential' EZ, with preservation of higher threshold seizure onset zones, may be associated with later seizure recurrence after resection of the lowest threshold ictal zone.[29] In summary, the analysis of historical observations recently advanced through modern concepts suggest that 'relevant' epileptogenic tissue may be present outside the boundaries of the actual ictal onset zone, and one of the keys to anticipate this possibility is through improvements in the analysis of the irritative zone.

Lesions and spikes: the various combinations between structural lesions and the irritative zone

Traditionally, the relationship between epileptogenic cortex and epileptogenic lesions has been a critical issue, particularly at a time when the extent of resection was determined intraoperatively on the basis of acute ECoG combined with visually identifiable cortical scars and other types of lesions.[7]

From the start, Penfield and Jasper demonstrated that spikes were to be expected in the cortex *surrounding* the structural lesions, particularly those lesions without neuronal components, such as glial tumors or cysts.[4] These surrounding regions – as well as atrophic cortical lesions – were thought to be 'injured areas of gray matter'. Thus, the early history of the relations between epileptogenic lesions and epileptogenic cortex was based on the concept of *abnormal gray matter within atrophic scars or surrounding foreign tissue lesions*, and particularly related to the fact that epileptiform discharges were to be expected in the structurally and functionally disturbed but still viable surrounding gray matter. These concepts were further supported by pathological examination of this surrounding tissue, which usually demonstrated some degree of gliosis.

Clearly, epileptiform spikes can be recorded from structurally normal cortex, as demonstrated in different epilepsy syndromes, from the benign rolandic epilepsy[30] to the mirror foci studied by Frank Morrell,[31] which represented epileptiform spikes recorded at a distance from a foreign tissue lesion, in regions synaptically connected with the area harboring the primary lesion. Demonstrations that not all epileptiform spikes indicate *structurally abnormal* cortex have actually been provided long ago by the Montreal Neurological Institute school, and prompted the terminology 'red' versus 'green' ECoG spikes, pointing respectively to epileptiform discharges recorded from abnormal cortical tissue – that could be related to seizure generation – and to discharges recorded from structurally normal underlying cortex.[32] The latter was regarded as not relevant for the production of seizures. Nevertheless, in a detailed follow up study published in the early 1960s, Jasper and colleagues demonstrated a significant (albeit not absolute) correlation between completeness of excision of the cortex displaying interictal spikes and surgical outcome, suggesting that cortically recorded spikes were, more often than not, relevant for the overall epileptogenic proneness.[6]

The advent of MRI has shown that the generation of interictal spikes in lesional epilepsies is distributed along a spectrum, one end of which being represented by those patients in whom discharges are restricted to the cortical area containing the lesion or its immediate surroundings, and the other end by patients whose interictal discharges are distributed over much larger regions of one or both hemispheres. One intermediate situation is that in which spikes are recorded from cortical regions which are more extensive than the 'surroundings' of a lesion, but are still contained, for instance, in a single lobe or 'quadrant' of the brain. A major challenge of the presurgical evaluation in patients with refractory lesional partial epilepsies is to synthesize the relationships between the structural lesion, the irritative zone and the seizure onset zone into a sound localizing hypothesis for the ultimate EZ.

Different types of irritative zone on invasive recordings and their contribution to the 'relevant' epileptogenic brain tissue

Not all spikes are the same

A major point in any discussion on the irritative zone, or the cortical region displaying 'interictal spikes', is the fact that such spikes may be generated from pathologic tissue or from tissue to which this is synaptically or ephatically connected. Thus, differentiating which spikes represent primary epileptogenic processes of abnormal tissue from those signaling nonpathologic low-threshold cortex is very important. This issue is even more important when related to invasive recordings because the direct cortical recordings enabled by such electrodes magnifies (in a spatiotemporal dimension) the recording of spikes. In other words, direct cortical sampling is often associated with the recording of spikes in regions where they were not seen in scalp EEG, as well as a higher frequency and a higher amplitude of discharges.[24,25] In this context, the attention to details is of utmost importance to correctly assess the irritative zone as determined through invasive recordings. What should one look at then?

First, whether spikes occur associated or not with background abnormalities. Spikes associated with regions of continuous (or frequent) slow wave activity[33] or with background attenuation[27] as recorded through any of the methods of invasive recordings are more significant as markers of 'relevant' epileptogenic brain tissue, than spikes recorded over a normal background.

Second, whether spikes are isolated, discontinuous, and infrequent or, alternatively, frequent, continuous or quasi-continuous, repetitive (that is, consistent in a given region), and with some hint of rhythmicity. Although I will discuss this further, it should be stated at this point that repetitive, continuous or almost continuous spikes tend to colocalize with pathologic cortex, most commonly in focal cortical dysplasias[8,12] (and, more rarely, on gliotic scars).[34] Frequent, but not continuous or rhythmic, spikes have also been shown to be correlated with underlying pathological epileptogenic cortex.[35]

Third, applying digital quantification tools to direct cortical recordings, some authors have shown that within a large cortical region displaying spikes, some subregions can be shown to lead the others. Apparently, these 'leading regions' tend to be more significant to the identification of 'relevant' epileptogenic brain tissue.[23,36] However, this kind of complex work has not been sufficiently replicated particularly in regard to the practical relevance of resecting these 'leading' regions in relation to surgical outcome.

In summary, as already dwelled upon above in the section on the relationships between lesions and spikes, it is yet to be fully determined which spikes are 'red' and which are 'green'. Association with abnormal background, consistency, continuity, rhythmicity, as well as high frequency and amplitude are all features that have been described as markers of 'relevant' epileptogenic brain tissue. Within this framework, the characterization of interictal spikes through invasive recordings may then provide useful clues to the delineation of the presently determined and potential EZ.

When the irritative zone largely defines the epileptogenic zone: histopathological relations

In some specific histopathological scenarios, the irritative zone may be crucial to *define* the extent of the EZ. This is the case with some types of neocortical pathology, most notably the focal cortical dysplasias and gangliogliomas.[8,12,19,35] In these contexts, the application of invasive recordings is of paramount importance to fully characterize the interictal features that have shown to be highly correlated with the extent of the EZ. Perhaps three examples will suffice to make this point. First, acute surface ECoG recordings of focal cortical dysplasias often show continuous, rhythmic or bursting spikes that tend to be exquisitely colocalized with the dysplastic lesion[8,37] (Figures 57.1 and 57.3a,b). In fact, this colocalization – and the pivotal role of such patterns as markers of the EZ – has been demonstrated by the highly significant correlation between persistence of cortical regions displaying such continuous spiking and poor surgical outcome. In a recent review of 41 patients with type II (Taylor-type) focal cortical dysplasia with extended follow-up, none of the 22 in whom cortical regions displaying continuous spiking remained in postresection ECoG recordings were seizure free after operation (Palmini *et al*, unpublished observation). Similar findings have been reported by the group at King's Hospital, in London.[9] Another example, with a different method of invasive recording, was provided by the group at Saint-Anne, in Paris. The authors report on the stereo-EEG findings in patients with type II focal cortical dysplasia and showed that rhythmic spike discharges were virtually always recorded intralesionally and that seizures virtually always started from the same electrode contacts which, interictally, displayed these rhythmic discharges.[12,19] These findings have been independently confirmed.[38] Finally, Rosenow and colleagues have reviewed interictal cortical findings recorded through chronic subdural grid implantation in patients with gangliogliomas and have also shown very frequent spikes in the regions surrounding these developmental tumors.[35]

Taken together, these interictal findings in focal cortical dysplasia and gangliogliomas are intimately linked to the ultimate delineation of the EZ. In a sense, one could say that coupled with the localization of the structural lesion, these interictal findings could suffice to determine the extent of tissue that should be resected to achieve seizure freedom. Of course, such statement would kindle the debate on the role of determining the ictal onset zone in patients with these *specific types* of lesion. If one accepts the concept of 'potential' EZ,[2,28] it may well be that more restricted resections based upon lesion location and the ictal onset zone may prove less successful in the long run than resections based on lesion location and the striking irritative findings uncovered by invasive recordings in focal cortical dysplasias and gangliogliomas.

How completely should the irritative zone defined through invasive recordings be resected: outcome relations

Evidence accumulated over the years suggests it to be wise to address the issue of the outcome relations of completeness of resection of the irritative zone according to topography and etiology of the epilepsy. In doing so, we will first discuss this issue in patients with the various etiologies of temporal lobe epilepsy, and then proceed with a similar approach to those with extratemporal epilepsies.

Outcome relations of completeness of resection of the irritative zone in temporal lobe epilepsies

It is now accepted that one should view temporal lobe epilepsies within a topographical/etiological framework. Broadly speaking, this approach leads to the identification of three topographical/etiological scenarios: TLE associated with hippocampal sclerosis, TLE associated with other focal lesions, and MRI-negative TLE. Even though it would be justifiable to further subdivide the TLE due to non-HS lesions according to the specific etiology and to mesial versus lateral topography, the three-tiered approach mentioned above probably fits best with the discussion on the relations between rsection of the irritative zone and surgical outcome.

When epilepsy is associated with a non-HS lesion or when no lesion is seen on the MRI in patients with otherwise clearcut TLE, there is evidence that resecting the lesion and the cortical regions displaying spikes is the best strategy.[39–41] On the other hand, there seems to be a convergence of data and authoritative opinion [42,43] that in patients with temporal lobe epilepsy due to mesial temporal sclerosis there is no benefit in resecting neocortical spikes beyond the planned margins of resection. This, of course, is corroborated by the equally high rates of seizure freedom in patients undergoing anterior temporal lobectomy (which resects neocortical tissue) and selective amygdalohippocampectomy (which does not).[44]

Outcome relations of completeness of resection of the irritative zone in extratemporal epilepsies

The decision-making process regarding the extent of resection in patients with extratemporal epilepsies is significantly more complex than that in TLE. Here, the two most relevant domains are *presence or absence* of a visible lesion, and also the *type of lesion*. Some studies have provided overall results across both domains, and other have focused in specific scenarios of lesional versus non-lesional epilepsies and on specific etiologies.

In general, studies with subdural grids and depth electrodes have suggested that complete resections of the irritative zone tended to correlate with a better surgical outcome. For instance, Bautista and colleagues from Yale [45] have shown that the persistence of interictal spikes recorded through invasive recordings was almost always predictive of surgical failure, even in patients in whom complete excision of the ictal onset zone was performed. Similar correlations between complete versus partial removal of the irritative zone and surgical outcome have been produced from Cleveland.[26] Of course, some considerations apply to these findings. For instance, in the Yale study, most of the patients in whom the irritative zone was multifocal and therefore not fully resected had non-lesional extrahippocampal epilepsies, usually due to microscopic dysplastic lesions. Other studies combining different types of pathologies showed somewhat different results. For instance, the series from Miami in children[27] and that from King's College Hospital[9] have both shown a lack of correlation between complete resection of the irritative zone and outcome. Interestingly, these two series have also to be analyzed in some detail, because in both the authors explicitly 'split' the irritative zone in two patterns, differentiating between very

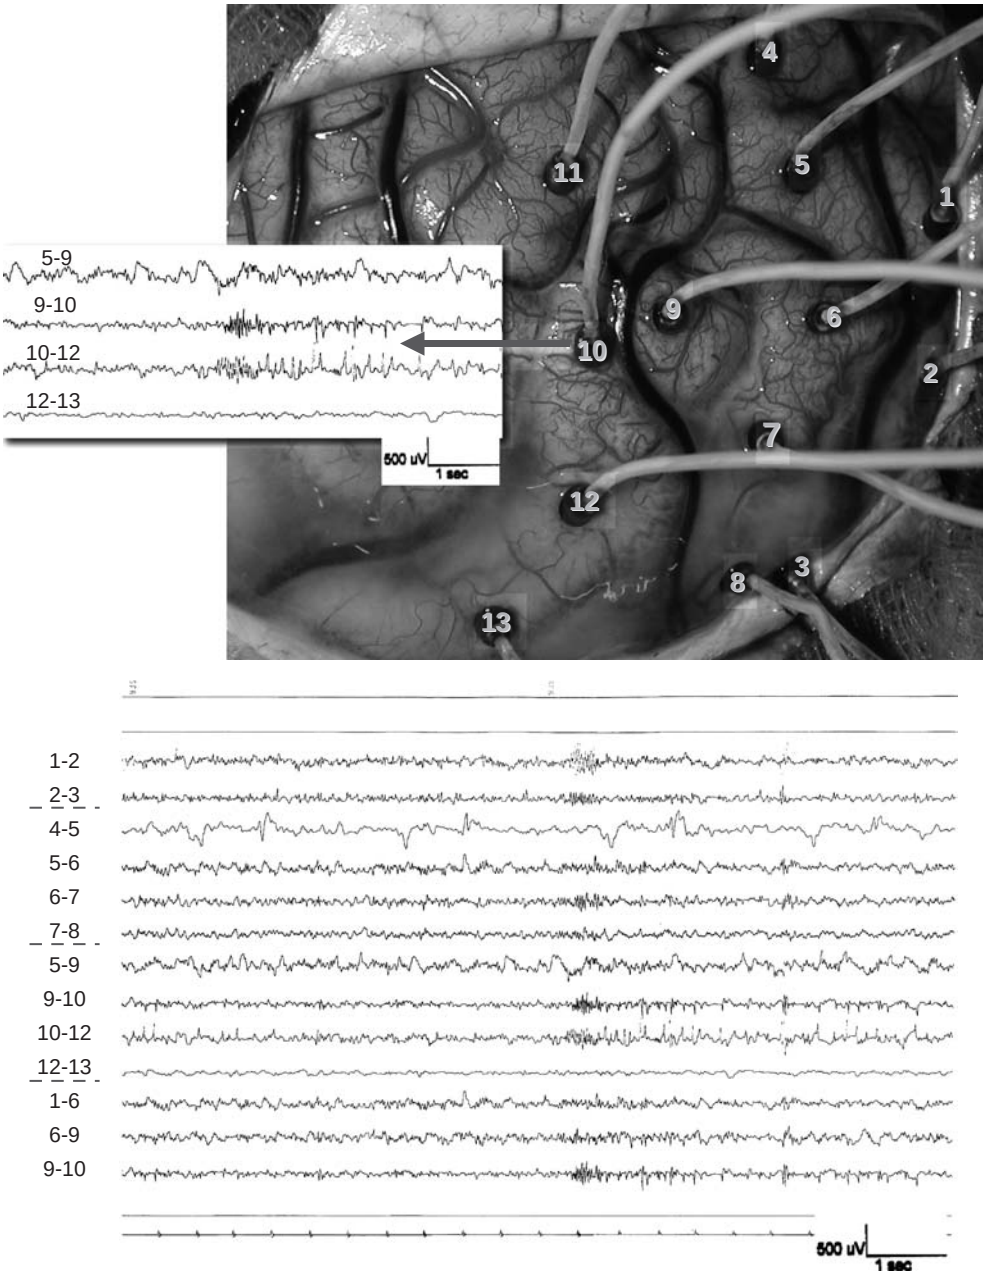

Figure 57.3 Top: Exposed craniotomy of the left frontocentroparietal regions. A 25-year-old man with refractory partial seizures beginning with a 'strange sensation' in the right forearm, then right hand, and rapidly followed by dystonic movement of the right arm and hand. Pathology showed focal cortical dysplasia. The frontal lobe is toward the right side of the picture. Thirteeen carbon-ball electrodes are shown overlying the exposed cortex. (The depicted electrode distribution followed several others fully exploring the exposed cortex; particulalrly, there were no epileptiform discharges in the 'non covered' posterior portion of the exposed cortex, in parietal the gyri beyond electrode 10). The arrow points to the ECoG recording and shows a paroxysmal burst of fast activity followed by repetitive spikes in the parietal lobe. Bottom: Acute ECoG showing a paroxysmal burst of fast spikes involving electrodes 2, 6, 9, and 10. Note that at electrode position 10 repetitive spikes follow the bursting discharge.

active, continuous or bursting spiking patterns – resection of which *did* correlate with outcome – and sporadic, infrequent, 'distant' spikes, resection of which *did not* correlate with surgical outcome.

From Montreal[46,47] additional data helps to shed light on the issue of the relevance of resecting the irritative zone. A review of the historical series of frontal lobe epilepsy surgeries in that institution showed that in patients with lesions, when acute ECoG spikes involved two or more gyri beyond the lesion, or when spikes persisted after the final resection, surgical outcome tended to be unfavorable. As expected, there was also a strong correlation between completeness of resection of the lesion and seizure control, which made it difficult to single out the specific role of the resection or persistence of ECoG spikes. The main positive message was the highly favorable outcome predicted by the combination of complete lesionectomy and complete resection of ECoG spikes, particularly when the latter were restricted to one or two gyri adjacent to the lesion. In patients with nonlesional frontal lobe epilepsy, both the extent of the irritative ECoG zone and post-resection data correlated with outcome: widespread spike distribution (involving more than two gyri) and persistence of spikes at some distance from the margins of excision correlated with unfavorable outcome. However, even in the context

of nonlesional frontal lobe epilepsies, complete resection of spiking cortex, particularly if spatially restricted, was occasionally associated with a good surgical outcome.

Finally, bringing pathology type to the forefront of this debate, the issue of the irritative zone in focal cortical dysplasias, particularly in type II (or Taylor-type) FCD[48] must be addressed. Several authors have independently confirmed the tendency of FCD to display two distinct types of interictal epileptiform discharges on acute ECoG.[8-10,49] The first type has a specificity of 75% for this pathological entity[9] and consists of a remarkable epileptiform pattern on acute ECoG manifesting as either continuous spiking, repetitive bursting of polyspikes, or recurrent electrographic seizures When cortical tissue displaying such continuous or bursting spikes are not included in the resection, seizures virtually always recur after operation.[8,9] Virtually identical findings have been recently reported from the Cleveland Clinic in a large series of patients with focal cortical dysplasia studied with subdural grids. Actually, the authors showed that the degree of resection of cortical regions displaying continuous or bursting spiking interictal patterns correlated with surgical outcome to the same extent as the resection of the ictal onset zone.[16]

The other type are the more usual *discontinuous* interictal spiking more or less adjacent to the dysplastic lesion. A recent reanalysis of our data in Porto Alegre shows that complete resection of these discontinuous spikes is also probably relevant to complete seizure control.[11] Caution, however, must be exercised in this conclusion, because more often than not patients had incomplete resections not only of the cortical tissue displaying these spikes, but also of the dysplastic lesion itself. The relevance of this discontinuous, sporadic, spikes recorded on acute ECoG in patients with FCD is still a matter of debate, because results have been conflicting. For instance, while our analysis from Porto Alegre and that from Montreal[11,47] suggests that cortical regions displaying these spikes should be included in the final resection, the series from King's College suggests that persistence of these spikes in post-resection ECoG do not correlate with surgical outcome.[9]

Taken as a whole, these findings on the outcome relations of completeness of resection of the irritative zone in extratemporal epilepsies inevitably transport us back in time to Rasmussen's concept of 'red' versus 'green' spikes. We believe the review presented in this chapter demonstrates that in the last 40 years or so we have been able to characterize some of the 'red' spikes. More work should be done to refine the separation between 'green' and 'red' isolated, sporadic spikes in different pathologies and also in MRI-negative scenarios. As a final word, we believe the results from different Centers[6,26,45] are indicative that it may be wise to step back and reappraise the relevance of the irritative zone in determining the 'relevant' epileptogenic brain tissue, and avoid giving so much more importance to the ictal onset zone. Even high class technology has not put to rest the importance of incorporating interictal epileptiform findings in the final planning of surgical resection.

Acknowledgment

I would like to thank my colleague and friend Eliseu Paglioli for providing the surgical pictures included in this chapter.

58 The significance of interictal fast ripples in the evaluation of the epileptogenic zone

A Bragin, RJ Staba, and J Engel, Jr

Introduction

Effective surgical treatment for focal epilepsy requires accurate delineation of the epileptogenic zone. The epileptogenic zone is defined as the area necessary and sufficient for spontaneous seizure generation, the removal or disconnection of which is necessary to achieve a seizure free outcome.[1] At the present time, the epileptogenic zone is a theoretical concept. Its location and extent are approximated by a presurgical evaluation designed to identify the irritative zone, which generates spontaneous EEG spikes; the ictal onset zone; the structural epileptogenic lesion; the symptomatic zone, which is responsible for initial ictal manifestations; and the functional deficit zone. There is, as yet, no diagnostic test that reliably and directly identifies the epileptogenic zone.

Interictal spikes are the electrographic hallmark of epilepsy, and are commonly used to diagnose epileptic conditions and to localize the area of epileptogenicity in patients who are candidates for surgical resection. The irritative zone, however, is often broader than the epileptogenic zone. Often, interictal spikes are recorded bilaterally even though seizures originate unilaterally. Intraoperative spike mapping is no longer used as the principal guide for determining the extent of tailored neocortical resections because it is well documented that interictal spikes are often falsely localizing. An approach that could discriminate between interictal spikes generated specifically within the epileptogenic zone and those that represent either propagation or transients initiated in irritable brain areas that are incapable of generating spontaneous seizures would make it possible to directly measure the epileptogenic zone, and would greatly facilitate presurgical evaluation. A unique electrographic epileptic abnormality, Fast Ripples (FR), offer an opportunity to develop a means to directly identify the epileptogenic zone.

FR are high frequency oscillations (150–500 Hz, in human (Figure 58.1) and 200–600 Hz in rats, (Figure 58.1) that occur in conjunction with interictal spikes, or occur independently of interictal spikes, but are strongly associated with brain tissue capable of generating spontaneous seizures.[2–4] To date, it is only possible to detect FR with wideband microelectrode recordings directly from hippocampus and other mesial temporal parahippocampal limbic structures. Although considerable work has now been done to characterize FR in mesial temporal lobe epilepsy, it is not known whether similar high frequency oscillations characterize the epileptogenic zone in neocortex. Also, in order for FR to become a useful diagnostic tool for determining the location and extent of the epileptogenic zone, it will be necessary to develop alternative methods to measure them noninvasively, preferably with neuroimaging that permits three-dimensional visualization of the entire brain. Even if noninvasive methodology for detecting FR is not developed, approaches that permit the direct brain recording of these phenomena with standard depth or grid electrodes would still greatly facilitate presurgical evaluation, because FR occur interictally and could be recorded intraoperatively, obviating the need for ictal recording.

Fast ripples as surrogate marker for delineating the epileptogenic zone

Fast ripples are epileptogenic events

In animals, high frequency oscillations in the range of 100–200 Hz, termed 'ripples,' occur in the normal hippocampus[5] and these normal electrical events can also be recorded from human hippocampus.[2,4,6,7] Ripples are believed to promote synchronization and information transfer across long distances.[8,9] Wideband microelectrode recording from epileptic hippocampus in patients with mesial temporal lobe epilepsy, and in the intrahippocampal kainic acid (KA) rat model of this disorder, revealed that normal ripples persist, but that much higher frequency oscillations FR can also be recorded in the epileptic hippocampus that are not typically present in the normal rat hippocampus, or contralateral to the hippocampus where seizures begin in the human.[3,4] These FR oscillations are similar to ripples in some ways. For example, both ripple and FR generation are state dependent. The rate of ripple and FR occurrence is higher during slow wave sleep compared to wakefulness.[6] However, during REM sleep, the rate of ripple occurrence decreases to a level even lower than that during the awake state, while the rate of FR occurrence during REM sleep remains higher than during wakefulness.[6]

Other distinctions can be made between ripples and FR. FR are common in the dentate gyrus where ripples never occur, and FR are generated by more localized neuronal networks than ripple oscillations (Figure 58.2).[7,10] The FR phase reversal in entorhinal cortex coincides with that of population

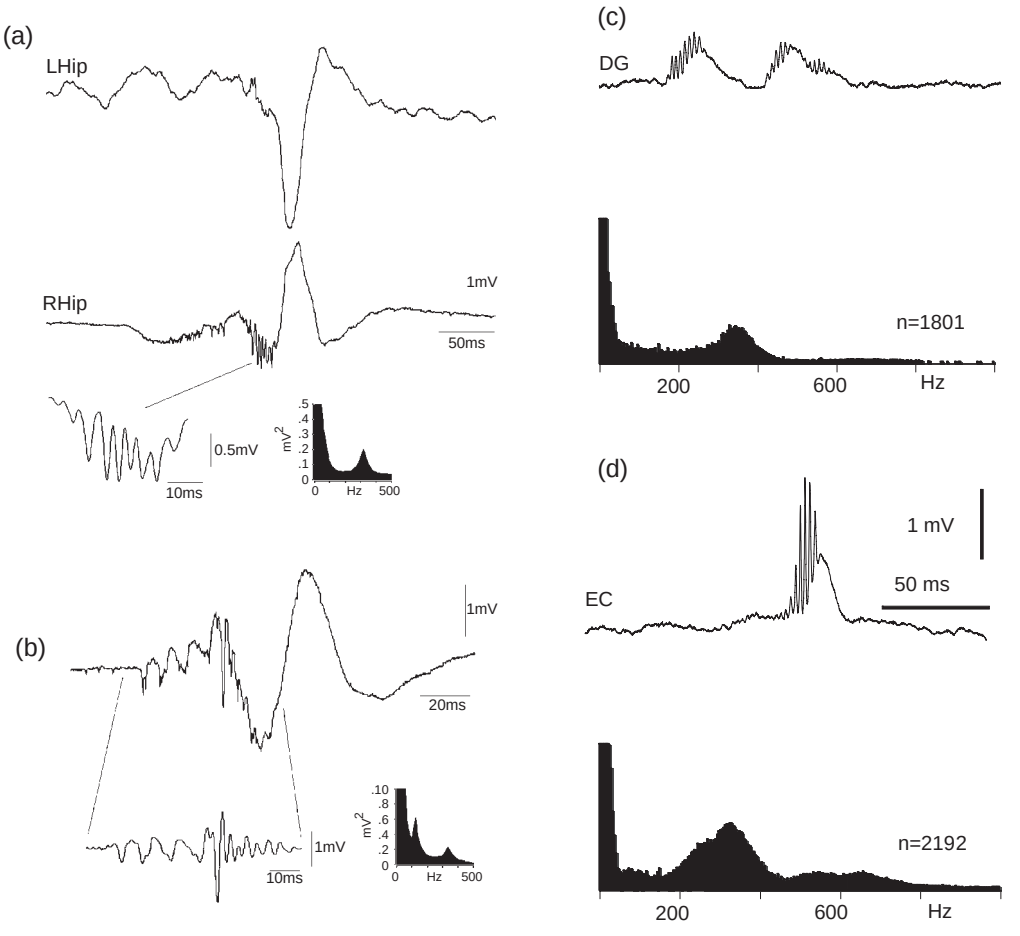

Figure 58.1 Wideband hippocampal electroencephalogram (EEG) recorded during a polysomnographically defined episode of nonrapid eye movement sleep. (a) EEG from left (LHip) and right hippocampus (RHip) recorded from a patient who had seizure starting in the RHip. Note the large amplitude EEG sharp wave detected in both LHip and RHip sites, whereas the small amplitude fast ripple (FR) oscillation was detected in only the RHip recording site. Power spectral analysis indicates a peak in power at approximately 320 Hz. Enlarged trace lowpass filtered 600 Hz. (From ref. 6 with permission). (b) Wideband EEG recorded from subicular complex shows FR immediately after a ripple oscillation. Enlarged trace below was bandpass filtered 80–500 Hz. The two peaks in the power spectra reflect the ripple (130 Hz) and FR (330 Hz). (c. Top) FR in the dentate gyrus of epileptic KA treated rat. (Bottom) Averaged power spectrogram of 1801 FR events. (d. Top) FR recorded in the entorhinal cortex of epileptic KA treated rat. (Bottom) Averaged power spectrogram of 2192 events (modified from ref. 10 with permission).

spikes evoked by electrical stimulation of hippocampus suggesting a common afferent input (Figure 58.2C).[7] Ripples appear to reflect summated synchronous inhibitory postsynaptic potentials,[11] whereas FR appear to represent summated action potentials from synchronously bursting neurons (i.e. bursts of population spikes),[3,10] The unique mechanisms generating ripples and FR are based on studies that show presumed granule cells discharge bursts of action potentials during FR oscillations recorded in the dentate gyrus,[3] and population spikes in this area reflect hypersynchronous discharges of granule cells.[12] In addition, voltage depth profiles of FR recorded in the dentate gyrus are similar to voltage depth profiles of population spikes evoked by electrical stimulation of the perforant path.[10]

Bursting neurons are known to be a characteristic of the epileptogenic region, and represent a large proportion of neurons in acute experimental foci, such as those induced by cortical penicillin.[13] The percentage of neurons that burst synchronously in chronic models of epilepsy, and in human epilepsy, however, are very small.[14] Whereas it can be extremely difficult to find synchronously bursting single units within epileptogenic regions of patients with epilepsy using microelectrode recordings,[15–17] a small number of synchronously bursting neurons can generate a field potential that is recordable over a much larger area. Recording FR, therefore, is an alternative and more sensitive approach to detect tissue that contains synchronously bursting neurons.

Fast ripples are unique to the epileptogenic zone

In experimental animal models of mesial temporal lobe epilepsy, FR can only be detected in the damaged hippocampal and parahippocampal structures involved in seizure generation.[2] They do not occur after kindling, for instance, because these animals do not generate spontaneous seizures. In patients with mesial temporal lobe epilepsy, FR are typically encountered in mesial temporal structures on the side where seizures originate, but occur much less frequently within contralateral homotopic structures (Figure 58.3).[4] Furthermore, rates of FR activity are higher in atrophic hippocampus compared to hippocampus that appears normal on MRI,[6] but FR are also present within parahippocampal structures and may occur most frequently in subiculum (Figure 58.4).[6]

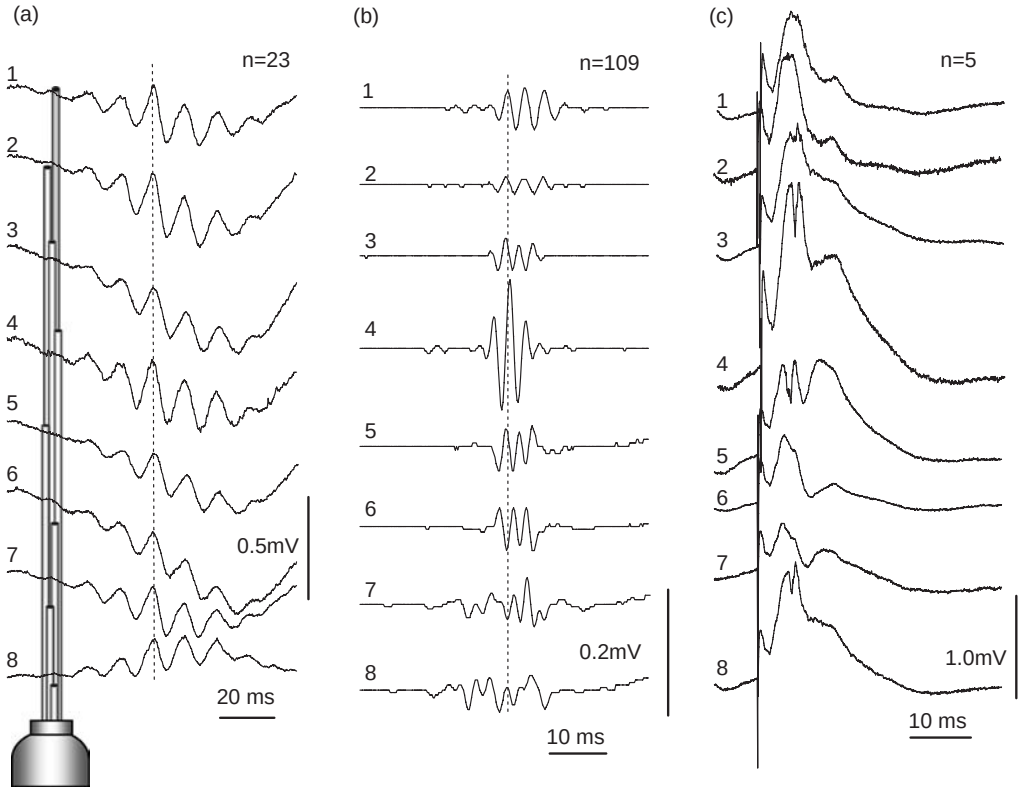

Figure 58.2 Comparison of voltage versus depth profiles of (a) ripples, (b) FR and (c) field potentials evoked in entorhinal cortex in response to hippocampal stimulation. Numbers on the left indicate microelectrode number in the bundle (shown in panel A), where microwire 1 is longest and was recording in the superficial layer of EC, while microwire 8 is shortest and was recording in the deepest layer of EC. The distance between microelectrode tips is 500 µm. Numbers on the top indicate number of events in each average. Notice that ripple oscillations do not show phase reversal at any of eight microelectrodes, while FR oscillations show phase reversal between microelectrodes 3–4 and 5–6. Maximum of evoked potential amplitude (c) is at microelectrodes 3 and 4 (from ref. 7 with permission).

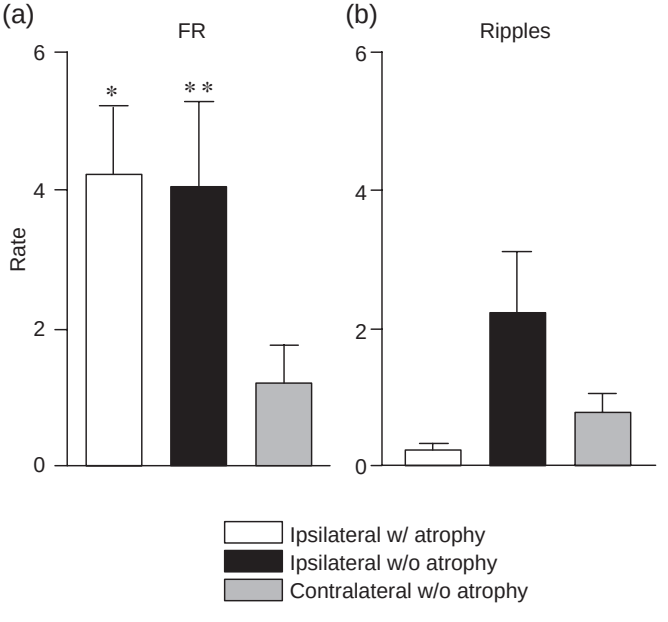

Figure 58.3 Rates of fast ripple (FR) and ripple occurrence in relation to epileptogenic zone. a. Mean (± SE) FR rates per 10-minute period in areas ipsilateral to seizure onset with atrophy and without atrophy were significantly higher that the FR rate in contralateral areas, none of which showed evidence of atrophy (*p=0.01, **p=0.02). b. Mean Ripple rates in relation to epileptogenic zone were not significantly different (from ref. 6 with permission).

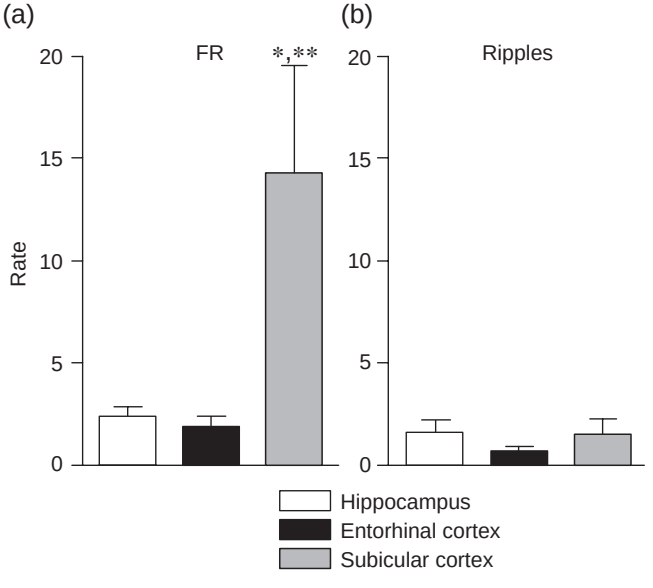

Figure 58.4 Rates of FR and ripples in relation to medial temporal location. c. Rate of FRs (per 10-minute period) in subicular cortex (n=4) was six times higher compared with rate of FR discharge in both hippocampus (n=27; *p=0.002) and entorhinal cortex (n=19; **p=0.001). d. Ripple rates were not significantly different between medial temporal structures. (from ref. 6 with permission).

Interestingly, subiculum has been implicated as a particularly epileptogenic region in patients with mesial temporal lobe epilepsy because of persistence of an immature excitatory response to the inhibitory neurotransmitter GABA.[18]

FR are associated with seizure generation

The intrahippocampal kainate rat model of mesial temporal lobe epilepsy displays both hypersynchronous and low-voltage fast ictal onsets, very similar to the types of ictal onsets seen in human mesial temporal lobe epilepsy.[19,20] The individual hypersynchronous EEG discharges that make up the hypersynchronous ictal events contain FR initially, and eventually are characterized by a complex consisting of FR followed by gamma frequency oscillations, referred to as an 'FR tail gamma complex'.[20] Interically, FR can be synchronized across distant structures, often beginning in dentate and rapidly occurring in entorhinal cortex, although they can begin in entorhinal cortex and rapidly appear in dentate[20] (Figure 58.5). The significance of the development of gamma oscillations at ictal onset is unclear, but these are believed to reflect inhibitory mechanisms[22,23] that may be a product of the so-called 'dentate gate',[24] which acts to prevent ictal discharges from propagating to the hippocampus proper and to structures outside the temporal lobe that are responsible for the manifestation of behavioral seizures. These hypersynchronous discharges in patients are either associated with auras, or no signs or symptoms.[19,25,26]

In the KA rat, hypersynchronous seizures occur preferentially during sleep and are unassociated with behavioral changes.[20] Hypersynchronous discharges, however, can rapidly evolve to low-voltage fast discharges which are then associated with contralateral propagation and complex partial seizures the human, and behavioral seizures similar to stage 5 amygdala-kindled seizures in the KA rat.[20] In the rat, low-voltage fast onset seizures also occur in the hippocampus during wakefulness, although they are much less frequent than the hypersynchronous ictal events. Occasionally, a single hypersynchronous discharge with FR precedes the low-voltage fast ictal discharge, but in most cases this is not observed.[2] Because these events in patients are usually regional, whereas hypersynchronous ictal onsets are much more focal, it is likely that the electrodes are not at the site of the seizure origin for low voltage fast onset, which is why the initial FR oscillation is not visible. These observations, however, strongly suggest that FR reflects the neuronal mechanisms responsible for seizure generation and are not merely a nonspecific effect of neuronal damage.

FR reflects mechanisms of epileptogenesis

In the KA rat, abnormal high frequency oscillations can be recorded in dentate gyrus days to weeks before spontaneous seizures appear.[27] Not all rats treated in this manner develop spontaneous seizures, and the appearance of FR predicts which rats will become epileptic (Figure 58.6). The earlier high-frequency oscillations are recorded, the earlier spontaneous seizures develop. FR also appear before mossy fiber sprouting can be detected, and there is no correlation between the location of FR-generating clusters and mossy fiber sprouting, suggesting that these two characteristic features of the epileptogenic hippocampus are unrelated.[20]

Fast ripples represent activity in small neuronal clusters

FR are not recorded homogeneously throughout epileptogenic structures, but are localized to small discrete areas approximately 1 mm^3 in volume (Figure 58.7).[10] The size and

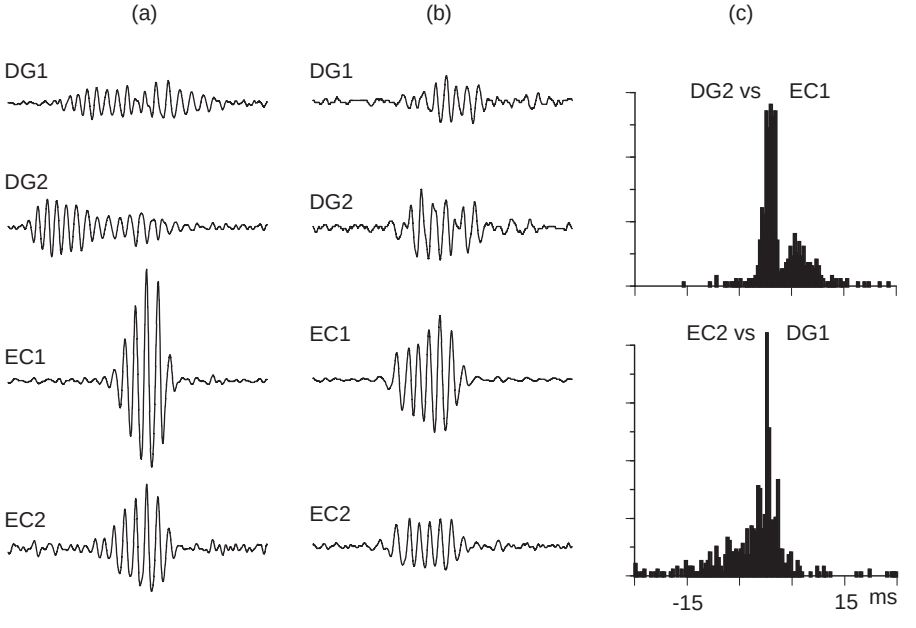

Figure 58.5 FR oscillations recorded in two areas of dentate gyrus (DG, DG2) and in two areas of entorhinal cortex (EC1, C2). a. Shows an example of FR oscillation occuring first in the recording site DG2 and than with different delay in other recording sites. b. Shows an example of FR oscillation occuring first in the entorhinal cortex. c. Crosscorellograms of FR occurrence between different recording sites. (from ref 22. with permission).

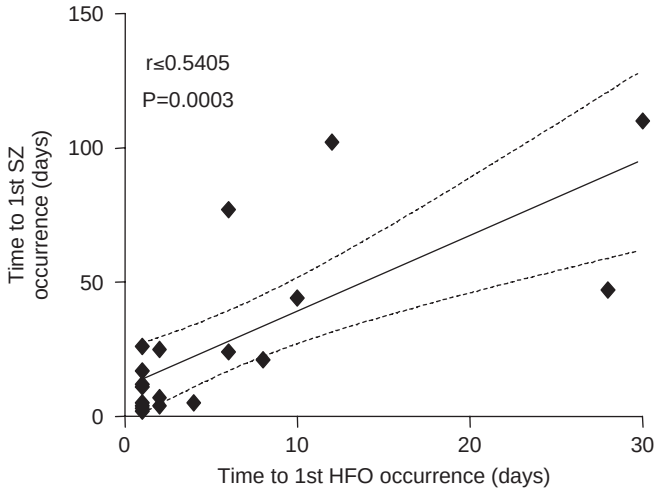

Figure 58.6 Correlation between first time of occurrence of high frequency oscillations (HFOs) and first day of seizure occurrence (from ref. 28 with permission).

location of these clusters remain stable over weeks to months (Figure 58.8), suggesting that they consist of tightly interconnected neurons that burst synchronously.[28] The volume of tissue capable of generating spontaneous or stimulation-induced FR can be increased, however, by application of small amounts of the GABA antagonist bicuculline.[28] This suggests a possible mechanism for seizure generation. Transient reductions in inhibition could cause these widely dispersed FR-generating neuronal clusters to increase in size, perhaps coalesce, and become synchronized until activity is sufficient to propagate and produce an ictal discharge.[29] This concept of ictal generation is supported by the observation that there is a positive correlation between the number of microelectrode contacts that record FR and seizure frequency (Figure 58.9), indicating that a greater density of FR-generating clusters makes it more likely that adjacent clusters will coalesce and synchronize so that the seizures might occur more frequently.

Conclusions

FR are abnormal high-frequency oscillations that appear to reflect fundamental neuronal disturbances responsible for epileptogenesis and epileptogenicity. FR can occur in conjunction with interictal EEG spikes, or can occur independently, but are strongly associated with brain tissue capable of generating spontaneous seizures. As such, FR are potential surrogate markers of epileptogenicity that could provide opportunities for directly identifying the location and extent of the epileptogenic zone. At present, however, there are two important issues that need to be resolved. First, FR have only been characterized in epileptogenic hippocampus and parahippocampal structures in patients with mesial temporal lobe epilepsy, and animal models of this condition. More research is necessary to determine whether FR can also provide similar opportunities to identify neocortical epileptogenic zones. Second, FR can only be recorded from microelectrodes within epileptogenic brain tissue using a

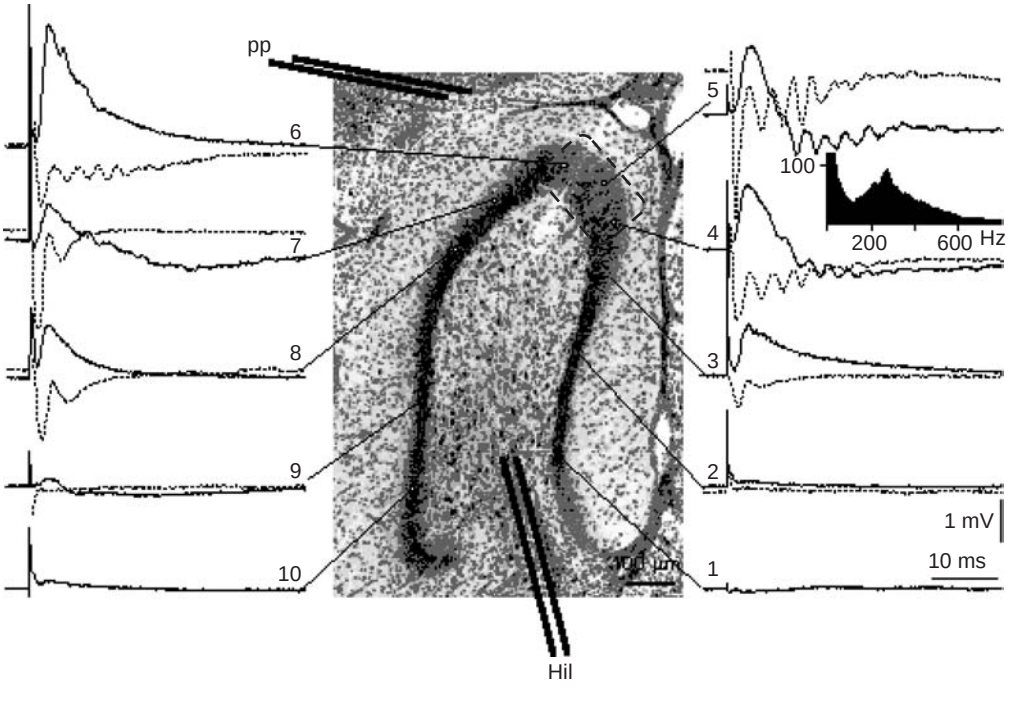

Figure 58.7 Map of evoked field potentials in the dentate gyrus slices obtained from an epileptic rat in response to perforant path (solid lines) and hilus (dashed lines) stimulation. Each recording is the average of five responses. Notice that FR-like responses are recorded at points 4, 5, and 6 in response to both perforant path and hilar stimulation outlined by dashed box. The inset is the power spectra of the evoked responses to hilus stimulation (from ref. 10 with permission).

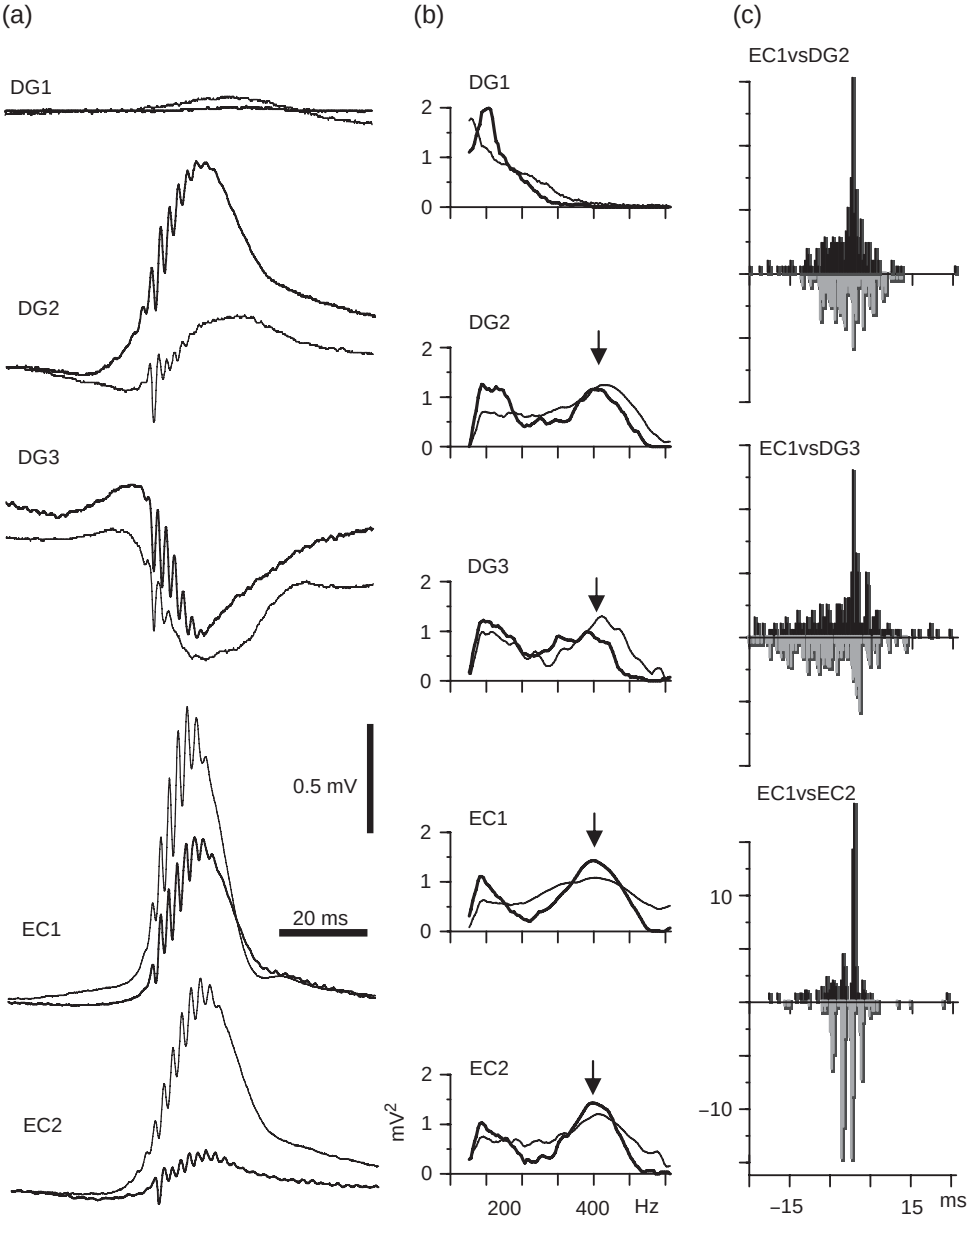

Figure 58.8 Characteristics of fast ripples recorded with five fixed microelectrodes within three different brain areas of the hippocampal-entorhinal circuitry ipsilateral to the kainic acid lesion in a single rat. DG1–anterior dentate gyrus; DG2–posterior dentate gyrus (3.5 mm from DG1); DG3–posterior dentate gyrus 1.5 mm away from DG2; EC1 and EC2–entorhinal cortex with 1.5 mm separation between the recording sites. 1.A. and 1.B., show FR recorded 47 days (heavy lines) and FR recorded 61 days (light lines) after kainic acid injection. A–averages of FR (second peak–see text) (n=300) in each recording site; B–power spectral analysis of averaged FR (n=300); C–crosscorrelograms between FR recorded at the EC1 site and FR recorded at EC2, DG2 and DG3. The upward black crosscorrelograms represent FR recorded at 47 days, and the downward, gray crosscorrelograms represent FR recorded at 61 days (from ref. 29 with permission).

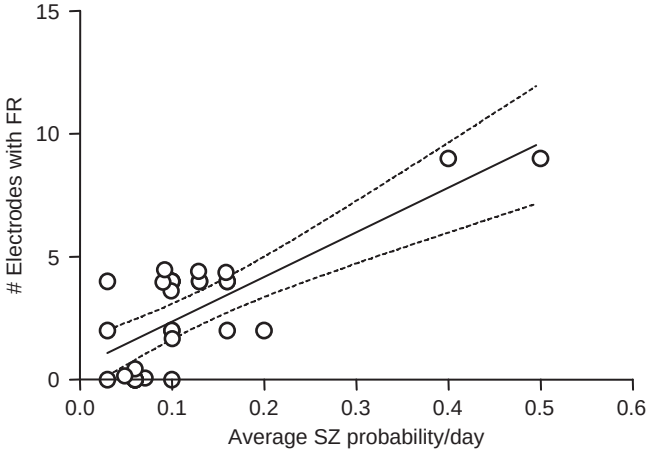

Figure 58.9 Correlation between the number of microelectrodes recording fast ripples and the average probability of seizure occurrence per day. Each circle represents one of the 22 epileptic rats. The number of electrodes implanted was always six pairs per animal. The coefficient of correlation (r) was 0.64, with P value < 0.0001. (from ref. 29 with permission).

combination of wide bandwidth and high sampling frequency. Techniques for recording FR with routine grid or depth electrodes would permit their use for directly determining the extent of the epileptogenic zone intraoperatively, or during chronic invasive monitoring. Noninvasive approaches to identifying the volume of tissue generating FR, in three dimensions of a whole brain, might ultimately be possible using MEG-MRI fusion, or EEG-fMRI averaging.

59 Magnetoencephalography in the evaluation of the irritative zone

M Iwasaki and RC Burgess

Summary

This chapter reviews the use of magnetoencephalography (MEG) for detection and localization of epileptic spikes. Qualitatively, MEG records the same activity as the scalp EEG does, namely 'brain waves'. In spite of its high cost and limited availability, MEG has an advantages in source localization, because the magnetic field is not distorted by inhomogeneous tissue conductivity, thereby improving the accuracy of the computerized source modeling technique. Clinical usefulness of MEG has been shown in selected cases of intractable focal epilepsy undergoing surgical treatment. The MEG-defined irritative zone usually provides good agreement with that defined by invasive EEG. One recent study has shown that, in a subset of patients, MEG can provide critical information which supplements the standard evaluation for surgical decision making.

Introduction

Ever since magnetoencephalography (MEG) in humans became available, there has been a major interest in employing MEG for detection and localization of epileptiform activity.[1] Recently, whole-head MEG systems have increasingly appeared in clinical settings. However, many clinicians are still not familiar with this diagnostic method.[2] In this chapter, we first introduce the basic principles and issues related to the analysis and interpretation of MEG data; secondly compare MEG with scalp EEG, the counterpart technique most often used in defining the irritative zone; and lastly review the previous literature to discuss the advantageous use of MEG in presurgical evaluation of epilepsy. Although MEG is also used for preoperative functional brain mapping, we focus only on measurement and localization of interictal spikes by means of MEG. Several good review articles in this area are also available for further reference.[3–7]

Technical background

Instrumentation

MEG recording of weak magnetic fields generated by the brain, became practically available after the invention of the SQUID (superconducting quantum interference device) technique.[8] Since the SQUID operates at a very low temperature, the MEG system requires a bath (dewer) of liquid helium to cool the sensors. Today, multi-channel whole-head MEG systems are commercially available and have become the standard clinical systems. Typically, the system has 100 to 300 SQUID magnetic sensors arrayed on the inner surface of the dewer. The dewer has a head-shaped concavity to accommodate the subject's head in order to scan the entire circumference of the head (Figure 59.1). The MEG system is placed in a magnetically shielded room, because magnetic noise from the external environment, such as a ticking watch and cars moving outside the building, crucially interfere with the measurement of weak brain magnetic fields.[9,10] Ferromagnetic materials attached to the subject's body, such as a watch, buckle, medically implanted devices, or metallic contaminants from a previous craniotomy, should be removed before the measurement, if possible, or they may significantly reduce the quality of recording.

Genesis of the MEG signal

The neurophysiologic process that generates the MEG signal is exactly the same as that which produces the EEG.[11,12] Because of the structural polarity of pyramidal neurons, the fluctuation of the dendritic membrane potential is observed as a current dipole perpendicular to the cortical surface.[13] These tiny dipoles generated by many pyramidal neurons summate within a certain volume of cortex that is more or less synchronously activating, to generate a 'brain waves' seen by MEG and EEG. This summated activity may also be represented by a dipole or sheets of dipoles along the cortex.

A current dipole produces a magnetic field oriented clockwise to the orientation of the current ('right-hand rule', Figure 59.2).[14,15] MEG measures magnetic fields coming out of or going into the surface of the head sphere. Such measurable MEG activities are typically generated by tangentially-oriented dipoles. The strength of the magnetic field decreases in proportion to the square of the distance, according to Bio-Savart's law[9]. The skull and other extracerebral tissues are practically transparent to the magnetic fields. Therefore, the field patterns outside the head are distorted hardly at all by the inhomogeneous tissue conductivity of the cranium.

Acquisition and analysis of MEG

Magnetic fields picked up by the sensor coil are enhanced by the SQUID and sampled at several hundreds to thousands

Figure 59.1 Typical arrangement for MEG measurement. The MEG system is placed in a magnetically shielded room. Instrumentation for conducting evoked potential or cognitive tests is outside the room and presents the stimuli through specialized feed-throughs. The dewer has a helmet-shaped concavity, into which the patient's head is placed. SQUID magnetic sensors are arrayed over the inner surface of the concavity (not visible), immersed in liquid helium. Recording may be performed in either a supine or sitting position.

Hz as discrete time signals. The resulting signals make up multiple traces of 'brain waves' measured at the sensor locations, in a fashion similar to EEG.[16]

For the first step of the analysis of MEG signals from epilepsy patients, they must be 'read' in order to find 'epileptic spikes'. This step is usually done manually by human interpreters scanning MEG brain waves, sometimes with help of the information from simultaneously-recorded EEG.

The generator of the chosen spike is then estimated by using computer-assisted source analysis software. Source analysis software analyzes actual observation in order to infer what the most likely phenomenon occurring in the head was; this inference from observations remote from the source is called the 'inverse problem' (Figure 59.3). The inverse problem in MEG in defining the location, distribution and amplitude of epileptic spikes is severely 'ill-posed', i.e., only a few parameters are available while there are numerous possibilities for the solution. Thus, to obtain a single 'presumed' answer, we always need to introduce artificial constraints or assumptions into the problem. The most popular assumption is an equivalent current dipole (ECD) model.[10,7] This model assumes that epileptic spikes emanate from a single (or multiple) dipole located at a certain point in the brain (i.e., a point source). An exhaustive, trial-and-error 'fitting' procedure seeks the location, orientation, and amplitude of the dipole that best explains the actual observation of magnetic fields. Because the model is too simple to entirely explain the natural phenomenon, the answer usually accompanied by another parameter quantifying the amount of the residual that the model does not explain (e.g., 'goodness-of-fit value').[18] It is experientially known that the ECD model provides a good approximation for localizing epileptic spikes in many cases.[11,19] The ECD model can be erroneous when the sources are distributed, however, and any epileptic spike may be more or less distributed.[20,21] Besides the simplicity of the model, the ECD approach is modified or biased by the analyzer's guess about the number and location of initial dipoles selected to start the search algorithm. There are several methods other than the ECD model that have been developed in an attempt to better approximate distributed sources or to eliminate the interpreter's biases.[22–24] None of the methods are perfect, and a completely reliable, automated, and objective method is still awaited.

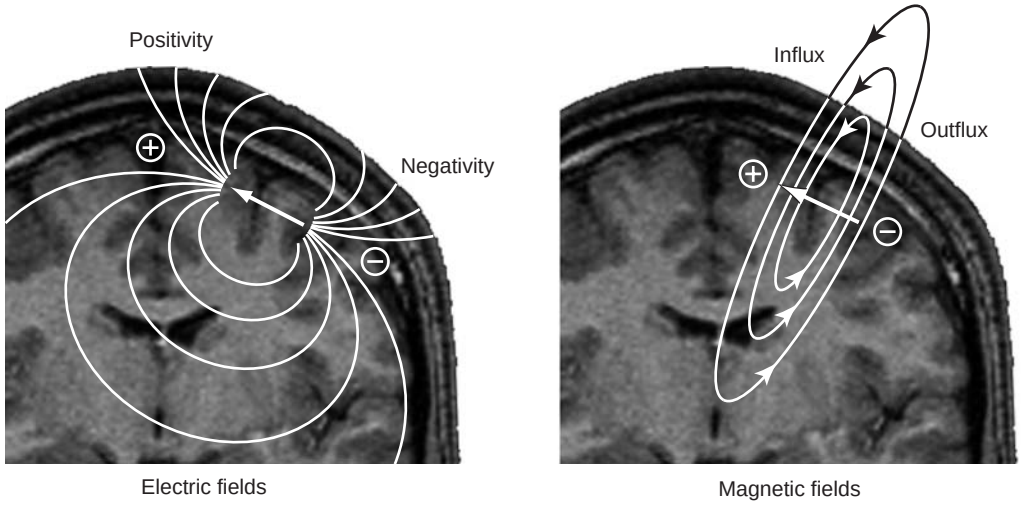

Figure 59.2 Electric fields and magnetic fields generated by a current dipole. A current dipole produces magnetic flux oriented clockwise to the current orientation. Dipoles tangential to the brain convexity are typically seen on the scalp surface as a pair of prominent field maxima representing the ingoing and outgoing magnetic flux. In contrast, dipoles perpendicular to the scalp contribute minimally to the surface field distribution. Electric fields are observed as a result of volume conduction of the electric charges from the positive and negative poles of the current dipole. (From Burgess RC, Iwasaki M, Nair D. Localization and field determination in electroencephalography and magnetoencephalography. In: Wyllie E, ed. The Treatment of Epilepsy,: Principles and Practice 4th edn. Philadelphia; Lippincott Williams and Wilkins: 2006:141–67 with permission).

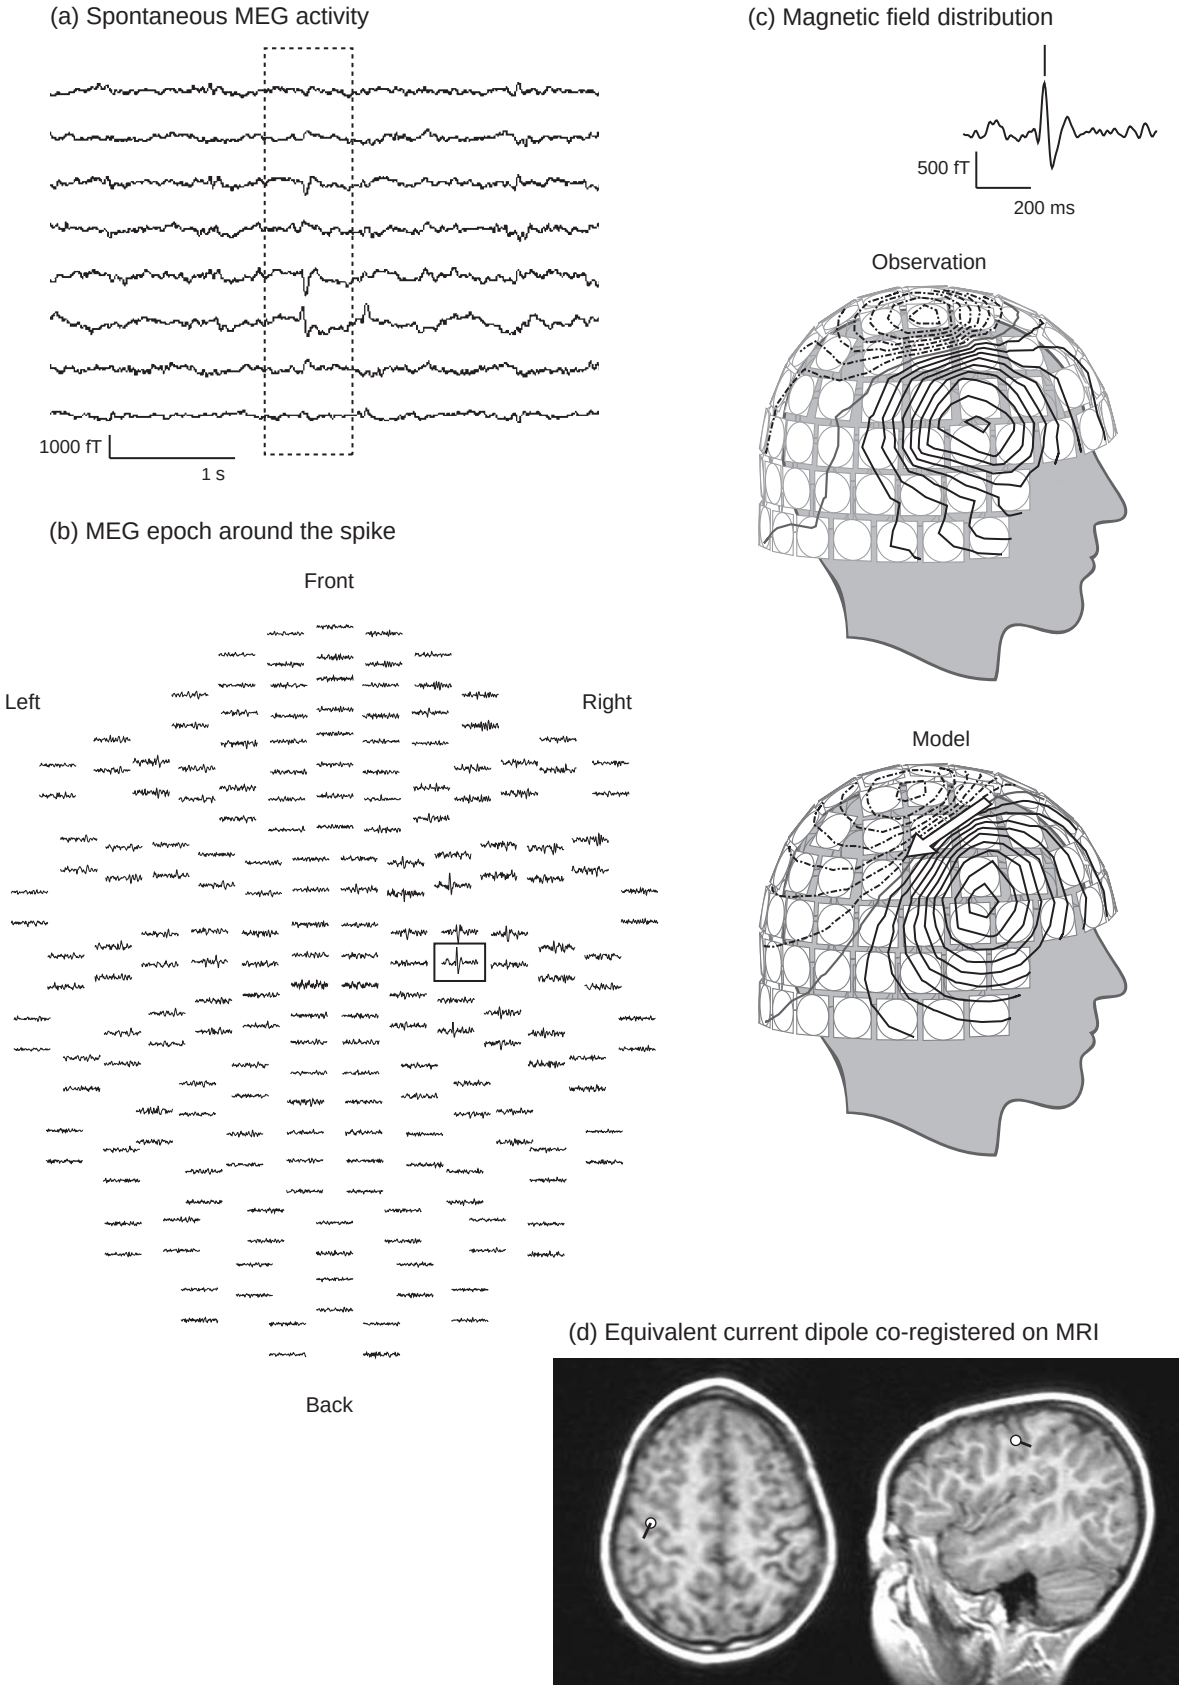

Figure 59.3 Inverse problem and spike source estimation by ECD model. Results of MEG evaluation and source localization are often shown co-registered with anatomic images. a. Typical MEG waveforms from sensors overlying the right central region; an epileptiform spike is outlined. b. MEG waveforms over the entire head during the bracketed epoch. c. The isocountours of the observed magnetic field distribution at the peak of the spike are shown along with the distribution generated by the computerized single equivalent current dipole model fit to the observed field. d. The location and orientation of the putative dipole source is shown on the MRI slices.

The result of source estimation is usually co-registered on the patient's brain MRI. When the ECD model is used, the image is typically shown as scattered dots and arrows representing the location and orientation of the dipoles for every spike analyzed (Figure 59.4). This picture is often referred to as 'magnetic source imaging (MSI)'. Actually 'imaging' is a misnomer, as this display is qualitatively quite different from the pixel- or voxel-based 'images' such as magnetic resonance imaging. The latter images utilize a large number of actually recorded data points, i.e., scanned pixels or voxels, to reconstruct a brain image. In contrast, the MSI utilizes only a limited number of parameters, i.e., MEG signals captured by a relatively small number of sensors, to 'estimate' the phenomenon occurring inside the head. The 'spatial resolution' of MEG is therefore lower than typical pixel- or voxel-based imaging modalities on a theoretical basis. However, in proper clinical use, the selection of appropriate models and assumptions does increase the reliability and spatial resolution of the estimation provided by MEG source localization software. Unfortunately, those factors are not generally accessible in MSI and are unknown to users. Clinicians who use MSI images must recognize that these operator dependent and manufacturer-specific factors play important roles and use caution.

Comparison with scalp EEG: similarities and differences

Since EEG and MEG are both measurements of the same underlying brain activity, MEG should be carefully compared with scalp-EEG to define its clinical role and establish its advantage.

MEG recording systems, together with a magnetically shielded room, dedicated computers, and running costs (e.g., liquid helium refills and annual maintenance contract) are highly expensive compared with conventional EEG systems. The machine is not portable, recording must be carried out within the shielded room, and recording duration is relatively short (10 minutes to a few hours). During the measurement, the patient must remain immobile.

For detection of underlying abnormalities, i.e. epileptic spikes, the MEG has power which is comparable to the scalp EEG.[26,27] The smallest activity detectable by the modality is determined by calculating the size of the brain volume that a sensor scans. The distribution and size of such 'sensitive volume' is very similar between MEG and scalp EEG, although the EEG can flexibly change the size by modifying the inter-electrode distance[28]. Simultaneous recordings of electrocorticography and MEG have shown that a considerable area of

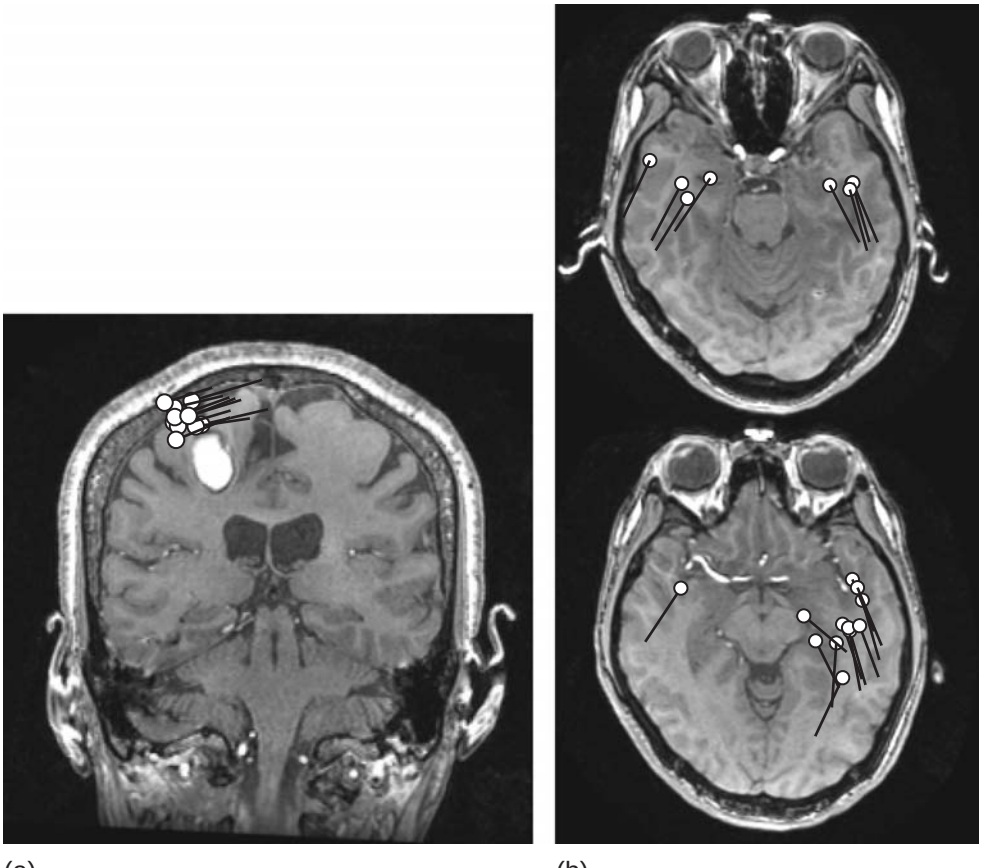

Figure 59.4 Typical examples of 'magnetic source imaging (MSI)', co-registration of equivalent current dipoles with anatomic images. White dots and black arrows indicate location and orientation of dipoles, respectively. a. A case with focal motor seizures caused by hemorrhagic cavernous angioma located in the right motor and premotor cortices. Dipoles are tightly clustered in the epileptogenic zone nearby the lesion. b. A case with nonlesional bilateral temporal lobe epilepsy. Dipoles are distributed in a relatively large area of bilateral temporal lobe. (Courtesy of Dr. Nobukazu Nakasato, Kohnan Hospital, Sendai, Japan).

the cortex must be activated in order for epileptic spikes to be captured by MEG.[29–31]

The detection ability of MEG and EEG is quite different in terms of the orientation of the current dipole.[32] MEG preferentially records tangential sources while EEG is better at recording perpendicular ones. However, since completely tangential or perpendicular sources are rare, the cortical area that MEG is sensitive to largely overlaps that of EEG.[33] Therefore, epileptic spikes are captured by both MEG and EEG in most cases, but the detectability (the number or signal-to-noise ratio of spikes) may differ significantly.[26,27] MEG and EEG are equally limited in their sensitivity to deep activity.

The greatest advantage of MEG derives from the feasibility of computerized source estimation techniques. Although the same computerized localization techniques are available for EEG, accuracy and reliability are higher for MEG. These models work much better in MEG, because magnetic fields are not distorted by the inhomogeneous tissue conductivity, and the volume conduction effect is often negligible.[10,34,35] The magnetic field distribution outside the head directly reflects the primary current of the source, making source modeling and calculation easier for MEG than for EEG.

Use of MEG to define the irritative zone

Temporal lobe epilepsy

Several MEG studies have focused on temporal lobe epilepsy (TLE), the most common form of intractable focal epilepsy.[36–40] It is known that MEG spike localization does not pinpoint the epileptogenic zone or seizure onset zone in mesial TLE. MEG detects interictal spikes generated in, or propagated to, the temporal neocortex.[41,42] Such irritative zone is occasionally separate from the mesial temporal region. Several recognizable patterns of MEG spike localization and orientation exist in TLE.[37,38]

The spikes localized in the anterior temporal neocortex, including those in the temporal tip with an orientation horizontal to the temporal lobe axis in a sagittal plane, and those in the superior or basal anterior temporal cortex with a vertical orientation, are relatively specific to mesial TLE. The other pattern is spikes localized vertically in the posterior temporal region, a pattern seen relatively frequently in patients with seizures originating from the lateral temporal lobe. However, this dipole pattern can also be seen in patients with mesial TLE.[39]

Studies of nonlesional TLE, in spite of limited number of case series available, have shown good correlation of MEG spike patterns and the seizure onset zone. Knowlton documented that three cases of nonlesional TLE, including two with mesial temporal onset and one with neocortical temporal onset, showed good agreement between MEG spike localization and the seizure onset zone, as confirmed by invasive EEG recording.[43] Baumgartner reported 11 cases of nonlesional TLE, including five with anterior temporal MEG spikes and six with posterior lateral MEG spikes. Invasive EEG recording was performed in three of those. In one, anterior spikes were associated with mesial temporal seizure onset; and in the other two with posterior spikes, seizure onset was more diffuse, including both mesial and lateral temporal lobes.[37]

Extratemporal lobe epilepsy

Most previous reports on the use of MEG in extratemporal cases document good agreement between MEG and invasive EEG for spike localization.[43–50] Some authors believe that MEG spike detection and the accuracy are better in extratemporal region than in the temporal regions – even superior to the scalp EEG.[51–53] Resection of the irritative zone as defined by MEG is correlated with better postoperative seizure outcome.[44,54] In selected patients with normal MRIs, MEG helps map the irritative zone, guide the correct placement of invasive electrodes for better surgical planning, or even obviate the need for invasive recording.[55,56] The distribution of MEG spikes has been employed to provide a hint about the extent of the epileptogenic zone, confirmed by invasive EEG: Spikes tightly-clustered in a small area suggest the seizure onset zone nearby. Loosely-distributed spikes tend to be associated with nonlocalizable seizure onset, suggesting a diffuse epileptogenic zone.[44]

Indications for MEG in presurgical evaluation of epilepsy

Although a good number of articles have been published on the use of MEG during the preoperative assessment of epilepsy surgery candidates, it is still not clear which subpopulation of patients can gain maximum benefit from MEG in terms of surgical decision making.

Stefan *et al.* conducted a retrospective review of the presurgical evaluations of 104 epilepsy patients in order to score the contribution of MEG relative to the other modalities.[57] The MEG findings were just 'confirmatory' in about a half of the cases (54%), 'additional' in 24%, 'additional information affecting the decision making in surgical strategy' in 10%, no contribution (no spikes detected) in 10%, and rarely 'contradictory' (2%). Although the study design is retrospective and the different nuances between 'additional' and 'additional in surgical decision making' were not clearly defined, this study implies that MEG can play a crucial role in estimating the epileptogenic zone and in surgical decision-making 'upon' the information collected from the other modalities such as MRI, video-EEG monitoring, and PET. On the other hand, this study shows that in more than half of patients who are undergoing presurgical evaluation, MEG does not add anything.[58]

Other studies have also attempted to relate the relative contribution of MEG, but unfortunately, no prospective study has yet been performed to address whether the addition of MEG to the standard evaluations improves the patient's outcome.[52,58] Although the selection criteria are as yet unknown, it is likely that patients should be carefully selected for MEG study, weighting its potential advantage against its high cost and limited availability.

The benefit of MEG recording is probably small in mesial TLE syndrome with hippocampal sclerosis, because clinical and imaging characteristics, along with the surgical strategy and outcome, are relatively well established. Therefore, the addition of MEG will most likely have marginal influence on the patient's outcome. The benefit of MEG is probably larger in neocortical epilepsy, especially in those with equivocal findings on MRI, EEG and other evaluations.[58,59] The addition of MEG may promote or discourage surgical treatment of those

patients with greater confidence than when evaluated without MEG, by supporting other evidence or by revealing new findings. The possibility that MEG can mislead exists, and clinicians must be careful not to overly depend on positive indications for surgical treatment from MEG.

MEG may have special advantages in patients with failed epilepsy surgery or previous craniotomy, since magnetic fields are not distorted by skull defects and other conductivity inhomogeneities.[60]

The key advantage of MEG over scalp-EEG is its improved accuracy in spike source localization. Co-registration of spike dipoles to the patient's MRI provides potentially rich information in estimating the epileptogenic zone. One can superimpose the result on other functional images,[61] and even bring it to the operating room as a part of the neuro-navigational system.[62,63] However, it is important that clinicians interpret the images carefully, because a) the MEG-defined irritative zone may not be identical to the epileptogenic zone or seizure onset zone, and b) the images include an unknown degree of error which is inherent to the source modeling technique.

Conclusions

It is likely that there is a subset of patients in whom MEG can be of significant benefit, either to help persuade for or against surgery, or to better help guide the boundaries of the surgical resection. Unfortunately, which subset this is, and how best to conduct the evaluation in these patients, is unknown at this time. A prospective evaluation of the clinical usefulness of MEG is still lacking. Such a study must be designed to determine whether the addition of MEG to the standard evaluations indeed leads to a better surgical outcome.[64]

60 Magnetic resonance imaging in the evaluation of the irritative zone

K Krakow, B Diehl, and JS Duncan

Introduction

Like physiological brain activity (and epileptic seizures), interictal epileptiform discharges (IED) and epileptic seizures are associated with alterations of cerebral blood flow and deoxyhemoglobin concentrations in the venous bed. BOLD-fMRI therefore should be capable of identifying the sources of IED in the same way that it can identify sources of functional activation from movement or cognitive processing. As BOLD-fMRI relies on contrasts between different defined stages and IED are usually subclinical phenomena, a second modality is necessary to identify these events. Hence, fMRI of the irritative zone was only made possible by recording EEG inside the MR scanner (EEG-correlated fMRI). The development of an EEG recording technique during fMRI acquisition has provided the opportunity to study directly hemodynamic surrogates of epileptiform activity and potentially combines both the millisecond time resolution of EEG with the millimetre spatial resolution of fMRI. In principle, it might be possible to evaluate the irritative zone also by other MR-techniques correlated to concurrent EEG-recordings, e.g., EEG-correlated perfusion measurements or MR spectroscopy, but there are currently no conclusive data available.

Whilst the 'ictal onset zone' is generally regarded as the best surrogate for the epileptogenic zone, ictal fMRI will remain restricted to exceptional cases for several practical reasons. Epileptic seizures usually occur unpredictably and are often associated with clinical symptoms that prevent acquisition of good quality fMRI data. Compared with ictal fMRI, mapping of interictal activity has several practical und conceptual advantages: (1) IED are a common phenomenon in many patients with epilepsy; (2) IED are usually not associated with stimulus-correlated motion and significant alterations of consciousness; and (3) taking into account the time resolution of fMRI, BOLD signal changes associated with single IED are less likely to be confounded with propagation effects than are those occurring with ictal activity.

Methodological aspects of EEG-correlated fMRI

The MRI scanner is a hostile environment for EEG-recordings. MR-compatible EEG recording equipment must ensure patient safety, sufficient quality of the EEG signals, and avoid compromising MR image quality. Since the first report on human EEG recording during MR imaging more than 10 years ago by Ives *et al.*,[1] these issues have been addressed by several studies and technical solutions have been proposed.[2–5] Several commercial systems for intra-MR EEG recordings are now available. The main specific features implemented in these systems are a battery-powered nonmagnetic amplifier with a fiberoptic link, a high dynamic range of the amplifier and careful choice of materials for the electrode assembly.

The most crucial practical difficulty that must be overcome before useful functional data can be acquired is EEG quality. The two most relevant artefacts obscuring the EEG recorded inside the MR scanner are (1) pulse artefact (or cardioballistogram) and (2) image-acquisition artefact.[6,7]

Cardioballistic and other movement-related artefacts are caused by movements of the body and EEG leads relative to the magnetic field of the MR scanner. This can be reduced by minimizing the area of the EEG wire loops, lead fixation and bipolar montage of the EEG with small inter-electrode distances. Remaining pulse artefact can be removed by averaging and subtraction of the artifacts synchronized to the ECG.[2,8,9] These methods provide a degree of EEG quality sufficient for the accurate identification not only of IED (2003),[10] but also sleep stages,[11] physiological EEG rhythms,[12] and evoked potentials [13] in the intervals between image acquisition.

During MR image acquisition, the EEG is obscured completely by large artefacts mainly due to induced voltages in the EEG leads subjected to the rapidly changing gradient fields. Two solutions to the problem of EEG-imaging artefact removal have been proposed.[3,9] Both rely on amplification with sufficient dynamic range to avoid saturation of the EEG amplifier due to the artefact. The method developed by Allen and co-workers uses a scanner generated slice-timing pulse. For each channel, online subtraction of a running time-averaged waveform is performed, followed by adaptive noise cancellation to reduce any residual artefact. Hoffmann *et al.* proposed a postprocessing filtering method based on the fast Fourier transform (FFT): segments of EEG without MR activity are compared with the FFT of the EEG recorded during imaging. Frequencies with amplitudes over a threshold determined based on the FFT of the normal EEG are then discarded. The inverted FFT gives the corrected EEG.

The ability to remove image artefacts determines the data acquisition of EEG-correlated fMRI experiments. Without image artefact removal, the EEG is obscured during imaging and interleaved data acquisition has to be applied. In epilepsy studies, this approach was introduced as spike-triggered fMRI. This method takes advantage of the delayed BOLD response

after a neuronal event. This makes is possible to observe the EEG recording online (which requires the presence of an experienced electroencephalographer during data acquisition) and start image acquisitions manually at a fixed interval after the event of interest (usually 3 seconds, as the BOLD response peaks at 2–7 seconds after an event) or during control periods. However, spike-triggered fMRI suffers from two main limitations, both linked to the obliteration of the EEG during the image acquisition. First, there are constraints on the scanning rate and the duration of each scan. The minimum time gap between successive image acquisitions must be of the order of 15 seconds to avoid signal variations due to the T1 signal decay, and the maximum duration of each image acquisition must be less than the expected duration of the BOLD response in order to ensure proper separation of the responses from events which may occur during image acquisition, and therefore remain undetected. Second, as mentioned above, the spike-triggered approach relies on assumptions about the BOLD response peak time and duration. However, spike-triggered fMRI is not able to reveal the hemodynamic response function due to a delayed image acquisition and the lack of preactivity baseline images.

With the possibility of image artefact subtraction, these limitations can be overcome by continuous and simultaneous EEG-correlated fMRI. In contrast to spike-triggered fMRI, continuous EEG/fMRI recording allows for full exploration of the temporal dynamics of activation in addition to spatial localization. For each voxel, an entire time series is available for interrogation in contrast to the limited number of time points available for comparison in spike-triggered fMRI. Another advantage is that continuous EEG/fMRI allows for post hoc analysis of the EEG-events of interest. Regarding image analysis, in spike-triggered fMRI there are no requirements to model the hemodynamic response. Scans can be simply grouped into spike and rest categories and a *t*-test can be performed to judge significance. In continuous EEG/fMRI, the IED are treated as events of interest in an event-related analysis of the fMRI data. This involves creating a model timecourse for the IED and convolving this function with an appropriate hemodynamic response function (HRF). This basis function is included in the analysis, and variance correlated to this model is compared to residual variance. Voxels are considered to be activated during IED when the modeled variance is significant compared to residual variance. As summarized by,[14] EEG/fMRI studies in epilepsy vary considerably in their analytical approach, including acquisition method, HRF model, as well as the statistical threshold reported as significant.

In general, the continuous EEG/fMRI technique is thought to lead to a greater sensitivity to identify BOLD signal changes associated with IED compared to the spike-triggered approach.[15] Continuous EEG/fMRI has largely replaced EEG-triggered fMRI not only in the field of epilepsy, but also in EEG/fMRI studies of sleep,[16] physiological EEG rhythms,[17] and evoked potentials.[18]

EEG-correlated fMRI in the evaluation of the irritative zone

So far, about 30 studies applying EEG-correlated fMRI to patients with epilepsy have been published. The first study using EEG-correlated fMRI in patients with epilepsy was reported by Warach *et al.* in1996.[19] In two patients with epilepsy, IED were associated with fMRI activations. In the following years several studies followed using spike-triggered fMRI.[20–25] Since 2001 an increasing number of studies using continuous EEG/fMRI were reported.[26–31] Most of the studies were performed in patients with focal epilepsy, often medically refractory epilepsy (Figure 60.1). A few studies concentrated on defined idiopathic epilepsy syndromes, like benign epilepsy with controtemporal spikes (BECTS, rolandic epilepsy) in children,[32,33] reading epilepsy[32] and idiopathic generalized epilepsy.[14,32,34–36]

In summary, the studies showed that EEG-correlated fMRI is a practicable method to be applied to patients with epilepsy showing frequent IED on scalp EEG. The EEG quality was sufficient to detect spontaneous IED off- or online. Discomfort or injuries of the patients due to the EEG-recording were not reported and the MR image quality was not significantly compromised by the EEG recording. In the patients with focal epilepsy, the activations were in general anatomically related to the proposed irritative zone, or other cortical zones anatomically related to the epileptic focus (as defined by interictal EEG, EEG source analysis, structural MRI, ictal video-EEG, or, in less than ten patients, intracranial EEG). In one of the largest studies, Krakow *et al.*[22] reported 24 patients investigated with EEG-triggered fMRI. Between 12 and 50 IED were captured per session. Twelve of the 24 patients showed reproducible focal activation, which occurred in close spatial relationship to the maximum of the IED on scalp-EEG. The range of pathologies included encephalitis, cortical dysgenesis, hippocampal sclerosis, low-grade astrocytoma, and dysembryoplastic neuroepithelial tumors (DNET). Nine patients had no detectable structural abnormality. Of the six patients with cortical dysgenesis, four showed activation in all cases located within the cortical malformation. In a patient with DNET, BOLD activation was shown adjacent to the lesion.[21] In accordance to more recent studies using continuous EEG/FMRI,[30,37] these results support the concept of varying relationships between the epileptogenic lesion and the irritative zone. Gray matter within cortical dysgenesis may have intrinsic epileptogenic properties, whilst other lesions, for example tumors, may generate IED in the vicinity.

Comparison of EEG/fMRI results with intracranial EEG and EEG source modeling

In some patients with refractory focal epilepsy, EEG/FMRI results could be compared with results of the presurgical evaluation and in a few patients surgery was carried out after the EEG/fMRI experiment. The first report correlating invasive recordings and pathological data with an EEG/fMRI activation was a single case study published in 1998.[20] The largest of the studies correlating invasive EEG recordings with EEG/fMRI activations was reported by Lazeyras *et al.*[24] A total of 11 patients were investigated with EEG-triggered fMRI, who also underwent presurgical evaluation for their epilepsy with video-EEG, PET, and SPECT studies. In eight of 11 patients, intracranial recordings were carried out, and in five of them, the irritative zone as determined by fMRI was

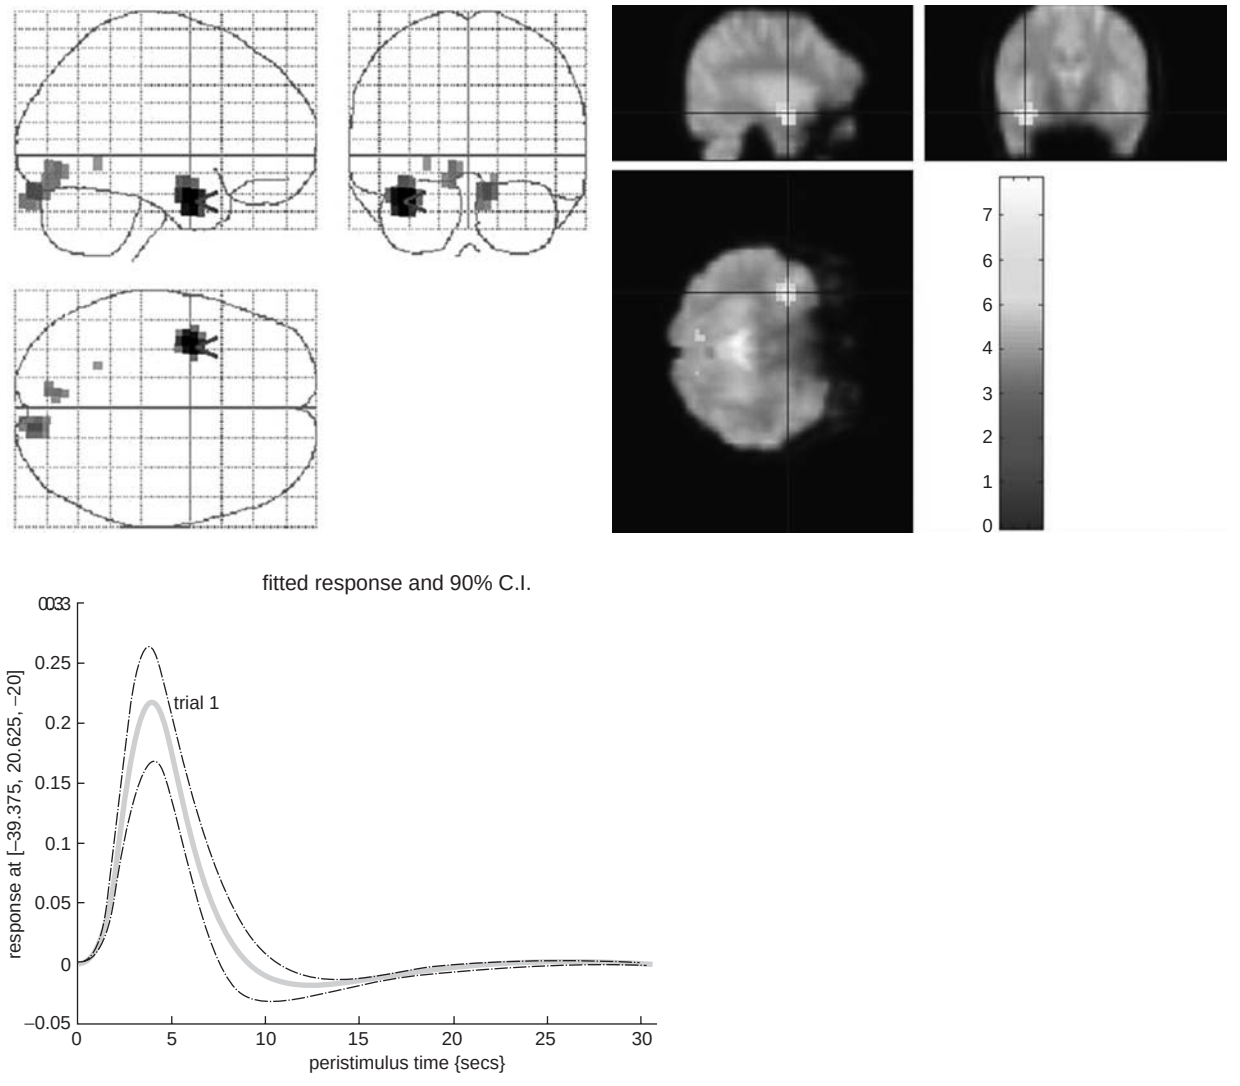

Figure 60.1 Result of a continuous IED-correlated fMRI study in a patient with complex focal seizures, a left hippocampal sclerosis and frequent left temporal IED. fMRI revealed a left temporal activation associated with IED (maximum indicated by arrow head in the glass brain and cross hair in the EPI overlay), which is concordant with the presumed irritative zone. There were significant negative BOLD signal changes associated with IED in retrosplenial areas (not displayed). The hemodynamic response is displayed below. (Courtesy of Afraim Salek-Haddadi, Department of Clinical and Experimental Epilepsy, Institute of Neurology, University College London, United Kingdom.)

affirmed, but activation was not always anatomically restricted. In a recent large series[15] either spike-triggered or continuous EEG/fMRI was obtained and interpretable in 31 patients. Four patients underwent invasive recordings. Two patients had interictal activity in both temporo-occipital regions, one in the left medial frontal region, and one patient multifocal in the left frontal lobe. EEG/fMRI provided concordant information. However, it appears problematic to draw any conclusion from such small numbers, particularly as no data on the surgical procedures or outcome were provided. It therefore remains unclear whether EEG-correlated fMRI has the potential to replace invasive techniques to identify the irritative zone in a larger scale or, at least, provide additional information to guide the placement of invasive intracranial electrodes where necessary.

Comparison of EEG/fMRI results with EEG source localization was performed in few studies. In six patients with focal epilepsy,[38] spike-triggered EEG/fMRI responses were compared with EEG dipole source analysis from a separate session using 64 EEG channels. Over the six patients, mean distances between dipoles and the center of the nearest fMRI response of 4.2 cm (spatiotemporal approach), 3.5 cm (moving dipole fitted to the first negative peak of the spike), and 2.3 cm (moving dipole fitted to the positive peak of the spike). In a recent study,[39] 33 patients with intractable focal epilepsy arising from various brain regions were examined using EEG-correlated fMRI and EEG source analysis, the latter based on a full set of electrodes according to the 10/10 system. The mean distance between the dipole location and the voxel of maximum positive change was 58.5 mm, and 60.8 mm from the voxel with the largest negative value. The distance between the dipole location and the closest voxel with a significant positive activation was 32.5 mm, and with the closest negative voxel 34 mm. The authors felt that reasons for poor concordance could be the relative complexity and widespread distribution of the field associated with epileptic activity.

Benar *et al.*[40] quantified the concordance between EEG/fMRI results, stereotaxic EEG (SEEG) recordings and surface EEG in

five patients with focal epilepsy. It was concluded that SEEG largely validated the results of EEG/fMRI. When there was an intracranial electrode (intracerebral or epidural) in the vincinity of a fMRI activation peak, (in the range 20–40 mm), then it usually included one active contact. This was the case for both fMRI signal increases and decreases. The concordance between surface EEG and fMRI was not as good as the concordance between either of these noninvasive techniques and SEEG. The authors concluded that both techniques are complementary for the localization of the areas involved in the generation of IED. Within a distance of 20 mm, the average percentages of matches between fMRI peaks (positive or negative) and intracranial EEG were better than those between EEG source localization and SEEG.

Limitations of the interpretation of EEG-correlated fMRI

The clinical implementation of EEG-correlated fMRI and the interpretation of the fMRI activation maps is difficult for various reasons:

1. The limitations of surface EEG affect the clinical application of EEG-correlated fMRI. It is well known by electroencephalographers that the majority of EEG recordings from patients with epilepsy are entirely normal or show only nonspecific slowing. Invasive recordings from the cortex or deep structures such as the hippocampus however may show frequent spiking, not evident on surface EEG. Therefore, EEG-correlated fMRI of IED remains limited to the minority of patients with frequent IED on surface EEG. In order to overcome the limitations of surface EEG, methods have been suggested to detect IED-related BOLD signal changes without concurrent EEG recording. An example of such an exploratory, data-driven technique is temporal clustering analysis (TCA). It is based on the premise that activation would cause the number of voxels reaching their individual maximum values at any given point, to rise beyond a certain threshold. It makes no assumptions with regards to the proximity of the voxels that constitute the clusters and is limited in that each voxel will reach its maximum only once in the time series. Using this approach, Morgan *et al.*[41] analyzed fMRI data in nine patients with focal epilepsy acquired during rest in an attempt to localize brain activation associated with IED. By looking for a particular subset of variance, specifically changes of between 2 and 10% from the resting BOLD intensity level, focal fMRI activations with a high degree of concordance to electro-clinical data could be identified in six patients. It was proposed that resting fMRI with temporal clustering analyses without EEG could contribute to localize the irritative zone. However, these findings could not be reproduced so far by other groups, and theoretical and methodological problems of this approach were asserted, e.g., the association of the fMRI activations with head movement.[42]
2. The size of the fMRI activation cluster is greatly variable between studies and also between subjects in individual studies. Some patients have a widespread, multifocal activation, others show a circumscribed activation. The extent of the activation is critically dependent on the applied statistical threshold, which partly explains differences between studies. EEG-correlated fMRI may contribute to localize the source of IED, but currently it cannot provide information about its extent. The reason for the variability between patients who were studied with identical methodology and thresholds remains unclear. No significant correlations between clinical characteristics (e.g., epilepsy syndrome, spike amplitude) and the size of the fMRI activation were found. The same applies for the number of IED which have been analysed: In some patients even individual IED are associated with large activations [43] in other patients as many as 50 IED are not associated with significant activations.[22] In patients with widespread fMRI activation, another problem is to distinguish the primary sources from activation, which may represent areas of propagation. In such cases with equivocal information on localization, a combination of fMRI data with EEG source analysis may provide complementary information.[20,38]
3. Until now, the results of EEG-correlated fMRI have not been systematically validated with a gold standard, which are intracranial recordings and outcome after epilepsy surgery. Before EEG-triggered fMRI can be used as a decisive method to identify the irritative zone (and therewith provide information for localization of the epileptogenic zone), the relation between fMRI results, invasive EEG recordings and surgical outcome in relation to resection of the activated area has to be established. Furthermore, in all EEG/fMRI studies mentioned above, less than 300 patients were reported in total. Patients for EEG/FMRI experiments were in general highly selected, particularly with regard to the frequency of their IED. It is questionable if EEG/fMRI has the potential to be applied to relevant numbers of patients in a clinical setting.
4. The high percentage of negative results even in the highly selected patients (up to 50% in the larger studies using spike-triggered fMRI[22–25] currently hinders the wider clinical application of EEG-correlated fMRI. The physiological explanation of a negative fMRI result is most likely that there is a nonsignificant difference in the blood oxygenation between activation and control states. This might be due to there being only a modest cerebral hyperperfusion following an IED, or due to an absence of a true control state, e.g., such as ongoing epileptic activity not detected on scalp EEG. In both cases the relative signal change within the spike generator may not achieve significance. It has been reported that possibly certain characteristics of IED may lead to greater likelihood of fMRI signal changes, such as prolonged bursts of IED, higher amplitudes and larger fields of IED,[39,44] but the results have remained contradictory. As mentioned above, it is conceivable that continuous and simultaneous EEG/fMRI will increase the sensitivity of the method. Further, the use of higher strength magnets will increase the signal to noise ratio and hence fMRI sensitivity. Multichannel EEG has already been recorded in a 4 Tesla MR scanner on humans and in a 7 Tesla MR scanner in animals.[47] An improved signal to noise ratio may not only increase the proportion of fMRI-positive experiments, but may also reduce the number of analysed IED necessary for a significant fMRI activation, thus rendering this method applicable to patients with less frequent IED.

5. The significance of BOLD signal changes associated with IED is currently not well understood. In focal epilepsy, positive BOLD signal changes typically localize the generators of IED, i.e., the irritative zone. However, some patients show widespread or multifocal activations not related to the irritative zone. In addition, many patients show solely or additional negative BOLD signal changes in association with IED, especially associated with polyspike and spike- and slow-wave discharges of longer duration (bursts).[45] These 'deactivations' were observed in most EEG/fMRI studies, but yet not systematically investigated. As IED are a marker of the neural hyperexcitability underlying epilepsy, the observation of fMRI 'deactivation' is intriguing. In some patients, negative BOLD signal changes are in good spatial agreement with the presumed irritative zone and may represent processes of focal inhibition.[45] More frequently, the negative BOLD signal changes occur widespread and bilaterally. In patients with idiopathic epilepsy, generalized spike and wave discharges (GSWD) were associated with negative BOLD signal changes in bilateral frontal, parietal cortices and retrosplenial areas (precuneus, posterior cingulum).[14,17,35] Together with bilateral frontal and temporo-parietal areas, restrosplenial areas constitute a functional network that may be active in a default mode of brain function during rest.[46] This activation pattern may indicate an aberrant suspension of this network's functionality due to the generalized IED. However, similar deactivation pattern occur also with focal IED, indicating the BOLD signal changes associated with epileptiform activity do not only localize generators of IED within irritative zone, but indicate also complex changes of functional connectivity.

Conclusion

EEG-correlated fMRI has proved useful to provide insights into the generation of IED in patients with focal epilepsy. In selected patients with frequent IED, EEG-correlated fMRI has the potential to reproducibly identify cortical areas involved in generating IED, i.e. the irritative zone. So far, the sensitivity of the method is in the range of 50%. To determine the specificity of the method, further studies are necessary to compare the EEG/fMRI results with the diagnostic gold standards, which are intracranial EEG recordings and postoperative outcome after epilepsy surgery. Until these results are available, the utility of EEG-correlated fMRI in clinical epileptology cannot be definitely determined.

61 Digital tools for reviewing the electroencephalogram: montage reformatting and filtering

TD Lagerlund

Introduction

Electroencephalographers often encounter records in which a transient phenomenon, such as an epileptic interictal or ictal discharge, is displayed such that its localization or interpretation is in doubt because the electroencephalogram (EEG) was recorded using a nonoptimal montage. Electroencephalographers recognize that there are particular advantages and disadvantages of any montage, including referential, longitudinal bipolar, and transverse bipolar montages. The most useful type of montage and the choice of reference depend on the type of EEG phenomenon being viewed.

Certain montages may make particular kinds of EEG phenomena more evident. For example, for examining a generalized spike-and-wave pattern that is predominantly parasagittal, an ear or mastoid reference (unilateral or averaged) may be appropriate. However, a focal temporal abnormality may cancel out and not show up well with use of an ipsilateral ear or mastoid reference. If a reference electrode is contaminated by the activity of interest, out-of-phase waveforms can appear in electrodes at a distance from the reference electrode, and only low-amplitude activity may be seen in electrodes near the reference electrode due to partial cancellation of activity in the 'contaminated' or active reference.[1] Bipolar montages have the advantage of avoiding contamination by an 'active' reference, but to properly localize the generators of various EEG waveforms by visual inspection of a bipolar montage requires the recognition of phase reversals in adjacent channels that share a common electrode. Phase reversals are much easier to recognize in transient waveforms and much more difficult to recognize in rhythmic activity or discharges. On a bipolar montage, looking for the channel that has the maximum amplitude can be misleading or falsely localizing.

Similarly, at times during EEG interpretation a transient phenomenon may be recorded while the EEG filter settings are inappropriate. This may occur, for example, if a seizure discharge is contaminated by muscle artifact, which could have been reduced or eliminated by use of a high-frequency filter. As another example, a transient slow wave may be attenuated by a low-frequency filter, but would have been more prominent if a less restrictive low-frequency filter setting was used.

A computer-based (digital) EEG system can eliminate these problems by allowing the montage and filter settings to be determined at the time the EEG is reviewed rather than at the time it is recorded. The EEG is recorded with minimally restrictive analog filter settings and with potentials at all electrodes measured with respect to a single common reference. A computer can then process the data as they are displayed on a screen or printer, reformatting the original referential montage to any desired referential or bipolar montage and digitally filtering the data as needed. If necessary, the same segment of EEG can be displayed repeatedly, using different montages and filters.

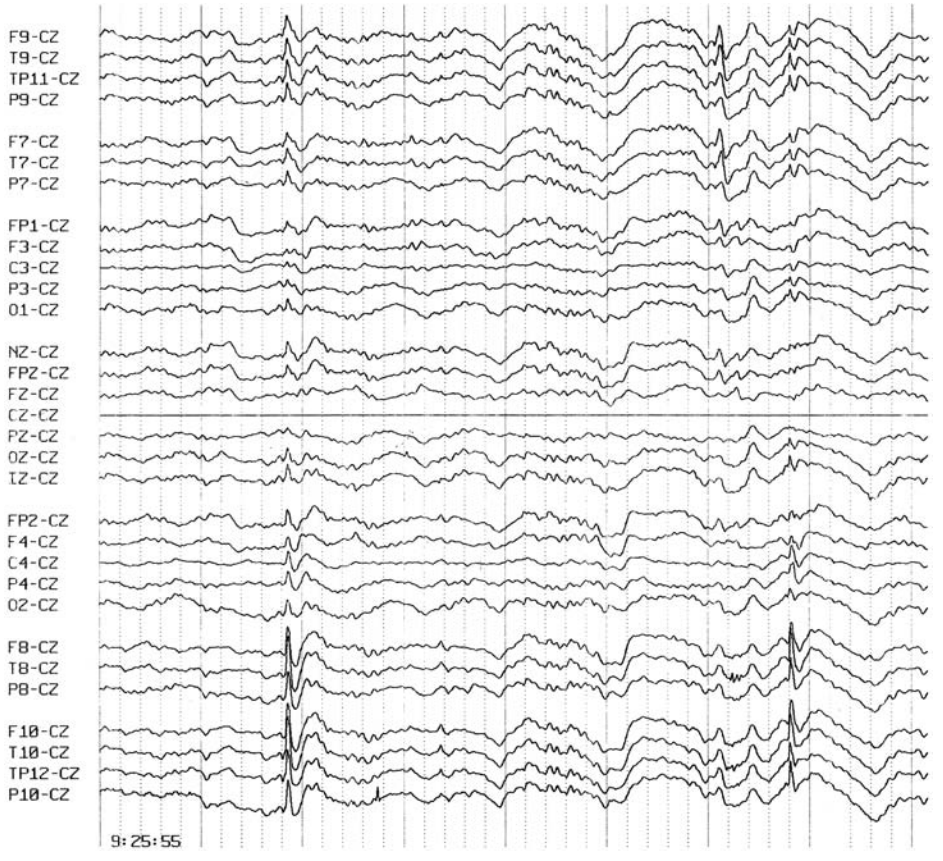
Reformatting to referential or bipolar montages

To generate a derivation such as $X_1–X_2$, which does not exist in the EEG as recorded, the computer looks for two existing channels, one of which records X_1 against a reference electrode and the other records X_2 against the same reference, and then subtracts the two. That is, $X_1–X_2 = (X_1–R) – (X_2–R)$, where R is the reference. This allows new referential and bipolar montages to be formed. For example, suppose that recorded EEG data include the following channels:

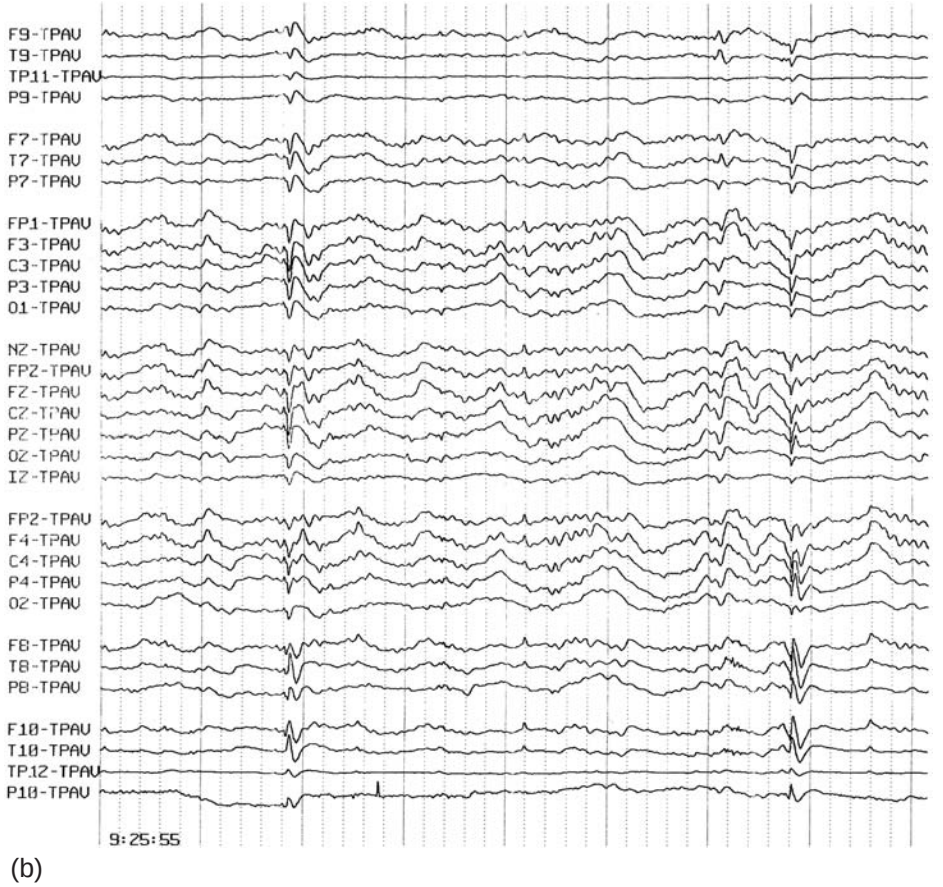
Channel	*Derivation*
1	$F_{p1}–C_z$
2	$F_{p2}–C_z$
3	$F_3–C_z$
4	$F_4–C_z$
5	$C_3–C_z$
6	$C_4–C_z$
7	$P_3–C_z$
8	$P_4–C_z$
9	$O_1–C_z$
10	$O_2–C_z$
11	$A_1–C_z$
12	$A_2–C_z$

A new referential montage with ipsilateral ear reference can then be created by subtracting pairs of channels as follows:

Channels	*Derivation*
ch1–ch11	$F_{p1}–A_1$
ch2–ch12	$F_{p2}–A_2$
ch3–ch11	$F_3–A_1$
ch4–ch12	$F_4–A_2$

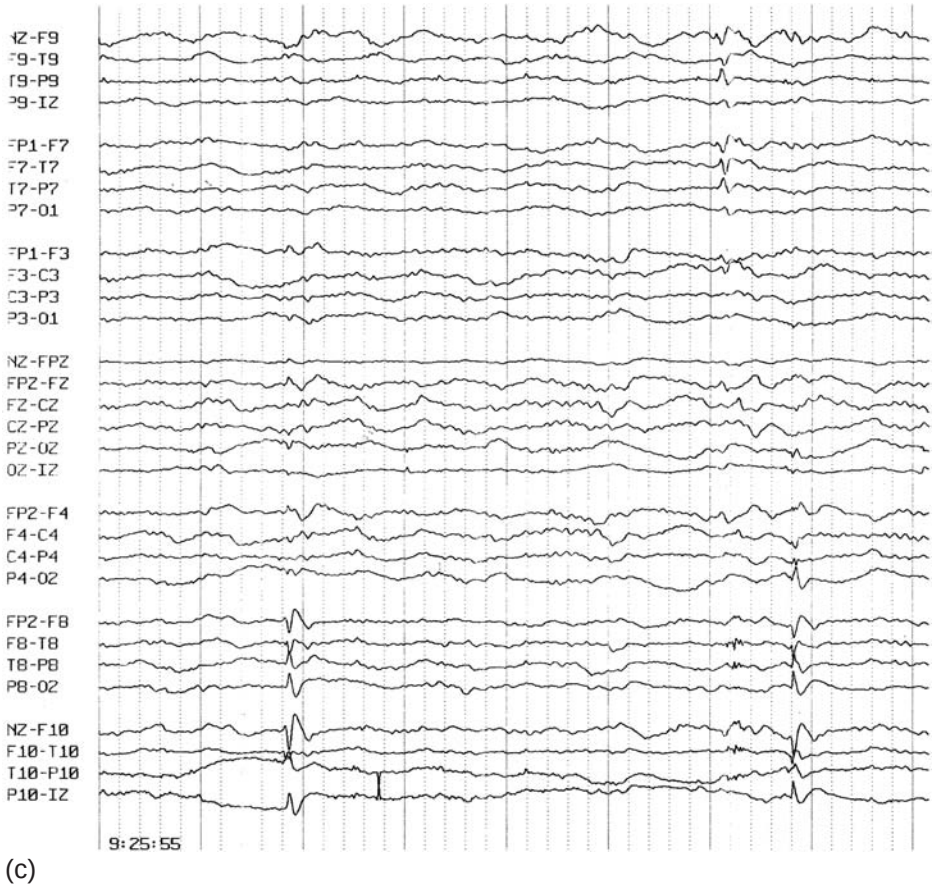


(a)



(b)

Figure 61.1 An electroencephalographic (EEG) recording showing interictal epileptiform discharges. a. EEG as recorded from a C_z reference. TP_{11} and TP_{12} are left and right mastoid electrodes. b. EEG reformatted to average mastoid (TPAV) reference.



(c)

Figure 61.1c cont'd, c. EEG reformatted to longitudinal bipolar montage. (From Lagerlund TD. Digital tools for reviewing the electroencephalogram: montage reformatting, filtering, and principal component analysis. In: Lüders HO, Comair YG, eds. Epilepsy Surgery 2nd edn. Philadelphia: Lippincott Williams & Wilkins; 2001: 367–77. Used with permission.)

Channels	*Derivation*
ch5–ch11	C_3–A_1
ch6–ch12	C_4–A_2
ch7–ch11	P_3–A_1
ch8–ch12	P_4–A_2
ch9–ch11	O_1–A_1
ch10–ch12	O_2–A_2

New reference electrodes can also be created by averaging data from two or more existing electrodes. For example, suppose an EEG is recorded with a C_z reference. A new derivation such as O_1–$A_{1/2}$ (where $A_{1/2}$ represents the average of the ear electrodes) can be calculated as O_1–$A_{1/2}$ = (O_1–C_z) – 0.5(A_1–C_z) – 0.5(A_2–C_z). Figure 61.1 shows the same interictal discharges viewed with various montages (one as recorded, two after reformatting).

Digital filtering of EEG

A digital filter is a computer program or algorithm that can remove unwanted frequency components from a signal. Just as for analog filters, they can be classified as low pass, high pass, band pass, or notch filters. Digital filters have several advantages over analog filters. First, they can be constructed and modified easily because they are software programs rather than hardware devices. Second, they can easily be made to have a relatively sharp frequency cut-off if desired (e.g., much sharper than the typical 6-db per octave roll-off of an analog filter). Third, if properly designed they need not introduce any time delay (phase shift) in the signal, as invariably happens with ordinary analog filters, and thus time relationships between different channels can be preserved even if different filters are used for each.

Most digital filters function by forming a linear combination (weighted average) of signal amplitudes at the current time and various past times.[2] The two types of commonly used digital filters are the finite impulse response (FIR) filter and the infinite impulse response (IIR) filter. The FIR filter output is a linear combination only of the input signal at the current time and past times. With this type of filter, the output necessarily becomes zero within a finite amount of time after the input signal goes to zero. The IIR filter output is a linear combination of both the input signal at the current time and past times ('feed-forward' data flow) and the output signal at past times ('feed-back' data flow). The output of the IIR filter may persist indefinitely in the absence of any further input because the output signal itself is fed back into the filter. IIR filters can be unstable and also have the undesirable property of noise buildup, since noise terms created by arithmetic round-off errors are fed back into the filter and amplified. For these reasons, FIR filters are easier to design. However, IIR filters may involve much fewer calculations and be considerably faster in operation than FIR filters having equivalent characteristics.

Figure 61.2a shows an example of an EEG segment contaminated by muscle artifact. In Figure 61.2b, filtering has

eliminated most of the artifact, revealing the underlying seizure discharge.

Spatial filtering using principal component analysis

Principal component analysis (PCA) by singular value decomposition (SVD) may be used to analyze an epoch of multichannel EEG into multiple linearly independent components, or features; the original epoch of EEG may be reconstructed as a linear combination of the components.[3–5] The result of SVD includes the components, expressible as time-series waveforms, and the factors that determine how much each component contributes to each EEG channel. By omitting some components from the linear combination, a new EEG can be reconstructed which differs from the original in useful ways. For example, artifacts may be removed or features such as alpha may be enhanced by suppressing the remainder of the EEG.

The SVD algorithm[6,7] can express any $m \times n$ matrix **E** as a product of 3 matrices: $\mathbf{E} = \mathbf{PAM}^T$, where **P** is an $m \times n$ matrix such that $\mathbf{P}^T\mathbf{P} = 1$; **A** is an $n \times n$ diagonal matrix; and **M** is an $n \times n$ matrix such that $\mathbf{M}^T\mathbf{M} = \mathbf{MM}^T = 1$. SVD is a method for PCA. If **E** is an epoch of EEG (n channels, m time points), **P** contains n normalized principal components of the EEG (linearly independent components or features that can be combined to give the original EEG). **A** contains n amplitudes that apply to the n principal components. Defining $\mathbf{W} = \mathbf{PA}$ (unnormalized principal components, displayed as multichannel waveforms), $\mathbf{E} = \mathbf{WM}^T$. **M** is the mapping (set of weighting factors) used to combine the n components, which may be displayed as a topographic map or a histogram; M_{ij} is the contribution of the jth component to the ith channel.

By zeroing selected columns of **M** to give a new matrix **M′**, a new EEG epoch ($\mathbf{E}' = \mathbf{WM}'^T$) can be found containing some but not all principal components. For example, if component 2 contains only eye movement artifact and component 4 only electrocardiographic artifact, a new EEG without either artifact is formed by zeroing columns 2 and 4 of **M**. In a variation of this technique, the factors that reconstruct the modified EEG from the original epoch are stored as a matrix **S**.[8] Since $\mathbf{E} = \mathbf{WM}^T$, $\mathbf{EM} = \mathbf{WM}^T\mathbf{M} = \mathbf{W}$, then $\mathbf{E}' = \mathbf{WM}'^T = \mathbf{EMM}'^T = \mathbf{ES}^T$ where $\mathbf{S} = \mathbf{M}'\mathbf{M}^T$. This matrix **S** is applied to multichannel EEG at successive times to create a new EEG continuously in real time. Specifically, matrix **S** is applied to successive column vectors $\mathbf{e}(t)$ of EEG values at time t to give $\mathbf{e}'(t) = \mathbf{Se}(t)$. This matrix acts as a spatial filter with useful properties. Note that **S** is calculated from one selected EEG epoch; the SVD need not be repeated, saving computation time.

Figure 61.3a shows a 5-second epoch of EEG using a 24-channel bipolar montage, along with the mapping matrix from PCA as a histogram for each channel. Figure 61.3b shows the 24 principal components resulting from PCA. Figures 61.3c through E show the EEG reconstructed in turn from each of components 1 through 3. Component 1 contains vertical eye movement artifacts and component 2 contains horizontal eye movement artifacts; component 3 contains another ocular movement-related waveform; other components not shown contain other parts of the EEG.

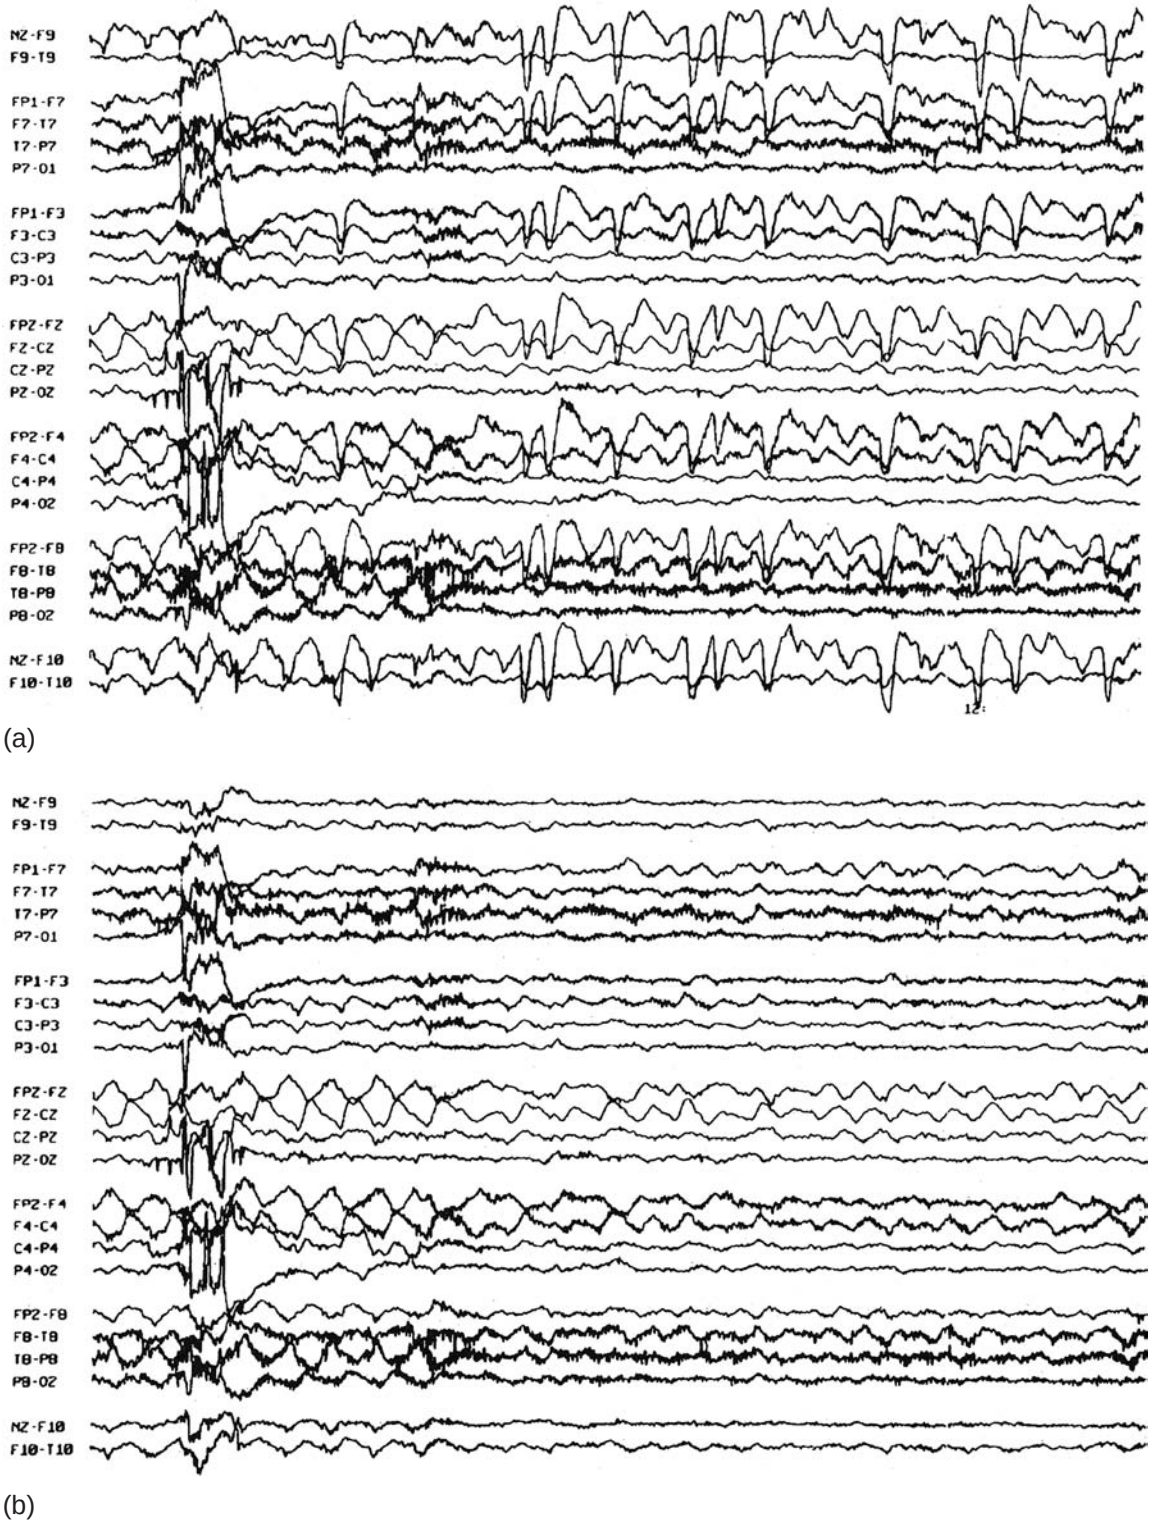

Figure 61.4 Spatial filtering of ocular movement artifacts with use of the principal component analysis results in Figure 61.3. a. A 12-second epoch of the electroencephalogram (EEG) on the same patient as in Figure 61.3. b. The same EEG after applying the spatial filter. (From Lagerlund *et al*.[8] Used with permission.)

Figure 61.3F shows the EEG reconstructed from components 4 through 24; ocular movement artifacts are almost completely removed. Figure 61.4A shows a 12-second epoch of EEG of the same patient as in Figure 61.3 at the end of a partial seizure, with rhythmic and polymorphic delta activity obscured by ocular movement artifacts. Figure 61.4B shows the same EEG after applying the spatial filter; ocular movement artifacts were largely removed, allowing the underlying slow waves to be seen. Some slow components in the frontal channels are attenuated but not removed; they are probably not ocular movement artifacts.

PCA is a useful method of removing artifacts or other unwanted features of an EEG while preserving or effectively enhancing other features. In effect, the method uses the spatial distribution across channels of artifacts or other waveforms as a 'signature' of the feature to be eliminated. All waveforms having the same spatial distribution are canceled out, whereas waveforms distributed differently are preserved. Thus, the matrix acts as a 'spatial filter', analogous in some respects to a digital 'temporal filter' designed to remove some frequencies from the EEG while preserving others.

The method works well for eliminating artifacts or activity with relatively high amplitudes and with a spatial distribution that remains constant throughout the EEG. Ocular movement and electrocardiographic artifact often have these characteristics. The method works less well for artifacts of relatively low amplitude and changing spatial characteristics, such as electromyographic artifact and some electrode artifacts; although elimination of these may not be achieved, a substantial reduction may still be attained.[8]

62 Average reference and Laplacian montages

TD Lagerlund

The average reference montage

Electroencephalographers have long recognized the value of a truly inactive reference electrode. Although it is not possible to find a 'distant' (and thus truly inactive) reference for scalp electroencephalographic (EEG) recordings,[1] a possible compromise is the average reference. This reference is calculated as the mean, or average, of the potentials at all (or nearly all) available scalp electrodes. By using an average of all electrodes, potentials that deviate from the average but affect only one or two electrodes are averaged out. This concept works well unless a very high potential is recorded in one or two electrodes, such as with high-amplitude interictal spikes (Figure 62.1 a and b), or unless a moderate potential is recorded in a great many electrodes, such as with eye blink artifacts that often produce a high-amplitude deflection in several electrodes at once (Figure 62.2a and b). In these situations, the potential will appear with reverse polarity but attenuated amplitude in all channels of the average reference montage, such that the potential may be difficult to recognize.

Considerable caution must be used in the interpretation of the average reference montage. Because the reference is the average of all electrodes, the potential at any given scalp electrode location depends on the location of all the other electrodes. Furthermore, when comparing any two channels, the relative phase and amplitude also depend on what all the other electrodes record. In Figure 62.3 Fourier analysis of a 2-second epoch of EEG containing alpha activity at 10.5 Hz was used to construct phase-magnitude plots for two different reference electrodes. Solid-line plots correspond to the left ear reference (A_1), and broken-line plots correspond to the same epoch but reformatted using an average reference. One apparent difference is that the F_{p2} electrode shows very low amplitude at 10.5 Hz in the left ear reference recording but large amplitude in the average reference recording. It may also be noted that the two labeled electrodes, F_z and C_z, are roughly in phase in the left ear reference recording (indicated by arrows pointing to the right) but out of phase (indicated by arrows pointing in opposite directions) in the average reference recording.[1] Of course, other choices of reference electrode would produce still other relative amplitudes and phases.

The Laplacian (source current density) montage

Electroencephalographers have used referential and bipolar montages commonly for many years, but the Laplacian, or source current density, montage[2–4] has not been widely used, primarily because few commercially available EEG machines implement it. However, it is relatively easy to implement a Laplacian montage in a digital EEG system, and it has several properties that make it a useful addition to the set of conventional referential or bipolar montages.

The name of this montage is derived from the mathematical concept of the Laplacian of a function of two variables, $f(x, y)$, defined as the curvature (second derivative) of the function f in the x direction plus the curvature of f in the y direction. The potential (voltage) on the surface of the head is a function of the two variables, x and y, representing coordinates on the head (for example, x could be distance in centimeters to the left or right of the origin, C_z, and y could be distance in centimeters anterior or posterior to C_z). The Laplacian of the potential is proportional to the radial current density (the current per unit volume flowing radially into a region of scalp from sources underneath). At a location with no underlying current sources, the Laplacian would be zero, whereas it would be maximal directly over a source (Figure 62.4). Thus, the Laplacian of the potential may be used to localize the underlying generators of the EEG. For this reason, a Laplacian montage is also called a source current density montage. As defined above, the Laplacian at a surface-positive potential peak is negative (corresponding to convex curvature of the potential peak; Figure 62.4). Thus, the Laplacian at a surface-negative potential peak is positive (corresponding to concave curvature of the potential peak). Thus, in practice a 'Laplacian' or source montage is often displayed as the negative of the Laplacian.

Although the potential at all locations on the head is not known, making an exact calculation of the Laplacian impossible, the nearest-neighbor method[3,4] is an easy method to approximate the Laplacian at positions corresponding to the location of the electrodes and is the one generally used to derive the Laplacian montage. The Laplacian at an electrode X

(c)

Figure 62.1 cont'd

can be approximated as the sum of the potentials at the four nearest neighbors to X minus 4 times the potential at X. To produce a derivation that has comparable amplitude and polarity to that of the original referentially recorded EEG, negative one-fourth of the Laplacian is usually calculated, which is the potential at X minus the average of the potentials at the four nearest neighbors to X. For example, at C_z the appropriate formula would be as follows:

C_z–Nav = (C_z–R)–0.25[(C_3–R)+(C_4–R)+(F_z–R)+(P_z–R)].

Here, R is the reference with respect to the measured potentials at C_z, C_3, C_4, F_z, and P_z. The notation 'Nav,' which stands for 'neighborhood average', indicates a fictitious reference electrode that is the average of the four neighboring electrodes.

In a Laplacian montage, as in a referential montage, the generator of a particular EEG waveform is generally located by the channel in which the amplitude of that waveform is maximal, rather than by a phase reversal as in a bipolar montage. However, a Laplacian montage is reference independent, like a bipolar montage. The most useful characteristic of a Laplacian montage is its ability to localize focal EEG features or waveforms more sharply than either referential or bipolar montages by removing unwanted contamination from signals originating at distant locations which are transmitted by volume conduction (the 'far-field' potential). Conversely, a Laplacian montage is a poor choice for examining generalized discharges. Figure 62.1 shows how the maximum of an interictal discharge can be most easily localized by using a Laplacian montage. The same discharge is shown as recorded from a C_z reference montage (Figure 62.1a), from an average reference montage (Figure 62.1b), and in a Laplacian montage (Figure 62.1c).

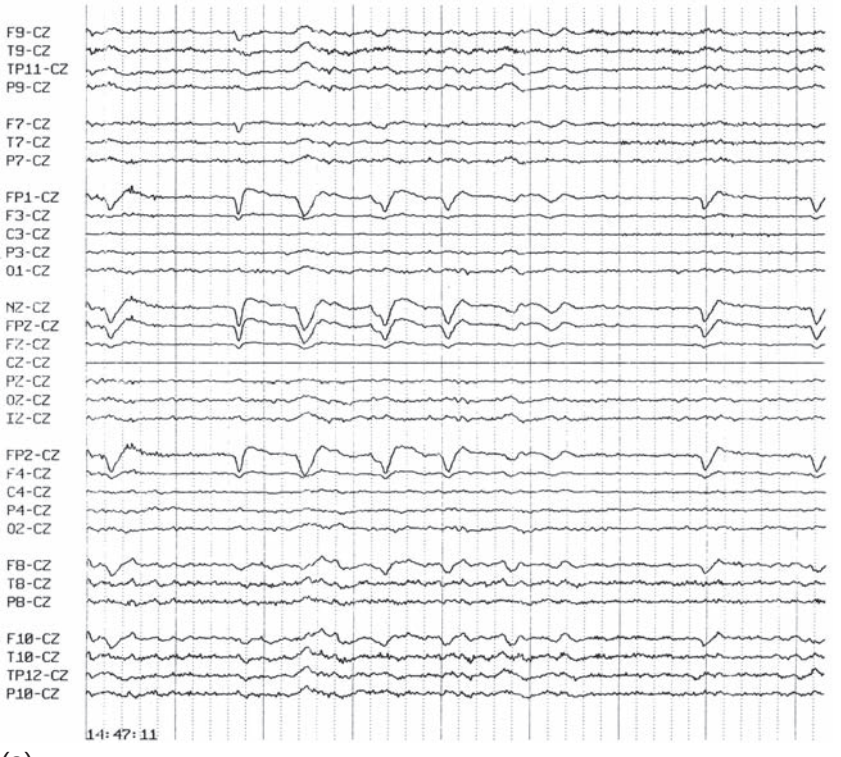
The neighborhood average approximation to the Laplacian is difficult to calculate at positions on the outskirts of the electrode array, where all four neighbors are not available. If three neighbors are available, an average of these (which may be denoted as 'N3' instead of 'Nav') may be used. Alternatively, additional electrodes[5] may be placed on the head in a circle passing through the nasion (N_z), inion (I_z), and the points just anterior to the tragus of the ears (T_9 and T_{10}) (Figure 62.5). These electrodes may be used in the calculation of the Laplacian at the frontopolar, lateral frontal, temporal, and occipital electrode positions and are also useful in their own right for recording ictal and interictal discharges originating in mesial and inferior temporal lobe structures (Figure 62.1c).

When the distances from an electrode to all of its neighbors are not equal, the neighborhood average must be modified by multiplying each potential in the average by the reciprocal of the distance. That is, each neighboring electrode potential is divided by the distance between that electrode and the center electrode; the results are summed, and from this sum the potential at the center electrode multiplied by the sum of the reciprocal distances is subtracted.[6,7] As noted earlier, negative one-fourth of the Laplacian is typically calculated, rather than the Laplacian itself. For example, if the F_{pz} and N_z electrodes are located at the positions shown in Figure 62.5, the appropriate formula would be as follows:

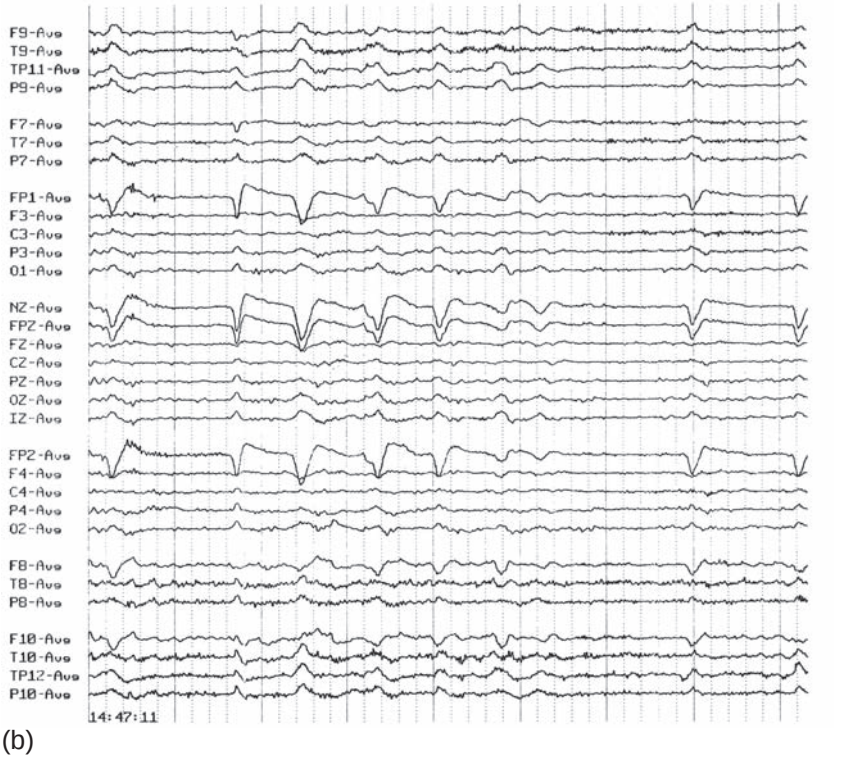
F_{pz}–Nav=0.875(F_{pz}–R)–0.25[(F_{p1}–R)+(F_{p2}–R)+(N_z–R)]–0.125(F_z–R)

because the distances from F_{pz} to F_{p1}, F_{p2}, or N_z are half the distance from F_{pz} to F_z in the 10–20 system.

The nearest-neighbor average approximation to the Laplacian is more accurate (closer to the true Laplacian, or



(a)



(b)

Figure 62.2 An electroencephalographic (EEG) recording showing eye blink artifacts. a, As recorded from a C_z reference. TP_{11} and TP_{12} are left and right mastoid electrodes. b, Reformatted to average reference.

radial current density) when the distance to the neighboring electrodes is small, but considerable error may be introduced with larger interelectrode spacing. The usual 6- to 7-cm interelectrode distances in the 10–20 system provide reasonable accuracy for most EEG potential distributions, but EEG features with complicated or rapidly varying spatial characteristics (such as relatively superficial tangentially oriented dipoles) can be misrepresented by an array of electrodes with standard (20%) spacing. This misrepresentation is an example of spatial aliasing, analogous to the aliasing in the time domain which occurs when a signal is sampled at too slow a rate to adequately represent its higher-frequency components. With spatial aliasing, the Laplacian montage calculated using the neighborhood average approximation may show artifactual phase reversals.

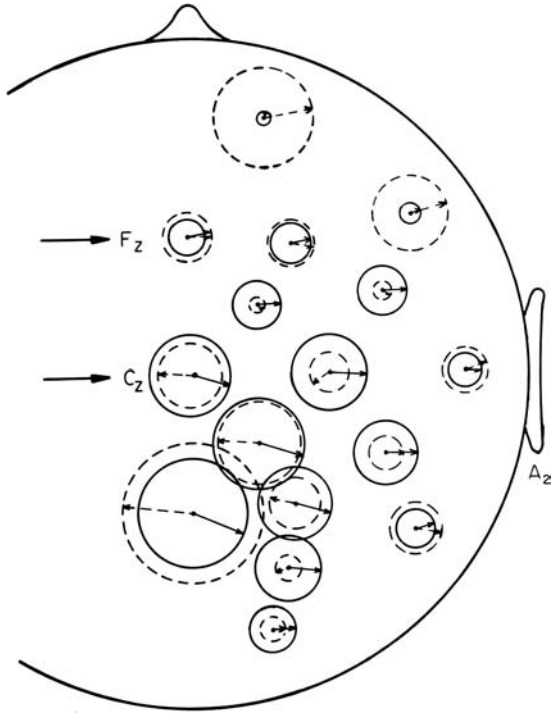


Figure 62.3 Electroencephalographic (EEG) phase-magnitude plots derived from a power spectral (Fourier) analysis of a normal waking EEG at 10.5 Hz (the spectral peak of the alpha rhythm). The radius of each circle is proportional to the amplitude at that location, and the angle of the arrow indicates phase. Solid and broken line plots correspond to an A_1 reference and average reference, respectively. (From Katznelson.[1] Used with permission.)

This occurs because the neighborhood average (which is contaminated by more distant, independent features rather than reflecting only the immediate surrounding potential), when subtracted from the central electrode potential to give the Laplacian, introduces the more distant activity reversed in phase. This problem may be seen in Laplacian derivations calculated with a 4-electrode average surround but occurs more frequently when only three electrodes are available for the surround (as for electrodes F_{p1}, F_{p2}, O_1, O_2, F_{pz}, and O_z when additional nasion and inion electrodes are not available).

More accurate approaches to calculating the Laplacian have been devised, but these involve more computation. One method is to calculate a neighborhood average for each electrode by using all of the available electrodes rather than just the four nearest neighbors, multiplying the potential at each electrode in the average by the inverse (or the square or cube) of the distance between that electrode and the central electrode.[8] This distance-weighted approach to the Laplacian is empirical but does sometimes eliminate or minimize the effects of spatial aliasing.

Other methods use an interpolation technique based on an analytic expression for the potential over the entire head surface that is fitted to the recorded potentials at each electrode position. The 'true' Laplacian can then be calculated from the analytic formula by differentiation. This type of approach not only allows a more accurate Laplacian to be calculated at the electrode locations, but also provides a means for generating interpolated data for drawing spatial maps of the potential or the Laplacian. Some of the interpolation techniques that can be used include two-dimensional rectangular surface splines,[9,10] three-dimensional rectangular splines projected onto a spherical surface[11,12] or ellipsoidal surface,[11] realistic scalp surface two-dimensional thin-plate splines,[13] spherical surface splines,[6,9,14] the spherical harmonic expansion,[7,15,16] or a single- or multidipole source model.[17]

Using matrices in reformatting montages

The mathematical concept of a matrix is a rectangular array of numbers (elements of the matrix) arranged in rows and columns. A matrix with only one column (or one row) is sometimes called a vector. Matrices with the same number of rows and columns can be added and subtracted by adding or subtracting corresponding elements, and a matrix can be multiplied by an ordinary number by multiplying each element by that number. Two matrices of appropriate dimensions can also be multiplied. Multiplication of a matrix **A** by **B** to give **C** involves multiplying successive elements in the *i*th row of **A** by corresponding elements in the *j*th column of **B** and summing the products to give the element in the *i*th row and the *j*th column of **C**. This definition of matrix multiplication turns out to be the most useful one, because each element of the product matrix is a linear combination of various elements of the original matrices.

If the set of measured potentials at each electrode position on the head at any instant of time t is represented as a 1-column matrix (a vector) called $\mathbf{e}(t)$, then the potentials in a reformatted montage at the same instant of time can be represented as another vector called $\mathbf{e}'(t)$. Then, it is possible to construct a montage-transformation matrix **S** such that $\mathbf{e}'(t) = \mathbf{S}\mathbf{e}(t)$; that is, the EEG data vector is reformatted to a new montage by multiplying it by the matrix **S**. Appropriate choices of the **S** matrix can be devised to reformat referential to referential, referential to bipolar, or referential to Laplacian montages, as well as to generate new channels by averaging subsets of electrodes or interpolating linearly to points between existing electrodes. Even the distance-weighted Laplacian calculation and many of the interpolation techniques used to calculate Laplacians can be expressed as a matrix multiplication. Many other types of computer processing of EEG data can be expressed in this manner as well, provided that the transformation performed on the EEG data is linear. For example, the spatial deconvolution technique[18] uses an approximate model of the volume-conductive properties of brain, skull, and scalp to estimate cortical surface potentials from recorded scalp surface potentials. Another example is the spatial filter described in Chapter 64.

The use of matrices for montage reformatting and related processing in computer-based EEG displays has several advantages. First, it provides a uniform framework by which the electroencephalographer may specify a type of reformatting or processing to be done. Each channel in the EEG display is calculated as a linear combination, with appropriate weighting coefficients (some of which may be zero), of all the recorded channels. For example, to calculate a bipolar derivation X_1–X_2, appropriate weights would be +1 for the X_1–R input channel, −1 for the X_2–R input channel, and 0 for the rest of the inputs. To calculate a nearest-neighbor approximation to a Laplacian of C_z, the required weights would be +1 for the C_z–R channel, −0.25 for the C_3–R, C_4–R, F_z–R, and P_z–R channels, and 0 for the rest.

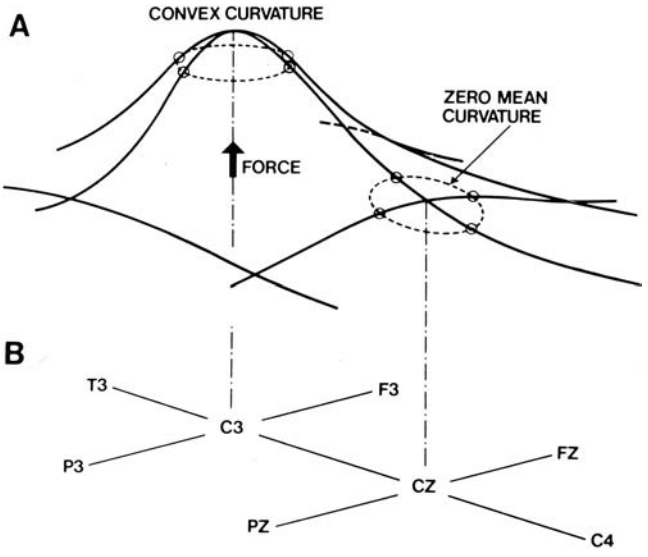

Figure 62.4 A plot of scalp potential $V(x, y)$ as a function of scalp position (x, y) resembles the profile of an elastic membrane displaced by a localized force. a, An upward force produces a bulge in an elastic membrane which extends over some distance. The mean curvature of the membrane in the x and y directions (Laplacian) is negative where the force acts but is zero at other locations because of cancellation between the positive (concave) curvature in the x direction and the negative (convex) curvature in the y direction (Laplace's theorem). Similarly, a cortical current source produces a peak in the scalp potential which spreads widely in all directions, but the Laplacian of the potential is nonzero only in the immediate vicinity of the source. b, The Laplacian at C_3 and C_z may be approximated from the potentials measured at an array of neighboring electrodes. (From Wallin and Stålberg.[4] Used with permission.)

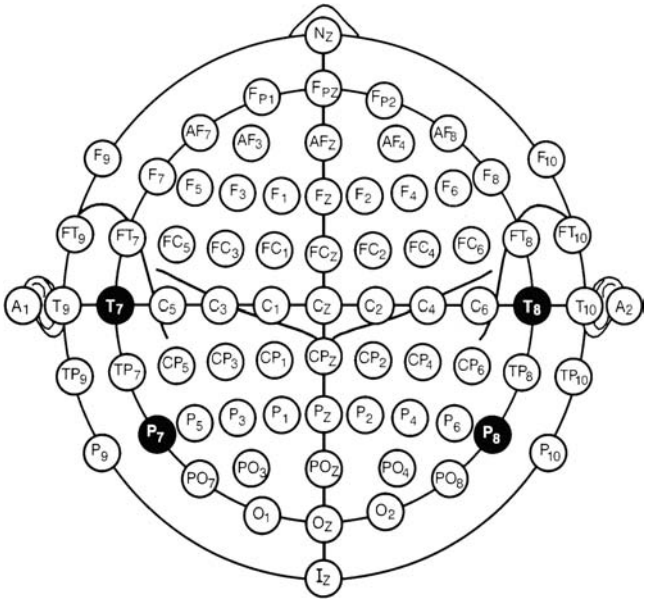

Figure 62.5 An extension of the 10–20 system of electroencephalographic electrode nomenclature. New electrodes with 10% spacing, including on the inferior circle passing through nasion and inion, are defined. (From Electrode Position Nomenclature Committee.[5] Used with permission.)

Second, use of matrices allows multiple successive transformations of the EEG to be performed in a single step, saving computer time by precalculating a single matrix that represents the combined transformations as a product of the matrices representing each successive transformation step. For example, if the matrix **B** transforms from a referential to a longitudinal bipolar montage and the matrix **A** transforms from a C_z reference to an average ear ($A_{1/2}$) reference montage, then the product matrix **BA** will first transform from a C_z to an $A_{1/2}$ reference and then from this to a bipolar montage. Of note, it can be shown by doing the multiplication that **BA** is equal to **B**, since it does not matter which referential montage one starts with when calculating a bipolar derivation; a bipolar montage is reference independent. As another example, suppose that matrix **B** transforms from a referential to a bipolar montage and matrix **S** performs spatial filtering of EEG recorded in that bipolar montage. Then, the matrix **A**=**SB** will, in one step, transform the referentially recorded EEG to a spatially filtered bipolar EEG.

63 Automatic detection of epileptic spikes

P LeVan and J Gotman

Introduction

In addition to the paroxysmal bursts of electrical rhythmic activity that characterize seizures, the electroencephalogram (EEG) of epileptic patients commonly features abnormal interictal activity, mostly in the form of sharp transient spikes. An appropriate investigation of these interictal discharges is often critical for the diagnosis and evaluation of epileptic patients, providing valuable complementary localization information for candidates for epilepsy surgery. Quantification of the timing and amplitude of the spikes can be an important indicator of the brain area where the seizures originate.[1] The documentation of ictal and interictal activity is generally accomplished with long-term monitoring sessions that can last several days. This is necessary because the EEG of epileptic patients may potentially display several types of spikes or seizures originating from various locations. The occurrence of some of these spike or seizure types may be quite sporadic, thus requiring a lengthy monitoring session to record all the events of interest. Moreover, various analysis methods may necessitate the recording of a large number of spikes from the same type; for example, many source localization methods rely on the averaging of several spikes to obtain more accurate results.

While seizures are frequently accompanied by clinical manifestations, spikes are purely electrographic events that can only be identified by a careful review of the EEG recording. However, the review of a continuous recording lasting several days can be a tedious and expensive task. Despite the possibility of using computers to digitally display the EEG on screen at an accelerated speed, the examination of a 24-hour recording may still take a few hours. In the last several years, the development of automatic spike detection methods has greatly facilitated this process. This chapter will introduce some of these methods and evaluations of their performance. Difficulties and limitations associated with automatic spike detection will also be presented.

Recording interictal activity

The interictal activity specific to epilepsy consists of spikes, sharp waves, and bursts of spike-and-wave. Patients with epilepsy also have abnormalities of background, which can be analyzed by computer methods. Paroxysmal interictal activity occurs unpredictably and sometimes infrequently. To obtain a full documentation of the different types of abnormalities, the traditional short recording may not be sufficient. Long-term monitoring may be required, including periods of the different stages of sleep, which most often activates and modifies interictal patterns.[2] The reduction of antiepileptic drug (AED) doses, often done during long-term monitoring to precipitate seizures, also results indirectly in increased spiking; it has been shown that spikes are more frequent after seizures.[3–5] It is clear that complete review of recordings lasting days and nights is an awkward method to document interictal activity: automatic detection methods can be very helpful.

Past methods

The usual approach in early systems for automatic spike detection consisted of (a) selecting EEG sections lasting 1 or 2 minutes, free of artifacts and including a sufficient number of spikes; (b) devising a method for their detection; and (c) comparing results of automatic detection to what qualified electroencephalographers considered 'true' spikes. Details of the various detection methods have been reviewed extensively.[6] In general terms, these methods relied on one of two approaches: In the first, the EEG is broken down into elementary waves, and the method then attempts to identify waves having morphologic characteristics normally associated with spikes (amplitude, duration, sharpness). In the second, the EEG is analyzed to find statistically improbable events of short duration. With most methods, very acceptable performance was obtained, usually with 80–90% of 'true' spikes detected and a low rate of false-positive detection. Many publications ended with statements such as, 'As computers become more powerful and less expensive, practical implementation of this method will be simple.' Computers did in fact become more powerful and less expensive faster than anybody had expected, but most methods did not reach practical implementation. One major reason is that the detection problem became much more complex when longer sections were analyzed; artifacts and normal transients had to be included, and they caused numerous false detections. In addition, some methods were not readily adaptable to online analysis and were therefore of limited practical utility. For short recordings, human inspection generally performs sufficiently well, so that there is little use for spike detection in these cases. Automatic methods would thus be most useful for prolonged recordings. It should be noted, however, that perfect performance is unlikely to ever be obtained by automatic systems. After all, EEG experts also show a less than perfect sensitivity; there is some inherent

variability associated with the subjective interpretation of EEG records.[7] Ambiguous EEG transients may or may not be marked as spikes by different reviewers.

It should also be noted that many clinical applications do not require the identification of all the spikes present in a given recording. A representative sample of all types of spikes occurring in a patient's EEG is generally sufficient for diagnosis and evaluation purposes. Automatic spike detection methods can thus be most useful in the role of identifying all potentially interesting events in the EEG, so that a human reviewer can then select the most relevant ones.

Difficulties of the problem

The major difficulty of spike recognition methods is their reliance on a very incomplete definition of a spike. The definition quoted by many publications is 'a sharp transient, easily distinguishable from the background, having a duration of less than 70 ms for a spike and 70 to 200 ms for a sharp wave' (adapted from Chatrian *et al.*)[8] This definition is extremely incomplete, because it lacks features for differentiating transients with the same local morphology that are not spikes, such as eye blinks, vertex sharp waves, isolated alpha or spindle waves, electrode artifacts, and movement artifacts. Such transients are common during prolonged EEG recordings, when automatic spike detection is useful. Figure 63.1 shows a typical example of results from standard spike detection methods; genuine spikes are mixed with false detections caused by nonepileptiform transients.

Which characteristics allow a human interpreter to separate an epileptiform sharp wave from an eye blink, even though the waves themselves may have the same morphology and emerge from a similar background? These characteristics most likely relate to the context in which the waves appear; this context likely encompasses a much wider space and time than the background activity surrounding the spike. When interpreting a wave having the morphology of a spike, the human observer takes into account events in other channels (spatial context) and in earlier and later parts of the recording (temporal context), and even non-EEG information, such as the age or clinical state of the subject. Optimism about early detection methods was based on a failure to appreciate how much spike identification relies on context.

It must be noted that the problems discussed above do not affect the ability to detect most epileptiform spikes, but they result in a large number of false-positive detections. For this reason, it is possible to make practical use of an automatic spike detection method, as long as it is conceived as a method to detect a high proportion of the spikes along with a possibly large number of nonepileptiform transients, rather than as a method to detect only spikes. Such a practical implementation was made with the spike detection algorithms developed at the Montreal Neurological Institute.[9,10] Pietila *et al.*[11] presented a system including automatic segmentation of the EEG followed by feature extraction. Compared with Gotman's system, this system showed a higher sensitivity but a lower specificity.

Newer approaches

Artificial neural networks (ANNs) have become a popular method for pattern recognition, including spike detection. By being presented with a sufficiently large number of training examples comprising spike and nonspike data, the ANN can learn to recognize spikes from background EEG. A representative set of features characterizing the EEG needs to be specified in advance (e.g., amplitude, sharpness, etc.), but it is not necessary to explicitly describe the morphology of a spike. The ANN automatically determines which combinations of features are characteristic of spikes by adapting its output to reflect the training data. The performance of ANN methods depends on the selection of an appropriate set of features and on the use of a sufficiently large training set containing a wide variety of spike patterns. It is also necessary to specify a priori the structure of the ANN; large networks can handle complex classification tasks, but may risk overfitting the training data and thus be unable to generalize to other types of spikes. It is also very difficult to investigate the operation of a large ANN; the network essentially acts as a black box that outputs classification values depending on the features it receives as inputs. One of the earliest use of ANNs for spike recognition was reported by Gabor and Seyal,[12] who obtained a good performance but evaluated their method on a very small sample.

When designing a neural network method, it is crucial to select an appropriate set of features to use as inputs to the ANN. The relatively short duration of spikes offers the opportunity to use the raw EEG data points as network inputs, thus foregoing the extraction of features. Webber *et al.*[13] using a relatively small data set for evaluation, compared the use of the raw EEG to that of preprocessed variables (including width, sharpness, slope, and amplitude) in the ANN and concluded that a better performance was obtained by using the preprocessed parameters. Ozdamar and Kalayci[14] obtained good performance with an ANN trained on raw EEG, but Ko and Chung[15] revisited the data and suggested that the results were erroneous due to inappropriate data preparation.

When using raw EEG instead of preprocessed parameters, the ANN needs to recognize all combinations of the data that can be relevant for the classification task. A very complex ANN will thus be required to obtain a satisfactory performance. It is possible to simplify the problem by using only a small amount of raw EEG as input, as was done by Kurth *et al.*[16] who used a data window of only 100 ms. However, the use of such a short window prevents their method from taking into account characteristics such as the slow wave that often follows interictal spikes. The lack of temporal context makes it difficult to prevent false detections caused by transients whose morphologies are locally similar to spikes. Their results are difficult to compare with other methods because they only used a limited dataset for validation, and they had separate ANNs trained and tested individually on the same patients. To reduce the complexity of spike detectors using raw EEG as inputs, Acir and Guzelis[17] proposed a multistage approach where the data is first reduced by identifying nonstationary transients using an autoregressive linear predictor. Only the identified transients are then further examined, by using the raw signal in a support vector machine for classification as spike or nonspike. A sensitivity of 90.3% with 9.5% of false detections was reported after validation with 4.2 h of EEG from seven patients.

The use of extracted features instead of raw data can result in simpler classifiers for spike detection. Wilson *et al.*[18] designed several simple rules for spike detection, and then

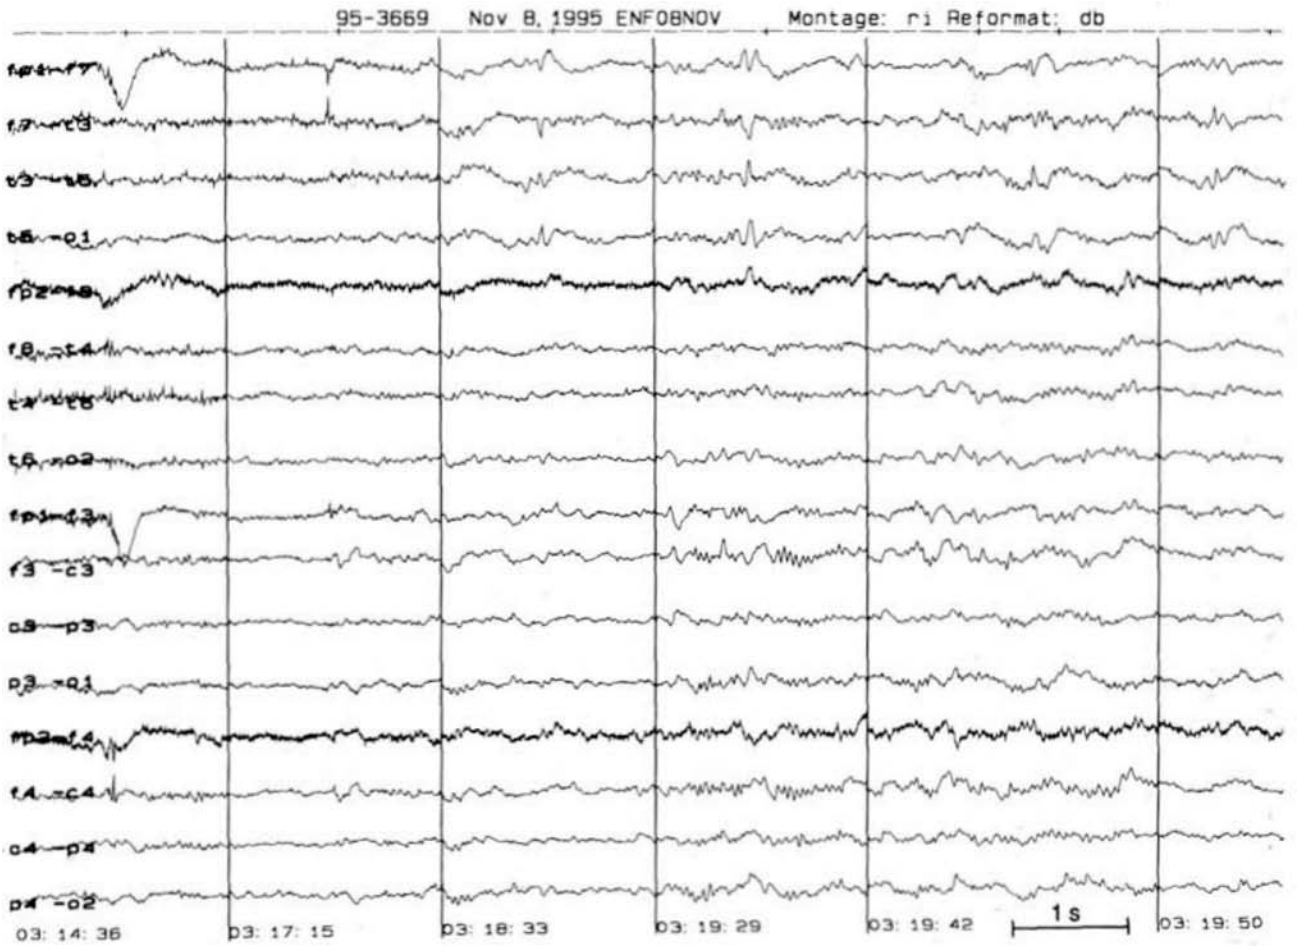

Figure 63.1 EEG sections recorded through automatic spike detection (method of Gotman.[10]) Vertical lines represent discontinuities in the recording; sections shown here represent automatically detected events during a 5-minute period (see time at the beginning of each section, at bottom of figure). The intervening EEG is not shown. The method enables detection of genuine spikes and sharp waves that are not very prominent (four rightmost sections). They are mixed with nonepileptiform transients (two leftmost sections). Even with false detections, the method provides valuable data reduction.

used multiple small ANNs to learn each rule. These rules included, for example, whether the spike was followed by a slow wave, or whether the spike stood out from local rhythmic activity. It was then easier to interpret how each small ANN implemented the individual rules. Wilson *et al.* also used a training set where EEG data epochs were marked with a probability value rather than a dichotomous classification as a spike or nonspike. This allowed the system to process ambiguous spikes without having to decide on a definitive classification. Hellmann[19] used cross-correlation to identify candidate spikes that resembled a given template, followed by classification using an ANN with various features, such as amplitude, slope, and timing information. The use of a template results in a system that is patient-specific and can only identify one type of spike at a time. Nevertheless, this method could be useful if the time of occurrence of known spike morphologies is desired, such as in functional imaging applications. In addition to ANNs, other data mining models can also be used to automatically generate classifiers for spike detection. Valenti *et al.*[20] implemented C4.5 decision trees and naïve Bayesian classifiers with good results, but EEGs from only three patients were used for training and validation.

There has been some interest recently in using wavelet analysis to identify interictal spikes in EEG records.[21–24] Wavelet features can be useful to describe the time and frequency relationships that exist between the spike and the following slow wave. These methods are well suited to the characterization of transient signals such as spikes.

Use of a broad context for spike detection

Another approach to improving detection performance is to make automatic methods operate more like humans, that is, to allow them to use information from a wide context. This is a simple concept but difficult to implement, because the context encompasses a very large amount of information and it must be decided which part of that information is relevant low spike detection. It is this selection process that humans do so well. Glover *et al.*[25] described a context-based system aimed largely at reducing false spike detections by making use of a wide spatial context; information from all EEG channels, as well as from electromyographic, electro-oculographic, and electrocardiographic channels is used to assess whether a transient in a particular channel is likely to be epileptiform.

An approach has been proposed by Gotman and Wang[26,27] in which a wide temporal and spatial context is used to decide on the nature of a sharp event. The method is termed state-dependent spike detection because criteria for spike detection are rendered dependent on the state of the EEG. Five states were defined in which spike detection should be performed

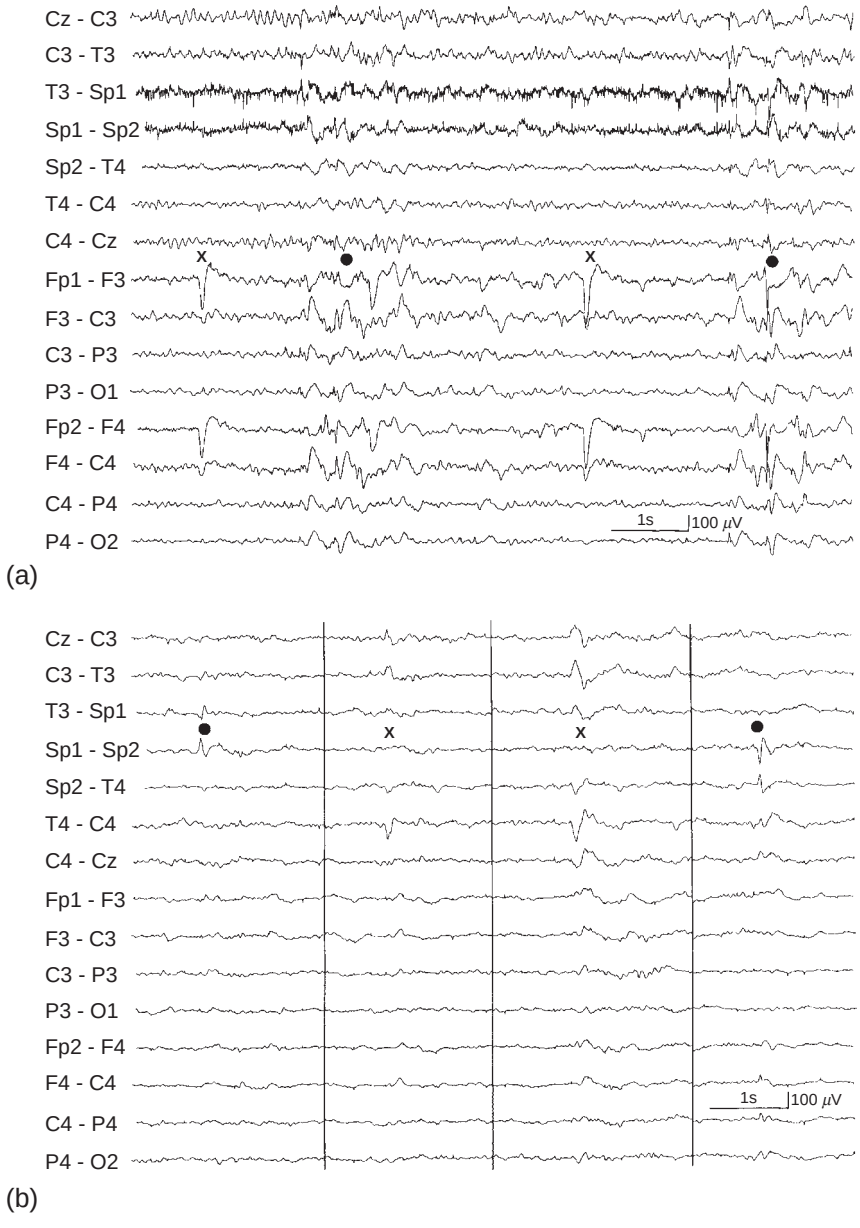

Figure 63.2 Use of spatial and temporal context in spike detection. Nonepileptiform transients are selectively rejected (rejected events marked with *x*). a: During active wakefulness, as determined by automatic state classification, waves having the morphology and distribution of eye blinks are eliminated. b: During phasic sleep, sharp waves having a maximum at the vertex are eliminated. Reproduced from Gotman and Wang.[27]

differently; active wakefulness, quiet wakefulness, desynchronized EEG, phasic EEG, and slow-wave EEG. In fact, in these different states it is not so much that spike detection has to be done differently, but rather that false detections have to be handled by different means. In active wakefulness, for instance, one must be particularly aware of symmetric frontal sharp waves that may be caused by eye blinks, whereas there is no such concern in the phasic EEG state; in that state, sharp waves maximal at the vertex are a problem (Figure. 63.2). The method was evaluated in 20 patients, each having close to 2 hours of EEG covering all states; it showed a reduction in false detection of 65% and an increased sensitivity of 35%, compared with the original method. Flanagan *et al.*[28] suggested an improvement to this method by using an equivalent current dipole to model each detection. The goodness of fit and the position of the dipole were then used as features to reject nonspike artifactual transients. It was not necessary to obtain an accurate localization of the spike generator; a simple dipole model provided sufficient information to reject many false detections. Using an independent data set of 20 patients to validate the method, Flanagan *et al.* reported a 53% decrease in false detections, while only removing 4.3% of true spike detections, compared to the original method of Gotman and Wang.[26,27]

Whether neural networks or more traditional methods are used, it is unlikely that local wave morphology is sufficient to differentiate epileptiform transients from other transients. Some form of context sensitivity appears necessary.

Conclusion

Automatic spike detection is a more difficult task than researchers in this area originally thought. An expert

electroencephalographer normally uses information from a wide spatial and temporal context to identify spikes during the visual review of an EEG recording. However, most computer methods are based on the analysis of a short window of EEG at a time. While powerful pattern recognition algorithms such as artificial neural network classifiers can achieve a very high sensitivity for spike detection, these methods also identify nonepileptiform transients whose morphologies are similar to spikes. Nevertheless, considerable data reduction can be achieved by automatic spike detection methods. False detections, if they are not too numerous, can be quickly removed during a manual review of the detected events. This procedure results in a significant economy of time, since the EEG record no longer needs to be reviewed in its entirety.

Recently, improvements in the performance of spike detection methods have been achieved by incorporating knowledge of a wider context, such as the state-dependent spike detection method mentioned above. This approach greatly reduced the amount of false detections by automatically rejecting artifacts or other nonspike transients that are known to occur during various clinical states. Further developments in this area will probably result in much better performance approaching that of humans. However, given that even human experts display some variability when marking spikes in EEG records, it is unlikely that perfect performance can be achieved by automatic systems. Nevertheless, these systems can still be extremely helpful when combined with a subsequent human validation of the detection results.

64 Source localization of electroencephalography spikes

TN Townsend and JS Ebersole

Introduction

For generations electroencephalographers have used visual inspection of scalp-EEG traces in various montage combinations in order to localize the source of epileptogenic spike and seizure potentials. Most of these schemes were an attempt to identify the negative voltage field maximum. The assumption implicit in these efforts was that the cerebral source underlay the electrode(s) recording this field maximum. As we will discuss below, this assumption is only correct in limited circumstances. Now that EEG recording and display are done digitally, there are far easier and more accurate ways to determine location (size, shape, and temporal stability) of voltage field maxima. Analysis of this voltage topography over the entire head is the basis of all EEG source localization methods. We will review several of these methods and demonstrate how they can be used clinically to localize epileptogenic foci non-invasively.

Attributes of cerebral spike sources and effect of source attributes on resultant spike fields

There are several physical and functional attributes of cerebral sources that influence how an epileptic spike will appear when recorded by scalp EEG. If there is a consistent relationship between scalp-EEG spikes and their cerebral sources, we can use EEG analysis to localize the origin of this epileptic activity reliably. In this section we will describe, and explain the basis for, some of these relationships.

When synaptic excitation and/or inhibition occur in the brain, there is electrical current flow into and out of neurons. This leads to the generation of an electrical potential gradient in the extracellular space of the cortex. If a sufficient number of geometrically aligned neurons (such as pyramidal cells) are simultaneously active, their potentials can summate to create a field that is detectable by the EEG. The orientation of this extracellular voltage field is the same as the net orientation of the pyramidal cells and orthogonal to the surface of the cerebral cortex generating it (see Figure 64.1). Epileptic transients are usually negative when recorded from electrodes on and directly above the cortical surface. However, electrodes which are on the opposite side of the active cortex record a positive potential. Thus electrodes recording the positive potential can be located anatomically in the underlying white matter or even on the scalp on the opposite side of the head. This leads us to a key concept; scalp-EEG voltage fields have a dipolar configuration, i.e., two maxima, one negative and one positive.[1] Sometimes the second maximum is not recorded because it is located on the 'southern hemisphere' of the head where commonly few electrodes are located.

Physical factors of cerebral sources that influence the scalp EEG voltage field are location, orientation and surface area. The *location* of the generator will clearly influence the position of the scalp EEG voltage field, however cerebral *surface area* involved also plays an important role. If the surface area of the generator is too small, no scalp EEG field will be generated. A longstanding maxim is that at least 6 cm^2 of gyral cortex must be similarly active to produce a spontaneous scalp EEG field.[2,3] In a recent study a comparison was made between the surface areas of intracranial-EEG sources that had scalp-EEG spike correlates and those that did not. The investigators demonstrated that typically at least 10 cm^2 of active cerebral cortex was necessary to generate a scalp spike.[4] They also showed that the origin of prominent scalp EEG spikes is considerably larger, namely 20–30 cm^2.

Source orientation is another important factor influencing scalp-EEG voltage fields. It is the orientation of the cerebral source that determines the location of the voltage field maxima on the scalp. For example, a cerebral source that is oriented tangentially to the scalp will produce no potential directly above it. Instead, there will be two maxima located on either side of the source (see Figure 64.1). A radially oriented cerebral source, on the other hand, produces a scalp field maximum directly above it. Accordingly, sources located in midline interhemispheric and basal cortical regions produce tangential fields while lateral convexity sources yield radial fields.[1,3] It frequently occurs that opposite banks of a sulcus as well as gyral crowns are active simultaneously. The activity on opposing sulcal banks cancels each other, leaving only the radial field of gyri to be appreciated on the scalp-EEG.

Functional factors related to cerebral sources that influence scalp EEG voltage fields are amplitude, synchrony and propagation. The relative amplitude of a negative versus positive field maximum determines the cerebral source location. If one draws a 3D line connecting the negative and positive scalp field maxima, the source is located along this line (Figure 64.2). The relative amplitude of the negative to positive maxima determines the source's location along the line. For example, if the negative maximum is of relatively higher amplitude, the cerebral source is located closer to it. In addition, sources that are deep in the brain tend to produce larger fields with lower potential amplitudes and more shallow gradients. To the contrary,

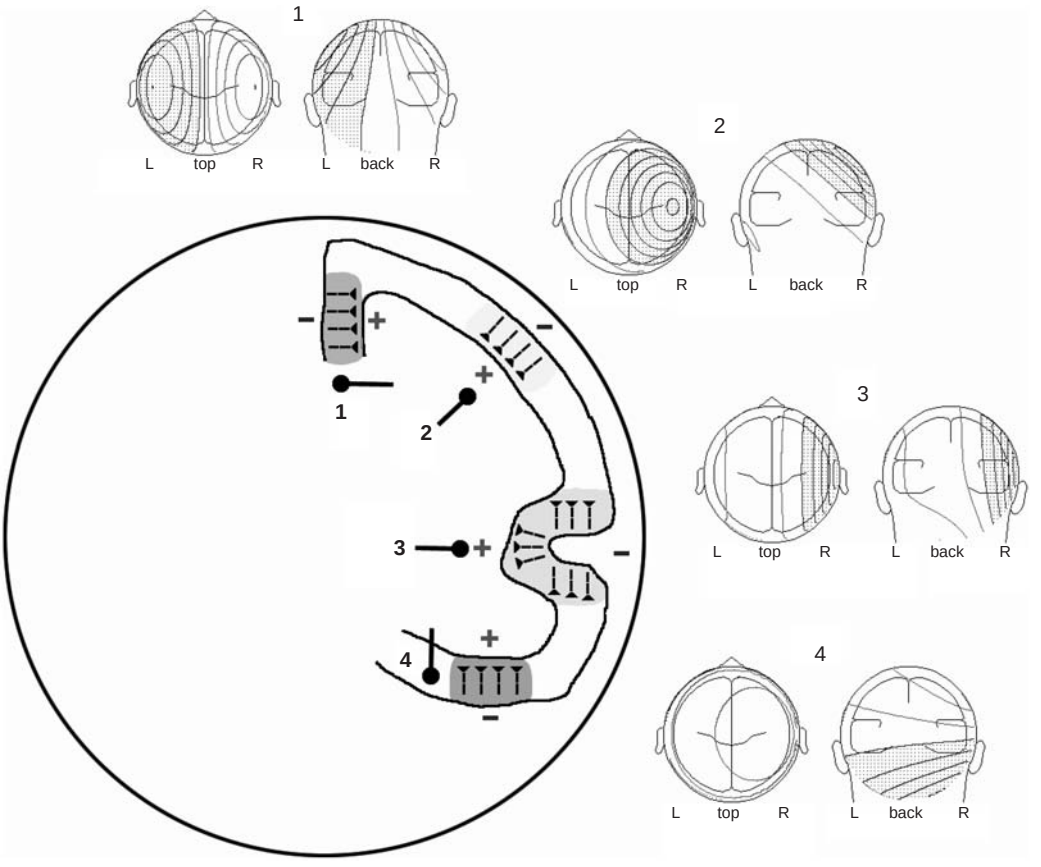

Figure 64.1 Example cortical sources 1–4 depicted in a schematic head/brain in coronal cross-section. Typical pyramidal cell orientations are shown for each source. Resultant scalp voltage field topography for superficial laminar depolarization is displayed above each source as isopotential lines of field strength (speckled=–negative, clear=positive). Typical dipoles modeling these sources are depicted beneath each source. Note that simple and more complex cortical convexity sources (1 and 2, respectively) produce radial fields with negative maxima directly above them and positive maxima contralaterally. Radial dipoles deep to the cortex model these sources. Interhemispheric source 3 and temporal base source 4 produce tangential fields with negative and positive maxima displaced on either side of the source and essentially no potential directly above them. Tangential dipoles deep to the cortex model these sources.

superficial sources yield small field of high amplitude and steep voltage gradients. Synchrony and propagation of cerebral sources also influence the scalp voltage field. Scalp spike EEG voltage fields that change in magnitude over time, but not in shape and orientation, are generated form discrete sources. A spike voltage field that changes in shape and location over time suggests a changing geometry in the cerebral source, which is most likely related to propagation.[3]

Spike voltage topography

Spike voltage topography has been used for 20 years as a method of analyzing EEG. The rationale for this, as discussed in the previous section, is that the *shape* of the voltage field, in addition to the location of the maxima and minima, provide valuable information for localizing its cerebral source. This information cannot be gleaned easily by mere visual inspection of the EEG. Most investigations in this field have focused on the analysis of temporal lobe epileptiform activity, in particular on the question of distinguishing spikes of basomesial versus lateral temporal origin by means of voltage topography. This can be difficult or impossible to do with visual inspection of the EEG.

The Cleveland Clinic Epilepsy group has used one form of spike voltage topography to analyze interictal activity in patients with fronto-temporal spikes. The location of the negative field where the spike voltage is at least 80% of the maximum amplitude recorded value is where importance is placed. If this maximum is situated over a unilateral fronto-temporal region and if there is a convergence of other data pointing to the same site, then surgery can be performed without invasive recording.[5,6]

Others have argued that this amplitude criterion is not likely to distinguish spikes from the baso-mesial versus lateral temporal regions because the negative maximum of both these groups of spikes is located in the same 'fronto-temporal region'.[7] Rather the voltage topography over the entire head is used to make this distinction. In one study,[7] 24 patients with fronto-temporal EEG spikes recorded during 2–7 days of continuous VEEG. Data were recorded to a common reference electrode on the mastoid located contralateral to the spike focus. Additional subtemporal electrodes were used ipsilateral to the focus. Eight of the patients underwent simultaneous scalp and subdural/strip/depth EEG recordings and scalp spikes from those recordings were also analyzed topographically. These results were compared with the location of the cerebral source as determined by invasive electrode recording. The investigators found that fronto-temporal spike voltage fields were much easier to assess using topographic maps than visual inspection of EEG traces. Furthermore, the topographic maps allowed investigators to distinguish two types of temporal spike voltage fields

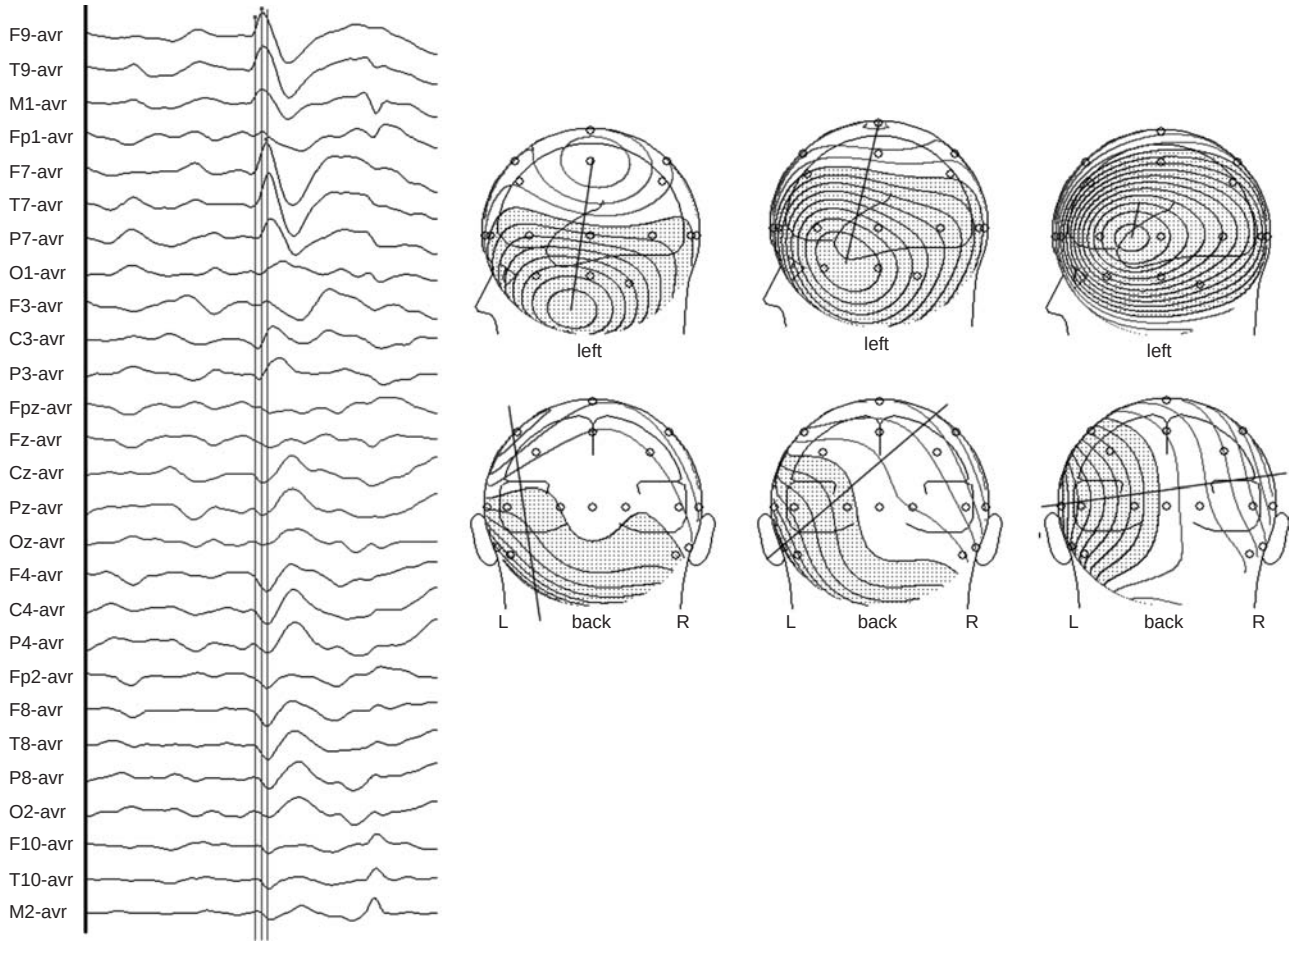

Figure 64.2 Scalp-EEG of a left temporal spike is shown at left. In this and subsequent figures scalp-EEG is illustrated in common average reference. Cursors mark three time points on the rising phase of this spike. Topographic maps depict the scalp voltage fields at these three points in isopotential lines. In this and subsequent figures voltage field negativity is shown as a speckled region and positivity as a clear region. A three-dimensional line defining field orientation connects the two maxima. Note that early in the spike the field is vertical and tangential. Later it is oblique, and at the spike peak the field is horizontal and radial. Such change in the location of voltage field maxima and field orientation are the result of spike propagation across basal and into lateral temporal cortex.

(Figure 64.3). Both had voltage fields with a maximum negativity around F8–T4. One spike group (Type 1) had a negative field that was relatively confined to the infero-lateral temporal region and had a steep voltage gradient. A distinct associated positive field was located in the contralateral vertex region. The second group of spikes (Type 2) had a negative field that was more diffuse and had more shallow voltage gradients. The associated positive field was of low voltage and located in the opposite temporal area. 13 patients (54%) had Type 1 spikes and nine patients (38%) had Type 2 spikes. Most of the patients had more than 80% of their spikes being of one type, although there were two patients (8%) with an equal number of Type 1 and 2 spikes. Out of the eight patients who underwent intracranial electrode monitoring, four had Type 1 and four had Type 2 spikes. Three of the four patients with Type 1 spikes had seizures arising from the medial temporal structures and one had frequent spiking from the prehippocampus and hippocampus. Of the patients with Type 2 spikes, intracranially recorded seizures were localized to nonmedial temporal or extratemporal regions. MRI studies of the patients with Type I spikes showed that nine out of 11 had hippocampal atrophy ipsilateral to the spikes. Eight of nine patients with Type 2 spikes had MRIs: one showed hippocampal atrophy but four had lesions in the nonmedial temporal lobe regions. The two patients who had equal numbers of Type 1 and 2 spikes had hippocampal atrophy. Investigators concluded that spike voltage topography can enhance the electroencephalographer's ability to understand the spatial characteristics of interictal spikes which are not readily appreciated using the usual bipolar EEG montages. It was noted by the investigators that although common average references can be used to enhance visual inspection of EEG spikes, topographic voltage display makes these features even more apparent.

Further studies have since demonstrated that the distinction between Type 1 versus Type 2 temporal lobe spikes is more complex. Voltage fields can evolve over time from Type 1 to 2 or vice versa. The location of the field maximum may also shift without a change in spike type. Accordingly, a thorough analysis requires the review of voltage field evolution, using a series of topographic maps, starting from the initial spike deflection to its peak. The earliest voltage fields are those most likely related to the cerebral source, rather than to propagated activity.[1]

Source modeling fundamentals

Three-dimensional EEG source localization is a logical extension of voltage topography. This form of EEG analysis could

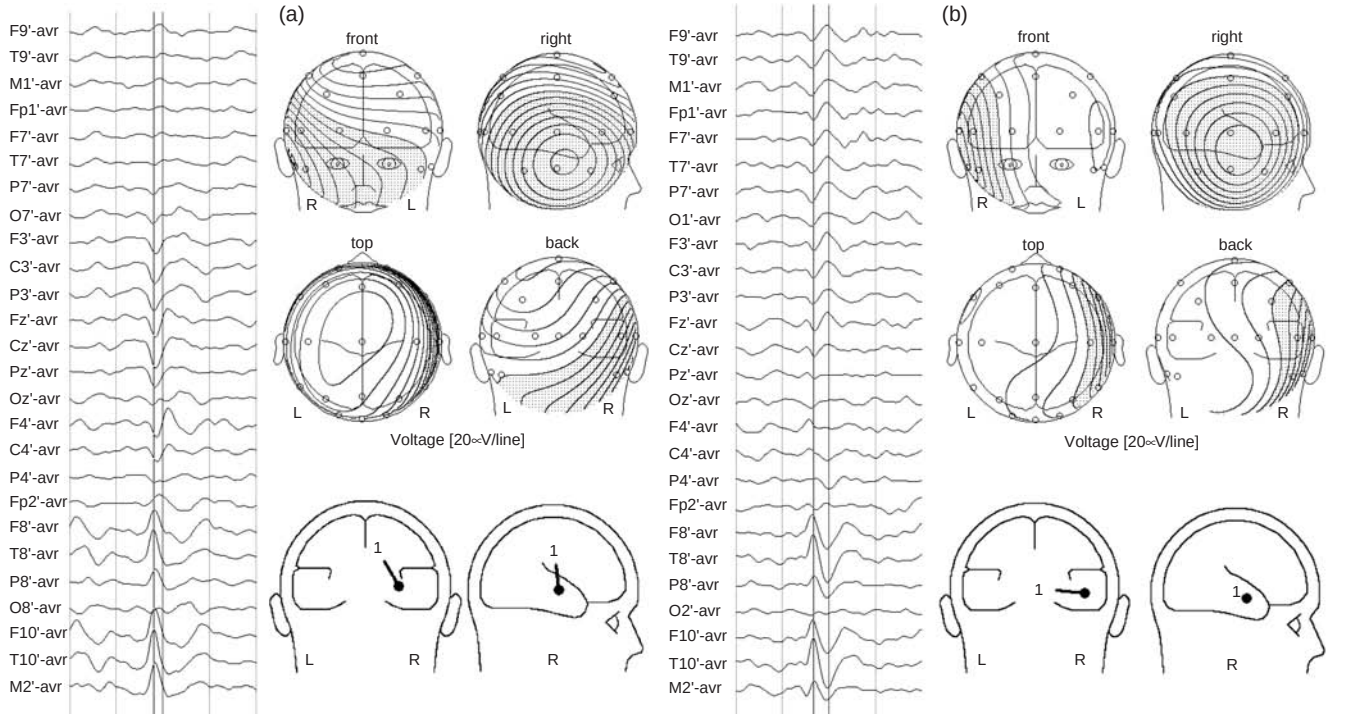

Figure 64.3 Scalp EEG, voltage fields, and single dipole models of (a) Type 1 and (b) Type 2 temporal lobe spikes.

help clinicians determine the location of foci for surgical resection and/or placement of invasive electrodes. Dipole modeling is one of the most well studied techniques for doing this type of 3D analysis of epileptiform EEG potentials.

Because scalp electrodes are relatively distant from the cortical neurons that generate the EEG, their cellular currents can be approximated as a dipole.[1] Dipole localization is based on the physical principles of volume conductor theory.[8–10] This states that for every dipolar source within a volume conductor, there can be only one resultant potential field distribution on the surface of the conductor. This is called the *forward solution*. The usual problem for the electroencephalographer is the opposite, namely determining the dipolar source given a measured EEG field. This is known as the *inverse solution*. Unlike the forward solution, there is no unique solution to the inverse problem because sources within a volume conductor can sum linearly to produce the resultant scalp field. As a result, many different source configurations can generate the same potential distribution across the scalp.[11]

In order to constrain the possible solutions to the inverse problem, certain a priori assumptions are usually made. These assumptions about the electromagnetic and geometric properties of the volume conductor are usually contained in the head models that are used in the inverse calculations and are expressed within what is called the *lead field matrix*.[11] To solve the inverse problem this lead field matrix is multiplied by an estimated dipolar source to produce a scalp potential distribution (i.e., the forward solution for that set of dipoles). This result is then compared with the actual scalp EEG topography. This is iteratively done with multiple possible dipole locations until the best match with the least unexplained variance is found (Figure 64.4).

An accurate head model is, therefore, essential for performing accurate dipole analysis. Several types exist, with the major distinction being between *spherical* and *realistic* head models. Spherical models, wherein the head is modeled as multiple concentric spheres, are the simplest. Accordingly, calculations solving the inverse problem are less complex and considerably faster. However, the head is not a sphere with uniform conductivity, so the accuracy of these models is questionable when precise localization of epileptic foci is the goal. An alternative is the *spherical head model with anatomic constraints* (SMAC). This method warps a given patient's 3D brain-MRI to a best fitting sphere. This allows for the simpler calculations of a spherical model, but provides more accurate results because one can exclude unlikely solutions (white matter etc.) from the possible solution space.[11,12]

However, it is now widely accepted that a *realistic* head model offers the most accurate dipole solutions for cerebral sources. The most popular of these is the BEM (boundary element method) (Figure 64.5). BEM models take into account the nonspherical shape of the head, particularly at the tissue boundaries between brain, skull and scalp.[13–16] The method achieves this by modeling these interfaces as triangular elements that form a mesh. The conductivity heterogeneities are then modeled by 'secondary dipoles' which are placed in the center and perpendicular to each surface element. The strength of the secondary dipoles is ultimately calculated in proportion to the conductivity difference and the electrical potentials, which are assumed to be constant over a particular surface element. Another realistic head model called the FEM (finite element method) tessellates the whole volume of head and allows investigators to consider individual anisotropic conductivities. For example, in contrast to the BEM, the FEM method can take skull defects into account instead of treating the skull as if it has uniform conductivity throughout its extent. However, full benefit the FEM head model has not been acheived because detailed information on tissue conductivities are not yet available.[11,15]

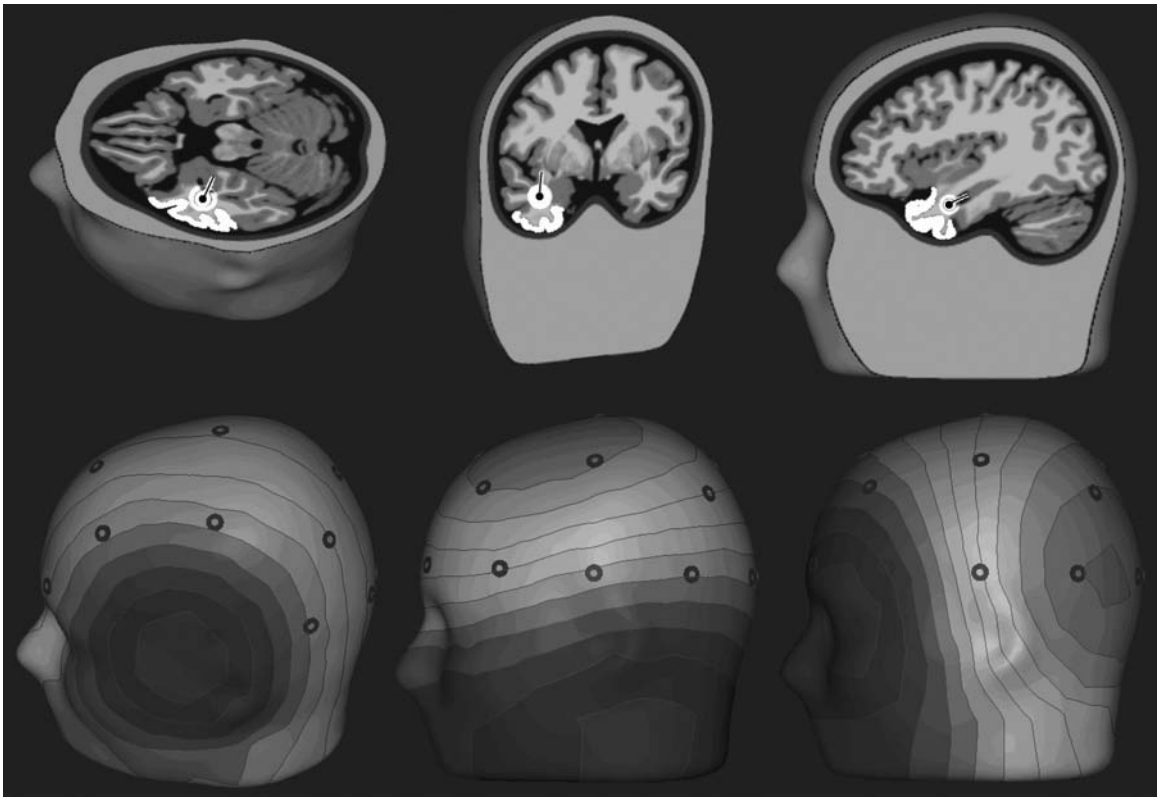

Figure 64.4 Illustrated as whitened cortex are the three most common types of temporal lobe spike sources, their resultant scalp voltage fields, and equivalent dipole models. Left to right: lateral temporal cortex, temporal base cortex, temporal tip cortex. Note that all the dipole models are located in temporal lobe white matter, but the dipole orientations differentiate the sources. Horizontal radial=lateral cortex source, vertical tangential=basal cortex source, horizontal AP tangential=tip cortex source. Note also that dipole orientation is orthogonal to the net orientation of the source cortex.

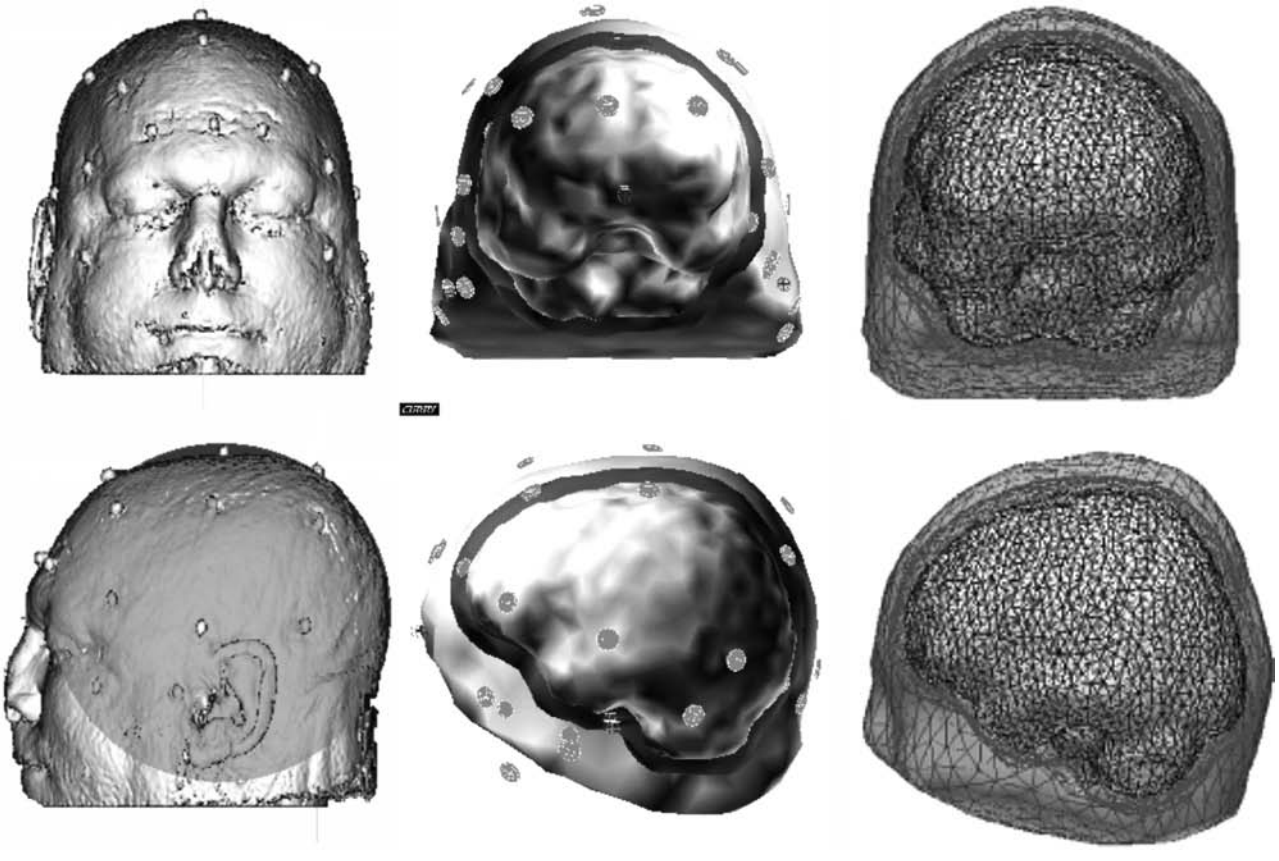

Figure 64.5 Middle: Realistic boundary element method (BEM) head model illustrating inner and outer surfaces of skull and scalp derived from 3D MRI reconstructions. Right: tessellation of these surfaces into a triangular mesh. Left: Shaded circle on patient's head depicts the typical shape of a spherical head model. Note the divergence of the brain and skull base from this spherical shape.

EEG recording and preprocessing for spike localization

In addition to the selection of a head model, there are several aspects of EEG recording and preprocessing that can improve the quality of the data for dipole modeling of spikes. A frequent question involves how many electrodes are necessary for accurate EEG dipole analysis? In the literature numbers from 21 to 123 can be found. However, if this technique is to achieve practical clinical application in the epilepsy monitoring unit, a balance needs to be struck between optimal high density sampling and the practicality of such electrode applications in a clinical setting.

Accurate source localization does require recording as much of the scalp voltage field as possible in a uniform fashion. Non-uniform sampling can distort results.[11] In the standard International 10–20 electrode distribution, the temporal electrode chain passes across the superior aspect of the temporal lobe. In order to sample the potential field from the basal frontal, temporal and occipital regions of the scalp, electrodes that lie inferior to this chain need to be used (Figure 64.6). Sphenoidal and/or 'anterior temporal' electrodes may be useful in this regard. However, for dipole modeling purposes, an entire chain of supplementary inferior temporal electrodes provides a better assessment of the voltage fields.[11,15] Recent investigations have demonstrated that not much is gained when using more than 40–64 electrodes when modeling spike or seizure potentials. This is because epileptic sources are spatially large (as compared to sensory evoked potentials, for example) and thus produce voltage fields of low spatial frequency.[15]

One can also co-register scalp EEG fields and dipole models to the patient's 3D MRI by digitizing the scalp electrodes and certain head landmark fiducials (such as nasion, preauricular points) (Figure 64.7).[15] Although standardized electrode co-ordinates can be used for screening purposes, the use of digitized, true 3D electrode locations will produce a more accurate dipole or other source model that is necessary when using the source analysis in a presurgical evaluation.

Because spikes commonly propagate into adjacent cortex, the voltage fields measured at progressively later latencies are less likely to reflect the initial source. For this reason the rising phase of the initial spike potential is considered the best time range for identifying the spike origin.[17] Unfortunately the signal-to-noise ratio is lower here than at the spike peak. Accordingly any source model is less accurate at this time. This limitation can be overcome by averaging multiple spike potentials.[18] This will reduce the background EEG noise and enhance the early spike signal in much the same way that sensory evoked potentials are made more evident. Unfortunately spikes cannot be triggered at will, nor are they necessarily all similar, as in the case of evoked potentials. Rather than simply rely on morphological similarity, it is best to review the voltage topography of each spike and average only those that have the same field shapes and temporal evolution.

Source models for spike localization

The most simple source localization model is the *single equivalent dipole*. This technique takes into account the entire EEG voltage field at a given time-point and then, using an iterative minimization technique, searches for a single dipole located in the head that best accounts for the given voltage field. This method is most appropriate for single and discrete sources that produce stable voltage fields showing little change shape or position over time (Figure 64.8).[15] If the source is more

Figure 64.6 Standard International 10–20 scalp electrodes plus supplementary inferior temporal electrodes are displayed on a three dimensional MRI reconstruction of a brain and head. Note that the standard temporal chain of electrodes passes across the upper portion of the temporal lobe, while the supplementary inferior temporal chain of electrodes are in a better position to record from the base of the temporal lobe.

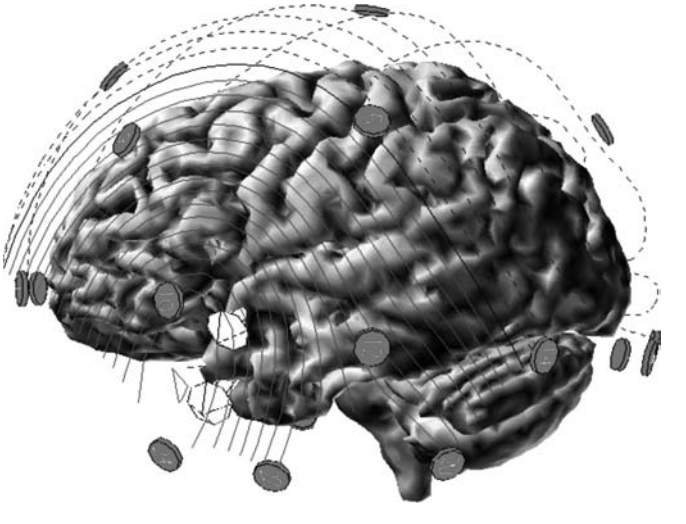

Figure 64.7 Three-dimensional co-registation of a patient's brain, scalp electrode positions, voltage field of a left temporal spike, and dipole models of that spike. Inverse solutions were obtained using a spherical head model (upper dipole) and a BEM realistic head model (lower dipole).

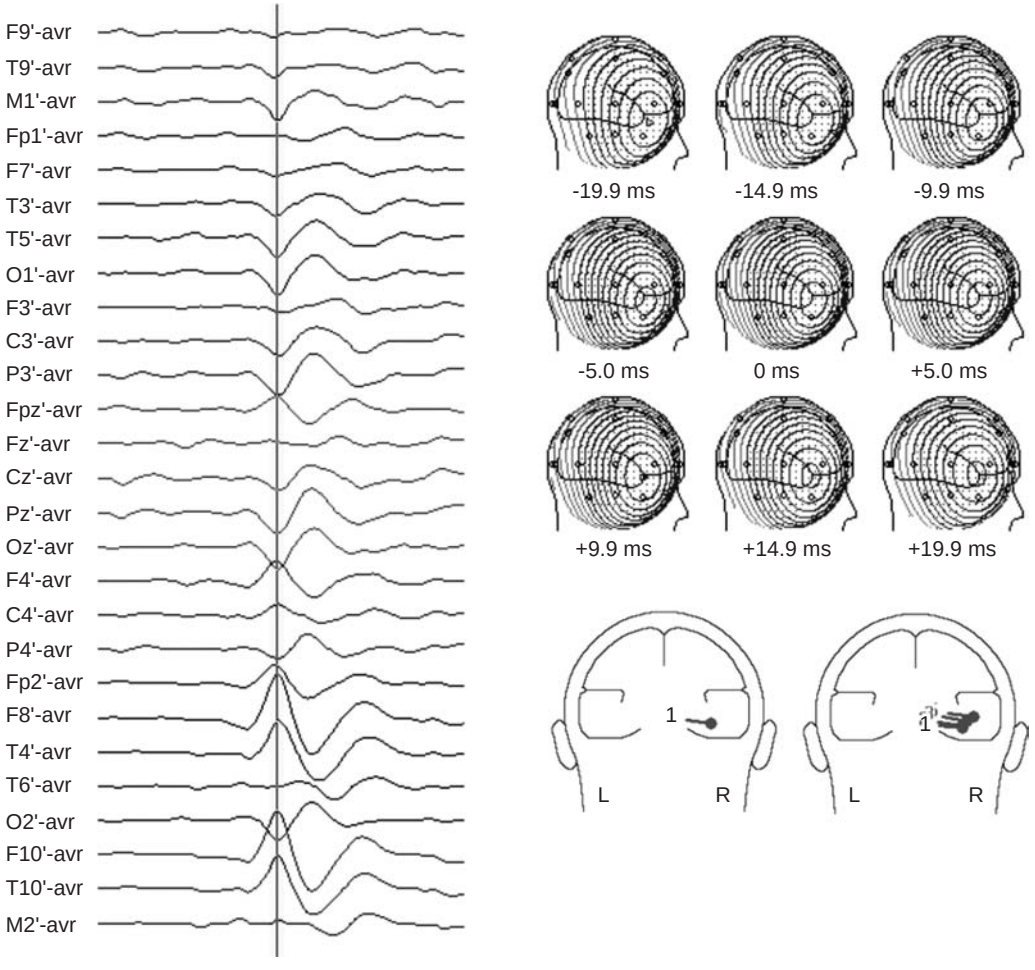

Figure 64.8 Scalp EEG of a right, Type 2 temporal spike. Cursor denotes 0 msec latency. Middle: sequential voltage topography of the spike. Note stable shape of the fields over 70 msec. Right: single and moving dipole models of the spike. Note that voltage field stability and tight cluster of the moving dipole model suggest a simple source for which a single dipole model is appropriate.

complex, this method will oversimplify what may be several spike sources into one single source, and no consideration will be given to possible spike propagation.[3]

It is possible to analyze more complex spikes and their propagation patterns using other methods, however. These models should be applied to spikes where voltage field topography reveals changing location and shape of maxima over time.[15] In the *single moving dipole model*, a separate dipole is calculated for each time point of interest during the spike. The dipole will change slightly in location and/or orientation with each alteration of the voltage field. Thus it will appear to 'move' (Figure 64.9).[3] This is reliable means of modeling propagation over time if it is unidirectional and if the propagation terminates before the original source repolarizes. Moving dipole models that spiral or make sudden changes in direction may be the result of multiple sources that are overlapping in time and space. In these cases, single dipole models are misleading and should not be used.[15]

Another method that takes into account overlapping activity from several cortical generators is the *spatiotemporal dipole model*.[3,19,20] In this method, dipoles are fixed in location and orientation but are permitted to vary in strength and polarity over time. Several dipoles may be active for each time point that is analyzed, but the goal is to obtaining the fewest number of fixed dipoles that can account for the voltage field both spatially and temporally.[3] These data allow the investigator to determine the best location for the spike source at a particular moment in time, as well as the relative strengths of contributing sources over the time period in question.

There is no single unique solution when solving for more than one dipole. In order to come up with the most realistic solution, one must use a priori knowledge about the most likely location of cerebral sources for a given EEG voltage field. For example, the early rising phase of an EEG spike and its corresponding voltage topography is most likely associated with a single cerebral source as opposed to later spike components when propagation could have occurred. Therefore, it is best to model early spike evolution with a single dipole first and then use additional dipoles for any unexplained residual fields. If a spike propagates, several dipoles may be necessary to account for the evolving voltage field produced by the contributions of multiple sources.[15]

The equivalent dipole is a useful model for the sources of EEG spikes, but it is not a very realistic one given that scalp-EEG spikes are produced by large areas of cortex being activated synchronously (6–10 cm^2). There is, however, a growing body of research concerning *extended* or *distributed source models*. These models are based on the reconstruction of brain electrical activity in a 3D grid or 2D surface of solution points. The number of possible source points is significantly greater than the number measurement points of the scalp, therefore the solution is highly underdetermined.

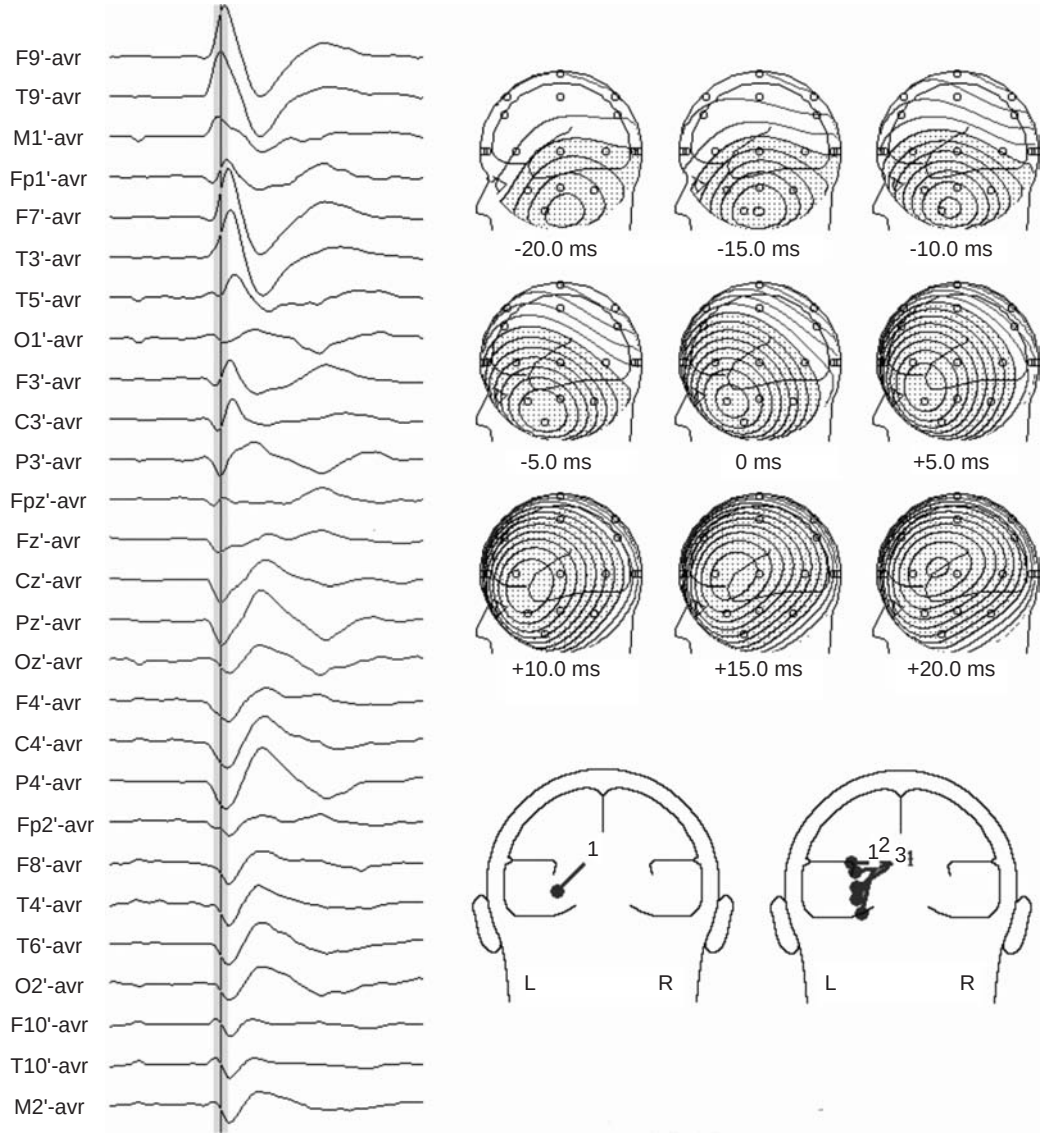

Figure 64.9 Scalp EEG of a left, Type 1 temporal spike. Cursor denotes 0 msec latency. Middle: progressive change in the sequential voltage topopraphy of the spike is evident. Right: single, moving dipole models of the spike. Single dipole at spike peak is oblique in orientation, while moving dipole model shows a progression in dipoles from vertical tangential to horizontal radial that suggests spike propagation.

However, in these exended models there are typically no assumptions about the numbers of possible points involved in the solution. The location of each potential solution point is fixed but their orientation and strengths can vary. The aim is to find a unique configuration of solution points that closely explains the surface EEG voltage field.[11] Certain assumptions are necessary in this type of analysis in order to restrict the number of possible solutions. These may involve pure mathematical constraints, while others take biophysical information into account. Ultimately the success of these models depends on how well the assumptions mirror reality.

Clinical application of source models

Most clinical investigations involving source localization of EEG spikes have studied temporal lobe epilepsy using dipole models. Recall that spike voltage topography in this patient population distinguished two types of spikes: *Type 1* generated by the medial/basal temporal lobe cortex and *Type 2* generated by lateral temporal lobe neocortex.[7] When modeled in 24 patients these two spike types differed significantly only in terms of dipole orientation.[7] The Type 1 spikes have a voltage field topography with basal temporal negativity and vertex positivity. Dipole models of these spikes had a mean dipole elevation of 42 degrees (SD5.0) from the horizontal. Type 2 spikes have voltage field topography showing negativity on the ipsilateral lateral temporal region and positivity on the opposite lateral temporal region. The mean dipole elevation was only 2 degrees (SD 10.0) for these spikes. Thus Type 1 spike dipoles are more vertical in orientation with both a tangential and radial component, whereas Type 2 spike dipoles are predominantly radial and horizontal.

When spike patterns were analyzed using methods that use multiple dipoles to model the spike activity, different patterns were observed between Type 1 and Type 2 spikes again. Type 1 spikes usually were best modeled by two dipoles, one vertical and tangential to lateral convexity and the other

horizontal and radial. Simultaneous intracranial recordings have subsequently validated the assumption that the vertical tangential dipole represents activity form the basal temporal region (not amygdala or hippocampus alone) while the horizontal radial dipole originates from the lateral temporal region.[21] Some spikes originating from basal temporal region had a propagation pattern to the temporal tip cortex. This activity is modeled best with dipoles that are horizontal in the antero-posterior direction, often in combination with another dipole of a different orientation. Finally, Type 2 spikes usually require only one horizontal radial dipole to model the activity even over time.[22]

Source localization has also been performed on extratemporal spikes. In particular, centro-temporal spikes in children with Benign Rolandic Epilepsy of Childhood (BREC) has been well studied. Initially spike voltage topography identified two spike categories: those with the typical horizontal dipole with a centro-temporal negative maximum and frontal positivity, and those spikes with atypical nondipolar complex voltage fields.[23] This study of 400 patients found that the atypical spikes were more likely to be found in BREC patients with other neurological abnormalities. Various subsequent studies using dipole analysis of rolandic spikes have had mixed results regarding confirmation of the existence of these two categories of spikes, and whether spike category correlates with different clinical phenotypes.[24–26] van der Meij, W. 2001.

There has also been some investigation of spikes in patients with focal cortical dysplasia.[18] In the this study nine patients (age 3.5–15.9 years) were studied who had focal epilepsy, an MRI suspicious for focal cortical dysplasia, and simultaneous MEG and EEG showing more than five EEG spikes. Single dipole analysis, as well as multiple dipole analysis of averaged spikes, were performed. A four-shell spherical head-model was used.

Ninty-three percent of the source models of the averaged and single EEG spikes localized to the MRI lesions. This source localization was validated by intracranial recordings in three of five of patients who underwent resective surgery. All had excellent outcomes. Two patients whose spike sources were localized outside the resected area had poor surgical outcomes.

Source model validation

Attempts have been made to test the reliability of dipole models of both interictal EEG spikes and of ictal EEG patterns. In two studies by Merlet and Gotman[27,28] spikes and seizures from previously recorded scalp-EEG data were compared to combined scalp and intracranial EEG data recorded at a later date. They confirmed that spikes recorded only from the hippocampus and/or amygdala on intracranial EEG were not recordable on scalp EEG. Larger areas of cortex must be involved in order to generate scalp spikes (estimate of around 6–8 cm^2). They also concluded that simple spikes were more reliably modeled by dipoles (error of about 1–2 cm) than complex propagating spikes or ictal patterns. The main limitation of these studies was that the dipole analysis was performed on spikes and seizures recorded in a prior EEG session with a 28-channel scalp data, whereas only 4–8 scalp electrodes were used during the intracranial EEG to attempt to identify the same spike populations as recorded earlier.

Lanz *et al.* have also published a study series using simultaneous scalp and intracranial EEG to confirm that dipole modeling can reliably distinguish spikes originating from the medial/basal temporal region versus the lateral temporal region.[29,30] As previously reported by Ebersole, orientation of the dipole was the major feature distinguishing the two groups of spikes in these studies as well.

In a recent study of 44 patients with partial epilepsy using 123 channels of EEG, Michel *et al.*[3] demonstrated that an extended source model (Epifocus) was capable of correct lobar localization in 90 % of patients and correct sublobar localization in 79%, when compared to the eventual surgical resection site that eliminated the patient's seizures. However optimal validation of dipole or other forms of source analysis as a reliable technique for localizing spike and seizure sources will require a prospective clinical trial using simultaneous scalp and intracranial EEG. The scalp data must be recorded with a sufficient number of electrodes to perform accurate dipole modeling, and the location of the intracranial electrodes must be co-registered with the patient's 3D MRI in order to localize the actual sources anatomically. This type of study has yet to be completed.

Conclusions

Dipole and other forms of source modeling provide a modern means for estimating the location and character of the cerebral source of epileptogenic spike and seizure potentials. These techniques are based on sound physiological and physical principles. They represent a more advanced and quantitative method of epileptogenic focus localization than that of simple visual inspection of EEG traces. However, it must be understood by those who use these techniques that the solutions are 'models' of the true sources. As such they must be interpreted with knowledge of the limitations of each technique. EEG source modeling is a worthy addition to, not a replacement for, other diagnostic procedures in the evaluation of epilepsy.

65 Antiepileptic drug withdrawal in presurgical evaluation: advantages, disadvantages, and guidelines

SP Claus, DN Velis, and W van Emde Boas

Introduction

For adequate presurgical evaluation, activation of the interictal epileptiform activity and access to ictal EEG and the clinical semiology of the patient's habitual seizures is still considered indispensable for an adequate lateralization and localization of the epileptogenic zone. The clinical aim and main advantage of antiepileptic drug (AED) withdrawal is to activate the interictal activity and to realize an increase of the natural frequency of the patient's seizures in order to reduce the duration of invasive or noninvasive long term EEG and video monitoring (LTM) for presurgical evaluation. Even for typical cases of mesial temporal lobe epilepsy (MTLE), most centers require at least three to five successfully recorded seizures. Less familiar forms of epilepsy, notably extratemporal seizure disorders, may require considerably more seizures for a reliable localization of the of the ictal onset zone and an estimate of the associated epileptogenic zone.[1–3] Long term EEG/CCTV procedures have implicit constraints on mobility and privacy which constitute a major burden for the patients. Moreover, LTM procedure is relatively labor intensive and expensive. Reducing LTM-time thus seems warranted and partial or total AED withdrawal is a generally accepted and widely applied method for this purpose.

However, the procedure is also associated with a potentially high number of disadvantages that may constitute health risks to the patient. Due to a lack of systematic data and a benefit-to-risk ratio analysis it is not clear if the advantages justify exposing the patient to the disadvantages. Although it is recommended that safety protocols should be used when withdrawing AEDs,[4–6] the available published[6] and anecdotal data suggests a lack of common practice, even within individual centers. This is not surprising, given the great heterogeneity in clinical material (type of epilepsy, lesions, etiologies, drug regimens) and local facilities.

In this chapter, the available literature will be summarized and analyzed. This will be complemented with the outcome of a survey concerning practice and experience with AED withdrawal for presurgical monitoring carried out in 37 European, NorthAmerican and Australian epilepsy centers (see acknowledgements). Some guidelines will be formulated which may further help to develop more generally applicable protocols for AED withdrawal procedures for presurgical monitoring.

Advantages: increased seizure frequency and reduction of monitoring time

AED withdrawal increases seizure frequency during AED tapering or while being effectively free of medication (AED serum level confirmed)[7–14] and generally shortens the total LTM recording time. This effect may vary between individual AEDs. The shortest reported average time for successful LTM in a group of patients with MTLE was 4.8 days.[15] Other studies reported average LTM periods ranging from 5.5–7.6 days.[16–19] All these studies are characterized by heterogeneity in patient population, etiology and method of AED withdrawal. No valid comparison is possible to identify any association between the method of AED withdrawal and the reported variations of LTM time and this is also corroborated by the outcome of our survey.

In general, AED withdrawal seems to be effective for seizure activation regardless of type of epilepsy, notably shortening the 'time to first seizure'.[6,7,12,15,17,20] Although extratemporal epilepsies show a stronger tendency to early seizures,[17,21,22] the total time needed to accomplish a successful recording did not differ significantly between the temporal and extratemporal groups, with exception of one study of 36 patients which suggested a slightly longer than necessary LTM time in temporal lobe epilepsy (TLE) patients.[17] Moreover, the reported frequency of the different seizure syndromes and types at home does not appear to predict the length of stay in the Epilepsy Monitoring Unit (EMU).[20] Obviously this situation will be different in childhood epilepsy syndromes with typically multiple seizures per day.

Other methods of activation do not appear to have the same rate of success. Neither sleep deprivation nor photic stimulation were effective in eliciting seizures during LTM.[4,23] Hyperventilation (HV) during LTM remains a matter of debate. Anecdotal evidence suggests its efficacy, and numerous centers, including our own, regularly apply HV during presurgical monitoring; published data however are equivocal. One study reports seizures elicited by HV when applied three times a day, for 5 minutes for multiple days in about 25% of patients, especially those with TLE.[(24)] Another found no effect of a single episode of HV for 5 minutes only.[25]

Medication withdrawal may enhance interictal abnormalities. Withdrawal of CBZ, VPA and PHT is associated with increased bursts of interictal epileptiform activity and slowing

in patients that also show an increased frequency of seizures. This advantage might be of limited value, because it is absent in patients that do not react to AED withdrawal with an increased frequency of seizures. Also, increased interictal spiking is reported to be widespread and not necessarily most prominent at the seizure focus. Promising effects are found with spectral analysis of the EEG: a greater absolute delta activity ipsilateral to the seizure focus less than 20 hours after a typical seizure may have lateralizing/localizing value.[26]

One minor advantage could be a positive effect of withdrawal on performance in neuropsychological tests. In a small group of patients with TLE, the lateralizing results of selective memory tests proved to be most reliable when testing was performed during the withdrawal period.[27] Language testing in patients with a probable left-sided TLE, however, should probably not be performed during AED withdrawal since in the same study these patients' test results deteriorated significantly.

Another minor advantage is the unexpected awareness of chronic unnoticed drug toxicity, because subtle symptoms disappear following AED withdrawal during LTM. This may lead to adaptation of the drug regimen by the treating physician.

Disadvantages: withdrawal symptoms, clustering of seizures, status epilepticus and associated morbidity

Possible disadvantages of AED withdrawal during LTM are medical complications directly or indirectly associated with pharmacokinetic changes or the occurrence of 'unwanted seizures or seizure events' certainly if resulting in prolonged LTM or time in hospital. 'Unwanted' seizures are generalized tonic-clonic seizures (GTCS), seizure clusters, and status epilepticus (SE), all of which are associated with complications such as trauma, systemic complications secondary to seizures (respiratory, cardiac or metabolic), psychiatric side effects (anxiety, mood disorders, insomnia, and psychosis), and possibly mortality.[4,5] Moreover, when measures have to be taken to intervene on these seizures; this prolongs, rather than shortens the duration of stay.[15] Seizures can also be considered 'unwanted' if they compromise the process of lateralizing and localizing in a technical sense.[14,18,28]

The AED withdrawal associated incidence of GTCS – single events or clusters – varies between 36 and 69%. These can be seizures that have been absent for years.[8,10,15] The rate of occurrence for clusters of CPS and/or secondary GTCS (sGTCS), sometimes called flurries of seizures or serial seizures), is also considerable and seems to increase in association with withdrawal. Reported incidence varied between 48 and 62%[8,11,15,29]compared to an incidence of seizure clustering in the home situation of only 30%.[20,30] For SE most reported incidence rates vary between 0 and 3%.[6,15,31] One remarkable study reports a rate of up to 50% of convulsive SE (convulsive activity for more than 30 minutes) in their patients.[28] This frequency appears extremely high, compared to other studies and our own and anecdotal experience; unfortunately, no specifics are provided concerning the method of AED withdrawal or the number of patients involved.

Unfortunately, the definitions for these types of seizures vary which makes it very difficult to determine specific complication rates. The current definitions for 'cluster' all include at least three seizures in a time span of 24 h, because seizures that occur within 8 h of a prior seizure are more likely to arise from a concordant focus than seizures more widely separated in time; this implies dependence and not randomness.[30] Some studies use even more strict definitions. One study made a distinction between GTCS only (three or more) and CPS only (five or more).[8,11,12] Another study made a distinction for a cluster of three or more seizures in 24 h versus a time span of 4 h.[6,13–15,28] Also for status epilepticus (SE) the definitions vary. Most studies that systematically looked at the relation between potential risk factors and SE used the old definition of clinically or electrographically ongoing signs or symptoms of ictal activity for 30 minutes or more. One study suggested that a definition of SE should also depend on seizure type and relate to abnormal duration of a seizure compared to the average duration of that type of seizure (e.g., CPS lasting 5 minutes or more).[6] This would be in accordance with more recent proposals for a new classification of SE[32] which, if applied in the LTM patients, probably would lead to higher reported incidence rates of SE, but not necessarily to higher rates of secondary morbidity.

The occurrence of 'unwanted seizures or seizure events' such as clustering or SE might be related to an increase of cortical excitability, as documented during the phase of CBZ or LTG withdrawal in healthy volunteers.[33] The observation of increased interdependence of seizures occurring less than 8 h separated from each other seems to indicate increased hyper excitability in certain focal areas.[30] Occurrence of seizure clustering at home is seen more often in patients with extratemporal epilepsy and possibly it is associated with a history of head trauma. Other risk factors are longer duration of the epilepsy and intractability.[13,30] Less conspicuous factors such as MTS on MRI, and possibly more than one seizure focus may also be associated with seizure clustering during LTM.[28] In their turn, seizure clustering both at home and during LTM constitutes a risk factor for SE.[13,14,28] It is claimed that the occurrence of clusters is predictable. With the use of the Poisson process it seems possible to make a calculation of the expected frequency which could be compared to the real seizure frequency at any time. Other approaches are also used. However, these methods depend very much on reliability of the patient reports/diaries. Also they become less accurate if the patient has a very high frequency of seizures, since the random fluctuations could be falsely identified as a cluster.[30]

Trauma, specified as fractures, joint dislocations, and external or internal soft-tissue injuries may result from seizures. Notably elderly patients appear prone to compression fractures of the vertebrae.[4] Trauma is not only associated with sGTCS, but also with partial seizures with violent automatisms such as particular forms of frontal seizures or due to accidents during seizures with impaired consciousness. Precise information on incidence rates is not available but the incidence appears very low. One report describes an unusual cluster of a humeral fracture in three patients within one year (3% of the annual recordings). All three had been treated with AEDs for many years; possibly this resulted in bone mineral loss which could explain the unusual incidence rate.[34]

In most EMUs specific care is taken to create a safe environment and to prevent the patient from becoming injured during a seizure. Alternatively, patients are kept in bed for most of the time and are always escorted by an experienced

paramedic when they have to move around the ward. Part of creating a safe environment involves the exclusive employment of experienced staff, i.e., nurses and technicians who are able to anticipate the occurrence of 'unwanted seizures' and take adequate action. More consistent use of a guideline or protocol might further reduce the risk of occurrence of these 'unwanted events'.[6]

Other possible complications are respiratory problems and renal insufficiency. The former predominantly appear to be associated with sGTCS in the elderly.[4] Moreover, they constitute the most serious possible complication of SE. Especially a long tonic phase in sGTCS and a protracted course of SE will cause hypoxia and respiratory acidosis. Renal insufficiency results from prolonged episodes of convulsive SE associated with excessive nephrotoxic release of myoglobine resulting from muscular damage.

Cardiac problems pose a potential problem that is associated with seizures and not with AED withdrawal per se. Risk groups are the elderly[4] and patients with known cardiac rhythmical problems, but one prospective study[35] reports it as a potentially more general problem. The authors detected postictal depression of the S-T segment in the ECG in 40% of 23 patients who exhibited an increased heart rate during the seizures. These changes indicate preischemic conditions in patients with epilepsy who were otherwise healthy. A possible relation with sudden unexplained death in epilepsy (SUDEP) was hypothesized. In this study the medication had been withdrawn from all patients, but there is no further discussion of the possible effects of medication withdrawal on heart function. The study does imply, however, that an increased seizure frequency carries an increased risk of cardiac complications in a potentially large group of patients.

Psychiatric and cognitive problems may present as a direct effect of medication withdrawal, independent of seizures or subsequent to seizures. Postictal psychosis (PIP) constitutes for about 25% of all cases of psychoses of epilepsy (POE). Although these are not necessarily directly drug related, they are seizure related and can occur with or be aggravated by clusters of seizures.[36] AED withdrawal for presurgical evaluation thus may provoke PIP. The incidence, following acute AED withdrawal, was reported to be up to 6.4%.[37] Commonly, ictus and PIP are separated by a lucid interval of 12 to 72 hours (mean 70 hours). Extratemporal foci are present in 30% of the affected patients (mainly frontal cortex or the cingulate gyrus).[36, 37] PIP has also been correlated with the presence of bilateral ictal and interictale foci in the limbic temporal region, hyperactivity in the bilateral frontal and temporal hyperactivity, as measured with HMPAO-SPECT,[38] with possible ictal activity in the left amygdala in one patient.[39] Other risk factors are lower verbal IQ, absence of febrile convulsions and absence of temporal mesial sclerosis. The most commonly reported psychiatric disturbances associated with AED withdrawal were depression and anxiety and then psychosis (PIP). A history of psychiatric problems is a risk factor for worsening of PIP and other postictal psychiatric complaints.[37, 40]

Interictal psychosis which represents approximately 9% of all cases of POE[36] is a persistent state not associated with ictal events; de novo transient interictal psychosis, provoked by AED withdrawal (VGB) has been described.[41] In the rare case that AED withdrawal and LTM would be performed in patients with active psychosis medication, specific complications can arise when they are treated with antipsychotic drugs (AP), such as clozapine, resperidone, olanzapine, chlorpromazine, thioridazine and also haloperidol, and when carbamazepine (CBZ) is reinstituted. CBZ can reduce serum levels of APs by as much as 60%.[36]

Mortality during LTM for presurgical evaluation has not been officially reported, not even in studies that specifically deal with mortality incidence in epilepsy surgery populations.[42–44] Incidence of mortality in patients who are evaluated and operated is 2.4/1000 person-years which is less than half the incidence of SUDEP in patients who, following evaluation, are rejected for surgery (6.3/1000 person-years).[44]

Nevertheless, one has to acknowledge that the LTM setting with AED withdrawal produces a situation in which reported risk factors pertaining to SUDEP may be introduced or provoked. High seizure frequency, polytherapy with AEDs, and (frequent) changes of AED doses have all been shown to increase the risk of SUDEP.[45] As mentioned earlier, seizures that are accompanied by an increased heart rate may also be followed by early signs of cardiac ischemia.[35] CBZ withdrawal has been associated with abnormal shift of the sympothovagal balance toward sympathetic activation during sleep; this could be a predisposing factor to SUDEP in the presence of seizure induced hypoxia.[46]

Although SE in general is associated with a high rate of mortality, this holds true predominantly for patients with acute encephalopathy. Patients, selected for presurgical evaluation do not usually have severe underlying encephalopathy, with the exception of children with catastrophical epilepsy (but in this group AED withdrawal usually is not indicated). Moreover, LTM provides conditions that allow early detection of SE which is why treatment is usually started in an early phase with a high rate of success. These two factors minimize the risk of mortality due to SE; given the overall low incidence of reported SE during LTM with AED withdrawal, the risk of death, due to SE during LTM appears negligible.

Aside from these physical risks, one has to consider the risk of attempted suicide. Suicide risk in the general epilepsy population is five- to ninefold higher than in the general population.[40] After withdrawal of medication, patients may show symptoms usually associated with increased suicidal risk (suicidal ideation, self-deprecation, hopelessness, and guilt). There are no reports of actual attempted suicides. However, should these symptoms be not acted upon, they could present a risk, especially in patients with psychiatric symptoms that are aggravated by a high frequency of seizures.[40]

Withdrawal of medication can result in the 'drug holiday' phenomenon.[47] Also in the clinical setting, of this type of recording this could be mistaken for an improvement of seizure frequency. In a prospective study, medication was withdrawn from 82% of 60 patients of whom 92% had partial epilepsy. Especially in the patients that used CBZ or PHT before and after recording, the lag time between discharge following LTM and the first extramural seizure was increased compared to the normal inter seizure intervals. Moreover, the time to first seizure increased with longer LTM 'off medication time'. Although hospitalization in itself is known to change seizure frequency independent of changes in AEDs, the drug-specific changes (CBZ and PHT compared to other AEDs that were withdrawn without effect), still indicate an effect of withdrawal.[47,48]

Drug specific advantages and disadvantages as reported in literature and the survey

Acute drug withdrawal within the setting of LTM is different than the more gradual drug withdrawal in general practice. This part of the review is also based on a very specific literature search for complications that arose from AED withdrawal in the setting of presurgical evaluation and thus is far from comprehensive regarding all possible drug withdrawal effects. The phase of withdrawal is usually defined as the first four or five half-life times of the drug that is withdrawn. Most authors who report on drug characteristics during acute AED withdrawal included a baseline phase (before withdrawal), a withdrawal phase, and the phase where serum levels of the drug are 'subtherapeutical' or undetectable. The term 'withdrawal symptoms' commonly does not refer to seizures, but more to other negative physical or mental effects.

Carbamazepine withdrawal increases the frequency of CPS both in the withdrawal phase and thereafter. In the withdrawal phase it is associated with clustering of CPS, sGTCS and isolated sGTCS; the occurrence of sGTCS in this phase was associated with 'fast withdrawal'. After this phase sGTCS were reported, but not clusters.[7,11,12,15,17,19,49–51] A shift towards sympathetic activation of the cardiac sympathovagal balance during sleep has been reported.[46] Withdrawal symptoms would be expected to be similar to those of tricyclic antidepressants, because of the similar chemical structure, but in one study where CBZ was withdrawn slowly (fastest rate 200 mg/2 days) these symptoms did not occur.[49] Fast withdrawal of CBZ did result in mood changes, notably anxiety.[52]

Clonazepam withdrawal has been associated with *de novo* interictal psychosis, interpreted as a withdrawal syndrome.[39,53] In both studies the drug had been acutely withdrawn. The symptoms were dysphoria, irritability, aggressiveness, anxiety, and hallucinations. Another withdrawal effect that has been described is delirium with catatonic features. This was associated not only with Clonazepam, but also with Clorazepate dipotassium.[54]

Lamotrigine (LTE) withdrawal increases the frequency, duration and severity of CPS during the withdrawal phase, according to one study with quick withdrawal (in 3 days to zero). For sGTCS there was a change in successive phases with aggravation and marked prolongation of the clonic phase rather than the tonic phase during withdrawal and of the tonic phase during the drug free period. The frequency of sGTCS increased only in patients who used CBZ in addition to LTG.[51]

Phenobarbital, when withdrawn quickly, increases the frequency of CPS both during the withdrawal phase and in the drug-free period. The critical serum level was reported to be 20–15 mg/l. The drug reportedly also caused first ever clusters of CPS or sGTCS.[3,7,15,55] Moreover, barbiturate withdrawal may result in nonconvulsive status epilepticus (NCSE).[56] If the drug is withdrawn slowly then withdrawal seizures probably do not occur.[7] Phenobarbital withdrawal has been associated with unexpected CPS that seemed to originate from outside the expected target area. Possibly these secondary localizations represent latent onset zones in patients with multifocal localization-related epilepsy. In one case surgery with resection of the target area yielded poor results, despite the unexpected CPS.[7]

Primidone is associated with an increased frequency of CPS in both the withdrawal phase and the drug-free phase. In the withdrawal phase it may provoke sGTCS.[7,8]

Phenytoin was associated with an increase in CPS and sGTCS during withdrawal and the drug-free phase. However, one study mentioned that this increase occurred only after 10 days counting from the moment where the serum levels were measured to be undetectable.[7–9]

Sodium valproic acid has an anticonvulsant effect that outlasts its measurable presence in the serum. In the drug-free phase it can cause an increased duration of CPS and also an increased frequency of hypermotor seizure symptoms.[19]

One respondent to our survey reported psychosis following withdrawal of Vigabatrine (VGB), a drug otherwise associated with psychosis notably following starting, not withdrawal.[41]

Results of the survey

We distributed a survey among colleague epilepsy centers while in the process of improving our own safety protocols, inquiring into their AED withdrawal procedures for presurgical monitoring, use of protocols, results and possible unwarranted experiences. The questions were simple and not formulated in the context of a scientific project. The answers obtained from 37 of 110 centers that were addressed, however, add to the limited published data and thus are included in this overview.

The more general data that pertain to the strategy of withdrawal are listed in Table 65.1 Most centers do withdraw medication in most patients. Usually there is no AED-withdrawal-specific medical emergency or calamity protocol. AED withdrawal is usually begun at, or right after, start of the recording procedure, less frequently between admission and beginning of the recording, and hardly ever in an outpatient setting. AEDs are usually withdrawn one at a time and at a gradual rate, usually to half or one-quarter of the daily dose. Most responders indicate that withdrawal rates are drug dependent and the following factors could change standard strategies: reported seizure frequency, seizure type, and history of SE. History of PIP, physical/neurological status, age, and invasive recording were deemed less important factors. A large number of centers (50%) agreed that BDZs and barbiturates are drugs that should not be tapered. A few centers, however, recommended slow tapering or preclinical tapering and some of them even listed these drugs as eligible for a full stop.

We specifically inquired about the occurrence of complications: SE, PIP, mortality, and 'other'. From the data we received, it was usually possible to approximate incidence rates. The incidence rate for SE ranged from 0–2% in 31 (out of 37) centers who responded to this item (0% for nine centers (29%), 2% for three centers (10%), and ranging around the mode of 1% for the others). A higher incidence rate is found in some centers that record invasively with subdural grids: in one center four out of 24 grid-patients needed intervention for 'probable SE' (17%). The rates for CSE (convulsive SE) only are lower. Only some centers responded with total rates for all types of SE; on follow-up inquiry usually their cases were evenly distributed between NCSE and CSE. We did not inquire about the exact definitions used to establish a case of SE.

Table 65.1 General preferences in methods of withdrawal in 37 centers worldwide

Do you withdraw	Always; mostly; occasionally; never	3%; 62%; 35%; 0%
Protocol present	Yes; no	19%; 81%
Preclinically/outpatient	Always; mostly; occasionally; never	0%; 11%; 38%; 51%
Clinically before recording	Always; mostly; occasionally; never	6%; 29%; 43%; 23%
Clinically during recording	Always; mostly; occasionally; never	19%; 56%; 25%; 0%
If polytherapy; how	One AED; more AEDs; all; varies	54%; 27%; 5%; 14%
Rate of withdrawal	Gradually; direct to full stop; varies	82%; 12%; 6%
Max dose reduction	¼; ½; ¾; full/varies	6%; 42%; 31%; 22%
Depending on AED	Yes; no	84%; 16%
Which of these are important for withdrawal strategy	Reported seizure frequency	95%
	Seizure type	84%
	History of SE	95%
	History of PIP	35%
	Physical/neurological status	27%
	Age	24%
	Invasive study	43%
Are blood levels monitored	Before; during; after; after AED introduction	43%; 35%; 22%; 57%
IV line present noninvasive	Always; mostly; occasionally; never	50%; 11%; 11%; 28%
IV line present invasive	Always; mostly; occasionally; never	76%; 3%; 5%; 11%*

*10% of the centres did not perform invasive recording.

In the case of PIP, 61% of the responding centers reported an incidence rate of 0%, and the remaining centers a range 0–5%, (mode 1%). The withdrawal related mortality rate was 0% for all centers. 'Other complications' resulted in varying individual feedback of the responders. Of the 36 centers that replied, 80% reported a 0% incidence rate; for the remaining 0–0.4%, with one exception of a center which mentioned 2% miscellaneous complications.

The following complications were specifically reported: a broken vertebra, fracture of the shoulder/spine, mild head trauma, and renal failure after SE. Due to large variability in AED withdrawal methods and the limited set up of the survey it was not possible to analyze the relation between the occurrence of these complications and specific withdrawal regimens.

Some drug-specific complications were reported as individual feedback by the responding centers. Bromide withdrawal was followed by an increased frequency of sGTCS in a patient with an SCV1A-mutation. BDZ and/or barbiturates were associated with atypical or provoked seizures. Acute BDZ withdrawal has been associated with a myoclonic status in two patients. Clonazepam withdrawal has been associated with exacerbation of seizures. LEV was reported to produce severe seizures in some patients, when tapered. Need for caution was reported with the use of LTG in combination with VPA. Probably this refers to the rapid reintroduction of the two drugs in combination which was associated with liver failure in the discussion of at least one report.[57] Also in this context the risk for Stevens-Johnson syndrome was mentioned. PHT withdrawal once provoked a cluster of GTCS in a child that subsequently developed ventricular fibrillation. VGB was mentioned as a relatively high risk for psychosis, associated with tapering of the drug. Patient compliancy with AED therapy can be reduced after withdrawal and reinstitution of therapy. The drug-free episode can be experienced as a relief from troubling side effects. This has been noted in multiple patients in multiple centers.

Overall, the varying and drug-specific practices among centers reflected consensus concerning the basic general rule for tapering of AEDs, specifically stated by numerous respondents: withdrawal of medication is first and foremost patient specific.

Recommendations

The recommendations that now follow are based on the literature review and the survey.

1. A single binding protocol is not practical, yet all presurgical monitoring procedures should be performed in a well-structured and standardized way, guided by and recorded in a standard document which should conform to published or local guidelines.
2. This document must be created, brought up-to-date and be available before planning and scheduling the monitoring procedure. During monitoring it must be available at the patient's bedside and annotated at least three times/24 hour. It may be created separately from the patient's standard clinical file. This file, however, should also be present during monitoring. Following conclusion of monitoring the monitoring file should be incorporated in the master file.
3. The document should record all relevant patient specific information, with the following items included: seizure history, general medical history, seizure semiology, aura, frequency, duration, tendency to clustering, history of SE or seizure-related accidents, associated cardiac or respiratory signs or symptoms, full medication history, history of changes in aura or seizure pattern, side effects or untoward events related to changes in AED, other medication, hypersensitivities, disturbances of haemostasis, psychiatric problems (spontaneous or associated with seizures). This information must be available before scheduling of monitoring.

4. Patients, family and/or carers have the best knowledge concerning seizure characteristics and should be consulted during the preparation of the document. Specific inquiries should be made concerning other diseases and medications, risk factors for clustering, SE, SUDEP, injury or psychiatric problems. Relying on previous correspondence or written data in the patient file exclusively should be discouraged.
5. In order to improve comprehensiveness the document should generally have a checklist format rather than open items. All items should be checked (skipping items should not occur; describe as 'not known' or 'not relevant', if applicable). However, space should be reserved for notes/descriptions where relevant, e.g., in case of semiology description, or for jargon used by the family or patient to describe their seizure symptoms.
6. A summary of specific risk factors involved in the procedure of AED withdrawal should be provided at the end of this part of the document. This should include possible drug interactions (AED to AED or AED to other drugs) in the course of withdrawal or during reinstitution.
7. A day-to-day AED withdrawal schedule should be made before start of monitoring, including specific pharmaceutical or procedural interventions in case of unwanted events. Patient-specific conditions that should lead to adaptations of the schedule or interventions should be predefined. Adaptation of the original schedule is possible but must be motivated in writing.
8. AED withdrawal should be individualized and determined first by patient-specific parameters and experience, second by pharmacokinetics and only lastly by presumed mechanism of action of individual AEDs.[5]
9. In patients with (multiple) daily seizures (often children or patients with frequent extratemporal lobe nocturnal seizures) AED withdrawal is usually not indicated.[4]
10. AED withdrawal for presurgical monitoring should be exclusively performed in a clinical setting.
11. If possible, monitoring should be performed in the presence of a family member or carer who can recognize changes in a patient's behavior or seizure pattern earlier than paramedical personnel. For children this presence is mandatory.
12. The monitoring environment must be designed to optimize patient safety and minimize risk of secondary trauma. Beds should be supplied with safety pillows. Emergency equipment must be available, including means for respiratory support and resuscitation. At least one qualified staff member, experienced with seizures and medical emergencies, should be physically present at all times.[4,5]
13. Independent of the obligatory recording of all changes in medication, time and dose of all drug administrations, occurrence and description of reported or observed seizures, peri-ictal and postictal phenomena and other clinical events and the usual associated observation and test results, a general assessment of the patient's physical and psychological condition should be noted at least 3 times/24 hours. Changes should be emphasized. For patients undergoing intracranial monitoring, additional surgically-determined parameters may have to be monitored.
14. In the absence of patient specific contraindications, AEDs can be withdrawn at a rate of 33–50% of the prescribed daily dose per day. In the case of polytherapy, withdrawal of one drug is preferred. AEDs that offer maximum protection against sGTCS to be withdrawn last.
15. Preferable drugs for first withdrawal are CBZ (or OCB) and VPA. VPA might be withdrawn at full stop, possibly unless combined with LTG. PHT withdrawal should be considered of limited value for limited periods of monitoring but, if relevant, should be performed at full stop in a clinical setting. Benzodiazepines and barbiturates should be withdrawn as last resort only or not at all. For most of the new generation AEDs there is a lack of experience and caution is advisable.
16. Alternative provocation methods can be combined with AED withdrawal. HV appears to be the most effective, notably in patients with TLE. Sleep deprivation probably is effective only in patients who report it as a provocative factor and should be applied with caution in patients with increased risk of unwanted events.
17. Following reported or observed seizures, patient should be assessed for neurological, neuropsychological or psychiatrical sequellae and should be monitored for possible ongoing EEG or ECG abnormalities. Notably following GTCI and when in bed, the patient should not be allowed to lie in full supine or full abdominal position and the unobstructed airway-passage should be secured.
18. Predefined conditions that warrant immediate interventions should include GTCI continuing for more than 2–3 minutes or seizure clusters exceeding the patient specific pattern either in number, time interval, or seizure characteristics. Seizure clusters should be defined depending on seizure type: 2 GTCI within 12 hours: intervention; within 24 hours, no acute intervention. 3 CPS within 4–6 hours: intervention; within 24 hours: no intervention. Series of tonic-myoclonic seizures habitual for the patient: no intervention; if unusual or de novo for this patient: intervention.
19. For a first GTCI lasting for more than 2–3 minutes or a first atypical seizure cluster, intervention may be limited to acute and short acting drugs such as benzodiazepines, in order not to interfere with the continuation of the monitoring. If severe or atypical seizures persist at unusual short intervals, regular medication should be reinstituted in part or completely, possibly with temporary, additional drugs (benzodiazepines, phosphenytoin). Deterioration of background EEG (a possible predictor of SE) or cardio-respiratory changes during or after seizures may be considered arguments for earlier reinstitution of regular AEDs and the same applies for elderly patients with a long history of seizures and AED use following atypical GTCI. Drug interventions, additional to reinstitution of regular AEDs, should be guided by locally accepted protocols for treatment of acute seizure disorder or SE.
20. Postmonitoring reintroduction of regular AEDs should be fast. For CBZ, PHT, LTG, VPA and LEV, when prescribed as monotherapy, reintroduction within 24 hours is possible, accepting some risk for minor and transient intoxication signs, notably for CBZ and PHT. In cases of polytherapy reintroduction should be individualized

(e.g., in the case of LTG combined with VPA). Depending on the clinical situation, additional BDZs may be prescribed for a few days to minimize the risk of additional seizures, clusters or SE during the postmonitoring period.

21. All AEDs should be reintroduced to the premonitoring dosages, unless specific arrangements have been made with the responsible treating physician. Patients who experience positive effects of monitoring associated drug withdrawal should consult the responsible physician for possible adaptation of treatment.

Acknowledgments

We would like to thank Ann Tierlier for proof reading this review. We would like to thank the following centers/physicians for their contribution to the survey: Adult Comprehensive Epilepsy Center, Institute for Neurology and Neurosurgery at St. Barnabas, West Orange (NJ), USA, E.B. 66 Effects of sleep and sleep deprivation on seizures and the electroencephalography in epilepsy

N Foldvary-Schaefer

Introduction

Interactions between sleep and epilepsy have been recognized since antiquity. However, prior to the last few decades, knowledge in this area was based solely on clinical observations. More recently, the use of video-EEG and polysomnography has significantly extended early observations. This chapter addresses the effects sleep and sleep deprivation on seizures and the EEG in epilepsy.

Effects of sleep on epilepsy

In 1947, Gibbs and Gibbs were the first to perform a systematic study of the diagnostic yield and localizing value of recording sleep during the EEG.[1] Among 500 patients with epilepsy, they observed interictal epileptiform discharges (IEDs) in 36% of waking EEGs, increasing to 82% with sleep. Sleep activated independent epileptic foci in some patients who had only one focus awake. The likelihood of detecting IEDs by recording sleep was greatest for patients with psychomotor seizures and least for those with petit mal. Patients with psychomotor seizures often had normal EEGs awake, but 95% had IEDs during sleep. Interest in this area spanning decades has produced countless publications on the effects of sleep on the EEG in epilepsy.

Effects of sleep on interictal discharges in focal epilepsy

Many investigators have observed the activation of IEDs by non-rapid eye movement (NREM) sleep in focal epilepsy.[2–12] In 1958, Gloor and colleagues found that 90% of over 300 patients with TLE had IEDs awake but the frequency was greater during sleep in 57%.[13] In another series, roughly 30% of patients with medically refractory TLE had IEDs only during sleep.[11]

Most report that spike rate increases at sleep onset, gradually peaks in SWS and then falls in REM sleep to levels lower than seen in wakefulness.[6,9,10,12,14,15] The field of an interictal discharge often expands during NREM sleep (ipsilaterally and even contralaterally), occasionally accompanied by the appearance of new foci. The field tends to become more diffuse in SWS compared to light NREM sleep and is often most constricted during REM sleep.[2,4,10,12,15]

Sammaritano *et al.* prospectively studied IED variability in sleep and wakefulness in 40 patients with medically refractory TLE undergoing presurgical evaluation.[12] The accuracy of IED localization was confirmed by surgery (in 32), electrocorticography and scalp ictal recordings. Spike rate was greater in sleep than awake in 39 of the 40 cases, and maximal in SWS in 78%, REM sleep in 13%, and light NREM sleep in 7% of cases. New independent foci appeared in NREM sleep in 53% but during REM sleep in only four patients. The extent of the epileptic field, analyzed for 15 unilateral foci that showed spiking in all three states, demonstrated the field to be more extensive in NREM sleep compared to wake in ten, unchanged in four, and more restricted in one case. Comparing REM sleep with NREM sleep, the field was more restricted in 12 and unchanged in three cases. Epileptic foci were identical during wakefulness and REM sleep in 19 and disappeared during REM sleep in 17 who had spikes during wakefulness. The localization of primary epileptogenic area was more reliable in REM sleep than wakefulness and in wakefulness than SWS. Spiking was concordant with the epileptogenic temporal lobe in REM sleep in 51% of cases and was never discordant (in the remainder, no spiking was observed in REM). Similar findings have been reported in depth electrode evaluations in TLE patients.[10,14,15] Recently, Adachi *et al.* found that the sleep EEG was more accurate that the awake EEG in predicting the epileptogenic temporal lobe in 83 patients seizure-free following temporal lobe resection.[16] Unilateral IEDs during NREM sleep were correctly lateralized in every case.

The effect of sleep on IEDs in patients with extratemporal lobe epilepsy (XTLE) has been less extensively studied. Epileptiform discharges were most frequent during SWS in three patients with extratemporal foci.[17] Localization during REM sleep best predicted the epileptogenic focus.

Several researchers have studied how sleep influences spike rate in children with benign childhood epilepsy with central-midtemporal spikes. In one series of 11 patients, rolandic spikes occurred most often during SWS, especially during the first cycle of NREM sleep.[18] Spike densities were greater on the ascending slope of a sleep cycle (deepening NREM sleep) and less on the descending slope (lightening SWS to stage 2 to stage 1 en route to REM sleep). Rolandic spikes appear to be related to spindle synchronization and therefore maximal during stage 2 sleep.[6,19] These studies suggest that sleep differentially affects the expression of IEDs in epilepsies arising from different regions.

Effect of sleep on interictal discharges in generalized epilepsy

Patients with generalized epilepsy also show variation in the occurrence of IEDs with sleep and wakeulness. Gibbs and Gibbs found sleep was less important as an activator of sleep in most cases of IGE because these patients usually have IEDs in their routine wake EEGs.[1] Still, IEDs in idiopathic generalized epilepsy (IGE) are usually further activated during sleep.[20–27] Interictal discharges usually increase in NREM sleep gradually from sleep onset to the appearance of SWS, diminish sharply in REM sleep, and increase sharply in the morning after awakening.[20,28] The morphology of generalized IEDs is also affect by the sleep/wake cycle. During NREM sleep, generalized spike-wave discharges often become more disorganized, increase in amplitude and slow in frequency, sometimes with the addition of polyspikes, whereas the morphology in REM sleep is similar to wakefulness.[25,26]

Physiological basis for NREM sleep activation of interictal discharges

The neuronal networks that generate wakefulness, NREM, and REM sleep give rise to different physiological characteristics influencing the likelihood that a seizure will occur. The two most salient state-specific components that determine seizure propagation are the degree of synchronization of cellular discharges and the presence or absence of antigravity muscle tone.[29,30] NREM sleep represents a state of EEG synchronization and relative preservation of antigravity muscle tone. Synchronous oscillations of cortical neurons that generate sleep spindles, K complexes, and tonic background slow waves promote seizure propagation during NREM sleep. REM sleep is characterized by desynchronization of the EEG and loss of skeletal muscle tone. Desynchronization of the EEG impedes seizure propagation during REM sleep and wakefulness. Preservation of antigravity muscle tone during NREM sleep permits expression of seizure-related movements; its absence during REM sleep blocks the clinical expression of seizures.

Effects of sleep on seizures

Before the development of EEG, research on sleep and epilepsy in the late 19th and early 20th century focused on the relation of seizures to clock time and sleep. In 1880, Féré graphed seizure occurrence over a three-month period in hospitalized patients on his service for the mentally ill.[31] He found nearly two-thirds of seizures occurred between 8 p.m. and 8 a.m. and that insufficient sleep seemed to activate seizures. Gowers noted that 21% of 850 institutionalized patients had seizures exclusively at night (nocturnal epilepsies), 42% only during the day (diurnal epilepsies), and the remaining 37% either night or day.[32] He further observed that: (1) sleep onset and awakening were periods of particular vulnerability for nocturnal seizures; (2) nocturnal seizures most often occurred near the end of the sleep period (around 5 a.m. to 6 a.m.) and less often 1–2 hours after sleep onset; (3) diurnal seizures clustered in the early morning and late afternoon. Some years later, similar observations were made in a study analyzing the timing of 2524 convulsions in institutionalized patients leading to the conclusion that seizure peaks occur in response to falling asleep and waking up.[33]

Three decades later, Dieter Janz described 'awaking epilepsy' as an epileptic syndrome characteristic of idiopathic epilepsy with generalized tonic-clonic seizures (GTCs).[34] Subsequent work emphasized how preferential timing of GTCs in relation to the sleep/wake cycle had diagnostic and prognostic significance. Among 2825 patients, GTCs occurred in sleep in 44%, at awakening in 33%, and randomly in 23% of cases.[35] Janz felt that this type of classification had etiological significance, as awakening epilepsies were unlikely to have a known organic cause (10%), whereas sleep and random epilepsies more often did (23%, 54%, respectively). Juvenile myoclonic epilepsy became the prototypical awakening epilepsy, commonly precipitated by a lack of sleep. It is now recognized that several epilepsy syndromes are characterized by seizures occurring predominately or exclusively from sleep or upon awakening (Table 66.1).

More recently, video-EEG monitoring techniques and successful surgical resection have been studied to further detail the relation of different focal epilepsies to the sleep/wake cycle. Sleep appears to activate frontal seizures more often than temporal seizures.[36–38] Secondary generalization of partial seizures tends to occur more often during sleep (28%) compared to wakefulness (18%), and frontal lobe seizures tend not to secondarily generalize during sleep.[36–40] Herman *et al.* found that 57% of frontal lobe seizures arose from sleep compared to only 44% of neocortical temporal, 40% of mesial temporal, and 13% of parieto-occipital lobe seizures.[38]

Few studies have examined circadian rhythmicity of seizures in humans. Quigg *et al.* compared clock times of seizures in patients with mesial TLE (MTLE), XTLE, and lesional TLE and in a rat model similar to MTLE in which rats

become epileptic after electrically induced limbic status epilepticus.[41] Subjects with MTLE had twice as many seizures during light hours (7 a.m. to 7 p.m.) than dark hours, with a peak incidence of 3 p.m. Seizure distribution in rats maintained in a 12-hr light-dark cycle with lights on at 7 a.m. and those kept in constant darkness was similar to the pattern observed in humans with MTLE. The authors argued that the fact that rats and humans with MTLE behaved similarly despite marked differences in the sleep/wake cycle between species (180° out of phase) suggests that factors other than the sleep/wake cycle regulate seizure occurrence. In contrast, seizures from patients with XTLE and lesional temporal foci occurred randomly with a peak incidence of extratemporal seizures in the morning, usually associated with awakening, suggesting the absence of a circadian influence.

Pavolva *et al.* more recently confirmed the day/night differences in patients with TLE and XTLE epilepsies.[40] Forty-one percent of the XTLE seizures began during sleep versus 19% of seizures in patients with TLE. Forty-six percent of TLE seizures occurred between 3 p.m. and 7 p.m.; had they been truly random, only 17% of seizures would have occurred during this period of time. Forty-seven percent of XTLE seizures occurred between 7 p.m. and 11 p.m. These studies illustrate how circadian influences might affect seizure timing, varying by the type and location of the generator. Mesial temporal seizures may be particularly vulnerable to circadian effects.

Effects of sleep deprivation on epilepsy

The effect of sleep deprivation on epilepsy has been the subject of much investigation and extensive reviews.[42–44] In the following discussion, total sleep deprivation (TSD) is defined as 24 hours or more of sleep loss; shorter periods of sleep loss are considered partial sleep deprivation (PSD).

Effects of total sleep deprivation on interictal discharges

Early case series reported convulsions in normal subjects following profound sleep loss.[44,46] While some of these individuals were also subjected to other stressors, sleep deprivation was the only factor common to all.[45] Subsequent larger studies in sleep-deprived military personnel found a significantly higher incidence of seizures than previously reported in similar, nonsleep-deprived populations.[47,48] However, the applicability of these findings to the epilepsy population was unclear. In the largest of these population-based studies, subjects with epilepsy and other medical disorders were excluded.[48] Concurrent EEG studies of normal subjects[47,49] and subjects referred for diagnostic evaluation[47,41] demonstrated a clear increase in IEDs following TSD.

These early reports stimulated the investigation of sleep deprivation as an activation technique in epilepsy. In the first systematic study, sleep-deprived EEGs (SDEEG) were performed after 26–28 hours of wakefulness in subjects with at least one seizure and a normal routine EEG, patients with convulsive epilepsy and IEDs on routine EEG, and subjects with neurologic disorders other than seizures.[51] Epileptiform abnormalities were recorded in 34, 56 and 0% of cases, respectively. No difference was observed between patients with generalized motor or psychomotor seizures.

In a series of studies in the 1980s, Degen and colleagues compared the effects of TSD on EEGs of subjects with different seizure types and epilepsy syndromes.[52–54] For most seizure types, they found that spontaneous sleep and sleep-deprived recordings produced similar activation rates (awakening grand mal 77% vs. 71%; atypical absence 78% vs. 72%; absence epilepsy 69% vs. 71%; complex partial seizures 49% vs. 51%). They also noted that seizures were more likely to be activated by sleep or sleep deprivation in patients with IGE than focal epilepsy.

One long-debated controversy is whether the IED activation produced by TSD is due to sleep itself (greater amounts of sleep recorded, sampling effects) or due to an independent activating effect. Some have argued that TSD does not offer greater activation than sleep alone[54,55] while others believe TSD does activate IED independent of sleep induction.[51, 57–63] Only a few have designed studies to answer this question.

Rowan *et al.* found a significantly greater IED yield following TSD compared to routine wake and drug-induced sleep EEGs; IEDs were recorded in 28% of their subjects only following TSD and TSD activated a new epileptic focus in 7% of cases.[63] As the yield of recording IEDs due to repeated recordings was estimated to be in the range of 14% to 19%, the authors claimed their findings were unlikely to be due to sampling effects. Declerck studied the timing of IEDs following TSD in 588 patients with epilepsy.[64] IEDs appeared in the first 30 minutes in 46%, after 1 hour in 57%, after the second hour in 69%, after the third hour in 73%, and after the fourth hour in 75% of cases. He argued that the greater yield of recording IEDs over time was produced largely by the presence of sleep alone (sampling effect). A recent prospective study of 721 subjects who had a second EEG (routine, drug-induced sleep, or TSD) after an inconclusive initial EEG found a significantly greater percentage containing IEDs after TSD as compared to a second routine record (22.6% vs. 9.5%).[65] In another study, recording sleep during a routine EEG provided additional information that led to a more accurate diagnosis in 20% of cases, but sleep was only critical for the diagnosis in 2%.[66]

When comparing sleep and TSD, only a few studies have attempted to control for duration of the recording.[56,57,63] Veldhuizen *et al.* found the spike rate was highest following TSD and lowest in routine wake EEGs when routine, drug-induced sleep, and TSD recordings of similar duration were performed in random order in 70 subjects with epilepsy.[56] They attributed this finding to a greater proportion of recording time spent in sleep in the TSD EEGs. Activation rates were greater after TSD (93%) compared with drug-induced sleep (86%) and wake (65%). However when analyzed during the wake period only, activation rates were comparable (24, 28, and 35%, respectively).

Several studies have suggested TSD can be useful in activating IEDs in wakefulness, especially in patients with IGE.[52–54,56,58,61,62,65,67–71] Fountain *et al.* found 7% of subjects had IEDs during wakefulness only after TSD.[57] However, another study quantified spike rates by state before and after TSD and found lower rates of spiking in wakefulness after TSD.[55]

TSD enhances responses to hyperventilation and intermittent photic stimulation[51,71,72] and provokes photoparoxysmal responses that remit with treatment in sleep-deprived patients.[73] Aguglia *et al.* found activation was greater following

TSD during a sleep EEG in untreated patients with epilepsy, whereas treated patients had comparable activation rates following each procedure.[74] Several studies have shown that TSD is equally, if not more effective in children with epilepsy.[62,67,69,71,75]

Table 66.2 summarizes findings of comparative studies demonstrating activation of IEDs by TSD in 23–93% of patients with definite or suspected seizures.[44,54,56–59,62,65,68,70,71,74,76–79]

Effects of partial sleep deprivation on interictal discharges

Partial sleep deprivation in epilepsy has been much less extensively studied. Limited work suggests that partial sleep loss may be an effective activation method,[80–85] however no studies compare the effects of PSD and TSD. Most studies utilizing PSD protocols examine pediatric subjects. In a prospective study of over 200 children with newly diagnosed epilepsy and normal routine EEGs, a repeat recording after PSD (sleep limited to 7 hours in children 3–10 years of age and 5 hours in adolescents) produced IEDs in 35% of cases.[81] Epileptiform abnormalities were present in wakefulness only in 15% and one subject experienced a generalized motor seizure. Kubicki *et al.* reported activation rates of 54% when restricting older children to 5 hours and younger children to 8 hours of sleep.[83] Peraita-Adrados *et al.* reported activation rates of 36% when they asked adults to sleep 3 hours less than usual, adolescents 2 hours, and children 1 hour in a retrospective study of 686 patients with at least one seizure and a normal routine EEG.[85] A second SDEEG, in 40 subjects in whom the first sleep-deprived recording was normal, detected IEDs in 39% of cases. In a study of 396 patients under 17 years of age, sleep was achieved after PSD in 77% of cases in contrast to 44% of subjects not sleep-deprived, supporting the feasibility of the technique in younger patients.[86]

Gilbert *et al.* compared the activating effects of routine and sleep-deprived EEGs (>11 years: awake after midnight; 3–11 years; awake after 2 am; <3 years: awake after 4 a.m.) versus PSD (awake 2 hours past usual bedtime in children ≥2 years and no napping in children < 2) in 820 patients.[87] They found sleep occurred in 22% of routine, 44% of PSD, and 57% of sleep-deprived EEGs. No procedure was superior in terms of the yield of recording IEDs.

Recommendations for the use of sleep deprivation in clinical practice

Based on the available evidence, SDEEG has proven effective in increasing the yield of EEG when initial recordings are inconclusive. Adults undergoing SDEEG should remain awake for 24 hours prior to the study and recordings should begin early in the morning with a period of wakefulness, recording at least one complete sleep cycle. As the yield appears to increase progressively with time, longer recordings are encouraged.[64] The study should end with a period of wakefulness during which hyperventilation and photic stimulation are performed. Sleep should be restricted as much as possible in children and adolescents unable to comply with TSD. The risk of seizures is low (1.2–5.8%).[67,71,72,76] Whether lesser amounts of sleep restriction are as effective is unknown.

Does sleep deprivation activate seizures?

Patrick and Gilbert in 1896 were the first in modern times to report the ill effects of sleep deprivation in humans.[88] While studying the effects of psychotropics in the late 1950s, Rodin became the first to describe the effects of sleep deprivation on seizures and the EEG.[44] Subsequent reports described GTCs in military personnel following prolonged sleep deprivation, estiimating the risk of a sleep-deprived seizure to be 1/10 000

after 24 to 36 hours of TSD and 1/2500 after two or more days without sleep.[47,48] However, the applicability of these findings to patients with epilepsy was unclear as this study and others excluded subjects with epilepsy and other medical disorders.

Sleep deprivation has long been recognized as a seizure precipitant, reported by 25% of epileptic patients, more often in those with awakening epilepsy.[46,61,89,97] Most of these observations are based on patient self-reports. In one series, 37% of patients reported that two or more hours of sleep loss contributed to or activated seizures.[61] Based on a review of seizure and sleep diaries, Neugebauer *et al.* found that seizures were more likely to occur following nights of short or interrupted sleep in 38% of cases.[95] Two larger questionnaire-based studies of adults with epilepsy found that 18–24% of adults reported sleep deprivation as a seizure trigger.[91,97]

Due to the pressures of modern society, people with epilepsy are vulnerable to the effects of chronic PSD. Its effects on seizures have only been addressed in one study in which night sleep duration was correlated with seizure frequency in 14 patients with TLE.[96] Subjects maintained sleep and seizure diaries for 2 years, logging 682 seizures. They considered a particular night as PSD when the patient slept 1.5 hours less than usual, and oversleep (OS) when they slept at least 1.5 hours longer than their mean sleep duration. They studied whether seizures occurred more or less often within 48 hours of sleep-deprivation or oversleep. Of 4995 recorded nights, 91% were characterized as normal sleep nights, yet only 58% of seizures followed normal sleep, while 34% followed PSD and 8% followed OS. The probability of occurrence of a seizure was significantly higher after PSD (0.58) than normal sleep (0.09) and OS (0.28). In eight subjects, PSD was felt to play a decisive role, while three subjects demonstrated a marked sensitivity to the OS condition. These findings suggest that modest amounts of sleep loss can precipitate seizures.

Clinical neurophysiologists often subject patients to PSD during long-term video-EEG monitoring to activate seizures. However, in a study of 84 patients with medically refractory epilepsy, the number of seizures per day was not significantly greater in sleep-deprived subjects versus controls.[98] Further studies are needed to better understand the impact of PSD on seizure threshold and identify the most vulnerable populations.

Conclusions

Over many years, researchers have compiled a large body of evidence confirming interrelationships between sleep and epilepsy. Synchronized NREM sleep facilitates and desynchronized REM sleep discourages seizure occurrence. Sleep deprivation provokes seizures and interictal discharges in some patients with epilepsy. The effects of sleep on IEDs can have important implications in epilepsy surgery candidates because new independent epileptic foci may appear in sleep and REM sleep may demonstrate the narrowest localization of the primary epileptic focus.

SECTION 7

The ictal onset zone

67 The ictal onset zone: general principles, pitfalls and caveats

A Arzimanoglou and P Kahane

Introduction

The 'ictal (or seizure) onset zone' is defined as the 'area of cortex that initiates clinical seizures'.[1] Although this definition is apparently simple and clear it generates a number of questions. At least five are of crucial importance:

1. Is it possible to define the 'ictal onset zone' without having recorded a seizure?
2. What is the meaning of the term 'clinical seizure'
3. What do we understand when talking about 'initiation' of a seizure?
4. Do we dispose of specific markers that can precisely define this region?
5. Is the identification of the ictal onset zone operant when it comes to surgery?

Is it possible to define the 'ictal onset zone' without having recorded a seizure?

It seems rather obvious that the proof of a seizure being generated within a given cortical region of variable extent cannot be provided without the recording of the seizure. If the opposite was feasible it would mean that using other investigational means (interictal EEG, bipolar modeling, structural or functional neuroimaging, etc.) it would be possible to constantly obtain a reproducible information, superimposed to what is obtained from seizure recordings. Abundant current literature indicates that such an option is an exception rather than the rule. For example, the relationship between regions that generate spikes and those that generate a seizure are far from being constant. This brings us back to the old debate on 'green versus red spikes',[2] debate still open despite abundant data now available from IRMf-EEG studies or from the use of source localization techniques. Even in the case of lesional epilepsies, for example in the presence of a dysplastic cortical lesion in which interictal spikes (or at least some of them) could be considered a reliable marker of the extension of the lesion 3–5, invasive recordings often demonstrate that the topographic relationship between the spikes and the onset of seizures may vary (Figure 67.1).

What is the meaning of the term 'clinical seizure'

By definition 'the ictal onset zone' refers to that region of the cortex at the origin of *clinically* detectable seizures. Such a definition indirectly leads to the question of how we define 'subclinical seizures'. Are these 'discharges' considered as seizures or not? Such discharges, very similar in terms of morphology to what can be observed at the onset of a clinical seizure, are often observed without any clinical accompaniment. The occurrence of accompanying symptoms may vary according to the localization of the discharge and to its electrographic pattern. This is notably true in temporal lobe epilepsy, in which an ictal discharge can remain confined to the amygdala[6] or to the hippocampus[7], the most often without any associated signs. It has been shown that subclinical seizures may have a high localizing significance,[8] even if the recordings of such 'subclinical' discharges do not exempt one from recording the fully developed electro-clinical seizures. In which case, the discharge at seizure onset may additionally involve other cortical structures, or cortical structures which are different from the area exhibiting 'subclinical' paroxysms (Figure 67.2).

This ambiguity on 'clinical' *versus* 'subclinical' seizures is reflected in the definition of the ictal onset zone when it is stated that the seizure onset zone includes the portion of the irritative zone that generates repetitive spikes 'that have enough strength to produce clinical ictal symptoms when invading eloquent cortex'.[1] In other words, what value should be attributed to 'spikes' in general, and particularly to those spikes occurring in the (supposed) noneloquent cortex? Are these 'symptomatic spikes' morphologically similar to those which, though located at the same place, do not give rise to any symptoms? And if recognizable, what is their significance with respect to the ictal onset zone?

Lack of an answer to the question of 'subclinical' *versus* 'clinical' seizures, and the introduction of the concept of 'symptomatic spikes' in the definition of the seizure onset zone may maintain the confusion between the concepts of seizure onset zone, irritative zone, and symptomatogenic zone. Defined as such the 'ictal onset zone' should theoretically be delineated on the basis of the very first clinical symptoms produced by 'hyperactive cortical neurons' that generate interictal spikes capable of producing, under certain circumstances, afterdischarges.

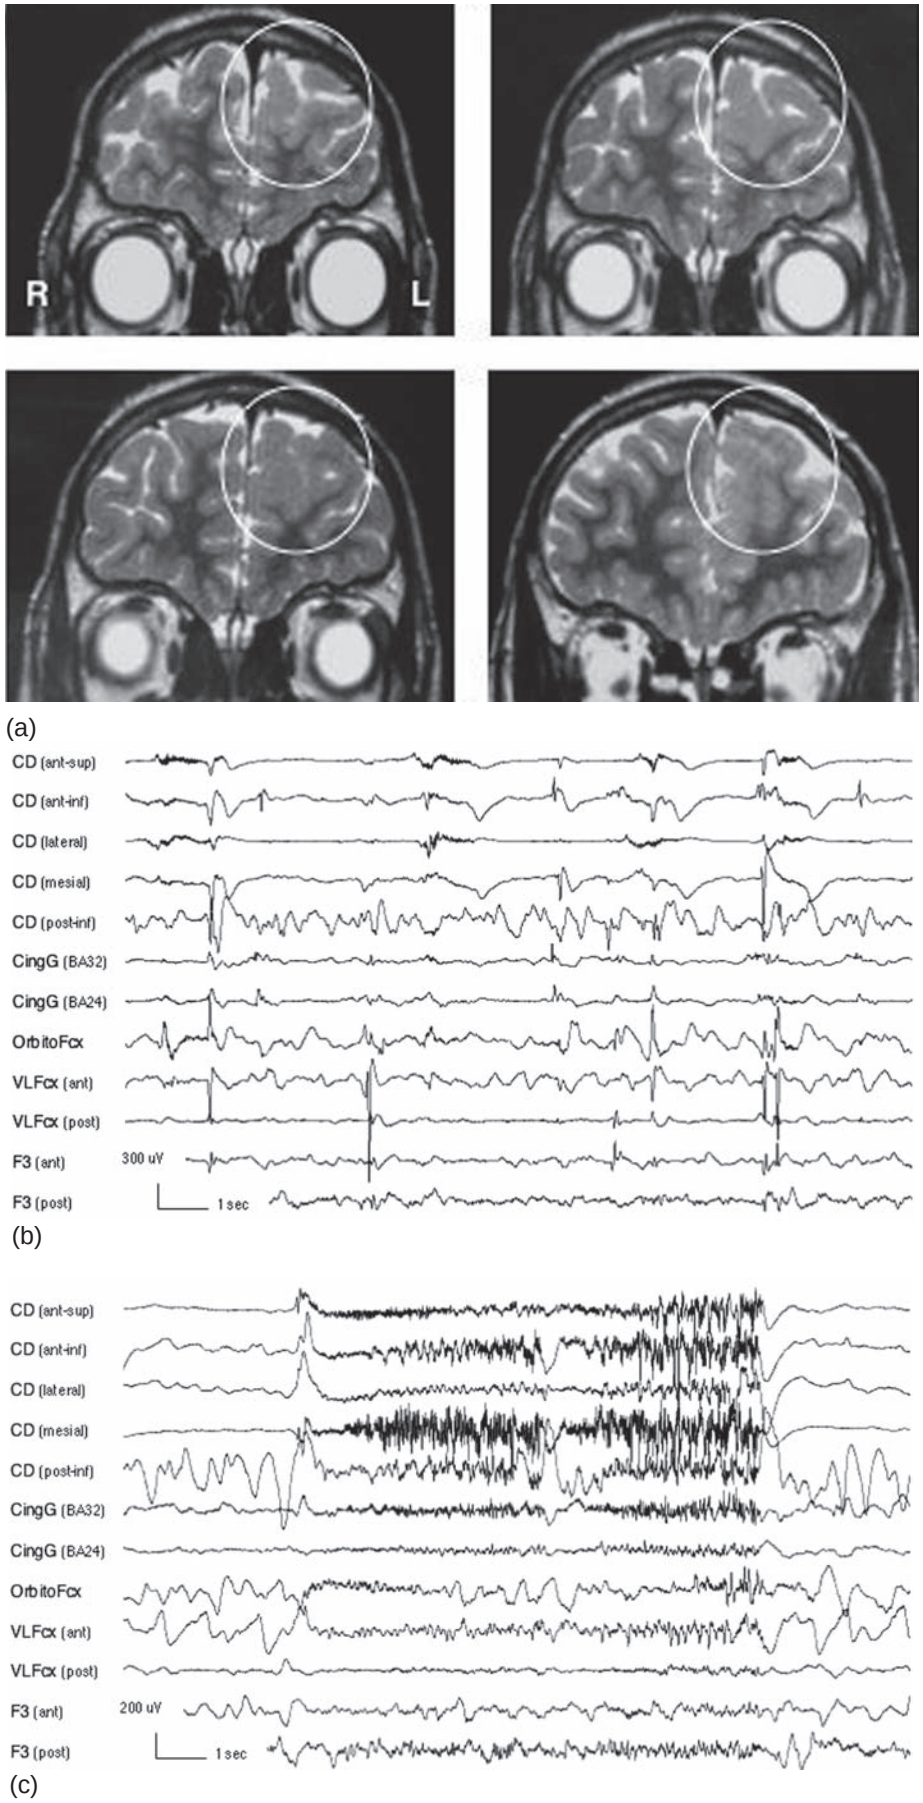

Figure 67.1 Nine-year-old boy suffering from drug-resistant hypermotor seizures. a. MRI: Left frontal cortical dysplasia (Type 2b on pathological examination) limited to the polar part of the 1st frontal gyrus. b. SEEG investigation, interictal activity. The main findings consist in the occurrence of bursts of low amplitude fast rhythms within the lesion, the distribution of which predominated over the antero-superior and lateral part of the dysplastic lesion. Interictal spikes were also recorded within the lesion, as well as over mesial and lateral frontal lobe structures distant from the lesional process.c. SEEG investigation, electro-clinical seizure. The seizure begins not only in the cortical dysplasia (at recording sites that were not strictly the same as those that exhibited fast rhythms interictally), but also within the cingulate cortex (BA 32).

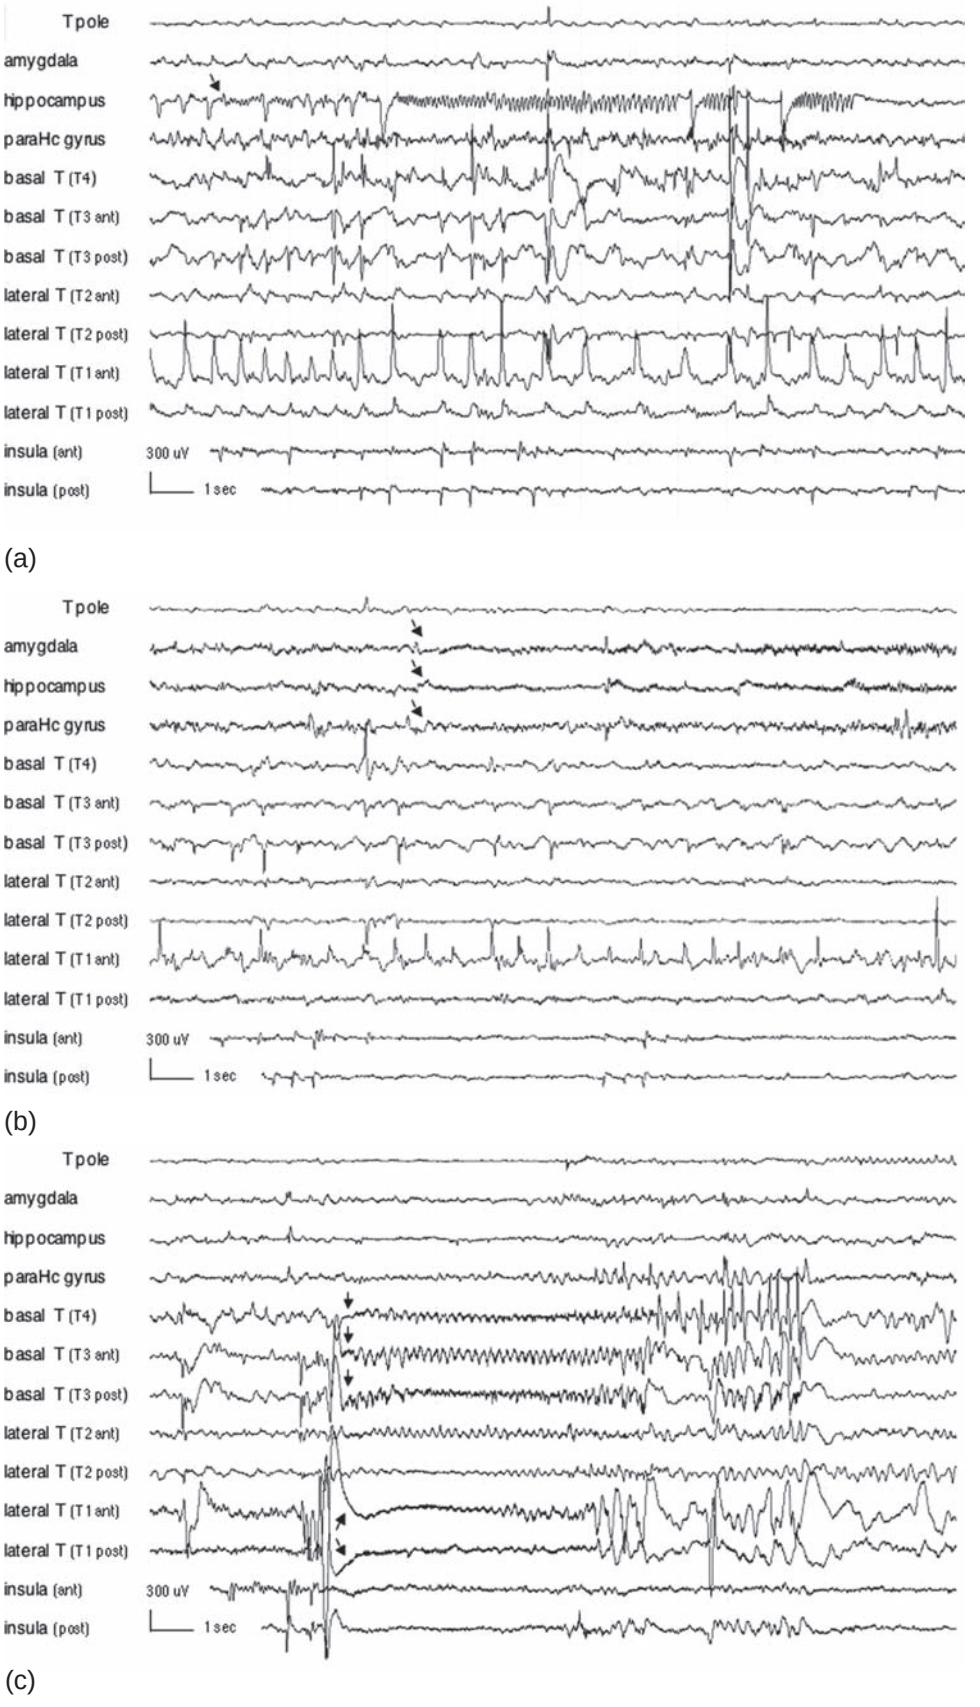

Figure 67.2 SEEG study in a 41 years old left-handed woman with right hippocampal sclerosis (right hemispheric dominance for language). a. Subclinical discharge well located within the hippocampus (arrow). b. Electroclinical seizure characterized by a feeling of distress over the head, pallor, arrest of activity, gestural and oroalimentary automatisms and dystonic posturing of the left arm. The ictal onset (low voltage fast activity) involved not only the hippocampus but also the amygdala and at a lesser degree the parahippocampal gyrus (arrows). c. Other electroclinical seizures were recorded, clinically characterized by auditory symptoms with word finding difficulties. The ictal onset involved in such cases the basal and lateral temporal cortex (mainly the first temporal gyrus), sparing mesio-temporal lobe structures (and notably the hippocampus).

The theoretical concept of ictal onset zone would be of great practical value if:

1. the 'ictal onset zone' was always localized in a sufficiently eloquent cortex to always manifest the very first clinical symptoms, ideally always detectable (in that case the ictal onset zone would be the cornerstone of the 'symptomatogenic zone', and theoretically it could in some cases fully overlap with it);
2. the interictal spikes of the 'ictal onset zone' were always of sufficient 'strength' to give rise to clinical symptoms (and in that case the ictal onset zone could overlap with the 'irritative zone').

In summary, it remains to be agreed if we will consider as ictal onset zone *the area in which arises the fast synchronizing discharge, prior or concomitant to the clinical onset of the seizure, or if we have to include the 'minimal' adjacent cortical area necessary to generate the first clinical symptoms.* In the first case the definition is an *electrophysiological* definition, which somewhere raises once again the issue of the significance of subclinical seizures. In the latter case the definition is an electro-clinical one which overlaps with the definition of the 'symptomatogenic zone'.

What do we understand with 'initiation' of a seizure?

If we accept the principle that the definition of the 'ictal onset zone' can only be based on seizure recordings, how do we integrate the notion of 'seizure initiation'? How do we define the region of 'seizure initiation'?

It certainly cannot be the cortical region that when removed (or disconnected) allows seizure freedom, since in that case it would correspond–by definition–to the epileptogenic zone.

To illustrate and discuss this ambiguity we will use the example of a lesion (cortical dysplasia or DNET) that has been removed rendering the patient seizurefree. According to the current definition this can be considered as the proof that the 'epileptogenic zone' has been removed (or that it was included in the cortical tissue removed). It also signifies that the seizure onset zone was part of the resected cortical tissue. Adversely, this cannot be interpreted as a proof that the seizures implicated, at onset and simultaneously, the totality of the removed cortex. In other words, even within one lesion, the zone that 'initiates' a seizure can be smaller than the epileptogenic lesion (Figure 67.3), and we can even have a number of seizure onset zones within the same epileptogenic lesion.

Consequently, we prefer *a pragmatic and electrophysiological* definition of the ictal onset zone, as the cortical area(s) from where the first clear ictal electrical change is recorded, using intracranial electrodes. To be retained, such a change must occur just prior to the clinical onset of the seizure (defined as the time of the first visible change in the patient's behavior, or when the patient indicates he is experiencing an aura). It would manifest as a fast synchronizing discharge (low-voltage fast activity of various frequency or recruiting fast discharge of spikes), the pattern and frequency of which may vary according to the cortical structures from where it arises.[9–11]

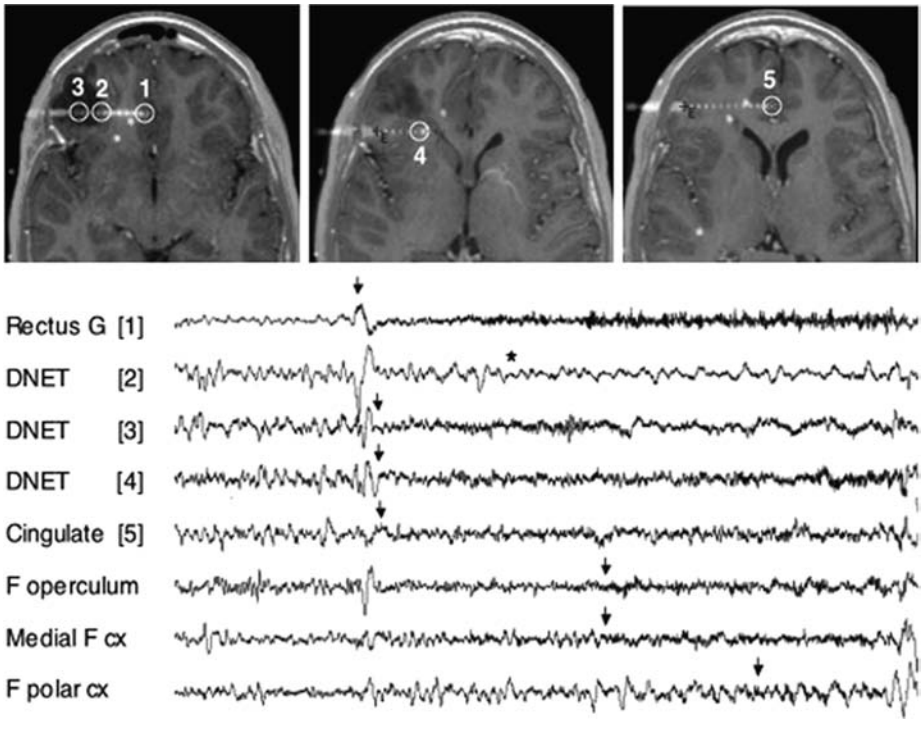

Figure 67.3 SEEG investigation in a 22-year-old woman with a right frontal basolateral dysembryoplastic neuroepithelial tumor. The seizure is initiated in the (nonlesional) rectus gyrus where it appears prominent, involving also the lesion and, at a lesser degree, the (nonlesional cingulate cortex). The fast activity then spreads over the frontal operculum, the mesial frontal cortex and, later, over the frontal pole (see arrows). Note that part of the DNET is not involved at seizure initiation but only a few seconds later (black star).

It is understood that in this context recognition of the seizure onset zone depends upon:

1. the spatial sampling of the electrodes;
2. the way 'a clear electrical change' is defined, knowing that its pattern may vary depending on the structures implicated;
3. our capacity to identify eventual triggering events of a seizure (in which case we also need to decide, for example when dealing with a reflex seizure, if we will consider as initiation zone the region that includes the triggering stimulus or only the region that generates the clinical seizure). Finally, we need to decide if the concept of 'seizure initiation' will include or exclude concepts introduced by the mathematical analysis of EEG signals, showing that some modifications can be detected much earlier than the appearance of the first clearly identifiable EEG changes.[12]

Do we dispose of specific markers that can precisely define this region?

From our point of view, for both clinical and neurophysiological reasons, current available investigation tools do not allow an exact measurement and precise delineation of the ictal onset zone.

From a 'clinical expression' point of view (if we accept the definition that a 'seizure' implies the presence of clinical symptoms) we can identify with today's available means only what the patient reports or what our audio-video tools, coupled to clinical examination during a seizure, can identify. Experience has shown that even in cases where the ictal onset zone is suspected to be in a very eloquent cortical area, the clinical symptoms obtained are in almost all cases the result of a 'very early' spread of the ictal discharge. It is highly probable that a limited number of 'hyperactive cortical neurons' have the capacity to act as a trigger (and in that sense these neurons represent the ictal onset zone) but they are unable to translate this hyperactivity to clinical symptoms. To do so they need to activate a neuronal circuit, capable of translating this activation to concrete symptoms. For example, even when dealing with a very well described primary somatosensory aura, it is highly improbable that Brodmann areas 1, 2, and 3 represent, as a whole, the 'ictal onset zone'. Consequently, even in cases where the ictal onset zone is localized in eloquent cortical areas, we can expect an accurate localization only by scalp or invasive EEG techniques and, eventually, ictal single photon emission computed tomography (SPECT). Whether these tools, however, are really able to reliably and consistently delineate the ictal onset zone remains a highly debatable issue.

Scalp electrodes offer a broad coverage of brain activity. Analysis of interictal and/or ictal EEG can in most of the cases provide strong clues suggesting the side and the approximate location of the seizure onset zone. However, as discussed in Chapter[71] Foldvary-Schaefer chapter in this book scalp EEG has relatively low sensitivity for the detection of the seizure onset zone because of the distance between the electrodes and the suspected triggering cortical region. Small discharges at the 'level' of the seizure onset zone are not detected or are already modified by the propagation to neighboring areas. The presence of a localized flattening, or even better of a fast localized activity, provides some clues for the identification of the cortical areas implicated at onset[13] but by no means can be considered as pointing to the cerebral structures that really generated the seizure.

Ictal SPECT provides only an indirect view of what is going on during a seizure. The simple fact that the tracer injection takes place only after the onset of the clinical seizure (that by definition follows the electrical onset) renders impossible the localization of the zone of seizure initiation. The tracer is captured after 15 seconds following IV administration and consequently it reflects both the regions of seizure onset and seizure propagation. Even within the artificial setting in which the tracer is injected before seizure onset (for example, seizures induced by electrical stimulation), the variations of cerebral blood flow observed are not systematically correlated to the topography of the underlying discharge, as this was demonstrated by ictal H20-PET,[14] and by ictal SPECT.[15]

Invasive cortical surface electrodes see Chapter[73] by xx in this book offer the advantage of eliminating some of the scalp EEG inconveniences (shorter distance, absence of scalp, bone and dura mater barriers). However, they can only cover the cortical surface and therefore do not provide access to deep seated cortical areas and sulci. Consequently they are often not in direct contact with the suspected ictal onset zone and can only better capture discharges that are part of the early propagation process. The quality of spatial sampling of intracerebral electrodes, when compared with subdural grids or strips which cover a larger cortical surface, can appear inferior since recordings are taken from a series of paired leads which only explore a very restricted part of the cortex see Chapter[74] by Kahane and Francione in this book). However, this depends obviously on the spatial sampling of the Stereotactic intracerebral EEG (SEEG) investigation,[16] so that caution is required to ascertain that the fast discharge which is supposed to mark the ictal onset is really localized at the place where it has been recorded (i.e., a volume of brain tissue approximating a cubic centimeter).

Is the identification of the ictal onset zone operant when it comes to surgery?

One of the major difficulties to which we are confronted in epilepsy surgery derives from the fact that the electrophysiological criteria used intracranially, for defining the most epileptogenic region, are not clearly determined. Neuronal mechanisms associated with the emergence of epileptic seizures, indeed, are still largely unknown, though several indices suggested that the transition from the interictal to the ictal state is not sudden. Recent studies conducted in epileptic patients by means of intracranial macroelectrodes have shown that epileptic seizures can begin with low amplitude fast activities in the gamma frequencies range,[17–20] and that in the period between seizures, there are brief bursts of high frequency oscillations (60–100 Hz) which seem to have the same spectral characteristics as the seizure onset activities.[21] These 'interictal' fast oscillations (are they truly 'interictal'?) seem to be recorded only in the seizure onset zone, supporting the idea that they are pathological oscillations. Whether they have rela-

tionships with fast ripples (high frequency oscillations up to 500 Hz) recorded in humans when using microelectrodes[22] is a very important issue, since these latter could be the signature of the cortical regions capable of generating spontaneous seizures. If this is to be confirmed in the near future, the capability to identify such rapid oscillations by noninvasive techniques (for example MEG-EEG) would be a major challenge.

Furthermore, we are living in an era where further developments in the understanding of the mechanisms underlying seizure generation (i.e., the result of what an ictal onset zone is supposed to produce) are constantly becoming available. Such developments will soon provide us, among others, with more precise data on the distribution of neurotransmitters and receptors involved in the pathogenesis of the epilepsies. It is to be expected that the important advances that recently became possible by the development of neuroimaging and numeric video-EEG techniques will continue to evolve, coupled to advances in genetics and in pharmacogenomics. The consequences of such an approach are evident, particularly if we integrate the fact that a number of epilepsies are not potential surgery candidates and that 'the ictal onset zone' concept should also be applicable to nonsurgical epilepsies. Being able to identify the ictal onset zone even in nonsurgical cases is not just a theoretical issue. Because if we were able to define the ictal onset zone in all epilepsies, we could then go a step further and define the eventual pharmacological reactivity of a given region. Factors influencing the 'road to a seizure' could then be better identified and controlled, which would also lead to a better approach, and eventually control, of the cognitive consequences frequently encountered.

68 Noninvasive electroencephalography in the evaluation of the ictal onset zone

N Foldvary-Schaefer

Introduction

The seizure onset zone is the area of cortex from which clinical seizures are generated and is closely related to the epileptogenic zone, the area of cortex capable of producing seizures, the complete removal of which is necessary to produce a seizure-free state.[1] Noninvasive EEG is routinely used to localize seizures 1-1, however, due to a variety of factors, precise delineation of the seizure onset zone is not possible.

General concepts of noninvasive EEG

Epileptiform activity does not necessarily originate from cortical tissue directly beneath or even in the vicinity of the recording surface electrode(s). Seizures originating in functionally silent cortex produce symptoms only when the ictal discharge spreads to symptomatic areas that may be at some distance from the generator. Therefore, the distribution of epileptic discharges on noninvasive EEG depends upon a variety of factors, including the spatial characteristics of the generator and the conductive properties of the surrounding tissue. The yield of noninvasive EEG varies with the depth, size and orientation of the generator and the duration and synchronization of an epileptic discharge.[2] Electrical activity of the brain is attenuated by the impedance characteristics of the intervening tissue, cerebrospinal fluid, meninges, skull and scalp. Higher frequencies, which are commonly observed during the evolution of ictal patterns, are attenuated more than lower frequencies. There is no consistent or direct relationship between the amplitude of epileptic discharges recorded simultaneously from intracranial and surface electrodes. Spikes recorded from subdural or depth electrodes are frequently not seen on noninvasive EEG.[3] As a result, epileptic activity is apt to escape detection or produce widespread discharges of limited localizing value, particularly when arising from deep or midline areas.

The location of the generator, seizure type, state of the patient, recording technique and seizure frequency may also affect the expression of epileptiform activity on noninvasive EEG. Nonrapid eye movement sleep (NREM) and sleep deprivation are potent activators of interictal discharges and seizures.[4,5] Prolonged sleep deprivation activates interictal discharges in approximately 40% of epileptic subjects with normal wake EEGs.[6] As compared to wakefulness, spike rate is increased during NREM sleep and reduced during rapid eye movement (REM) sleep.[7,8] The extent of the field is typically more restricted in REM sleep as compared to wakefulness, while extension of the field and new spike foci are observed in slow wave sleep (stages 3 and 4 NREM). Therefore, the localization and distribution of epileptic activity in REM sleep may be a better indicator of the seizure onset zone than NREM sleep or wakefulness. Spike rate increases markedly during the first 24 to 48 hours after a clinical seizure.[9,10] Changes in antiepileptic drug concentrations do not appear to expression of interictal discharges.[10,13]

Special recording techniques are particularly helpful in the localization of focal epilepsies arising from deep or midline regions and when the seizure onset zone is confined to a small area of cortex. Closely spaced scalp and semi-invasive electrodes improve the yield of spike detection over the standard 10–20 system.[14] Epileptic activity is more commonly observed in patients with temporal lobe epilepsy (TLE) as compared to epilepsies arising from deep or midline regions. This is particularly true when sphenoidal or additional scalp electrodes are employed.

Anterior temporal epileptic activity is best defined noninvasively using additionally placed electrodes recording from the basal or mesial temporal regions. Surface electrodes placed 1 cm above a point one-third the distance between the external auditory meatus and the external canthus (T_1, T_2), FT_9, and FT_{10} electrode placements of the 10–10 system and sphenoidal electrodes increase the yield of recording interictal discharges in patients with TLE.[15,16] Several investigators have found sphenoidal electrodes superior to scalp electrodes alone in detecting temporal lobe seizures.[17–19] However, this was not confirmed by two recent studies investigating the utility of sphenoidal electrodes in TLE.[20,21]

Despite the above limitations, the distribution of epileptic activity on noninvasive EEG provides a reasonable estimate of the seizure onset zone in many cases. While, the extent of interictal discharges tends to be larger than the area of cortex from which a seizure originates, it is generally believed that the interictal EEG provides more reliable localizing information than ictal recordings. This is because a seizure has usually spread outside the seizure onset zone by the time an ictal pattern is detected by surface electrodes. In a series of patients with TLE, the presence of a single interictal spike focus in the anteromesial temporal region accurately predicted temporal lobe onset whether the surface ictal EEG was focal, regional or

lateralized.[22] In cases with multiple temporal foci or mid to posterior temporal epileptiform activity, the interictal focus was less accurate in predicting the seizure onset zone.

Overview of noninvasive ictal EEG

Ictal recordings have long been considered a critical component of the pre-surgical evaluation. However, with the exception of TLE, the localizing value of ictal EEG not been extensively studied. Most studies include patients with focal epilepsy in whom precise location and extent of the epileptogenic zone is unknown, presumed or not reported. Variations in EEG interpretation largely preclude comparison across studies.

The transition from the interictal to the ictal state is variable and may be difficult to identify, particularly when seizures are brief or occur during state changes.[23] An abrupt cessation of interictal spiking immediately before ictal onset has been described.[24] Focal seizures are typically characterized by rhythmic sinusoidal activity in the beta, alpha or theta range or repetitive discharges that evolve in frequency, field or amplitude.[23–27] Variations in seizure evolution consisting of increasing or decreasing amplitude and/or frequency have been described.[24,28] Isomorphic patterns, such as the repetitive interictal discharges that characterize seizures in some of the idiopathic generalized epilepsies, are typically not observed in focal epilepsy.[23] Ictal discharges limited to one or two electrodes are relatively uncommon in noninvasive recordings. A sudden generalized or lateralized suppression or attenuation of amplitude has been reported in seizures arising from the orbitofrontal, mesial frontal and temporal regions.[27,29,30] With few exceptions, there is no clear correlation between the specific pattern and frequency of ictal onset activity and the location of the seizure onset zone.[24,31] Clinical manifestations frequently precede EEG onset. Approximately 10% of complex partial seizures are not accompanied by EEG change.[24,32]

It is generally accepted that the early appearance of paroxysmal fast activity during focal seizures reflects proximity of the ictal onset zone to the recording electrode. However, this concept was not confirmed by a study comparing seizures from patients with lateral versus mesial epileptogenic lesions.[31] Paroxysmal fast activity was observed in seizures arising from the inferior aspect of the supplementary sensorimotor area (SSMA) and cingulate gyrus, where the distance between surface electrodes and the generator is considerable. This pattern was virtually never observed at the onset or during the course of seizures in patients with hippocampal sclerosis (HS), suggesting that its presence may require extensive neocortical activation or vary with the pathologic substrate.

The localizing value of noninvasive ictal EEG is largely dependent upon the location of the epileptogenic zone. Using lateralized rhythmic theta and alpha activity, postictal slowing and activity at seizure onset as criteria for localization, only 47–65% of extratemporal seizures were correctly lateralized as compared to 76–83% of temporal lobe seizures.[33] Another study combining temporal and extratemporal cases localized by depth electrode recordings found only 21–38% of seizures to be correctly localized and less than one-half correctly lateralized.[34] In a series of predominately temporal lobe seizures, the ictal EEG correctly localized 40% and lateralized 9% of seizures, while the remainder was nonlateralized or uninterpretable.[35] Methodological differences likely contribute to these findings.

The postictal EEG can be extremely valuable in localizing seizures. Postictal regional or lateralized delta activity and attenuation are reliable predictors of seizure origin.[33,36,37] In one study, lateralized delta during the postictal state predicted the side of seizure origin in 96% of TLE cases.[38]

Few have studied the reproducibility and reliability of ictal patterns in focal epilepsy. In 68% of patients with TLE, the first recorded seizure was representative of subsequent seizures and was concordant with the final localization of the epilepsy in 91% of cases.[39,40] When the initial seizure was nonlocalized, particularly if it occurred in sleep, subsequent seizures were likely to remain nonlocalized.[40] Patients with unilateral interictal discharges are more likely to have consistent ictal patterns than those with bitemporal independent spike foci.[39] A minimum of four seizures was required to identify 100% of 18 patients with ictal patterns arising from both temporal regions independently.[39] However, in a recent series of 32 children with presumed focal epilepsy, the ictal onset was similarly localized in all recorded seizures in only ten cases.[41] Seizure outcome after anterior temporal lobectomy (ATL) was comparable whether or not video-EEG monitoring was performed in patients with unilateral temporal interictal discharges concordant with neuroimaging and functional studies, emphasizing the importance of the interictal EEG.[42,43] In extratemporal epilepsy, the first recorded seizure was correctly localized in 61% of patients.[44] Correct localization of the first recorded seizure occurred most often in dorsolateral frontal lobe epilepsy compared to seizures arising from other locations.

We previously compared the distribution and morphology of ictal patterns in nearly 500 focal seizures of 72 patients arising from different regions.[31] Localization of the epileptogenic zone was confirmed by the presence of a seizure-free 1-1 state following surgical resection. Noninvasive ictal EEG was more likely to be correctly localized in TLE than extratemporal epilepsy. Localized ictal onsets were seen in 57% of seizures and were most common in mesial temporal lobe epilepsy (MTLE), dorsolateral FLE and parietal lobe epilepsy (PLE), while lateralized onsets predominated in neocortical TLE, and generalized onsets in mesial FLE and occipital lobe epilepsy (OLE). The time to appearance of the most localized/lateralized pattern occurred at the EEG onset in 79% and within 10 seconds of onset in 91% of seizures. Approximately two-thirds of seizures were ultimately classified as localized, 22% generalized, 4% lateralized, and 6% mislocalized. False localization or lateralization occurred almost exclusively in parietal and occipital lobe seizures. Overall, noninvasive ictal EEG adequately localized 72% and correctly lateralized an additional 7% of cases. Ictal EEGs were entirely mislocalized in only two patients and were localized to more than one region in four cases. Arguably, these cases were chosen for surgery because components of the pre-surgical evaluation (ictal EEG included) demonstrated localizing features. Therefore, the localizing value of ictal EEG may be slightly overstated and not necessarily representative of video EEG monitoring results from refractory epilepsy patients overall.

In contrast to the Cleveland Clinic findings, Lee and colleagues found only 42% of nearly 300 neocortical seizures

to be localized.[45] Localized EEGs were more common in lateral TLE (52%) and OLE (70%) than FLE (23%) and PLE (10%). False localization was observed in a minority of EEGs in all groups (4.5–9.9%). Theta rhythms were most common in neocortical TLE while beta activity predominated in seizures arising from the occipital lobe. In a recent study by the same investigators, ictal EEG correctly localized the resected lobe in 63 of 89 patients (71%) with nonlesional neocortical epilepsy who underwent invasive evaluations.[46]

Noninvasive ictal recordings of simple partial seizures (SPS) are significantly less likely to yield useful information compared to partial seizures with overt manifestations. Electrographic changes were detected in only 21% of SPS in one series, more often in those with motor (33%) than nonmotor (15%) manifestations.[47] Proximity of the recording electrode to the motor cortex is one proposed explanation for this finding. The use of additional closely spaced scalp electrodes increases the yield of noninvasive EEG during SPS.[48] Another series found the ictal EEG to be localized in only six of 41 SPS, the majority showing no discernable EEG change.[45] These findings illustrate the limitations of noninvasive EEG during seizures with relatively limited clinical manifestations.

Temporal lobe epilepsy

Mesial temporal lobe epilepsy

Noninvasive ictal EEG manifestations of seizures arising from the temporal lobe have been well described. Rhythmic 5- to 9-Hz activity, localized to the temporal region, appearing at onset or within the first 30 seconds of the electrographic or clinical seizure onset is observed in 80 to 90% of patients with MTLE (Figure 68.1).[27,49–53] Lateralized or nonnlateralized ictal patterns are seen in less than 10% of seizures of mesial temporal origin. We recently identified this pattern in 90% of seizures and 91% of patients with unilateral HS and found that the ictal EEG was localized to the temporal lobe from the onset in 76% of cases.[31] Of 261 extratemporal seizures, none began with rhythmic temporal theta activity, and only 5% had this pattern at some time during the evolution. In pediatric series of MTLE due to HS; 20 (71%) of 28 cases and 21 (60%) of 35 cases, respectively had ictal patterns localized to the temporal region.[54,55] False lateralization has been observed in 0–18% of patients with presumed TLE, however, the higher percentage was reported in patients studied prior to the advent of high-resolution MRI.[27,31,49,50,53] In another series, ictal EEGs were consistently nonlateralized in only 4% of patients with HS or other temporal lobe lesions.[56] Rhythmic theta at ictal onset was significantly more common in patients with moderate to marked hippocampal atrophy (79%) than those with mild or no hippocampal atrophy (19%) and a positive correlation between the median frequency of the initial ictal discharge and the severity of HS has been reported.[52] A seizure-free outcome after temporal lobe resection is significantly more likely in patients with ictal recordings localized to the lesioned temporal lobe (83%), as compared to those with nonlateralized seizures (63%) or seizures that propagate contralaterally (46%).[57] However, rarely the ictal onset is mislateralized to the contralateral temporal lobe in MTLE due to a severely sclerotic hippocampus (the burned-out hippocampus). This was observed in five of 109 cases with suspected TLE who underwent depth electrode evaluation at two large epilepsy centers.[58] Bilateral independent seizure onsets, asynchrony of ictal activity over the two temporal lobes and switch of ictal activity from one hemisphere to the other are predictive of bitemporal epileptogenicity.[59] Lateralized postictal slowing or background attenuation correctly predicts the side of seizure origin in 96–100% of cases.[33,49]

The results of several studies suggest that the yield of additional information with noninvasive ictal recordings is limited when the MRI and interictal EEG are concordant in cases of suspected TLE (i.e., HS with anterior temporal discharges). In the largest series, ictal and interictal EEG lateralization was concordant in 92% of 170 cases; all patients with unilateral hippocampal atrophy had concordant EEG findings.[60] Ictal and interictal EEG was discordant in only 2.9% of patients, all of whom had bilateral interictal discharges. In 84 patients with unilateral hippocampal atrophy and concordant interictal EEG, 76% of ictal tracings were concordant with the presumed side of seizure origin, whereas, 4% were discordant and 20% were indeterminate.[61] Over 90% of patients had an excellent post-operative outcome regardless of the degree to which the ictal EEG agreed with other findings. In another series of 24 patients with unilateral hippocampal atrophy and concordant interictal EEG, ictal recordings were correctly localized in over 80% and lateralized in approximately 90% of seizures.[51] The majority of seizures were localized or lateralized to the side of the imaging lesion and interictal focus in 95% of cases. Concordance of MRI and interictal EEG was most closely associated with surgical outcome after temporal lobe resection; 77–80% of patients were seizure free regardless of the ictal EEG.[62] However, the mere presence of a lesion does not assure causality, as rarely the MRI can be misleading in localizing the seizure onset zone.[63] Video-EEG monitoring provides the opportunity to analyze clinical semiology, rule out nonepilepticss seizures and identify extratemporal abnormalities that may suggest the presence of dual pathology.

Neocortical temporal lobe epilepsy

While, neocortical and mesial temporal seizures may be indistinguishable by noninvasive ictal EEG, some features have been shown to be useful in differentiating the two.[64,65] An initial, regular 5- to 9-Hz inferotemporal rhythm was found to be more specific for hippocampal onset seizures.[64] However, the presence of this pattern requires the synchronous recruitment of adjacent inferolateral temporal neocortex. In fact, seizures confined to the hippocampus produce little or no change on noninvasive recordings.[66] Neocortical seizures are more often associated with irregular, polymorphic 2- to 5-Hz lateralized (less commonly, regionalized) patterns or nonlateralized arrhythmic activity (Figure 68.2).[64,65,67] Patients with seizures with a regular 5- to 9-Hz rhythm at the onset having a temporal or subtemporal distribution were significantly more likely to be seizure free after ATL than those with irregular, slow rhythms (<5 Hz) having a widespread lateral temporal distribution.[68] Bilateral ictal patterns, particularly when appearing early in the evolution of

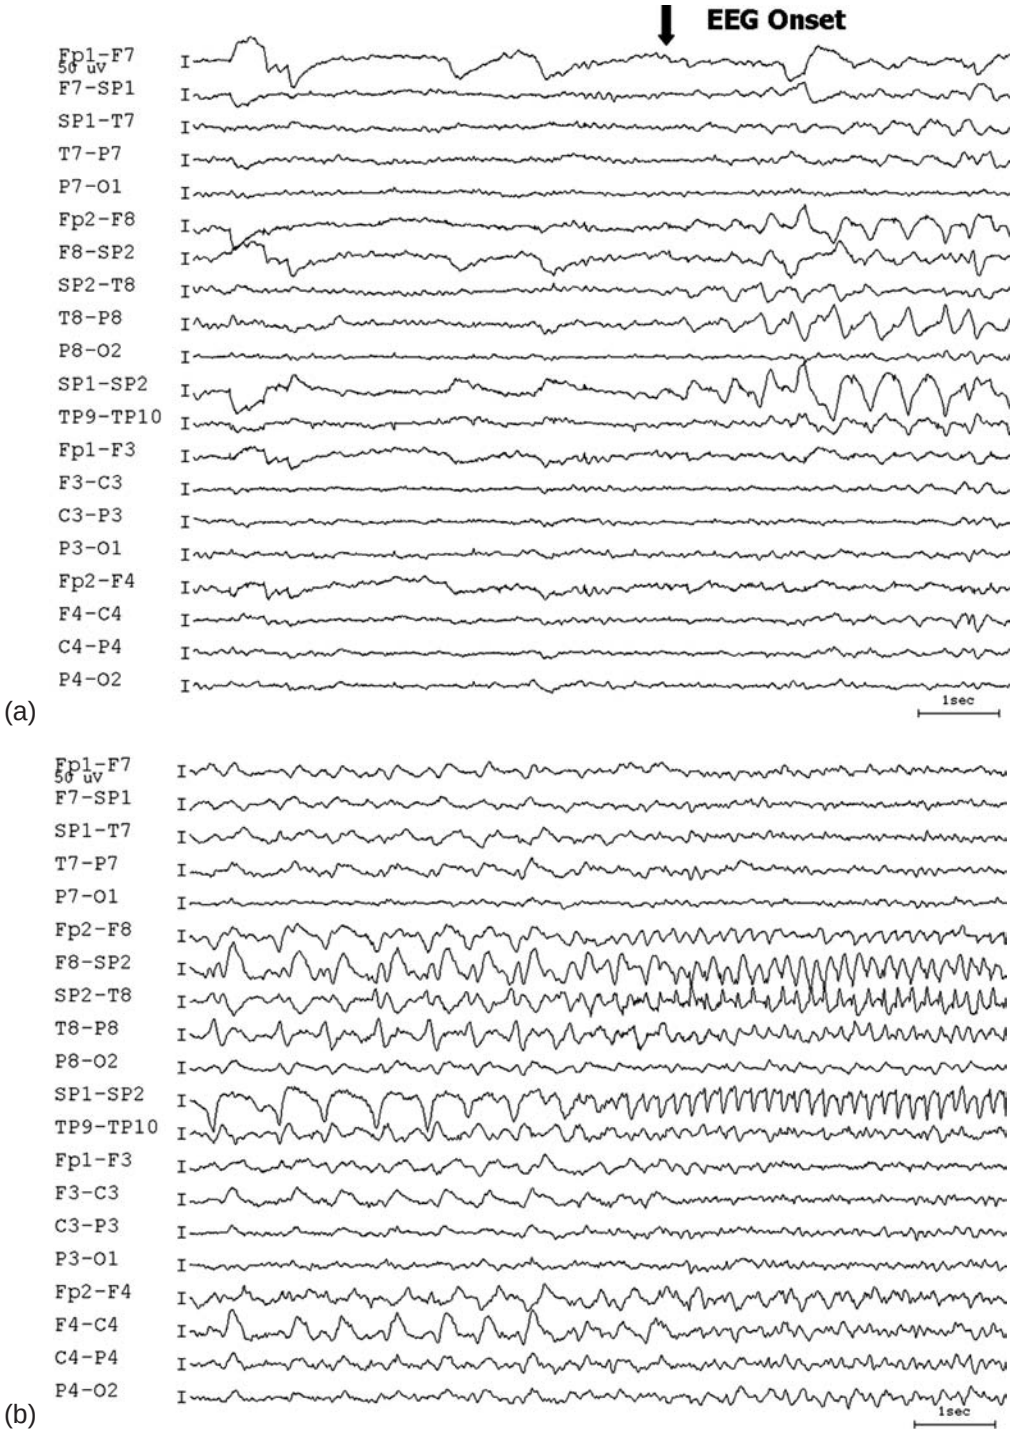

Figure 68.1 Consecutive 10-second epochs of a seizure arising from the right mesial temporal region in a woman with refractory TLE and right HS. The arrow depicts seizure onset from REM sleep (a) with repetitive spiking that evolves to rhythmic theta phase-reversing at SP2 within 10 seconds of EEG onset (b). The clinical onset occurred 30 seconds later.

a seizure[67] and hemispheric rhythmic activity[65] are additional features suggesting neocortical temporal origin. Delta frequency ictal onsets were significantly more common in patients with mild or no hippocampal atrophy (63%) than those with moderate to marked atrophy (13%), further supporting the notion that seizures arising predominately from mesial structures attain greater frequencies than those originating in temporal neocortex.[52] Although lateralized ictal patterns are significantly more common in neocortical TLE than MTLE, nearly three-quarters of neocortical seizures are still localized.[31]

The ictal EEG in frontal lobe epilepsy

Several factors contribute to the reduced yield of noninvasive EEG in FLE. These include the inaccessibility of much of the frontal lobes to surface electrodes, the rapid spread of seizures

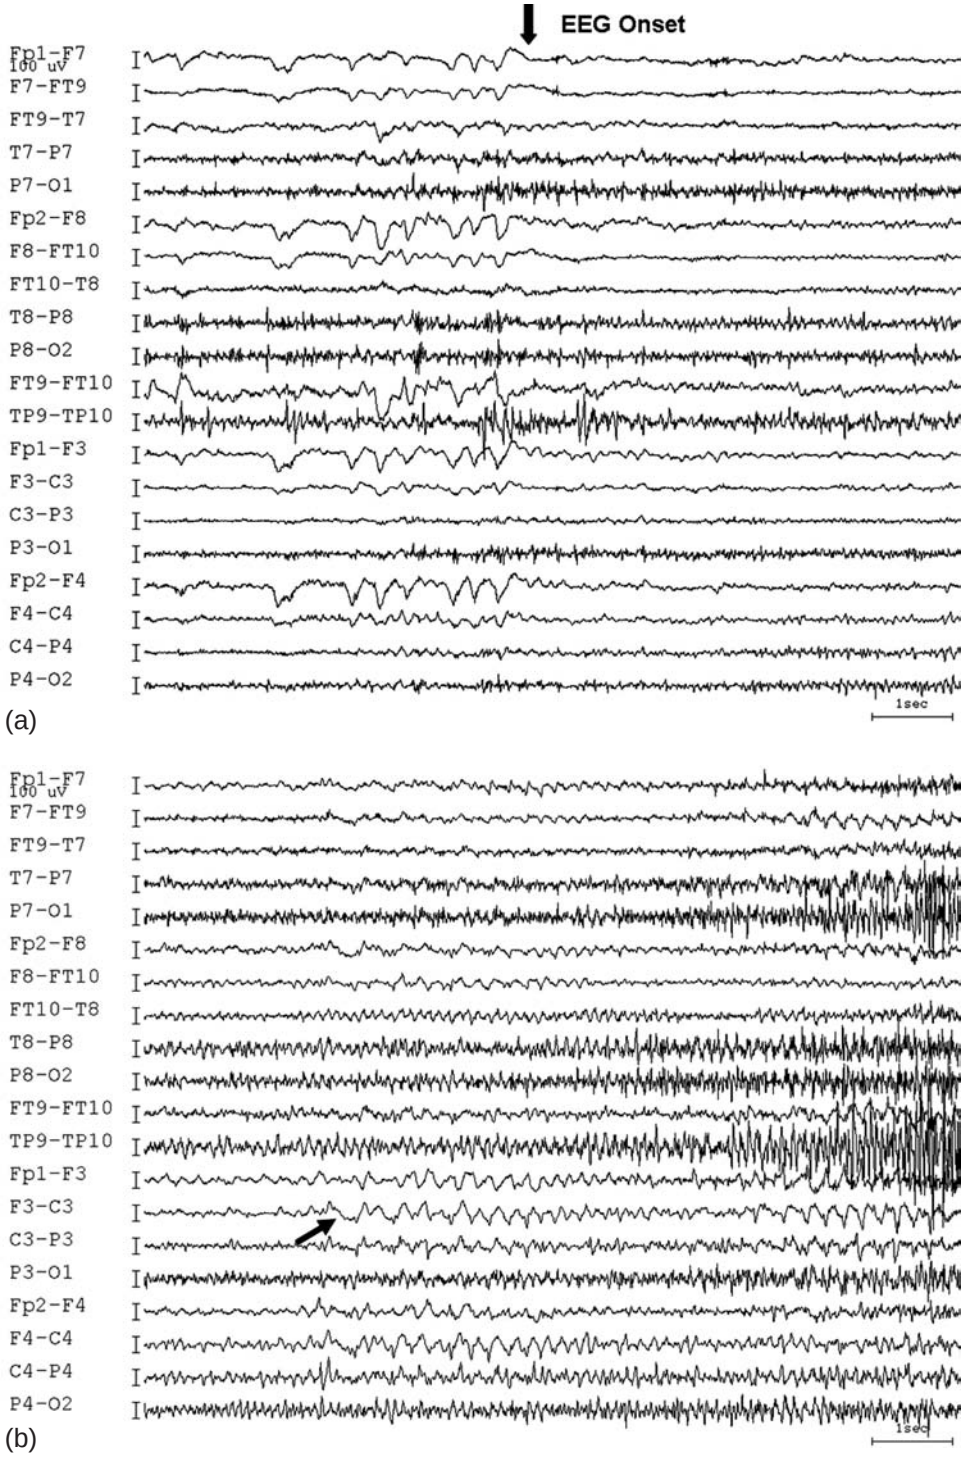

Figure 68.2 Two consecutive 10-second epochs of a seizure in a young woman with a right temporal pole malformation of cortical development and normal mesial temporal structures. EEG onset is characterized by diffuse suppression (a) evolving within seconds to a hemispheric alpha rhythm followed by contralateral rhythmic slowing (b, arrow). Habitual seizures were characterized by a behavioral arrest with oral and manual automatisms evolving rapidly (within 10 to 15 seconds) to a generalized motor seizure beginning several seconds prior to the EEG onset. These findings are characteristic of neocortical TLE.

within and outside the frontal lobe, secondary bilateral synchrony and bilateral epileptogenesis due to bifrontal injury, and variability in size of the seizure onset zone.[69]

Frontal lobe partial seizures are typically brief, beginning and ending abruptly, and are frequently characterized by excessive movement or tonic posturing resulting in obscuration of the EEG.[69–71] In our series of nearly 500 focal seizures, virtually all seizures that were entirely obscured or had no EEG change were of frontal lobe origin.[31] Ictal recordings were either obscured by muscle or failed to identify changes in 44% of 100 subjects with nocturnal FLE.[71] Similar findings are observed in children in whom the ictal EEG commonly shows bifrontal, bilateral independent, multifocal patterns or no identifiable change.[72] Approximately one-third of frontal lobe seizures are not accompanied by discernable rhythms[70,73,74] and another one-third are characterized by nonlateralized

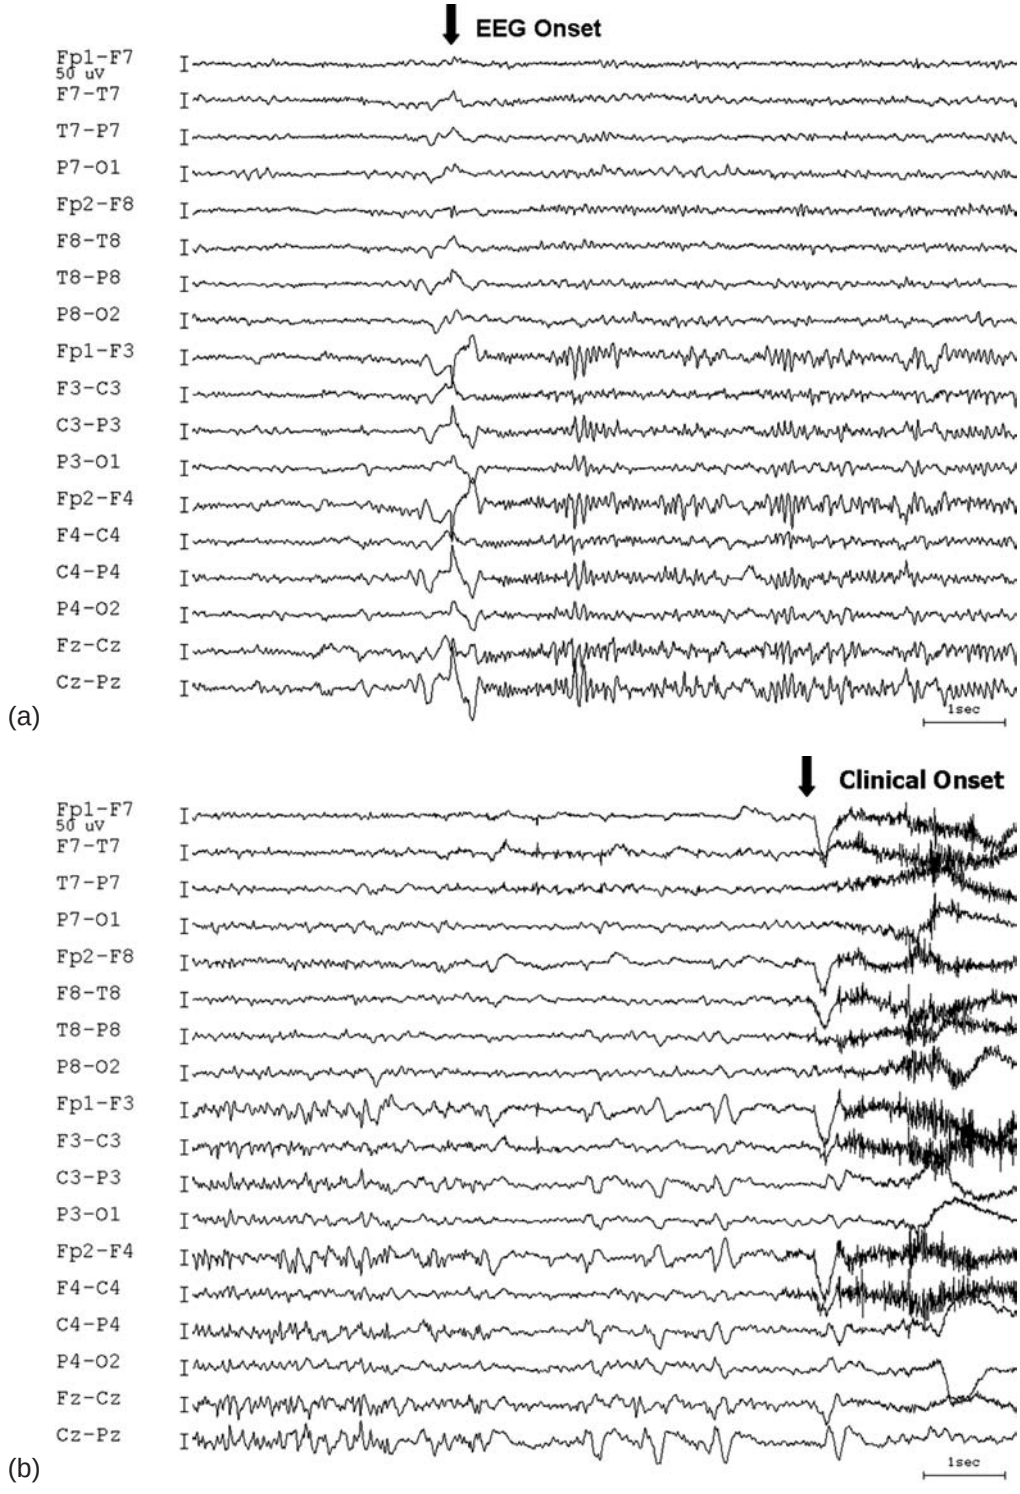

Figure 68.3 Left mesial frontal (SSMA) seizure characterized by brief axial tonic posturing with preserved awareness. The ictal EEG demonstrates a vertex spike (a, arrow) followed by bilateral frontocentral paroxysmal fast activity arising from sleep. Seizures occurred multiple times per night. The clinical onset (b, arrow) occurred 16 seconds later.

slowing, rhythmic activity or repetitive spiking.[69] Lateralized or localized patterns are seen in 33–50% of cases.[69–71,74–76] Mislocalization to the contralateral frontal or temporal region has been described.[70] In contrast to temporal seizures, frontal seizures are less likely to demonstrate focal patterns.[76]

Mesial frontal epilepsy and cingulate gyrus

Seizures arising from the mesial frontal lobe are particularly challenging to localize noninvasively. Supplementary sensorimotor area seizures are typically obscured by artifact of have no definite ictal pattern.[31,73,77] In fact, the clinical and electrographic manifestations are shorter than in seizures arising from virtually any other area.[31] Rhythmic alpha, beta, or theta at or adjacent to the midline was observed in 45% of cases in one small series.[73] In another series, the ictal onset most commonly consisted of generalized suppression or paroxysmal fast activity (Figure 68.3).[31] Rarely, the ictal pattern may be maximal over the contralateral hemisphere. Known as paradoxical lateralization, this phenomenon is observed when a generator is

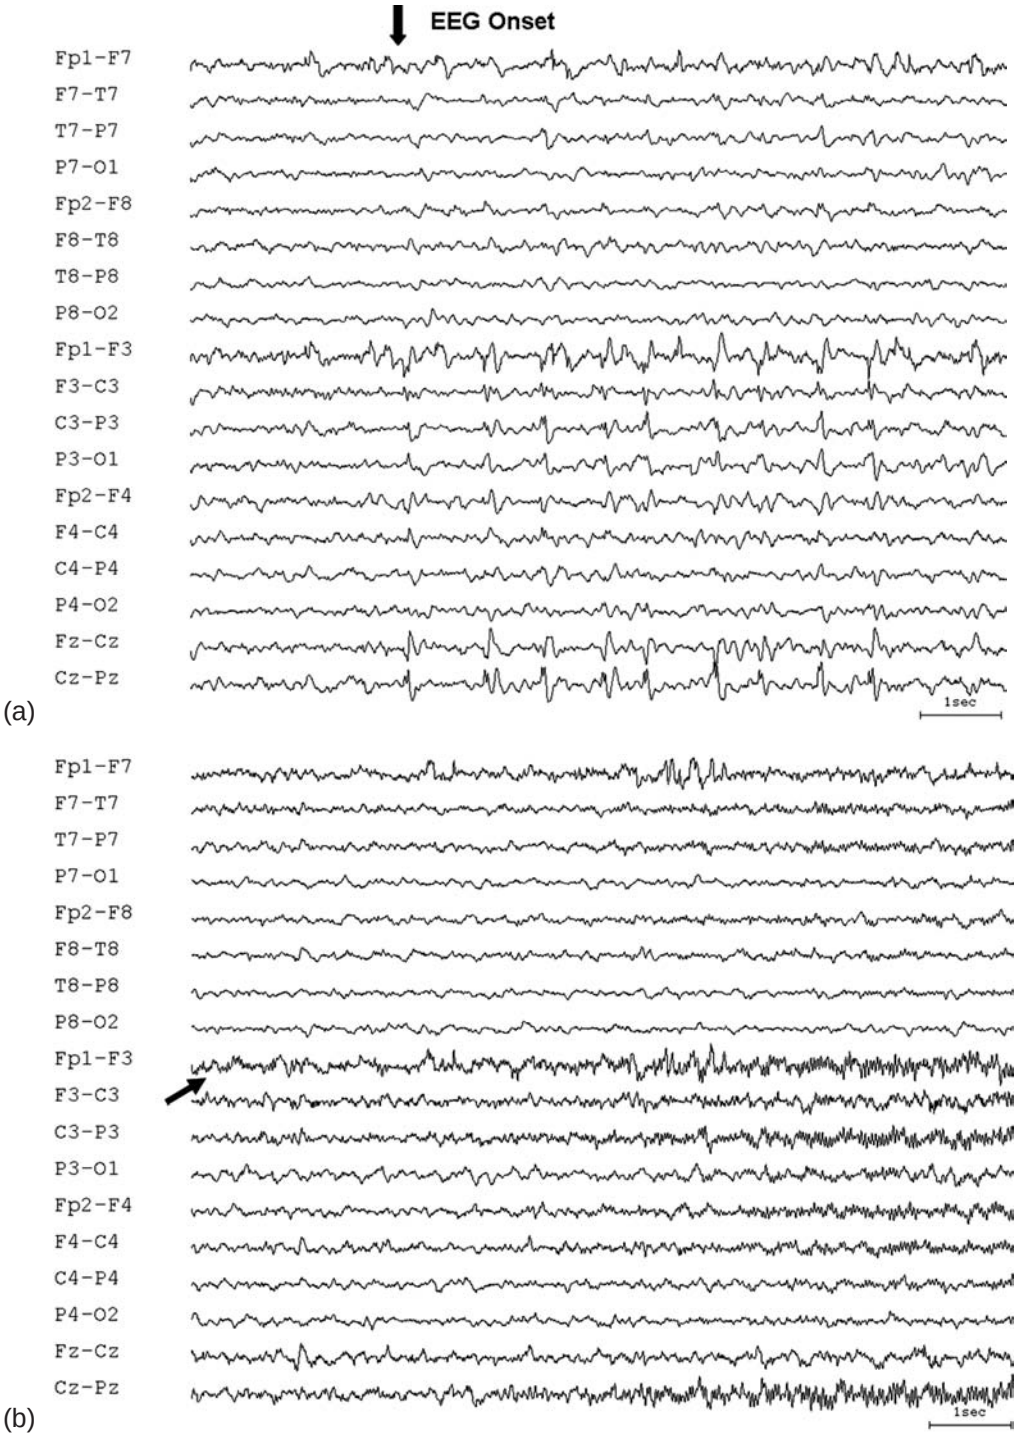

Figure 68.4 Repetitive spiking (a) evolving within 10 seconds to paroxysmal fast activity (b) in a seizure arising from the left dorsolateral frontal region due to a malformation of cortical development.

located within the interhemispheric fissure and produces an obliquely oriented dipole that projects to the opposite hemisphere.

Ictal EEG correlates of seizures arising from the cingulate gyrus have not been adequately detailed. In the only systematic study (see Chapter 44), ictal patterns obtained from seven patients with cingulate lesions on MRI were determined to be regional vertex in four cases; the remainder were nonlocalizable (two) or lateralized (one) to the lesioned hemisphere (personal communication, Eliana Garzon). In only three cases (43%), did the ictal EEG correctly predict the side of the lesion.

Basal frontal epilepsy

The noninvasive EEG is equally challenging in orbitofrontal epilepsy. Among four such cases seizure free following resective surgery in the literature, none had localized ictal recordings.[78–80]

Lateral convexity frontal epilepsy

Seizures arising from the lateral convexity are commonly localized (68% in one series) and typically consist of rhythmic alpha, beta or repetitive spiking (Figure 68.4).[31,77] Focal beta activity at the ictal onset was present in 26% of 54 patients with intractable lateral frontal seizures. Unlike lateralized ictal onsets,

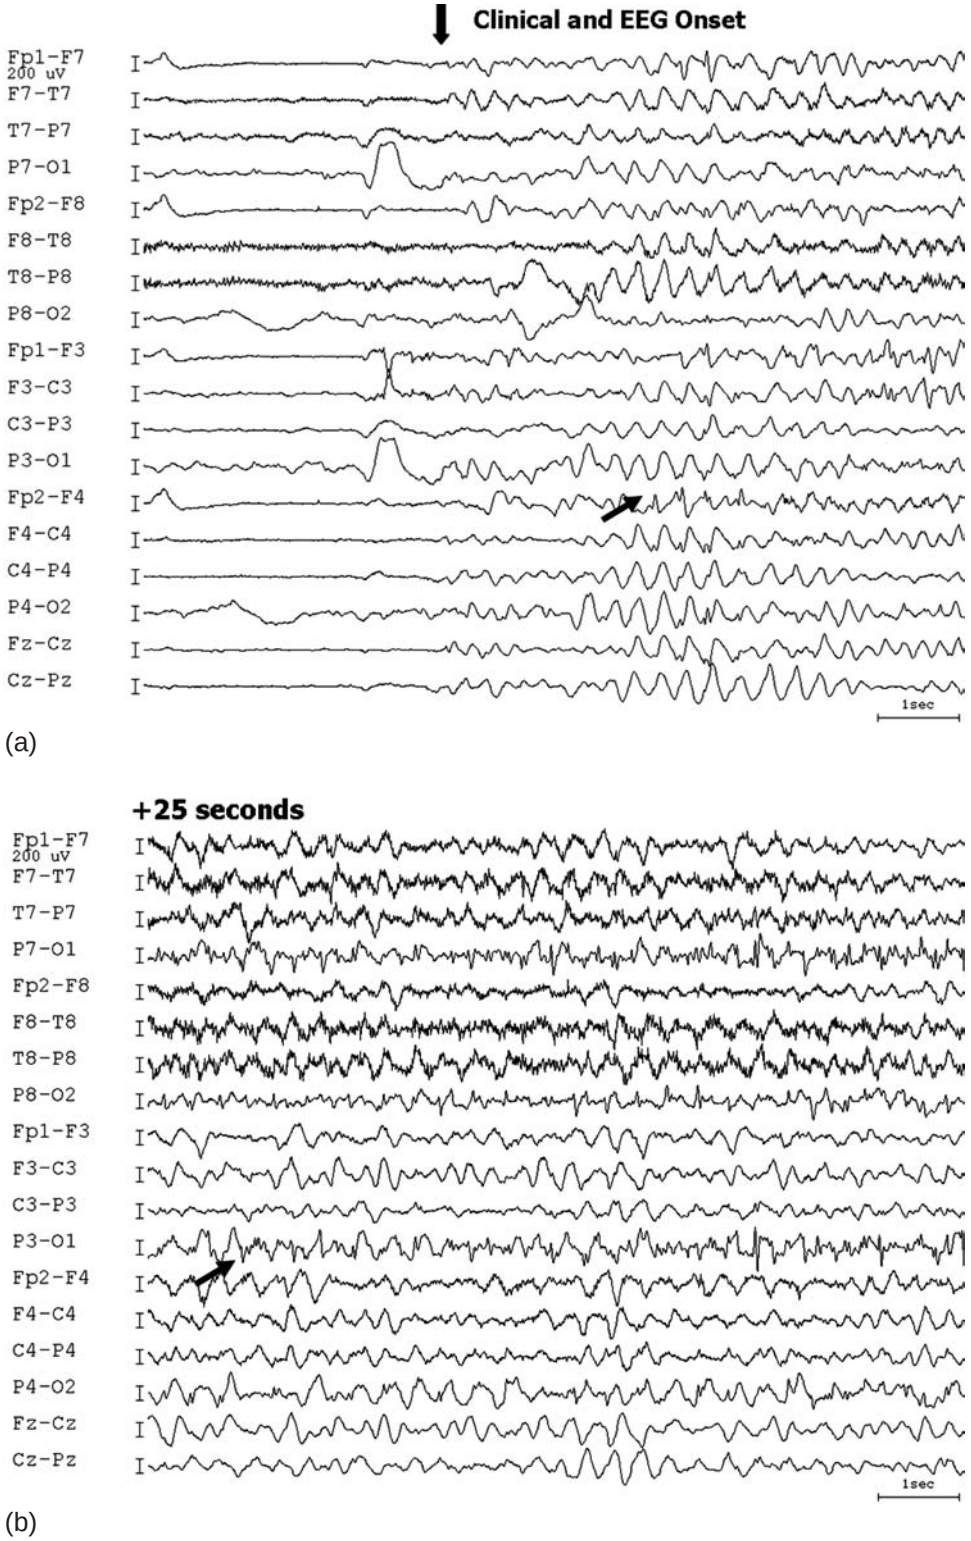

Figure 68.5 Two nonconsecutive epochs of a seizure arising from the left parieto-occipital region. The ictal onset (a) is characterized by rhythmic delta, initially maximal in the left hemisphere that becomes generalized within 2 seconds and evolves to spiking in the contralateral frontal region (arrow). The ictal recording otherwise remains nonlateralized until repetitive spiking (arrow) emerges from the area of the epileptogenic lesion 25 seconds after EEG onset (b).

focal beta at the onset was associated with an excellent surgical outcome independent of MRI findings and the location of the epileptogenic zone.[81]

The ictal EEG in parietal lobe epilepsy

Seizures arising from the parietal lobe usually present with lateralized somatosensory auras or nonspecific sensations evolving to asymmetrical tonic posturing, unilateral clonic activity or contralateral version when the ictal discharge propagates to the frontal region.[82] Temporal lobe activation produces alteration of awareness and automatisms.[82,83] Consequently, the ictal EEG varies with the pathway of propagation and may erroneously suggest temporal or frontal lobe origin. Simple partial seizures of parietal lobe origin frequently produce no discernable EEG change.[47,84] Other

seizure types are more commonly associated with diffuse suppression, nonlateralized rhythmic activity or lateralized changes.[82–84] In a series of 11 patients with lesional PLE, nonlateralized patterns were observed in eight patients; the EEG was localized in only one case.[82] Localized ictal onsets were recorded in 4 of 36 patients with nontumoral PLE, the majority of the others having lateralized patterns.[83] In another early series, lateralized patterns were observed in five of six patients.[85] These initial reports do not detail the location or extent of the epileptogenic zone. In a recent series of 14 seizure-free patients with lateral PLE based on MRI and/or invasive ictal recordings, the noninvasive ictal EEG localized the epileptogenic lobe in only five cases and was lateralized in one, nonlateralized in one, and falsely lateralized to frontal, temporal or occipital regions in seven cases.[86] The Cleveland Clinic series findings were more favorable, as 55% of seizures from seven patients with lateral parietal lesions seizure free following lesionectomy had localized ictal onsets and 62% of recordings were deemed localized.[31] However, mislocalization to the frontal or temporal region was observed in 16% of seizures, and 54% of seizures had independent, bilateral rhythms, highlighting the limitations of noninvasive recordings in PLE (Figure 68.5).

The ictal EEG in occipital lobe epilepsy

As in the case with PLE, the clinical and ictal electrographic manifestations of occipital lobe seizures reflect different patterns of propagation.[87,88] Invasive recordings demon-strate propagation from the occipital region to the mesial temporal structures, the supplementary motor area or dorsolateral frontal convexity before generalization.[88] Infrasylvian spread to the temporal lobe produces alteration of awareness and automatisms. Suprasylvian spread to the mesial frontal lobe produces asymmetric tonic posturing, while propagation laterally results in focal motor or sensory seizures.

Ictal recordings show diffuse suppression or rhythmic activity that is usually generalized but may be lateralized or maximal over the temporo-occipital region.[87,88] Seizures localized to the occipito-temporal region were observed in approximately 50% of cases, however, localization was restricted to the occipital region in less than 20% of case.[87,89] Among six patients seizure free after resective surgery in the Cleveland Clinic series, nearly 70% of seizures had localizing features.[31] However the ictal onset was typically generalized; only 21% of seizures were localized to the occipital region at the onset. The time from EEG onset to appearance of a localized rhythm was longer than seizures arising from any other area. Mislocalization was observed in 28% of seizures; in most cases, occipital seizures were mislateralized to the contralateral occipital lobe, although ipsilateral fronto-temporal ictal patterns were also observed. Even more favorable EEG characteristics were observed in another series of 16 patients with occipital epilepsy seizure free following resective surgery.[90] The ictal EEG was localized in 13 (81%) of 16 cases, and lateralized, nonlateralized and mislateralized in one case each, although the location of lesions within the occipital lobe was not provided.

A recent study was the first to compare the clinical and electrographic manifestations of seizures arising from the lateral and mesial occipital surfaces.[91] Among 41 cases, seizures were correctly lateralized in 20 (49%) and mislateralized in one (2%). The majority of the first five recorded seizures were correctly localized in four (36%) out of 11 patients with laterally originating occipital seizures versus none of 20 patients with mesial occipital seizures. These findings support the widespread and variable propagation of occipital lobe seizures and highlight the limitations of ictal EEG, particularly in epilepsies arising from deep or interhemispheric structures.

Conclusion

Noninvasive EEG remains extremely useful in the localization of focal seizures. However ictal recordings cannot precisely delineate the seizure onset zone. Very little is known about the yield of noninvasive ictal recordings in epilepsies arising from areas such as the orbitofrontal cortex, cingulate gyrus and mesial occipital region. However, anecdotally, it would seem that the value of ictal recordings is limited in these cases. As neuroimaging continues to improve and the need for cost containment increases, the role of noninvasive ictal recordings may need to be redefined.

69 Indications for invasive electroencephalography evaluations

SR Sinha, NE Crone, and RP Lesser

Introduction

At the dawn of the modern era of epilepsy surgery in the early and middle portions of the 20th century, acute invasive intracranial recordings were commonly used to determine the extent of resection of epileptogenic tissue.[1–3] These recordings typically provided information about interictal epileptiform discharges and only rarely about ictal activity. Thus, they were, and are, helpful in defining the 'irritative zone', the region of cortex that generates interictal epileptiform discharges[4]; however, they usually cannot define the 'epileptogenic zone', the region of cortex that can generate epileptic seizures. With modern advances in imaging techniques (especially MRI scanning) and the use of scalp video-EEG to record actual ictal EEG data, acute invasive intracranial recordings have become a much less important part of the evaluation of patients for epilepsy surgery. However, there are many situations in which chronic invasive intracranial recordings using subdural or depth electrodes are essential for the optimal management of a patient.[5,6] This chapter will discuss the indications for invasive EEG evaluations in the modern era, and will focus on the use of subdural electrodes. Details of the specific techniques are covered in other chapters of this book. Some illustrative examples are given at the end of this chapter.

Selection of patients for invasive EEG recording

A substantial fraction of patients with epilepsy are intractable to treatment with antiepileptic drugs, either due to lack of efficacy or intolerable side effects. For patients with partial-onset seizures who continue to have seizures in spite of adequate trials of two or more appropriate antiepileptic medications, trials of additional medications, even in combination, offer little chance of obtaining seizure freedom.[7] In contrast, for appropriate patients with partial-onset seizures, surgical resection of the seizure focus can offer significant improvement in their seizure control. Beyond basic evaluations such as anatomical (MRI) and functional imaging studies (i.e., PET scans or MR spectroscopy) and interictal EEG recording, presurgical evaluation generally requires ictal video-EEG recording. In situations where the localization of the seizure focus by ictal scalp-EEG and ictal clinical semiology are consistent with a known lesion on imaging studies, surgical resection can sometimes be performed without additional testing (Table 69.1, Figure 69.1a). An additional requirement is that the lesion be far removed from eloquent cortical areas (such as motor cortex or language areas). A common example is unilateral mesial temporal sclerosis on MRI with clinical and EEG findings consistent with a focus in that temporal lobe.[8] Another example is a patient with a known tumor in the region of ictal-EEG onset. Such patients can often proceed to surgical resection without invasive EEG monitoring[9]. In fact these cases are often the ones in which surgery is most successful in controlling seizures.

However, there are many situations in which noninvasive testing is inadequate for proceeding to surgical resection. Jayakar proposed that relative indications for invasive EEG recording include normal imaging, extratemporal location, discordant noninvasive data, proximity to eloquent cortex, tuberous sclerosis, and cortical dysplasia.[10] In broader terms, any situation where the criteria in Table 69.1 are not met should be considered for possible invasive EEG monitoring. These include situations where the ictal scalp-EEG is nonlateralizing (see Case 1) or lateralizing but nonlocalizing (see Case 2). Walczak *et al.* found that scalp-EEG lateralized the epileptogenic region to one side in 47–65% of extratemporal cases and 76–83% of temporal lobe cases.[11] Other authors have reported that scalp EEG was localizing in as few as 42% of cases with a neocortical onset and may falsely localize the site of onset in 4.5–9.9% of cases.[12] The use of additional scalp electrodes beyond the standard international 10–20 system, may improve localization.[13] Even with a localizing scalp-EEG, invasive recording is often necessary in cases where there is no corresponding lesion on imaging to guide the resection (Figure 69.1b). Invasive recording is essential in situations where noninvasive tests are discordant. One example of this situation would be when the ictal EEG pattern does not co-localize with an obvious imaging abnormality (see Case 5).

Lastly, invasive recording can be useful in situations where the ictal pattern or lesion is close to eloquent cortex, e.g., motor cortex or language areas (see Cases 3 and 4). Once the site of seizure onset has been determined, using either invasive or noninvasive means, one must consider the functional consequences of resecting the presumed epileptogenic tissue. This is based on several pieces of information, including normal functional neuroanatomy. In addition tests such as the intracarotid sodium amobarbital (Wada) test are useful

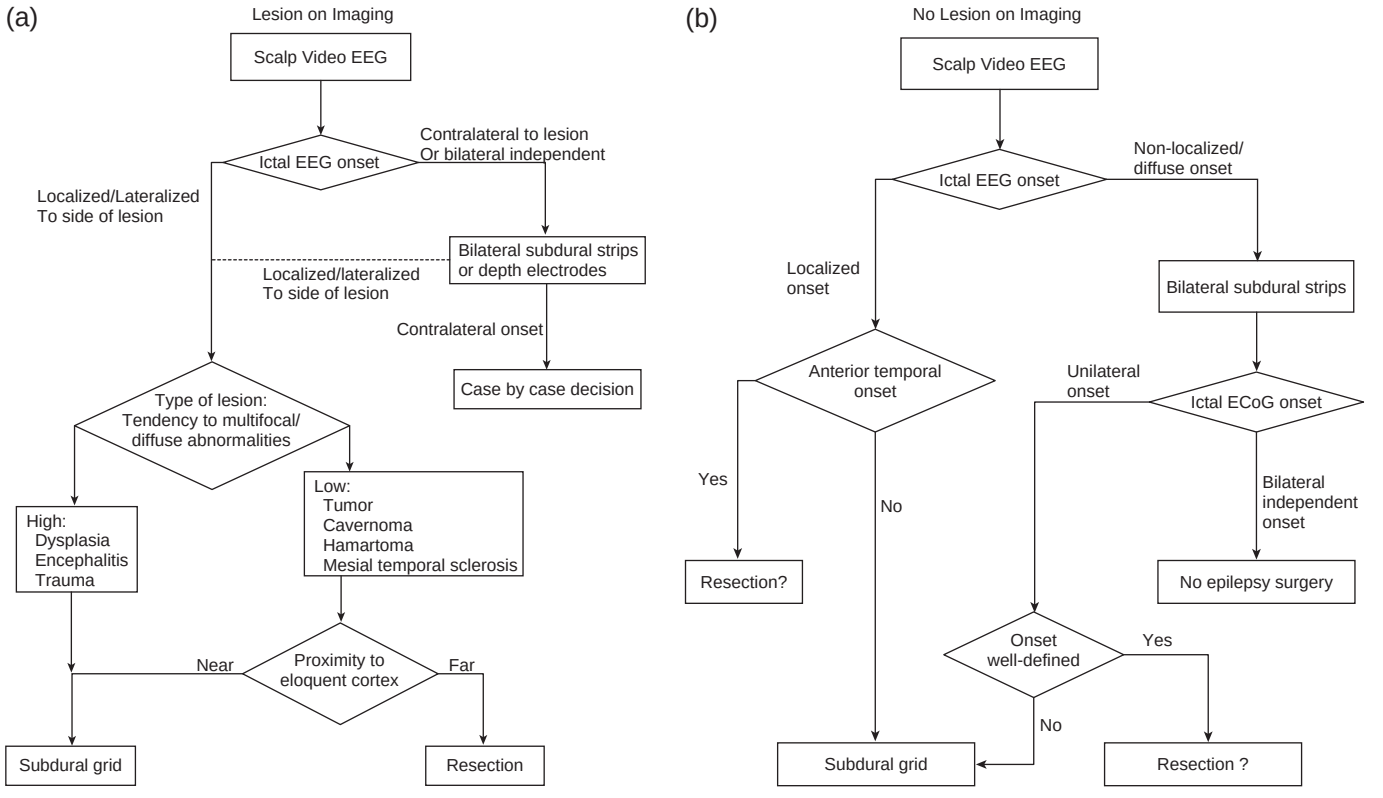

Figure 69.1 Flowcharts demonstrating the decision-making process involved in determining if a particular patient needs invasive EEG monitoring. a. Suspected epileptogenic lesion on imaging studies. b. No epileptogenic lesion on imaging studies. See text for more details.

for lateralization of language[14] and memory.[15] Functional MRI and magnetoencephalography are also being increasingly used for localization of language, sensation, movement, and memory. However, at present cortical mapping using implanted subdural electrodes provides a unique opportunity to precisely map the relationship between the epileptogenic zone and functional areas.[16,17] Furthermore, because the same electrodes are used for both cortical mapping and mapping the epileptogenic zone, the precise relationship between eloquent cortex and the epileptogenic zone can be determined. Resection can be planned using the subdural electrodes as landmarks (see Case 3). Also, unlike mapping with acute invasive electrodes during surgery, this type of mapping allows sufficient time for confirming results and mapping large areas, including those outside the immediate exposure of the craniotomy. One of the major disadvantages of stimulation is the possibility of provoking epileptiform discharges that can confound the results of testing and even provoke clinical seizures[18]; for example, see Case 4.

In some situations in which the scalp-EEG adequately identifies a seizure focus that has a corresponding lesion on imaging studies invasive monitoring might still be appropriate. The most common examples are situations in which the seizures are associated with multifocal damage to the brain or in which the epileptogenic zone is larger than the abnormality apparent on imaging studies. These situations include meningoencephalitis, tuberous sclerosis, head trauma, cortical malformations. For example, with malformations of cortical development or focal cortical dysplasias, the epileptogenic area is often larger than the lesion visualized on imaging studies and possibly extends well beyond the histological lesion.[19–21] In such cases, mapping of the 'epileptogenic zone' using invasive EEG might be important for successful surgery even when scalp EEG, clinical semiology and imaging are in rough agreement.

Some have proposed the use of direct stimulation of intracranial electrodes to localize seizure foci. Some studies have suggested that the threshold for provoking clinical seizures and/or afterdischarges is lower near the seizure focus. However, many factors beyond the intrinsic excitability of a piece of tissue determine its response to electrical stimulation. This includes the quality of contact between the electrode and the cortex (e.g., intervening cerebrospinal fluid, hematoma, or meninges), the orientation of the cortex in relationship to the electrode(s), and the background state of the brain at the time of stimulation (e.g., awake vs. asleep, attentive vs. inattentive). In addition, there is significant variability in thresholds at

Table 69.1 Requirements for proceeding to surgery without invasive recording

1. Well-localized ictal-EEG.
2. Semiology consistent with presumed seizure focus.
3. Known lesion by imaging studies at site of seizure focus.
4. Absence of other candidate intracranial lesions.
5. Seizure focus remote from known eloquent cortex.
6. Presumed etiology of epilepsy does not predispose to diffuse or multiple foci.

different points within a small area and at the same point during different trials.[18] Some have suggested that electrical stimulation could be used to provoke afterdischarges/seizures to confirm the location of the seizure focus after it has been mapped by other means[22]; however, we have not found this to be reliable.

Advantages of invasive EEG recordings

Invasive recordings offer many advantages compared to scalp-EEG. These include improved spatial resolution, sensitivity and frequency range, and decreased noise from the environment and from the patient (e.g., EKG and muscle artifact). It has been estimated that an interictal spike needs to activate >6 cm^2 of contiguous cortex to be detected by a scalp electrode.[23] Thus, many epileptiform discharges that are apparent on intracranial recordings are missed on scalp EEG.[24,25] The same epileptiform discharge recorded with subdural electrodes will be approximately an order of magnitude larger in amplitude compared to scalp-EEG.[26] In addition to increased sensitivity, intracranial EEG also broadens the frequency range that can be recorded. The improved frequency range is especially important for neocortical seizure foci, where the ictal pattern often consists of beta and gamma, or higher, frequencies. Higher frequencies are preferentially attenuated by the skull and scalp and are additionally obscured by muscle artifact. Ultrahigh frequencies, which may prove to be useful for seizure localization,[27] can also be recorded with invasive techniques but not with scalp-EEG. Another advantage of invasive recordings is the ability to access structures that are not well evaluated with scalp EEG. These include cortical areas such as the orbitofrontal portion of the frontal lobe, basal portions of the temporal and occipital lobe and interhemispheric portions of the frontal, parietal or occipital lobes (see Case 4). They also include deep structures such as the mesial temporal lobe, periventricular nodular heterotopia,[28] and other deep lesions.

Disadvantages of invasive EEG recording

Beyond the basic risks related to undergoing anesthesia for a surgical procedure, invasive recordings also pose a risk of hemorrhage, infection and cerebral edema. Complication rates are highly variable and depend on many factors including the expertise/experience of the surgeon,[29] the type of procedure, the number of electrodes being used, and the length of implantation. For example, in one series, complications were significantly more likely in cases with >60 electrodes, >10 days of implantation, older age of patient, and left-sided procedures.[30] Complication rates also appear to be declining with time, likely as a result of changes in electrode design, better aseptic techniques, and decreased implantation times.[31] These factors help explain the broad range of complication rates in the published literature. For subdural grid electrodes, infection rates range between 4–14% and bleeding rates are between 3–8%.[30,32,33] Infarction and significant cerebral edema are much rarer. For subdural strip electrodes placed through burr holes, complication rates are generally much lower, 1–4%,[33–35] and primarily involve infection and hematoma. Cerebral edema is rarer, but more likely when large numbers and/or bilateral strips are used. With depth electrodes, the main complication is hemorrhage, with rates in the 1–4% range.[36]

Another important disadvantage of invasive recordings is their limited coverage. Unlike scalp recordings, which typically provide a sampling of all accessible cortical regions, invasive recordings only cover specific areas.[37] Thus, if the actual seizure focus is covered by an electrode, than it will be correctly identified; however, if it is not, then the apparent seizure focus will appear to be the first location that is covered by an electrode. However, this could be a site of seizure spread, not seizure onset. An extreme example would be a situation where the seizure focus is actually in the right hemisphere but subdural electrodes are placed only over the left hemisphere (based on falsely lateralizing imaging and/or scalp EEG recordings). In one series of patients, poor sampling of the epileptogenic zone was felt to be responsible for a failure to localize the seizure focus in 13 out of 110 cases.[38] Thus, great care needs to be taken in evaluating all the noninvasive data to plan placement of the invasive electrodes. Sometimes, this concern also forces the use of larger numbers of invasive electrodes than would be necessary otherwise, i.e. if the noninvasive data are unclear or discordant, more electrodes may be necessary to cover the possible areas of seizure onset.

Another disadvantage of invasive electrodes is the additional cost incurred, which includes the surgical procedures, the electrodes themselves, and a longer hospital stay, typically about 7–10 days and including 5–7 days of video EEG monitoring.

Case examples

Case 1: Scalp EEG is nonlateralizing

This patient was a 33-year-old right-handed man with diabetes mellitus type I and hypothyroidism and seizures since age 29. Seizures began with a feeling of *déjà vu*, and tingling in the arms, and typically progressed to staring, confusion and oral automatisms. Seizures had responded only partially to trials of several medications. Physical exam was significant for some deficits in short-term memory but was otherwise nonfocal. MRI of the brain and PET scan were normal. Previous EEGs had shown some spikes and focal slowing in the left temporal regions. Video-EEG monitoring with scalp-EEG recorded eight typical seizures; two had their onset in left temporal-frontal head regions; the others were nonlocalizing. In the absence of any abnormality on imaging studies, it was felt that the scalp-EEG data was not sufficient to lateralize the patient's seizure focus. Therefore, bilateral subdural strips were placed through burr holes over the frontal and temporal lobes (Figure 69.2a). On this admission, all clinical seizures showed a left temporal-frontal onset (a more precise localization was not possible with the limited sampling provided by strips). In addition, four electrographic seizures, without obvious clinical accompaniment, were also recorded; three

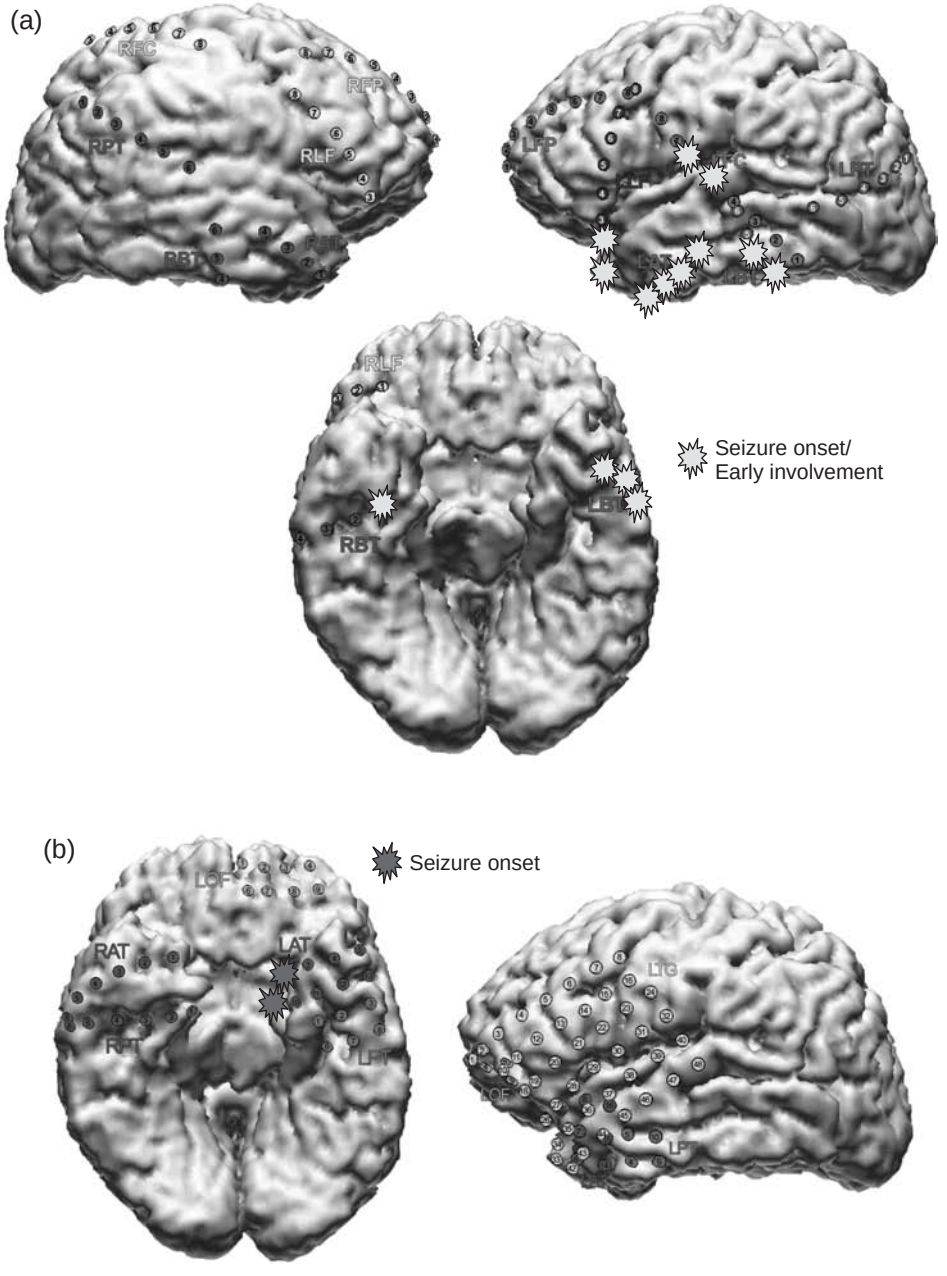

Figure 69.2 See case 1 for details. a. Reconstructed images based on preoperative MRI of the brain and postoperative 3D head CT showing the locations of subdural strips used to lateralize the patient's seizures. The electrodes where seizures appeared to start are indicated. Note: due to the limited coverage obtained with subdural strip electrodes, it is usually not possible to distinguish between the true seizure onset and areas which may only be involved early in the seizure. b. Reconstructed images showing the grids and subdural strips used to localize the patient's seizures. The electrodes where the seizures started are indicated.

originated from the left temporal-frontal region; however, the fourth suggested a possible right-sided focus. Of note, the subdural strips covering the right temporal lobe were not symmetric with those on the left in the anteromesial portion of the temporal lobe (Figure 69.2a, inferior view). Thus, while the majority of the evidence suggested a left temporal-frontal seizure focus, a right temporal focus with rapid spread to the left might have been missed.

In the next step, the patient had extensive subdural grids placed over the left temporal and frontal lobes, including the orbito-frontal surface and the mesial and basal portion of the temporal lobes (Figure 69.2b). Two subdural strips were placed over the mesial/basal portion of the right temporal lobe through a burr hole. On this admission, all seizures originated from the most mesial and anterior contacts over the left temporal lobe. At the completion of this recording, the patient underwent a standard left temporal lobectomy, including the amygdala and hippocampus. As a result, the patient had marked improvement in his seizures.

This case provides a good example of the utility and limitations of invasive EEG recording. Without intracranial electrodes, it would not have been possible to localize the patient's seizure focus and provide the opportunity for surgical resection. However, this case also points out the limited coverage provided by intracranial electrodes. A larger number of electrodes could have been placed during the first

surgical procedure, but at greater risk to the patient. Often, subdural strips, as in the first procedure, are adequate to localize the seizure focus. However, this case also illustrates the difficulties in accurate placement of subdural strips through burr holes.

Case 2: Scalp EEG is lateralizing but nonlocalizing

The patient was a 29-year-old right-handed man with a history of meningoencephalitis at age 6 and seizures since age 9. His seizures consisted of loss of awareness, oral automatisms and drooling. His seizures occurred approximately once a month, in spite of trials of multiple medications. Physical examination was significant for loss of vision in the left eye only. MRI of the brain was normal. A PET scan showed subtle left temporal hypometabolism. Video-EEG with scalp electrodes showed diffuse semirhythmical slowing in the left fronto-temporal region followed by build-up of rhythmic activity in the temporal-frontal head regions, maximum in the temporal regions. Thus, scalp-EEG was lateralizing but not localizing. Therefore, the patient underwent placement of extensive subdural grid electrodes covering the left temporal and frontal lobes, including the orbitofrontal region and the mesial and basal aspects of the temporal lobe (Figure 69.3a). With these electrodes, the seizures appeared to originate from the most medial and anterior contacts on the temporal lobe (Figure 69.3b). The patient underwent a standard left anterior temporal lobectomy and showed marked improvement in the control of his seizures. This case illustrates the situation of a nonlesional patient in whom the scalp EEG was lateralizing but not localizing and intracranial electrodes were necessary for precise localization.

Case 3: Scalp EEG localizes the epileptogenic region to be near eloquent cortex

The patient was a 34-year-old right-handed woman with a history of intractable complex-partial seizures (staring and decreased responsiveness) that remitted for several years after resection of a left posterior temporal dysembryoplastic neuroepithelial tumor. However, her seizures subsequently returned including some secondarily generalized tonic-clonic

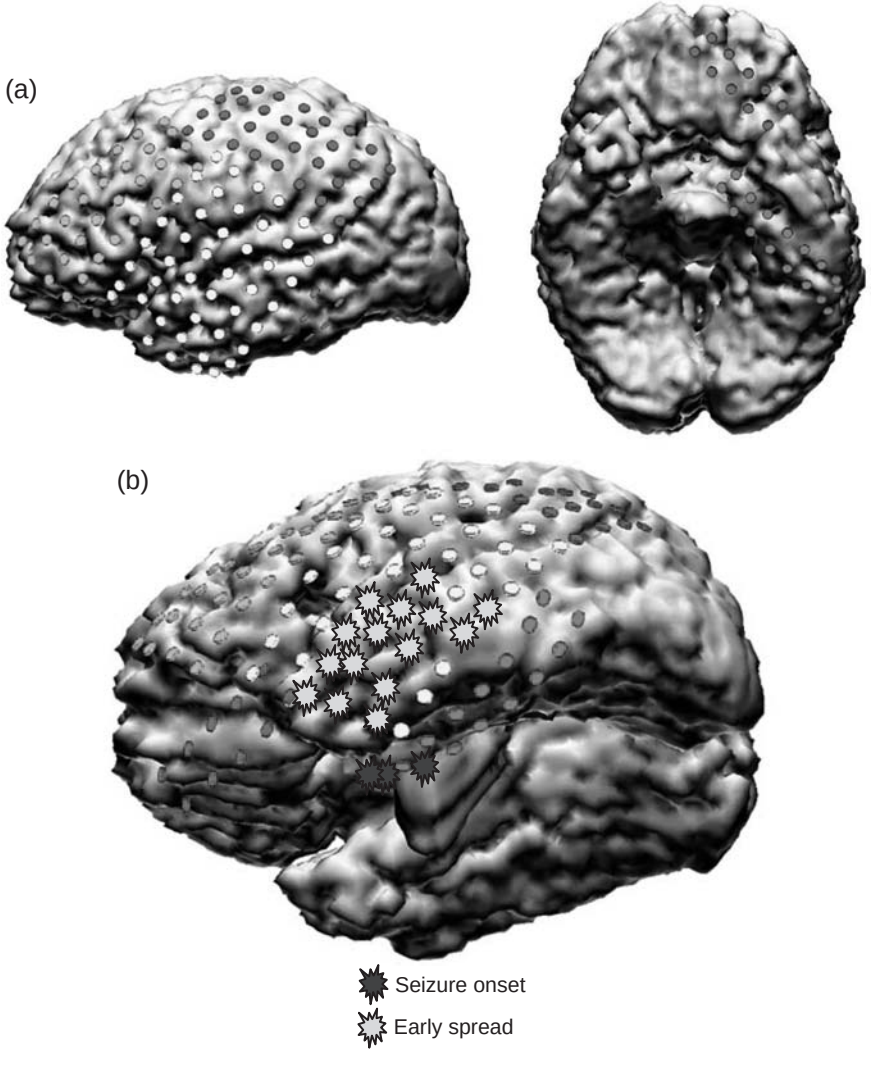

Figure 69.3 See Case 2 for details. a. Reconstructed images showing location of subdural grids (lateral and inferior view). b. Reconstructed image (inferior oblique view) showing the sites where the patient's seizures started and those involved very early in the seizure.

seizures and episodes of complex-partial status epilepticus, in spite of continued use of multiple antiepileptic medications. Video-EEG monitoring with scalp electrodes confirmed that the seizures still originated from the left temporal region. MRI of the brain showed no evidence of residual or recurrent tumor. Intracarotid sodium amobarbital test (Wada test) had previously shown that the patient's left hemisphere was dominant for language. Due to the proximity of eloquent cortical areas to the presumed area of seizure focus, a large subdural electrode array was placed over the posterior portion of the left temporal lobe (extending up to the frontal and parietal lobes as well) with some additional strips wrapping around the inferior aspect of the temporal lobe (Figure 69.4a). Several clinical seizures were recorded and appeared to originate from the lateral contacts on the left temporal lobe. In addition, there were electrographic seizures arising from contacts on the lateral aspect of the basal temporal-occipital cortex. When language function was mapped using electrical stimulation of these same electrodes (Figure 69.4b), some language areas were found to overlap with contacts involved in the electrographic seizures. Thus, the resection margins (Figure 69.4a, dashed lines) were selected to preserve all areas with significant language function, even though this left some presumably epileptogenic areas intact. After this resection, the patient had some limited improvement in her seizures; her language function was entirely preserved. This case illustrates the situation in which both scalp EEG and a known lesion localize the epileptogenic region near eloquent cortical areas and intracranial electrodes are used both for precise seizure localization and for functional mapping. It also illustrates the importance of removing the entire 'epileptogenic zone' for seizure control.

Case 4: Lesion is in a location not well-surveyed by scalp EEG and near eloquent cortex

The patient was a 19-year-old right-handed woman with seizures since age 14. Seizures consisted of flashing lights in the left inferior quadrant of the visual field followed by pounding headaches. These occurred 4–5 times per week in spite of trials of multiple antiepileptic agents. MRI of the brain revealed a calcified lesion in the right occipital region; cerebral angiography was unremarkable (Figure 69.5a). Scalp EEG revealed seizures originating in the right occipital region, near electrode O2. Because of the deep midline location of the lesion and the proximity to primary visual cortex, it was felt that scalp-EEG was not sufficient to precisely delineate the epileptogenic zone, and differentiate it from eloquent cortex. Thus, the patient underwent invasive EEG monitoring. A large grid was placed over the right occipital region and a smaller grid was placed in the interhemispheric fissure between the two occipital lobes (Figure 69.5b). Both interictal and ictal recordings showed that the seizure focus was limited to the superior contacts of the interhemispheric grid (Figure 69.5c). This was superior

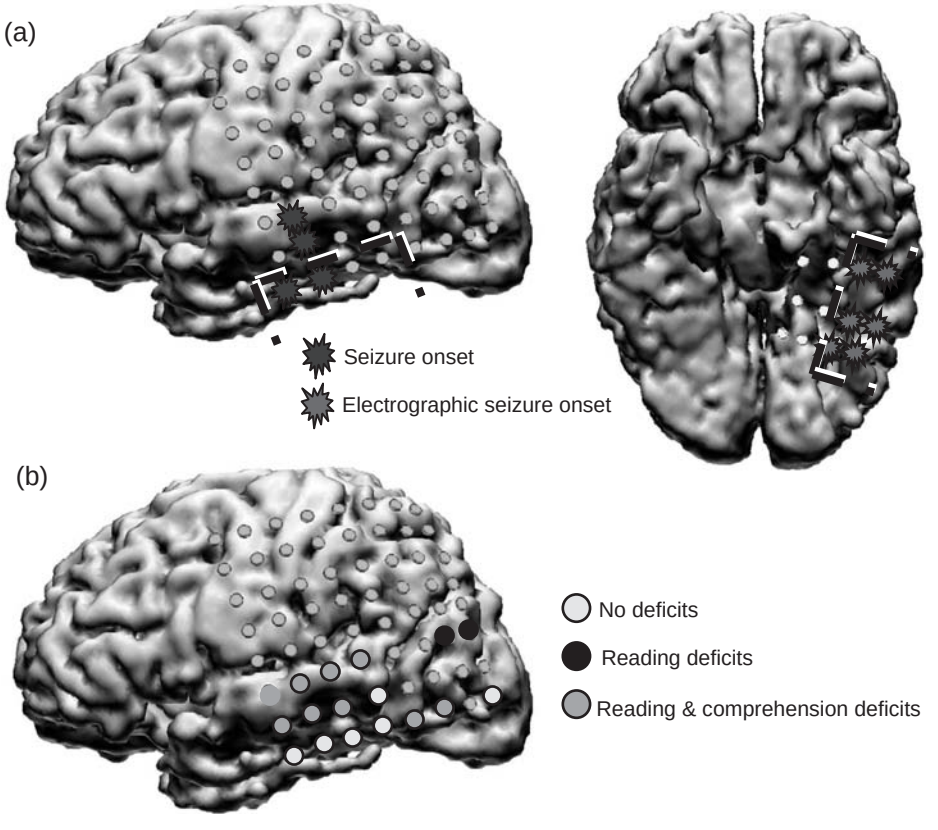

Figure 69.4 See Case 3 for details. a. Reconstructed images showing location of grids along with the site of seizure onset (both clinical seizures, blue, and electrographic seizures without associated clinical activity, red). The dashed lines represent the margins of the planned resection. This based on consideration of the site of seizure onset and the results of cortical mapping shown in b. b. Results of cortical mapping of language function.

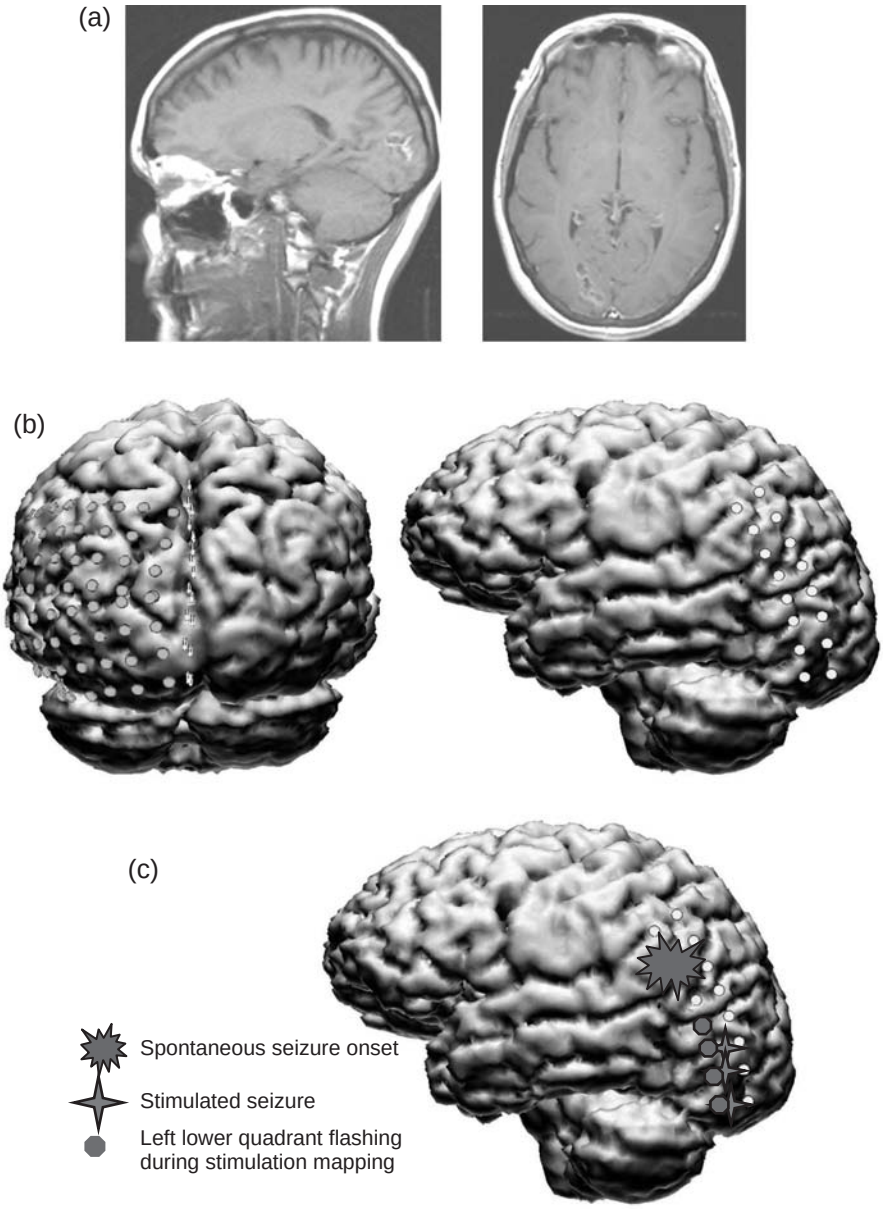

Figure 69.5 See Case 4 for details. a. Sagittal and axial T1-weighted MRI showing location of calcified lesion in the midline of the right occipital lobe. b. Reconstructed images showing the grids placed in the interhemispheric fissure between the occipital lobes and on the lateral aspect of the occipital and parietal lobes. c. Reconstructed image showing site of seizure onset along with results of cortical mapping and sites where stimulation provoked seizures.

to the presumed primary visual cortex based on MRI and cortical stimulation mapping. Thus the resection was tailored to remove the known lesion and the region covered by these contacts, with the goal of sparing vision. Note the occurrence of electrical stimulus evoked seizures from regions that were not the focus for the spontaneous seizures. After surgery, the patient continued to have occasional simple partial seizures consisting of flashing lights and headaches. She also had an irregular inferior quadrant visual defect in the left hemifield, but most of her vision on that side was preserved. In this case, although the scalp-EEG suggested a seizure focus near a known imaging abnormality, invasive EEG was necessary for two reasons. First, the abnormality was deep to the surface of the brain in an area not easily assessed by scalp-EEG. Second, the abnormality was near eloquent cortex.

Case 5: Scalp-EEG and imaging are discordant

The patient was a 22-year-old right-handed man with seizures since age 21. Seizures consisted of staring, inappropriate answers to questions, automatisms, and excessive drooling with no recollection of the event. Seizures continued every 1–2 months in spite of multiple medications. MRI of the brain showed a 1 cm lesion in the posterior portion of the cingulate gyrus on the right (Figure 69.6a), which had not changed for over 6 months. By MRI plus magnetic resonance spectroscopy, the lesion appeared to be a low-grade tumor. Routine EEGs were normal. With video/EEG with scalp electrodes, interictal spike- and slow-wave complexes were seen over the anterior to middle portion of the right temporal lobe. With his typical seizures, right temporal activity was noted at onset. Even though scalp-ictal and interictal-EEG and clinical semiology suggested seizure

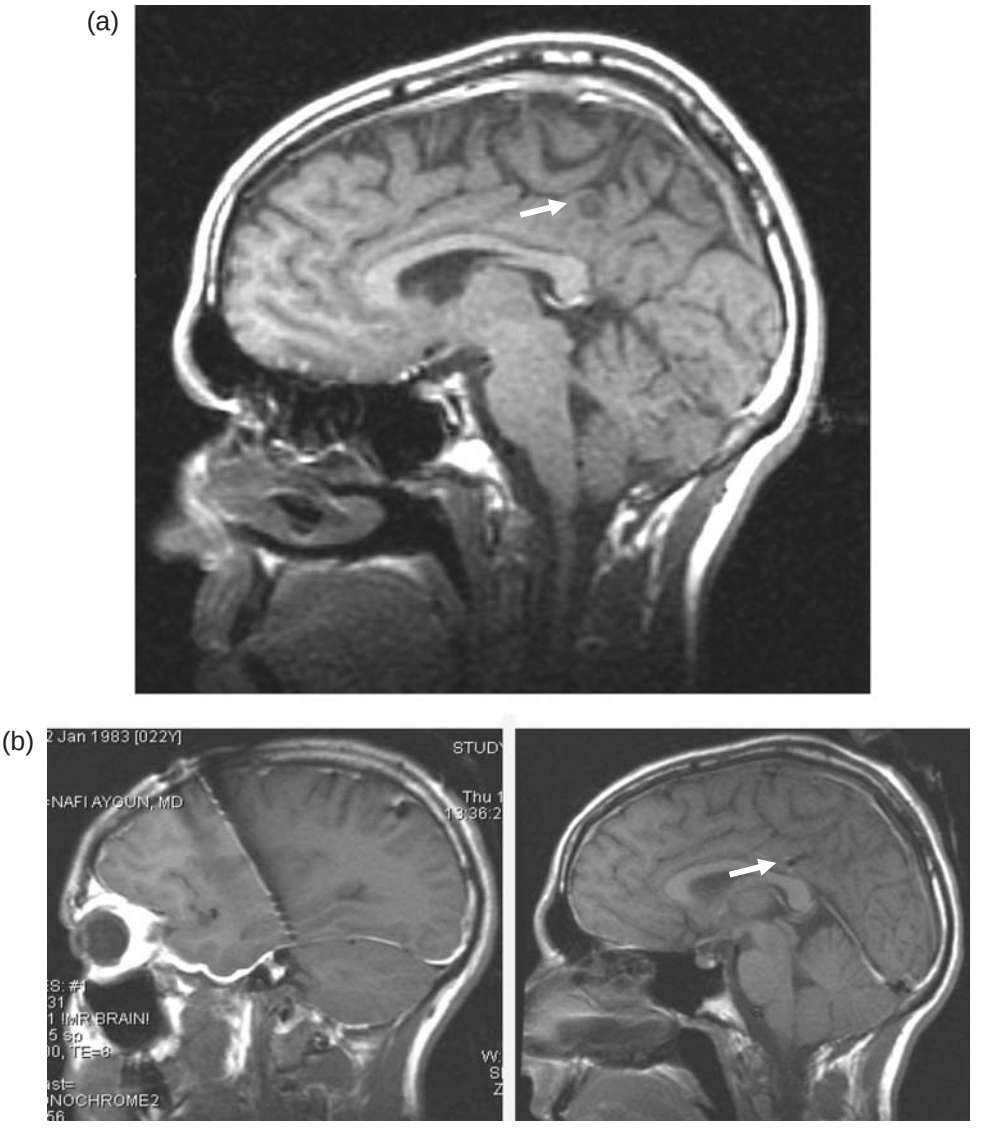

Figure 69.6 See Case 5 for details. a. Sagittal T1-weighted MRI showing location of lesion near right cingulated gyrus (arrow). The remaining of the MRI was normal. b. Sagittal T1-weighted MRI showing track of depth electrodes placed in the right hippocampus (left), and cingulate gyrus (right, arrow).

onset in a surgically favorable site, the anterior right temporal lobe, the presence of a lesion near the right cingulate gyrus raised concerns that scalp-EEG might have mislocalized the site of seizure onset. For this reason, depth electrodes were placed in the right amygdala, right hippocampus and through the right cingulate lesion (Figure 69.6b). Depth electrode recordings revealed that the earliest ictal discharges were in the right cingulate lesion, preceding discharges in the right hippocampus by 6–9 seconds. Thus, the right temporal lobe was a site of seizure spread and may have produced much of the clinical symptomatology (the 'ictal symptomatogenic zone'[4]) but was not part of the 'epileptogenic zone.' The patient underwent resection of the right cingulate lesion. After surgery, the patient no longer had seizures and had no deficits. In this case, invasive electrodes were essential in resolving differences between scalp-EEG, which localized the seizure focus to the right temporal region, and a known lesion at a site not easily assessed by scalp EEG.

Summary

As the above examples illustrate, there are many unique situations that can arise in the course of evaluating a patient for epilepsy surgery. Studies and procedures must be tailored to each individual situation; however, there are basic principles that can be applied as shown in Figure 69.1 and Table 69.1. Invasive EEG recording is neither something to be avoided nor something to use indiscriminately. In situations where there is uncertainty about the location of the seizure focus or about the safety of resecting the seizure focus, i.e., due its to proximity to eloquent cortex, invasive EEG can be invaluable. However, it is also important to acknowledge the risks and limitations of invasive EEG evaluations. First, the question(s) to be addressed by the invasive EEG recordings should be formulated; only then can a surgical plan be made that is likely to be implemented with an acceptable level of risk compared to the likely benefit. If appropriate questions and plans cannot be formulated, invasive recordings may not be needed.

70 Invasive electrodes in long-term monitoring

GH Klem and S Nehamkin

The ability to provide long-term monitoring implies that there are adequately trained technologists, skilled in the use of a variety of monitoring equipment. This equipment includes EEG instrumentation, video recording devices, and electrical stimulation equipment to map functional cortex with either direct cortical stimulation of invasive electrodes or evoked potentials from the scalp or invasive electrodes. The variety of electrodes, both scalp and invasive, extracranial as in eye and EKG electrodes, and other devices including pulseoximetry to monitor for oxygen desaturation during events are also routinely used in the long-term monitoring setting. Particular training in the recognition and management of seizures and medical emergencies must be emphasized. Incorporation of these diverse techniques routinely used in both adult and pediatric long-term monitoring units often make the technologist's role significantly more demanding than in the routine EEG laboratory.

In April 1939, Penfield performed trephination over both temporal regions and placed electrodes on the dura, intending to lateralize seizure origin in a patient with bitemporal epilepsy. The patient underwent serial EEGs with this technique. Since this time in medical history it has been shown that localization of epileptic foci and areas of elequent cortical funcation with appropriately placed epidural, subdural, and depth electrodes has helped to make epilepsy surgery a safe and efficacious option for the successful treatment of epilepsy that is refractory to medication. Invasive electrodes can be used both for monitoring and stimulation of the underlying tissue to identify functional cortex.

Epidural pegs

Epidural electrodes were first used by Hans Berger.[1] Berger's epidural electrode consisted of a needle inserted epidurally in the area of a skull defect. Many other epidural electrode types have been developed since, including a wire balled fused at the end of the wire as described by Jasper, or an array of multiple contacts imbedded in flexible Silastic stips.

There are cases where the usual EEG scalp recordings, even when combined with the use of sphenoid electrodes, do not provide clear evidence of the onset of a focal seizure. When this occurs, it may be difficult to use electrical activity in planning for a more invasive surgical approach in localizing the seizure foci. Epidural electrodes or epidural peg electrodes placed over a variety of locations covering the scalp may be employed.

The epidural peg electrode consists of a 3/16 inch stainless steel disk embedded in a mushroom-shaped body of Silastic. A multistranded stainless steel wire is soldered to the disk and exits through the cap of the electrode. The length of wire exiting the peg is approximately 20–25 cm in length and terminates with a standard electrode jack. These electrodes are placed in the operating room with the patient under general anesthesia. The surgeon places the electrode under the skin, opening the cranium with a twist drill allowing the electrode direct contact with the dura. Localization for the sites is determined through previous recording sessions and special anatomical considerations derived from imaging studies.

Technical recording considerations when using epidural pegs include adjustment of the sensitivity setting on the EEG recording equipment to the range of 20–30 microvolts per millimeter (μV/MM), as compared to the usual range for scalp recordings.

Sphenoid electrodes

The routine use of sphenoid electrodes for all patients with a history of complex partial seizures aids in the localization of epileptiform discharges. These electrodes in combination with standard scalp electrodes may help in defining whether the foci is in the lateral or mesial structures of the temporal lobe. Although it is generally agreed that the sphenoid electrodes record primarily from the temporal lobe, there is no real evidence that they do not pick up activity from the orbital frontal cortex.

The sphenoid electrode consists of a multistranded stainless steel or platinum wire that is insulated except at the tip. Inserted transcutaneously through the mandibular notch the electrode wire that is placed ranges from 50–75 mm and is inserted with a 20 or 22 gauge needle that is removed leaving the electrode wire in place. Sphenoid electrode packages are gas sterilized. These electrodes are inserted using aseptic technique at the patient's bedside. Topical anesthetics, or in some cases a light sedative, are used prior to electrode placement.

Foramen ovale electrodes

Foramen ovale electrodes have been used to record from mesial temporal structures and are less invasive than depth electrodes.[2] The electrode consists of platinum pellets embedded

on thin wire in a Teflon tube. The contacts are usually 1–1.5 cm apart and the wires run through the tube exiting at a connector. The electrodes are inserted percutaneously in the operating room through a small incision in the cheek. Passed through a 20 gauge needle, entering Meckel's cave cistern, the electrode is then advanced so that the most proximal contact rests at the level of the foramen ovale. These electrodes, like sphenoid electrodes, are placed bilaterally. Flouroscopy is used in the operating room to verify placement location. Foramen ovale electrodes are well tolerated by most patients, including adolescents.

Subdural arrays

The subdural array is a 'grid' or 'strip' of electrodes placed directly on the cortex or dura under general anesthesia in an operating room.[3–6] Subdural strip electrodes, generally consisting of four to ten contacts spaced at 0.5–1 cm intervals in a single row Figure 70.4. Subdural stips may be placed through a burr hole. Subdural grids are often designed anywhere from two to ten rows in length and four to eight rows in width, with a variety of intraelectrode spacing options, shaped as square, rectangle, or with a curved edge, and are placed through a craniotomy Figures 70.5 and 70.6. The location and size of the subdural array is determined by the results of previous recordings, localization of an intracranial lesion or AVM, vasculature, and scar tissue. Adequate coverage for the most accurate localization must include any lesion or structural abnormality and the surrounding cortex.[7–14] The epileptic onset zone may not be located within the borders of the identified structural abnormality, therefore the surrounding tissues must be thoroughly investigated by appropriate coverage with invasive electrodes Figure 70.8.

Subdural electrodes consist of stainless steel or platinum disks embedded in a flexible sheet of medical grade silicone. The electrode is soldered to a stainless steel multistranded wire. The wire is insulated with a Teflon coating. Wires are arranged on the array in an order that allows the surgeon to cut out one or more of the electrode disks in order to adapt the array to the surgical site without compromising the integrity of the electrode. The wires are then gathered into a flexible Silastic tube that terminates into a microminiature connector. The use of this small connector allows the surgeon to tunnel the cable away from the site of the burr hole or craniotomy and exit the scalp through a stab wound. The microminiature connector is then attached to the input cable that will plug into the EEG amplifiers.

When a large number of electrodes are required, i.e., an 8 × 8 subdural grid of 64 electrodes, the wires that are connected to the disks are brought through the Silastic tubes terminating in two or four microminiature connectors and number or color coded as 1 through 16, 17 through 32 and so on, corresponding to the pin positions of the amplifier. The total combined number of electrodes, scalp, sphenoidal, subdural, depth, and noncephalic, is limited by the number of amplifier inputs. Our institution, University Hospitals Case Medical Center, utilizes Nihon Khoden equipment which presently allows for 192 electrodes.[15–22]

Depth electrodes

Depth electrodes have been used to record from a variety of locations, primarily from the mesial structures of the temporal frontal, and occipital lobes. The most common use of depth electrodes is for localization of the seizure focus within the temporal lobes, especially when lateralization is difficult (Figures 70.1 and 70.2).

These electrodes consist of multiple stainless steel or platinum contacts approximately 2–5 mm wide usually spaced at 2–5 mm intervals encirciling a closed plastic, 0.8 mm tube. The number of contacts is typically between six and twelve. Three dimensional reproductions of the brain recreated with MRI and/or CT imaging allows for minimally invasive implantion of these electrodes through burr holes in a surgical setting. Depth electrodes are often used along with other invasive electrodes to maximize coverage.

Figure 70.4 Subdural strip electrodes.

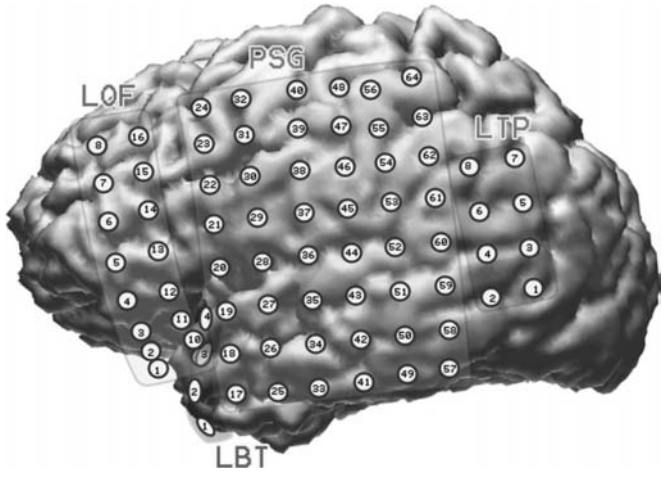

Figure 70.6 Subdural grids designed from two to ten rows in length and four to eight rows in width, with a variety of intraelectrode spacing options, shaped as square, rectangle, or with a curved edge, are placed through a craniotomy.

Electrical stimulation

Electrical stimulation of the subdural stip and grid electrodes and depth electrodes in the long-term epilepsy monitoring unit and the operating room provides detailed information for localizing cortical function relative to the seizure onset zone which is the ultimate surgical target. The patient can be tested at the bedside without the need for any type of local or generalized anesthesia. The rate of testing can be slow allowing time for the patient to rest during relatively long testing periods and in the event of a clinical seizure, either spontaneous or activated by the stimulation.[23–28]

Electrical stimulation of invasive electrodes may be done with a variety of devices. The free-standing battery-powered Integra Ojeman stimulator, or stimulation delivered through the EEG recording equipment like the Nihon Khoden equipment used at University Hospitals Case Medical Center Epilepsy Monitoring Unit are both reliable options. Electrical stimulation parameters for invasive electrodes consist of 50 Hz, 0.2–0.5 msec alternating polarity square wave pulses of varying duration, usually 5 seconds in length. The surrounding EEG activity is watched for afterdischarges. An after discharge is defined for our purposes as a retetitive sharpwave clearly distinguished from the ongoing interictal activity, which occurs immediately following the electrical stimulation and involves one or more electrodes, including always the electrode stimulated Figure 70.7. The duration must exceed 1 second following cessation of the stimulus.

Stimulation begins at 0.5–1 mA and increases in increments of 0.5–1 mA until an after discharge occurs, functional alterations occur, or until an intensity of 15 mA is reached. Functional alterations are defined as the occurance of motor contractions, sensory phenomena in the resting patient, or impairment of activity if stimulation occurs during the performance of a task.

It is possible that electrical stimulation will not provide the information desired due to the position of the subdural or depth electrodes. In these cases additional electrical stimulation may be carried out in the operating room. Stimulation may be carried out under light sedation with the patient awake, speaking and following commands, or with the patient under

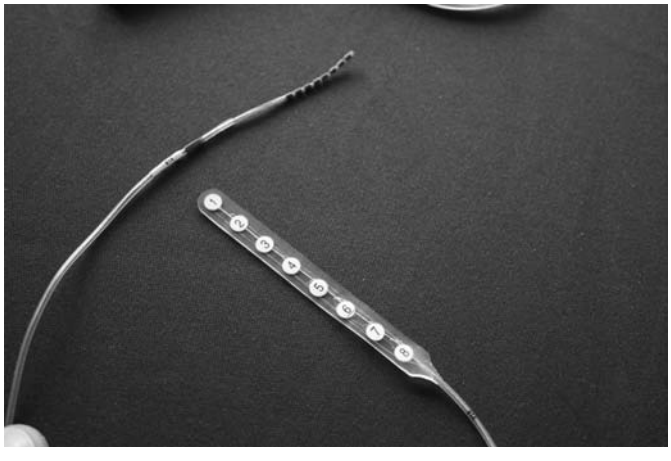

Figure 70.5 Subdural grids.

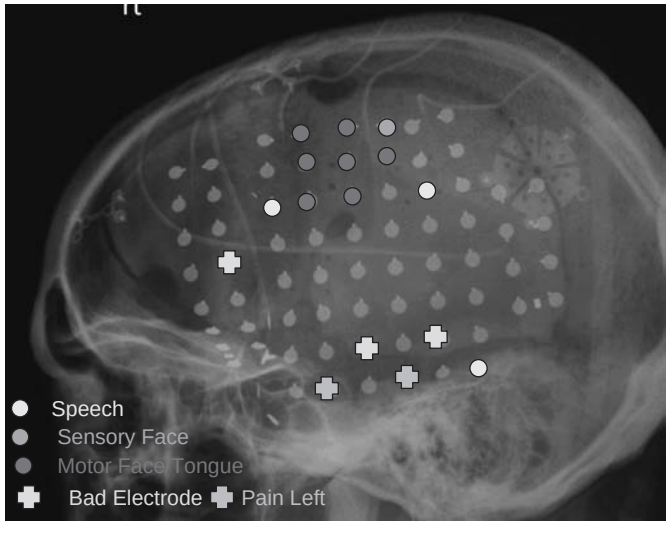

Figure 70.7 Electrical stimulation of invasive electrodes.

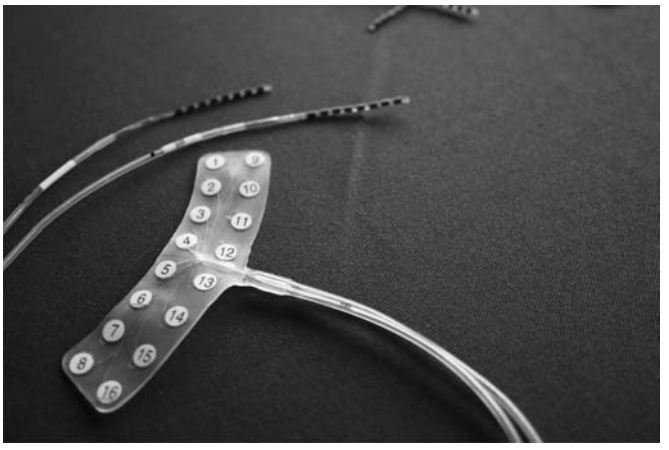

Figure 70.8 Subdural invasive electrodes.

general anesthesia with no muscle relaxant on board to watch motor movements. EEG activity is closely monitored to determine if afterdischarges or seizure activity occurs.

Evoked potentials

Somatosensory evoked potentials elicited by stimulation of either the median nerve or posterior tibial nerve may be recorded from the invasive electrodes to identify afferent areas. Visual-evoked potentials are routinely recorded from electrodes placed on the occipitals lobes. These techniques combined with direct cortical stimulation assist in identifying cortical function that may not be found in the predicted region of the brain based on normal anatomy.[29–33]

Evoked potentials may be performed either at the patient's bedside or in the operating room. Mapping for central sulcus, especially in a patient that may not be able to cooperate during other cortical mapping procedures is a reliable technique for localization.

Conclusion

The ability of current EEG recording equipment to allow sampling rates as fast as 5000 Hz coupled with the quality of invasive electrodes has created major advances in the field of epilepsy. Recording and identifying high frequency oscillations, called ripples, of 200 Hz and greater, prior to seizure onset may soon be shown to offer more precise localization of epileptic foci Figure 70.3. The priority for all medical professionals should always be maintaining or creating the best quality of life possible for each patient. Advances in computer technology relative to EEG recording equipment, functional mapping techniques, imaging devices, image guided surgical techniques, and invasive electrode options have come together to help insure safe and successful outcomes for epilepsy surgery patients.

71 Foramen ovale and epidural electrodes in the definition of the seizure onset zone*

HG Wieser and K Schindler

Introduction

The objective of presurgical evaluation of patients with focal drug-resistant epilepsy is to delineate the primary epileptogenic zone. The epileptogenic zone is defined as the brain tissue that has to be surgically removed to render the patient seizure free.[1] However, the epileptogenic zone is a theoretical concept, a way to think about the structure of the epileptic brain. Therefore it is not surprising that no single diagnostic method is able to detect the epileptogenic zone alone. Instead, a series of methods such as detailed analysis of seizure semiology, noninvasively and invasively recorded ictal and interictal EEG, MRI, PET, neuropsychological assessments and in some patients ictal SPECT and MR-spectroscopy, are clinically applied. The epileptogenic zone is then approximated by the brain region that is shown to be pathologically altered by these different methods. In this process the results of the diverse methods used are differently weighted. One of the most important pieces of information is where the seizures start, i.e., where the seizure onset zone is localized. Actually, other definitions of the epileptogenic zone or epileptogenic focus contain the seizure onset zone as an integral part.[2] The initial ictal activity of cortical neuronal networks is typically characterized by fast oscillations, i.e. oscillations in the frequency range of 20 –100 Hz or even higher.[3,4] Specifically important in regard to presurgical evaluation is that localized high-frequency activity has been found to be associated with good surgical outcome.[5] In addition, recent findings indicate that high frequency epileptiform oscillations do not only spatially delimit the seizure onset zone, but also may occur more often before seizures and therefore be helpful to detect a preseizure time period,[6] which is a precondition for developing an EEG based seizure prediction method.[7] In vivo and in vitro animal experiments and computer simulations even imply that fast cortical oscillations may have a causal effect in seizure initiation and may be physiologically sustained by interneuronal gap junctions or by synchronizing effects of the electric field.[8,9] An important practical problem in presurgical evaluation is that these high frequency cortical oscillations – so important in localizing the seizure onset zone – can not be reliably recorded by scalp electrodes. This is on one hand because of the frequency dependence of transmission from cortex to scalp with a strong attenuation of higher frequency activity due to mutual cancellation by spatial summation.[10] On the other hand, electrical activity from contracting scalp muscles – often occurring at seizure onset – obscures activity of cortical origin most strongly in the frequency range above 20 Hz.[11] A way to work around these technical and biological limitations is to use intracranial electrodes, which are mostly unaffected by electromyogenic artefacts and monitor high frequency activity much better. Intracranial electrodes comprise different categories. In this chapter we mainly focus on foramen ovale (FO) electrodes, but also give a brief description of epidural peg electrodes. The latter have been used much less during recent years, mainly due to the very good risk/benefit ratio of other methods such as FO electrodes. A representative case report illustrates how certain limitations of FO electrodes may be compensated for by additional subdural strip electrodes.

Development history of FO and peg electrodes

The FO electrode recording technique was developed in Zürich in 1983/4[12] in order to simplify the neurophysiological investigation of the presurgical evaluation protocol for candidates for selective amygdalohippocampectomy (AHE). Prior to 1983, stereoelectro-encephalography (SEEG) had been used in Zürich in the majority of patients being evaluated for epilepsy surgery.[13–15] Accumulated SEEG experience revealed that the mesial temporal lobe structures, and in particular the hippocampus, the parahippocampal gyrus and the amygdala, play the crucial role as seizure generating structures in most patients with temporal lobe epilepsy (TLE). Based on these findings, in 1975 the so-called trans-sylvian amygdalohippocampectomy (AHE)[16] was developed and has in the following become the surgical approach of *first choice* for surgical treatment of mesial TLE (MTLE) in Zürich, but also in many other centers. Data obtained from Engel's survey carried out prior to the 1992 Palm Desert Conference showed that already then 15 centers (15%) had been using FO electrodes. FO electrodes had been used only in 5% of all

*A similar chapter has been published in Engel J Jr and Pedley TA (eds) Epilepsy: A comprehensive Textbook (Lippincott-Raven Publishers, Philadelphia, 1997) 1707–17 and is going to be published in the second edition of this book (Chapter 171; in preparation)

reported patients operated on 1986–1990 (*n*=7664), but in 21% of 662 reported AHE patients.[17]

Peg electrodes were developed at the Cleveland Clinic in 1988.[18,19] They are usually used as sentinel electrodes in combination with other invasive techniques for obtaining epidural ictal recordings.

Indications

FO and peg electrode recording techniques have been referred to as *intermediately invasive* or *semi-invasive* approaches.

Peg electrodes allow artifact free recording of the electrocorticogram in relatively small but widely separated regions of the cortical convexity to determine surgical suitability in patients in whom the clinical, electrographic and neuroimaging information did not well localize the seizure onset zone. They were also designed to be used when exact placement of a subdural grid array was uncertain from the clinical, neuroimaging and scalp EEG data. Therefore, peg electrodes may serve as sentinel electrodes contralateral to subdural grid placement in order to confirm that ictal discharges are not starting contralaterally. Depending on the particular clinical circumstances, peg electrodes may be used with other electrodes including foramen ovale electrodes, depth electrodes, and subdural strip and grid arrays.

FO electrodes record from the mesial aspects of the temporal lobe. Compared to intracerebral depth-, subdural grid-, and most probably also to subdural strip electrodes they are 'less invasive', but nevertheless the possibility of complications is inherent to the FO electrode technique, too. Therefore its use should be restricted to presurgical evaluation of possible candidates for epilepsy surgery. Due to their monitoring restricted to the electrical activity of mesial temporal lobes their main indication is for patients with TLE and in particular for patients suffering from the syndrome of MTLE.[20]

Whereas in Zürich during the period 1970–1983 a total of 94 patients underwent SEEG exploration and this resulted in a total of 69 operations (73%), from 1984 until today FO electrodes have been used in a total of 263 patients resulting in a total of 235 operations (83%). In 18% FO electrodes were combined with other invasive recording techniques. Table 71.1 lists details in this respect.

It is interesting to have a look at the Zürich AHE series, which started in 1975. In this context, it is important to remember that since 1978 there was CT, since 1985 MRI, since 1987 SPECT, since 1988 PET, and since 1987 31P-, and since 1993 proton magnetic resonance spectroscopy (1H-MRS) at the Zürich center.

This Zürich AHE series now contains a total of 512 AHE patients. 275 (53.7%) had intracranial EEG monitoring, 32 (6.2%) had SEEG only, 198 (38.7%) had FO electrodes only, 45 (8.8%) had combined intracranial electrodes (SEEG and FO, FO and strips/grids). The remaining 237 (46.3%) had AHE without intracranial recordings (Table 71.2). Table 71.2 shows the obvious trend for less invasive presurgical evaluation in candidates for AHE: In the last years the percentage of AHE without intracranial presurgical evaluation amounted to 69.2%.

Despite the overall less invasive presurgical evaluation, the seizure outcome at 1 year after AHE improved steadily over time. In the 1975–1992 period Engel Classes I–IV were 69, 9, 13, 9, and 9% (*n*=254); in the period 1993–1999 the respective numbers are 75, 10, 13, and 2% (*n*=115); in the period 2000–2001 the outcome assessment for 50 AHE patients revealed 89, 11, 0, and 0%.[21]

Table 71.3 lists the types of operations in the most recent consecutive 100 patients with FO electrodes. In these 100 patients who had FO-electrodes alone (*n*=67) or in combination with other intracranial electrodes (*n*=33), 87 patients had resective surgery, mainly AHE (*n*=72). In 13 patients the results of the presurgical evaluation did not indicate ablative surgery. The relatively high number of patients with FO in combination with other intracranial electrodes (33%) reflects two trends. First, MTLE patients with clear-cut concordant findings undergo AHE without intracranial recordings, and secondly, our center is increasingly confronted with more difficult cases in whom more elaborated intracranial seizure monitoring is necessary.

Technical aspects: electrode design, insertion and removal, and recording from the FO electrodes

In recent years several types of FO electrodes have become commercially available. However, the original FO electrodes

used in Zürich were home made.[22] In brief, these electrodes consist of ten Teflon-insulated, helically wound silver wires (diameter 0.1143 mm=0.0045 inches) ending in ten poles. They are mounted on a 'surgical', i.e., highly corrosion-resistant stainless steel wire 0.1 mm in diameter. This carrier, isolated with a special varnish, has adequate mechanical properties. It is flexible enough and has a special end to avoid penetration of the arachnoidal-pial layer. Each pole consists of 90 parallel windings and is 2 mm long. The distance between two contacts is 2 mm. The external diameter of the FO electrode in use is such that it passes through a special splittable 18-gauge cannula (produced and marketed by Medialimed SA, 1604 Puidoux, Switzerland). This splittable cannula (Figure 71.1B) has an external diameter of 1.23 mm and an internal diameter of 0.93 mm and permits the 4-pin connector to be mounted, soldered, and the stabilizing insulator poured in well before implantation. The electrode impedance ranges from less than 200 ohms to a maximum tolerated 700 ohms, respectively, whereas the DC offset potential is less than 2 mV. Electrodes can be armed with other specific recording devices. Temperature-sensitive devices, have been used in 14 patients,[23] and special ictal and interictal DC recording with monopolar FO electrodes were carried out in five patients.[24]

Insertion of the FO electrode can be done under local anesthesia. Currently, however, the procedure is done under general anesthesia in Zürich.

With the stylet inside the special cannula, the FO electrode is inserted 3 cm lateral to the oral commissure and directed along the intersection of two orthogonal planes: (*a*) the plane defined by the insertion point, a point on the lower eyelid corresponding to the medial border of the pupil, and the tip of the electrode directed towards the foramen ovale, and (*b*) a plane defined by the insertion point, a point 5 cm anterior to the external meatus acusticus, and the tip of the electrode directed towards the foramen ovale (Figure 71.1A).

To avoid asystoly (atrioventricular block has been reported) we administer atropin before insertion. The patient usually responds to the passage of the needle through the foramen ovale with a wince and a brief contraction of the masseter muscle. After withdrawal of the stylet, cerebrospinal fluid usually drops and the electrode can then be carefully positioned under radioscopic control. In most instances, the tip of the electrode slips without any resistance into the caudal end of the ambient cistern. As can be seen from Figure 71.2F–H, modern 3D image reconstruction and

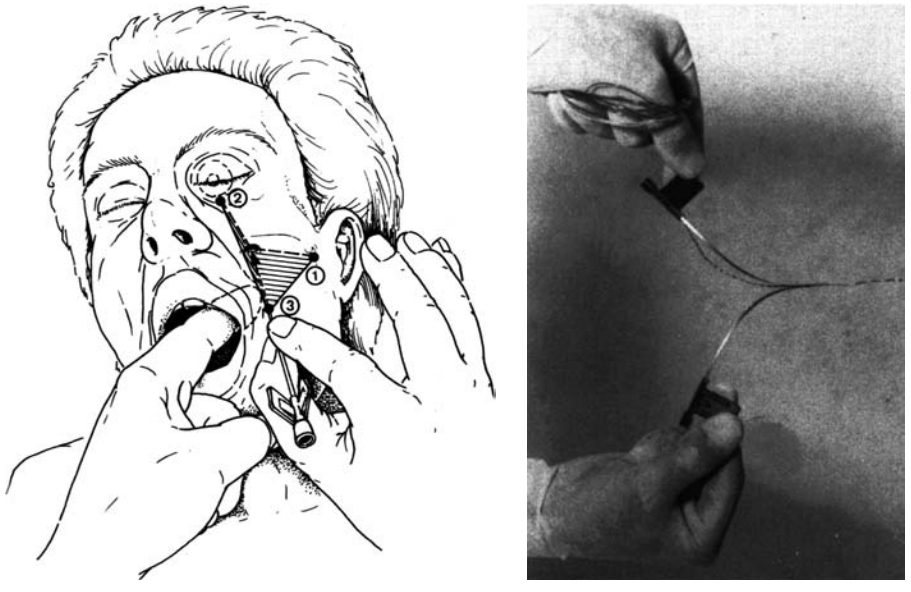

Figure 71.1 a. Insertion technique of FO electrodes according to the technique of Kirschner[30] using the landmarks of Härtel.[31] 1 = point 5 cm anterior to external auditory meatus. 2 = medial pupillary point. 3 = electrode entry side 3 cm lateral to oral commissure. The index finger is in the pterygoid fossa. The needle is inserted as described in the text, then the special splittable cannula is withdrawn and broken as displayed in b. (Modified from Wieser and Morris, 1997).[33]

superposition techniques of CT and MRI allow for more precise studies of the anatomical details in relation to the FO electrodes.[25]

The splittable cannula is then withdrawn and broken (Figure 71.1B) and the freed electrode is fixed by the use of a special clamp to the skin. Gauze and adhesive tape cover the electrode where it penetrates the skin. Oral antibiotic protection is given throughout the recording period and is continued for 3 days after removing the electrode.

For the removal of the FO electrode, anesthesia is not necessary. During the withdrawal of the electrode a short-lasting painful sensation in the ipsilateral teeth is relatively common and the patients should be carefully informed about this possibility before the explantation.

Montage, recording and analysis

Whereas more sophisticated DC recording was done hard wired with 32 channels in the laboratory (Figure 71.3), long-term digital video-EEG monitoring in AC mode is now possible with up to 128 channels with the patient on the ward.

For routine monitoring an uninterrupted bipolar montage connecting the ten contacts of both FO electrodes is recommended, as shown in Figure 71.4. The other channels are used for simultaneous scalp EEG and polygraphy, if indicated. Figures 71.4 and 71.5 give examples of ictal EEG recordings obtained with this system.

In Figure 71.6 the case of a 19-year-old patient is illustrated. He suffered from pharmaco-resistant epilepsy. At the beginning of his habitual seizures he would briefly scream and cross his arms. The latter was a 'semi-automatic' sign he had learned to use over the years to indicate the beginning seizure to his parents. After becoming confused he would then normally try to get up and walk away (Figure 71.6A–F). MR imaging revealed atrophy and signal hyperintensity of the mesial temporal lobe structures on the left (Figure 71.6G). In addition, slight atrophy of the lateral left temporal lobe was detected. Because of the pronounced ictal motor signs frontal seizure onset or rapid seizure spread to the frontal lobes were considered. Therefore bilateral FO and additional strip electrode recordings (Figure 71.6H) were used to localize the seizure onset zone. Seizures were demonstrated to always begin in the left mesio-temporal region (Figure 71.6I). However there was intensive interictal epileptiform activity in the left latero-temporal region. Because of the latter finding and the slight atrophy of the left mesial and lateral temporal lobe a resection of the anterior two thirds of the left temporal lobe was performed. Histological examination revealed hippocampal gliosis and loss of neurons and a slightly abnormal focal layering of the neocortex. The patient has been free of seizures and of auras (ILAE outcome 1a) since surgery.

Epidural peg electrodes design

Epidural peg electrodes (Figure 71.7) are mushroom shaped composites of silastic plastic with a 'cap' diameter of 12.7 mm, a slightly tapered stalk and the tip is a 4.5 mm disc electrode made of either platinum or stainless steel. The electrodes are made with different stalk lengths to adapt to different thicknesses of the skull. A1–1.5 cm scalp incision is made to expose the skull at the predetermined electrode positions. A twist drill with a 'stop' is used to create a 4.5 mm burr hole; the electrodes are then inserted by hand into the hole. The 38-gauge Teflon-coated steel wire from the electrode is threaded through a surgical needle and exits the scalp approximately 2 cm distant to the electrode itself. The scalp over the electrode is then sutured. The Bethel Epilepsy Center reported on a slightly smaller version of the original epidural peg electrode.[26]

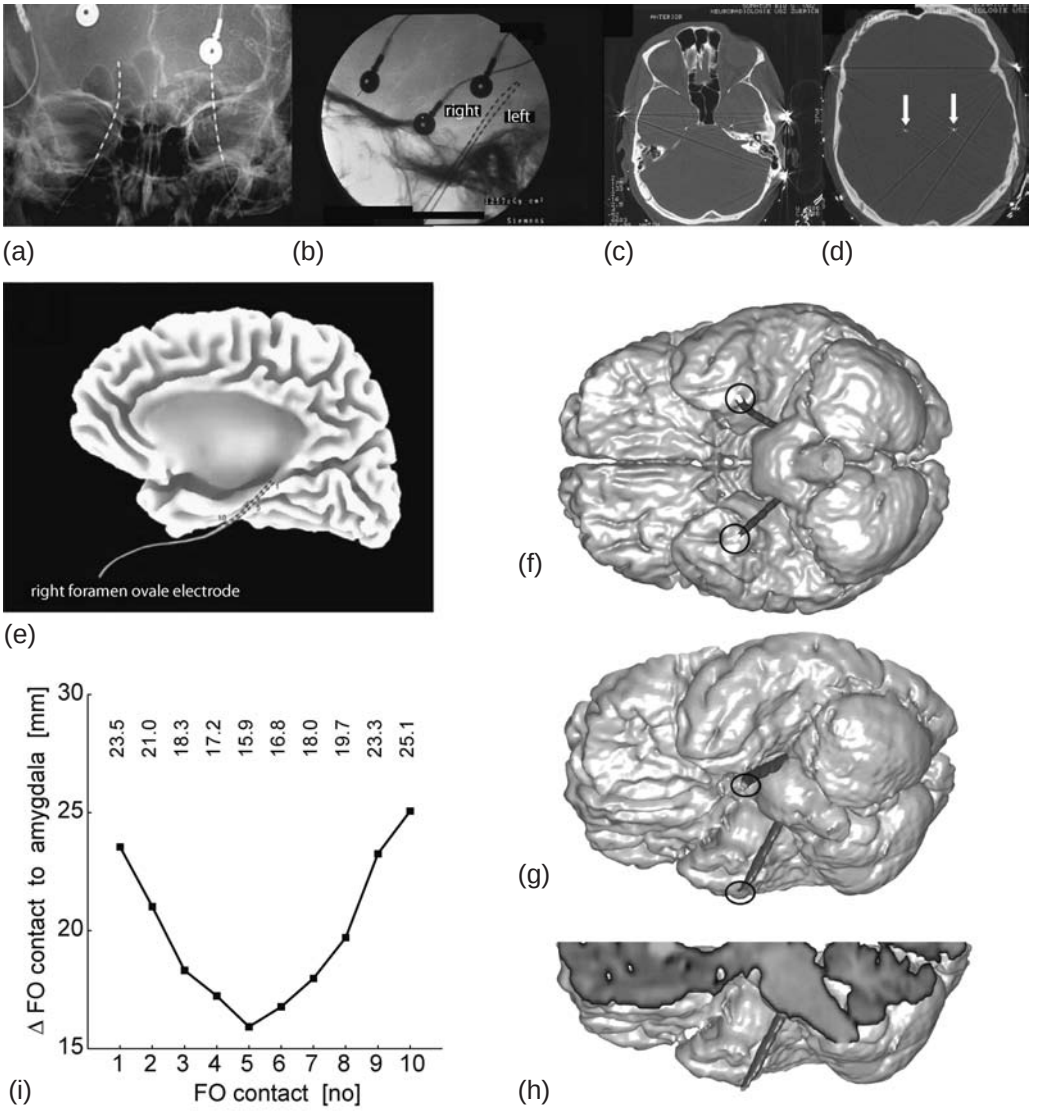

Figure 71.2 Position of implanted 10-contact FO electrodes as illustrated by ap (a), lateral (b) X-ray and CT imaging (c,d), as well as schematic drawing (e) and three-dimensional anatomical location (f–h) of FO electrodes. In f–h the intracranial course of both FO electrodes is shown in red. The positions of the foramina ovale are marked by the open circles. i. Mean distance of each FO contact to the center of the amygdala. f–i With kind permission of PD Dr.Urs Schwarz; e with kind permission of Dr. Dominik Zumsteg. (See Color plates.)

Patients data of the Zürich FO electrodes series

With two exceptions (the first FO electrode patient had no epileptic seizures, but trigeminal neuralgia, and one patient had aggressive outbursts thought to reflect limbic seizures), all patients who underwent FO electrode implantation in Zürich had medically refractory complex partial seizures with or without secondary generalization. In most of the patients, prior to FO electrode implantation, there was rather strong suspicion of mesiobasal limbic seizure foci, as evidenced from the seizure symptomatology, interictal and ictal scalp-EEG, neuropsychological examinations, structural (CT, MRI) and functional (SPECT and PET) imaging. These patients were evaluated with the aim of demonstrating a unilateral mesiobasal limbic seizure focus with the degree of confidence necessary for surgical intervention. Thirty patients had less clear evidence for mesiobasal TL seizure onset with some contradictory findings pointing to lateral TL or extra-TL seizure onset. These patients were evaluated simultaneously with FO and stereotactic depth electrodes. In 18 patients mesiobasal limbic seizure onset was rather unlikely. These patients underwent long-term monitoring with FO electrodes in order to definitively rule out mesiobasal limbic seizure onset (in which case they would have been no longer candidates for surgical treatment) or to prove a possible secondary pacemaker role of one mesiobasal TL (in which case a so-called 'palliative' AHE would be considered as a treatment option).

Seventeen percent of this series were considered inoperable and 80% underwent surgery, mostly selective AHE. In the last 10 years 87% of patients with FO electrodes underwent resective surgery (see Table 71.3). Patients evaluated by FO electrodes prior to AHE did not differ significantly in their postoperative seizure outcome when compared to the overall AHE series evaluated mainly by SEEG.[27, 28]

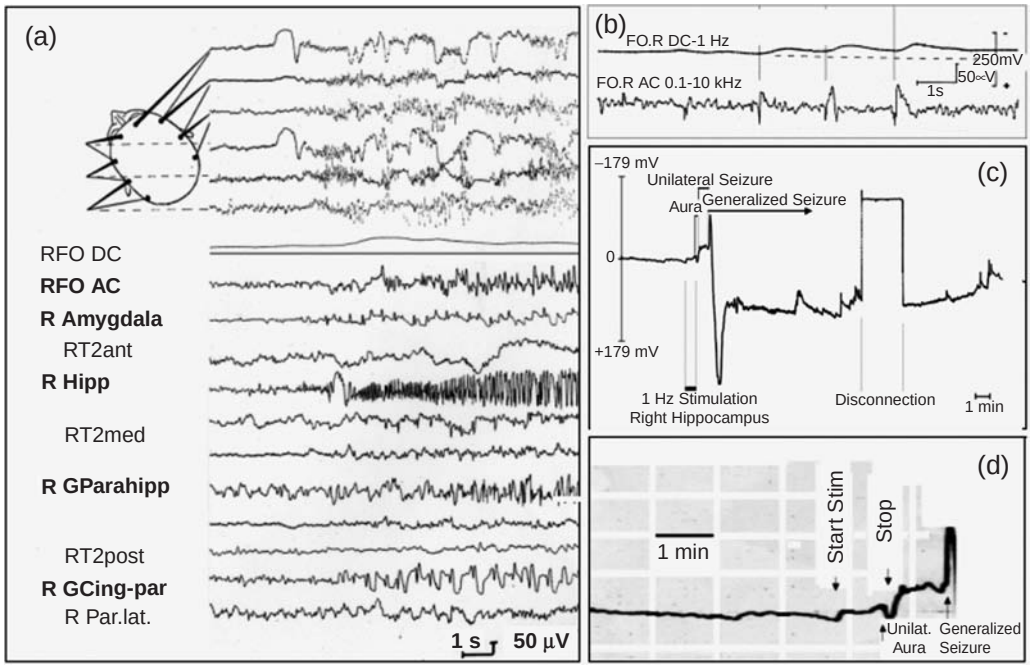

Figure 71.3 DC-recordings with self-made special FO electrodes. a. Section of combined scalp- FO-electrode- and depth-electrode-EEG recordings with a right hippocampal (R Hipp) seizure discharge with modest spread to the right amygdala, the right parahippocampal gyrus (R GParahipp) and to the ipsilateral parietal cingulate gyrus (R GCing-par) which is reliably depicted by the ipsilateral FO electrode (RFO AC) and accompanied by a negative DC shift (RFO DC). b. Repetitive spikes in the FO electrode recorded in AC mode are accompanied by stepwise negative DC-shifts. c and d (D, detail of C): DC shifts recorded by FO electrode with DC amplifier during an electrically induced partial seizure with an aura and secondary generalisation. During the electrical train stimulation of the hippocampus (Start Stim, Stop) a slight negative shift is seen, which increases during the induced seizure discharge in the hippocampus. With onset of the secondary generalized seizure a further marked DC negativity can be observed, which then inverts to DC positivity. This DC positivity is most probably due to the reference electrode used. The reference electrode for DC recording was a disk-shaped sintered Ag-AgCl electrode 12.5 mm diameter (In Vivo Metric Systems, Healdsburg, CA) subgallealy implanted over the vertex at Cz. The FO electrode used for DC recording consisted of a cylindrical Ag-AgCl pellet (0.4 mm diameter and 4 mm length; for further details see Wieser *et al.*, 1985).[12]

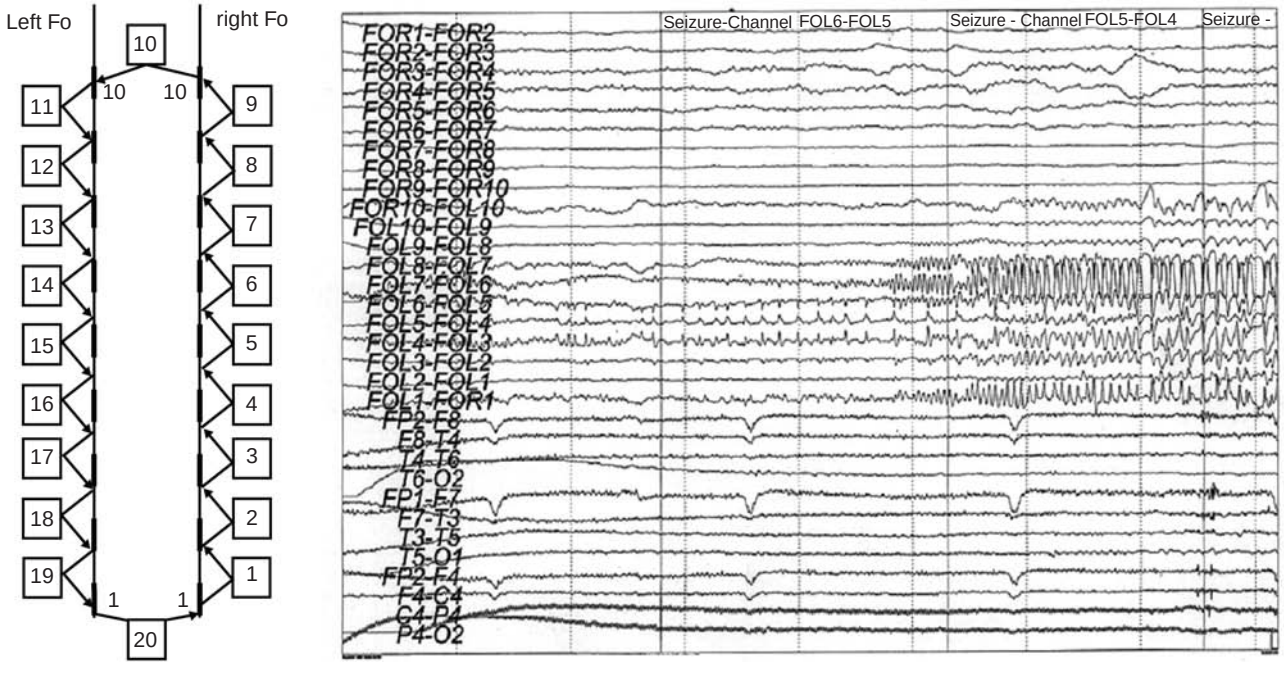

Figure 71.4 On the left the montage for recording from 10-contact FO electrodes is displayed. For routine long-term seizure monitoring we prefer the depicted closed chain with 20 channels (number in boxes). An example of a FO-electrode-recorded seizure onset at contact 5 of the left FO electrode (FOL5) with repetitive 6–7/s sharp waves and evolving rhythmic more wide-spread spike discharges of 19/s. Note that the scalp-EEG channels do not show the seizure onset.

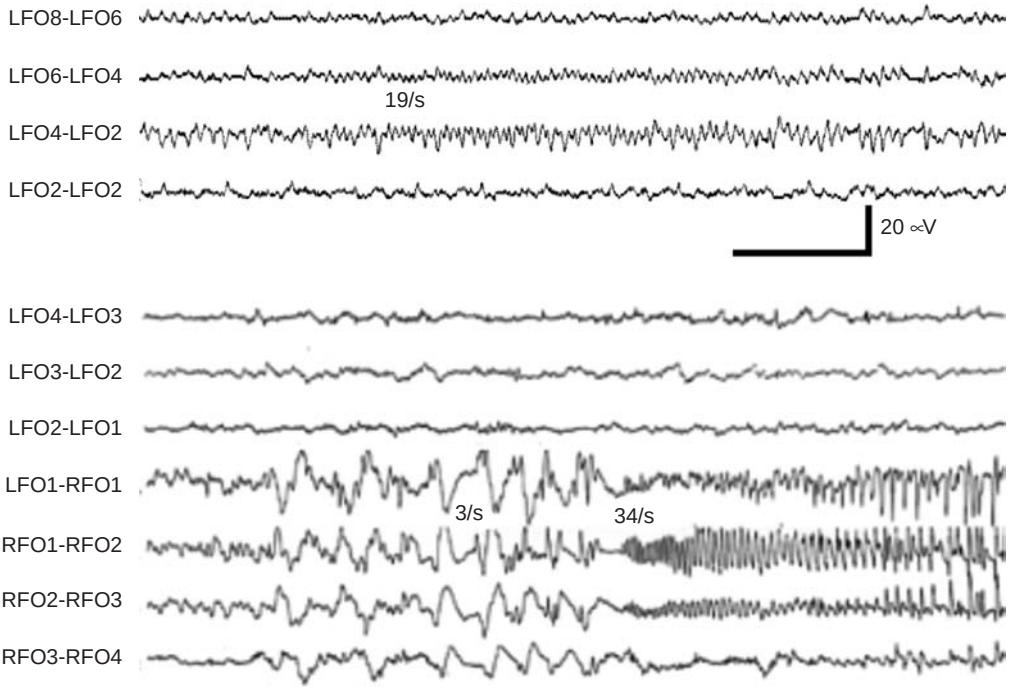

Figure 71.5 Two examples of FO electrode recorded seizure onset patterns in two patients. A. High-frequency low-amplitude spike trains recorded with 10-contact FO electrodes. B. 'Hypersynchronous onset pattern' recorded with 4-contact FO electrodes.

Comparison of FO and peg electrodes with other recording techniques

Advantages

FO electrodes provide a definite advantage over scalp EEG and over sphenoidal electrodes. In a recent study it was for example shown that intracranially recorded epileptiform discharges may often only be detected by scalp electrodes after averaging (Figure 71.8).

In several instances, where the Zürich group has used sphenoidal and FO electrodes simultaneously, it was clearly shown that FO electrodes are superior in detecting epileptiform activity from the mesial region of the temporal lobes.[27] This is particularly true for epileptiform discharges originating in the posterior hippocampal formation. In comparison with depth electrodes the FO electrodes reliably pick up epileptiform activity generated or involving the hippocampal formation. Pure amygdalar discharges may, however, escape detection in the FO electrodes. A further advantage of FO electrodes is that they offer an excellent possibility to monitor mesial TL EEG changes in selective TL amobarbital tests.

As has been shown, appropriate intracranial EEG recorded from depth electrodes or FO electrodes in combination with scalp EEG is indispensable for a reliable interpretation of the amobarbital effects of the selective tests. FO electrodes proved to be very useful, to monitor electrophysiologically the topo-selective effects of amobarbital in the so-called selective temporal lobe amobarbital tests.[29]

The increase of delta activity is considered to be the most typical amobarbital-induced EEG effect. Other amobarbital-induced EEG patterns are isoelectric lines, the burst suppression pattern, and high and low voltage beta-activity. In the Zürich selective temporal lobe amobarbital series the delta-increase, the 'activation-phenomenon' and the spike-reduction were observed both with scalp- and with intracranial electrodes, but the activation-phenomenon and the spike-reduction were only detected with intracranial-EEG recording techniques. As expected, delta increase at the site of amobarbital action was the most commonly observed EEG pattern and was present in 75%. Interestingly a somewhat unexpected delta-increase was also observed contralateral to the side of injection in 36% of the tests. As a rule contralateral delta-increase was, however, markedly less pronounced and shorter in duration.

In a comprehensive study,[29] in which the amobarbital-induced memory performance was correlated with the amobarbital-induced EEG changes, a significant correlation between the dosage and the duration of the EEG changes ($p < 0.05$), was found, but there was no significant correlation between the dosage and the EEG pattern. Moreover, the appearance of an 'activation phenomenon', i.e., the evocation or increase of spikes (or other epileptiform graphoelements) predisposed to a marked decrease of the memory performance not only for material specific for the side of injection, but also for material specific for the contralateral, noninjected hemisphere. Combined FO electrode- and scalp-EEG monitoring during selective TL amobarbital tests is therefore superior in several aspects to functional imaging of the injected area. This is because appropriate EEG monitoring is able to detect the amobarbital induced dysfunction better in time and gives additional information on provoked epileptic phenomena.

In summary, the Zürich experience indicates that the FO electrode has substantially facilitated the presurgical evaluation of the majority of candidates for temporal lobe surgery by decreasing the risks of more invasive neurophysiological evaluation without significant loss of information.

The main advantages of peg electrodes are that they can be used as sentinel electrodes with better, i.e., muscle artifact-free recordings, of cortical activity. The risks and costs of insertion

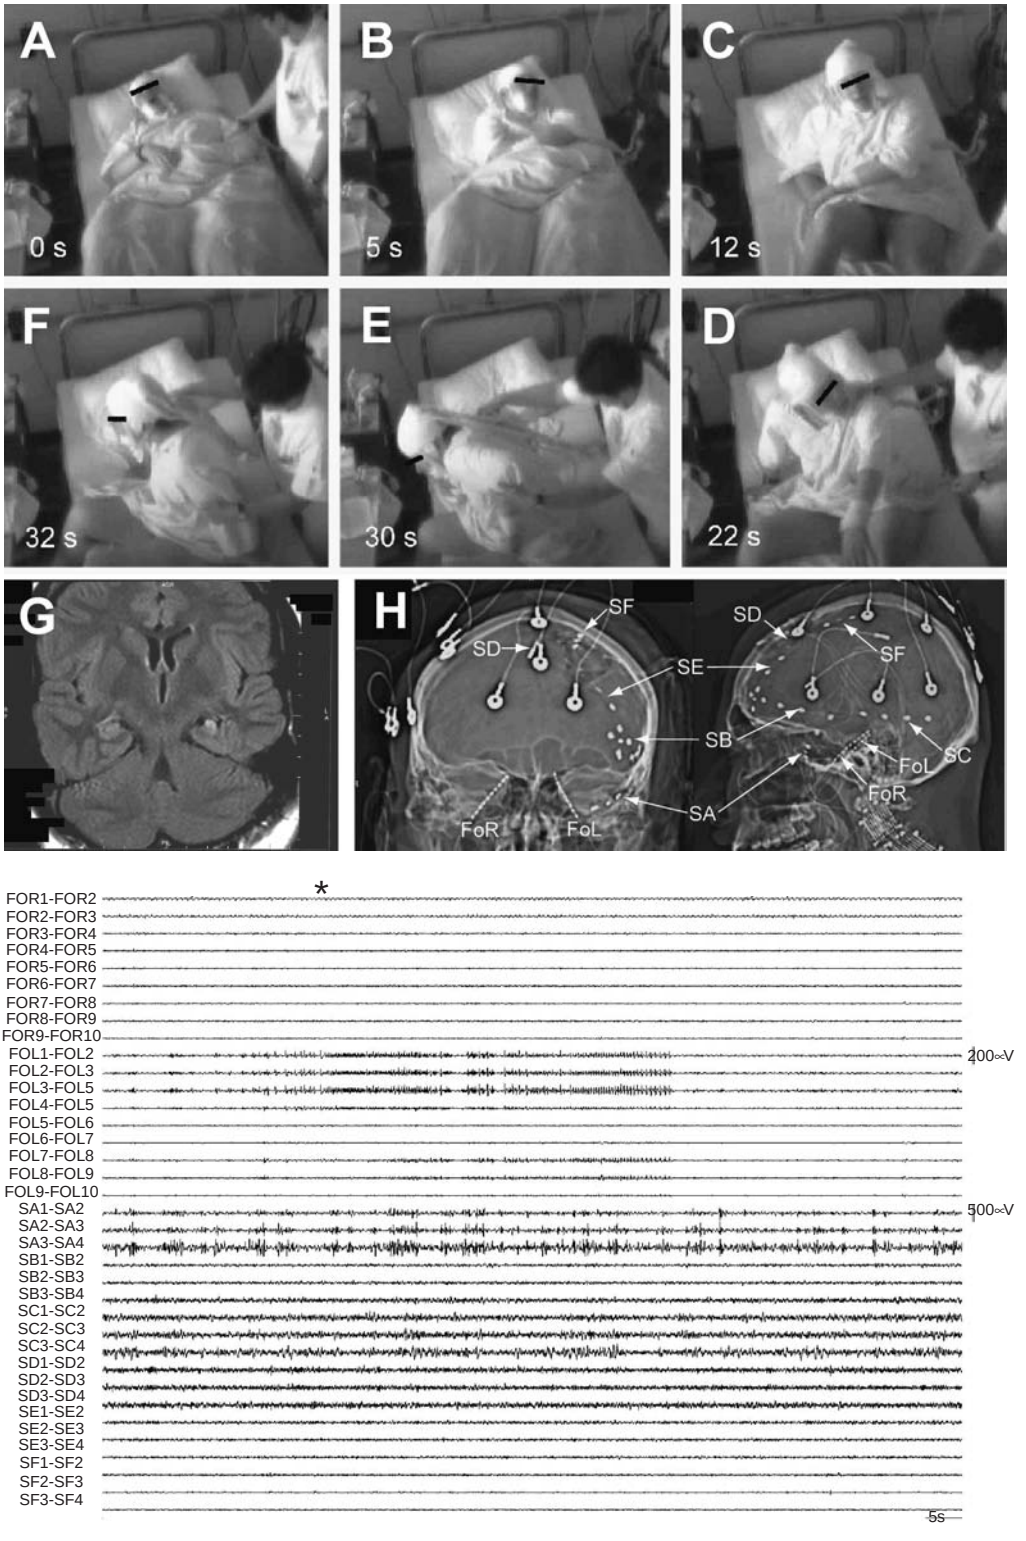

Figure 71.6 'Tailored' presurgical evaluation with FO and additional strip electrodes. A–F. Seizure semiology consists of an initial scream, then crossing of the arms, confusion and deambulation. G. MR imaging (FLAIR sequence) indicates signal hyperintensity and atrophy of the left hippocampus. In addition slight atrophy of the left lateral temporal lobe structure is visible. H. Localisation of electrodes. FOR and FOL are 10-contact FO electrodes. SA-SF denote additional 4-contact strip electrodes. I. EEG during the seizure is displayed in A–F. Seizure onset is first recorded with FOL. There is intense interictal epileptiform activity recorded by SA. * = clinical seizure onset (initial scream).

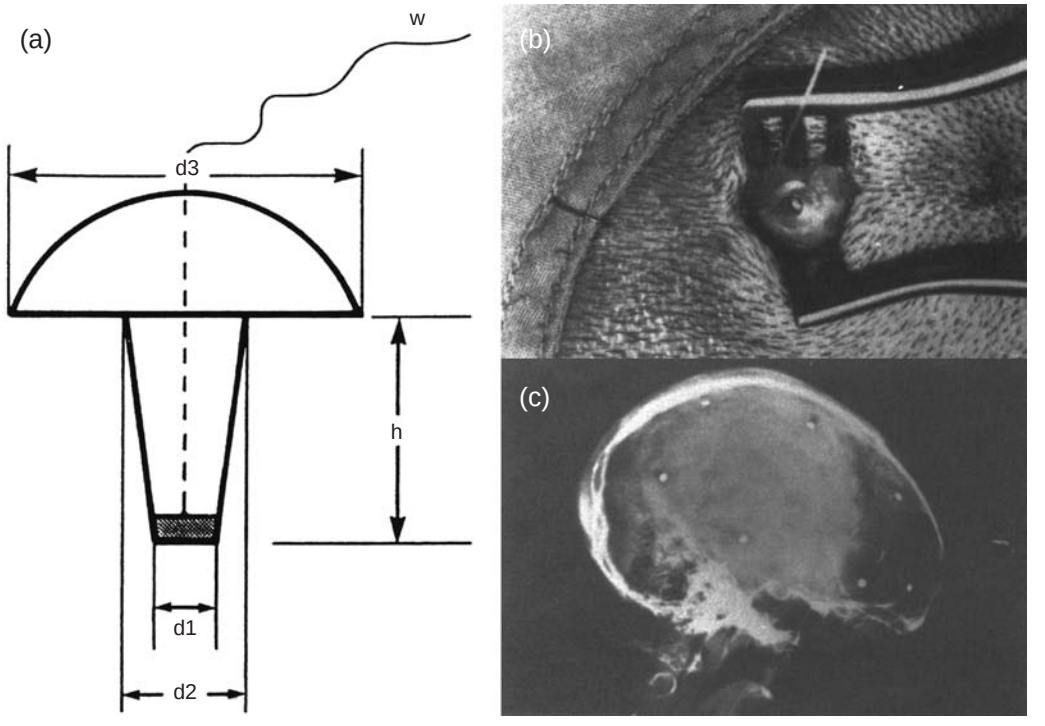

Figure 71.7 Epidural peg electrodes. a: The electrode consists of a stainless steel or platinum disc embedded into a mushroom-shaped silastic housing. The stalk has a gradual taper from a maximum diameter (d2) of 4.7 mm to a tip diameter (d1) of 4.5 mm. Stalk heights (h) range from 3–19 mm in 2-mm increments to match skull thickness. The cap has a diameter of 12.7 mm (d3) and a height of 2.5 mm (MDX4-4210, Dow Corning Corp., Midland, MI). The peg is implanted via 1.5-cm scalp incision and burr-holes (b). c: lateral skull X-ray with epidural peg electrodes (Modified from Wieser and Morris, 1997[33]; original sources see Barnett *et al*. 1990[18] and Awad *et al*. 1991.[19]

are considerably less than that for grid electrodes, but peg electrodes may not obviate invasive intracranial evaluations.

Limitations

FO electrodes have definite limitations: The nature of the FO electrode recording technique implies that only restricted questions can be answered, namely: (a) do the seizures originate at the mesiobasal temporal lobe structures? If yes, (b) are they constantly lateralized? In addition, (c) information is obtained as to whether the seizure origin is more anterior or posterior. However, if the seizures do not originate at one mesiobasal temporal lobe, the patient is by definition no longer a suitable candidate for 'curative' selective AHE, and it must then be decided whether further evaluation is indicated with a view toward more extensive temporal lobe or even extratemporal surgery.

There is evidently a risk of falsely localizing an apparent seizure origin in the mesiobasal TL and missing the true origin outside these structures when the FO electrode technique is used. The best way to minimize this risk is to carefully study the clinical features accompanying the seizures by recording the occurrence of the subjective auras and/or the objective signal symptoms and to correlate these with the simultaneously recorded EEG. In addition, as already mentioned, FO electrodes can be combined with other recording techniques, such as subdural strips as illustrated by the case described above (Figure 71.6).

The most reliable seizure onset patterns recorded with the FO electrodes are the high-frequency low-amplitude discharge pattern and the so-called 'hypersynchronous' seizure onset pattern (Figure 71.5)[28]. In the absence of these patterns, the localization of the seizure onset zone should be questioned. A very local decrement at the FO electrodes is the most frequently observed initial seizure pattern in the Zürich FO electrode series. If it was followed within 3–5 seconds by a high-frequency discharge at the same localization, it is also a reliable pattern for seizure onset localisation. From analysis of simultaneous recordings from depth electrodes inserted directly into limbic structures, such as the amygdala, anterior and posterior hippocampus, and parahippocampal as well as fronto-orbital and cingulate gyrus, and from FOelectrodes, it became evident that a very local initial flattening of the EEG record from the FO electrode was nearly always associated with a high-frequency low-amplitude discharge observed in the stereotactic depth recordings from the hippocampal formation and/or amygdala. Usually the FO electrodes pick up mesial temporal lobe epileptogenic activity very reliably.

Only in the very rare cases of prolonged discharges totally confined to the amygdala and not affecting the hippocampal formation, the FO electrode may miss these amygdala discharges (Figure 71.9). This is because the amygdala behaves like a closed electrical field. In our SEEG series, however, these amygdalar seizures account for only about 3% of all psychomotor seizures.

The limited placement of peg electrodes represents their main limitation. The usage of the epidural peg electrodes at the Cleveland Clinic has declined significantly over the past years. In part these changes reflect surgical preferences but to a large extent they are due to improvements in non invasive evaluations including (1) high-resolution MRI scans, (2) volumetric analysis of the hippocampus and (3) digital EEG allowing reformatting and filtering of data. It has also become apparent that

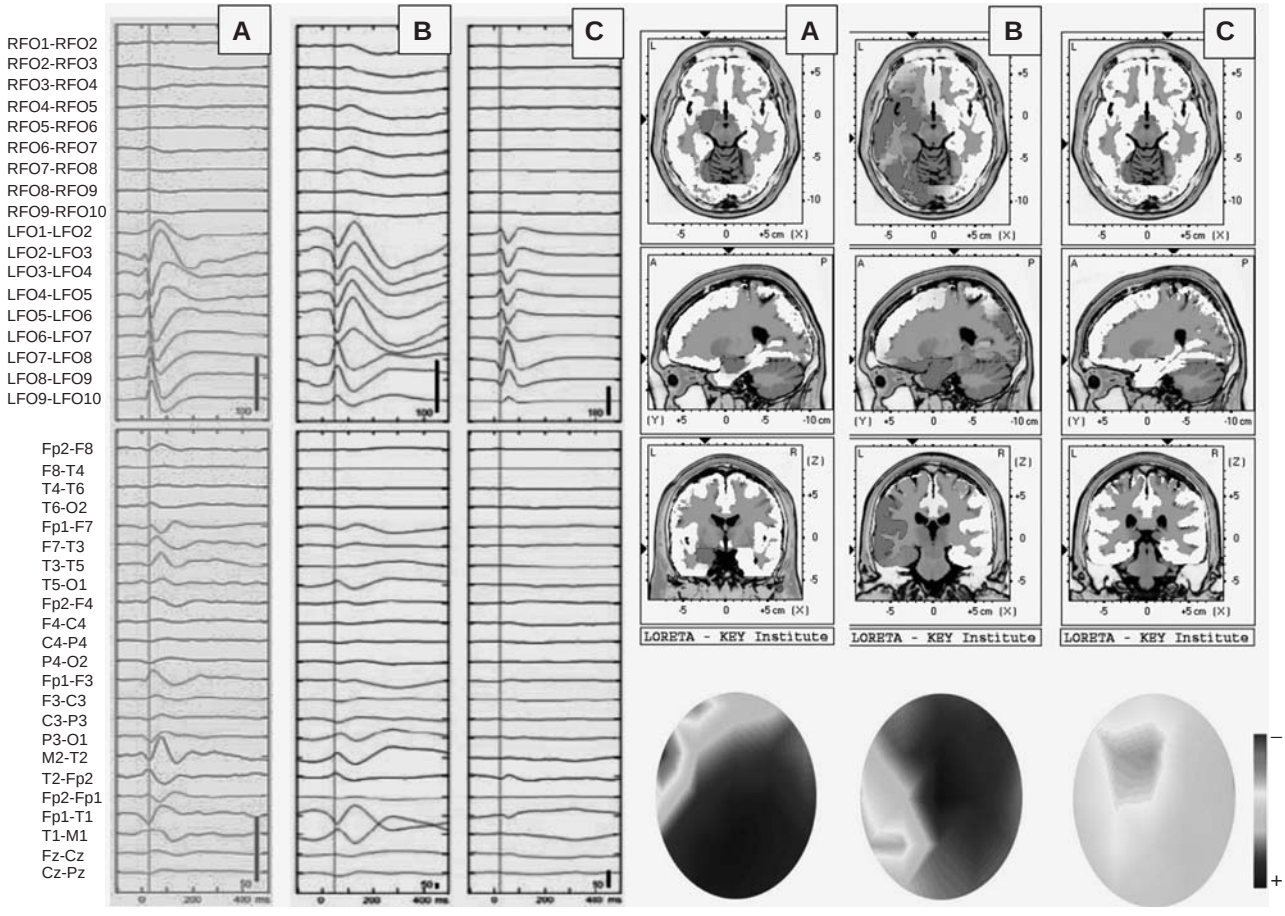

Figure 71.8 Averaged FO electrode and scalp EEG spikes for three representative interictal epileptiform discharges (A,B,C) and statistical LORETA (low-resolution electromagnetic tomography) solutions shown as two-dimensional orthogonal brain slices (right upper part) representing significant cortical activation during the ascending phase of the intracranial spike and topographic voltage maps (right bottom). For A 199, for B 90, and for C 180 events have been used for averaging and statistical nonparametric testing of each spike. Constellation A, i.e., a very restricted activation of ipsilateral mesial temporal lobe, was seen in 11/15 studied patients and represents 19/30 IED patterns (63.3%). The averaged intracranial spike could be reliably detected in the scalp-EEG after averaging. Constellation B, i.e., a widespread neocortical activation involving frontal and temporo-posterior structures, occurred in 5/15 patients and represents 6/30 IED patterns (20.0%). The spikes could be reliably detected in the scalp-EEG without averaging! Constellation C, i.e., a very restricted mesial temporal spike, occurred in 4/15 patient and represents 5/30 IED patterns (16.7%). The spikes could not be detected in the scalp-EEG, despite averaging. Courtesy of Dr.Dominik Zumsteg; see also Zumsteg *et al.*, in press).[32]

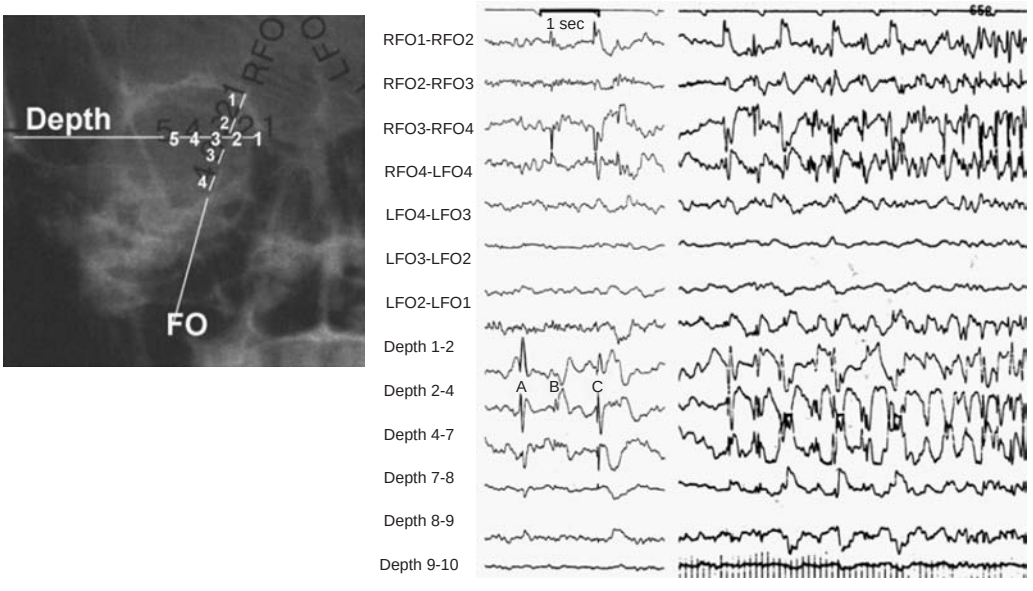

Figure 71.9 Combined depth- and FO electrode recording with interictal spikes A,B,C (left) and ictal discharge (right). Note the discrepancies between spikes recorded in depth and FO electrodes. Spike A, obviously generated in the right amygdala, is not reliably reflected in the FO electrode contacts, whereas spikes B and C and the discharge at the right are visible in both electrode types, although with obvious form differences. (Modified from Wieser and Morris,1997).[33]

in evaluation of a patient with a focal epilepsy but whose studies include no focal MRI abnormalities and no localizing EEG abnormalities epidural peg electrodes are unlikely to demonstrate a clear epileptogenic focus. In other words they are not very helpful in this kind of 'fishing expedition'.

Complications

In 1987 we had one serious complication in the Zürich FO series consisting of a subarachnoid hemorrhage, which led to a transient upper pontine syndrome. MRI-documented subarachnoid hemorrhages without any neurological deficits occurred in two other patients. Meningitis occurred in two patients and was treated by innaveneas antibiotics without sequels. Placement of FO electrodes may be associated with transient morbidity, especially facial pain. Temporary facial pain has occurred in 19% of our patients. Two patients reported mild transient temporo-mandibular joint dysfunction. Recurrence of labial herpes was seen in 5%. A transient hypo- or dysesthesia, localized in one corner of the mouth, was reported in 9% of the cases. There were no other side effects or complications, and, in particular, no persisting trigeminal impairments.

One patient pulled out one FO electrode in a postictal confusional state, one patient damaged one electrode during shaving. Since the information was not sufficient both had to be reimplanted.

Complications of epidural peg electrodes

By the end of 1993, approximately 77 patients had over 500 epidural peg electrode insertions and studies at the Cleveland Clinic; at the Bethel Epilepsy Center 36 patients underwent evaluation using approximately 420 epidural peg electrodes. In these patients no major complications were seen. In one Cleveland patient a single cortical contusion was discovered on CT scan.

Culturing the peg electrodes at time of removal yielded a bacterial colonization rate of approximately 22% in the Cleveland Clinic Series; no patient had a clinical infection due to these electrodes. The lack of clinical infection was in part due to prompt treatment with appropriate antibiotics if the electrode cultures proved positive.

Costs

The costs of FO and peg electrodes are considerably less compared to other invasive techniques. Insertion of FO electrodes can be done in local anaesthesia and does not require a sophisticated neurosurgical procedure or a neuroradiological examination under stereotactic conditions. Usually no intensive care is necessary and patients with FO electrodes alone can be evaluated outside highly specialized units. However, the major expenses derive from the long-term monitoring and they are similar whether the electrodes used are semi-invasive or invasive.[17]

Future directions

Whereas FO electrodes may be viewed as a major step in making presurgical evaluation less invasive, the usefulness of peg electrodes remains limited.

It is our guess that FO electrodes will continue to be increasingly used in nonlesional TLE patients being candidates for AHE, whereas the use of peg electrodes obviously declines. Arguments for this prediction are that in TLE very effective standardized surgical procedures are offered and the main goal of the preoperative evaluation is to answer the question whether or not a patient is a suitable candidat for one of these surgical procedures. In nonlesional extratemporal epilepsies, however, exact localisation of the epileptogenic area remains still a very demanding and difficult task asking for usually – at least additionally – invasive intracranial recording techniques.

Conclusions

From the Zürich experience based upon strict indications the semi-invasive technique of FO electrode recording is suitable for the evaluation of potential candidates of AHE. Since AHE has virtually abolished larger TL resections in Zürich a considerable proportion of patients considered for surgical treatment of TLE are candidates for bilateral FO electrode evaluation. The aim of the FO electrode implantation is to record and study the patient's spontaneously occurring habitual seizures.

Epidural peg electrodes are a useful and safe addition to the surgical epileptologist's toolbox. However, they should be seen as being complimentary to other invasive electrodes and not as a replacement.

72 Subdural electrodes

MZ Koubeissi

Introduction

Success of resective surgery for intractable epilepsy is dependent on accurate localization of the epileptogenic focus. Whereas all areas of interictal epileptiform discharges need not be resected in order to achieve seizure control,[1] the most reliable criterion for localizing epileptic foci for subsequent surgery is identification of the area of onset of spontaneous seizures.[2,3]

Localizing epileptogenic focus can be achieved with higher accuracy by recording intracranial ictal discharges, than by other localizing abnormalities, such as imaging, neuropsychological testing, extracranial EEG recordings, and seizure semiology.[4-6] The majority of the cases monitored with intracranial electrodes will have successful localization of the epileptogenic region leading to resection.[7] Henry *et al.* found that the ictal onset zones in 47 of 50 patients, who had had inconclusive extracranial ictal EEG, were successfully localized with intracranial recordings, leading to efficacious resections in 38 patients, regardless of the neuroimaging findings.[5] Even in situations when there is evidence of more than one epileptogenic focus, monitoring with intracranial electrodes may help identify the focus most responsible for the patient's stereotypical seizures, the resection of which promises to at least lessen the burden of epilepsy.[4]

The indications for monitoring with subdural electrodes and the implantation procedures are discussed elsewhere in this book, but will be briefly reviewed here.

Indications

Selected patients can undergo resective epilepsy surgery without the need for intracranial monitoring. This commonly occurs when noninvasive presurgical results, including electrophysiologic and neuroimaging data, are concordant.[8] However, there are situations when extraoperative monitoring with subdural electrodes is needed to allow identification of the area of ictal onset and its relation to brain regions that need to be preserved by epilepsy surgery. This permits maximal resection of epileptogenic cortex with minimal functional deficits.

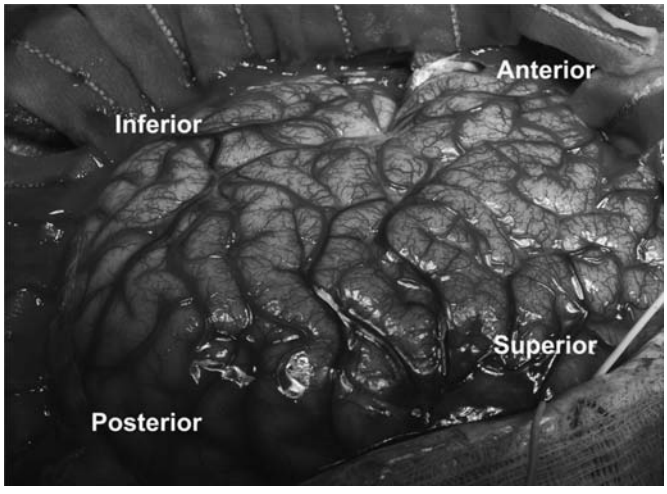
The following scenarios are examples of situations where subdural electrode implantation is needed. Subdural electrodes are used for localization of ictal onset in patients with medically intractable epilepsy, who have no medical or psychiatric contraindications for invasive monitoring, when:

(1) less invasive studies fail to lateralize or localize the epileptogenic focus, e.g., seizure semiology strongly suggests the area of origin, but extracranial EEG fails to lateralize the ictal discharge,
(2) neuroimaging is normal despite clinical evidence of localization-related epilepsy,
(3) localization of ictal onset by extracranial EEG is discordant with the results of neuroimaging, raising the question of dual pathology,
(4) extracranial EEG and MRI data are concordant, but are discordant with seizure semiology, location of interictal epileptiform discharges, or results of neuropsychological evaluation, and
(5) mapping of cortical function is needed, as in patients who appear to have epileptic foci close to, or overlapping with, their eloquent cortex.

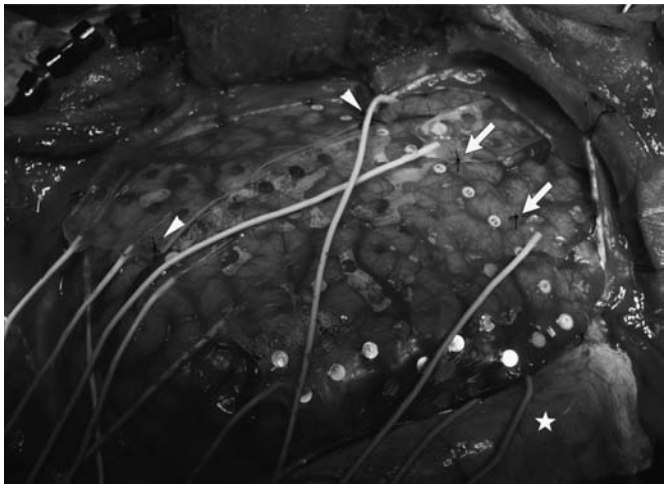
Procedure

Subdural grid electrodes are implanted under general or local anesthesia. Commonly used electrodes consist of platinum-iridium[9] or stainless steel discs[10,11] with exposed surfaces of 2.3 mm diameter. They are embedded in a transparent soft silastic sheet, and are evenly spaced with an interelectrode distance of 1 cm. Depending on the indication, they can be placed over the cortical convexity, within the interhemispheric fissure, and over the basal surface of the brain. For example, in patients with dominant temporal lobe epilepsy (TLE), a 6×8 or an 8×8 grid is usually implanted over the perisylvian cortex, and a combination of strips, or a smaller grid, is implanted over the basal temporal cortex. Usually, half of the perisylvian grid is above the sylvian fissure and half is below it. The grid allows electrocortical stimulation mapping of language, as well as the inferior sensorimotor strip that includes the tongue and the inferior portion of the hand areas. In patients with seizure foci in other regions, implantation of subdural electrodes is tailored to maximize the chances of covering the epileptogenic region; they can be implanted over the visual, sensorimotor, or supplementary motor cortices.[12] Subdural electrodes are anchored in place by suturing the silastic sheet to the overlying dura mater (Figure 72.1).

Subdural strips consist of 4–8 disk electrodes, with an interelectrode distance of 1 cm. They are placed along with grid electrodes through a craniotomy, or through burr holes on either side to help lateralize seizure focus. A common procedure is to implant three to four strips through a frontal burr hole, and three to four through a temporal burr hole on each side. Such an implantation is needed for lateralization of the seizure focus.



(a)



(b)

Figure 72.1 Intraoperative photographs help determine the location of most subdural electrodes with respect to cortical anatomy. a. Left craniotomy in a patient who had been monitored by scalp electrodes with poor localization of seizure onset in the left hemisphere. b. Extensive subdural electrode implantation aims at maximizing the chances of identifying the area of ictal onset as well as mapping eloquent cortical areas. The dura mater has been retracted (white star). The subdural electrodes are embedded in a transparent silastic sheet that allows visualization of the underlying gyral anatomy, and is carefully fitted over the cortical surface and sutured to the overlying dura mater. Note that the 8×8 suprasylvian grid is sutured to two 2×5 frontal grids (arrows) and to a 4×8 infrasylvian grid (arrowheads), and that each cable connects two rows of electrodes to the EEG amplifier.

Intraoperative photographs are important for determining the location of some electrodes with respect to gyral anatomy (Figure 72.1). Some electrodes, however, cannot be directly visualized intraoperatively, as they do not lie within the margins of the craniotomy. The position of such electrodes, and that of strip electrodes implanted through burr holes, are verified by postoperative X-rays, and by superimposition of postoperative volumetric CT scan (with 1.0 mm axial slices to reconstruct the patient's skull and locations of subdural electrodes) on a cortical surface rendering of a preoperative volumetric magnetic resonance image (MRI) (Figure 72.2). Once implanted, the patient undergoes continuous video/EEG monitoring for 1–2 weeks for accurate localization of the seizure focus and mapping of eloquent cortical function.[13,14]

Seizure patterns

Interpreting ictal patterns recorded by subdural electrodes requires awareness of not only pathologic patterns, but also physiologic and artefactual phenomena. Familiarity with such patterns is needed for identification of the epileptogenic zone, defined as the zone whose resection or complete disconnection is necessary and sufficient to eradicate seizures.[15] The ictal onset zone, where the first electrical changes are detected, *regardless of their morphology*, prior to the clinical manifestations of the seizure (Figure 72.3), is presumably included within the epileptogenic zone.[16]

Early ictal patterns recorded by subdural electrodes may take one of various morphologies, including rhythmic sinusoidal waves, irregular spike discharge, spike and wave activity, and low voltage fast activity.[16] These patterns are not different from those described in extracranial recordings. Blume *et al.*, studied the ictal pattern of partial seizures recorded by scalp EEG in 66 patients,[17] and reported electrodecremental pattern in 11% of the seizures recorded, sinusoidal waves in 47%, and repetitive epileptiform discharges (most commonly spikes and sharp waves) in 39%. Originally, guidelines for interpreting intracranial ictal tracings were anecdotal, but the criteria for identifying ictal patterns recorded by subdural electrodes have been evolving. High frequency oscillations, for example, are now recognized as an electrographic ictal signature.[18] This has become possible, in part, because digital EEG, unlike analog EEG, is not dependent on the response rate of the pen, and can have sampling frequencies of up to 10 kHz, allowing recognition of faster frequencies. Numerous studies over the past three decades assessed the morphological patterns of ictal EEG, and correlated them with brain region, pathology, and surgical outcome.[7,16,18–20]

In the context of describing an analog-digital circuit that detects electrographic seizures, Babb *et al.* defined seizures as high-frequency, high-voltage spikes lasting 5 seconds.[2] They argued that, while physiologic brain activity tends to show an inverse relation between voltage and frequency, ictal discharges can have a high frequency (up to 30 Hz), but will still maintain a high amplitude. The same objective of automatic recognition of seizures lead Gotman *et al.* to define ictal discharges as activity that is paroxysmal, rhythmic, and sustained.[21] Other authors defined ictal discharges recorded from intracranial electrodes as significant and specific deviation of EEG patterns from the baseline that consists of electrodecremental patterns or rhythmic activity *with or without apiculate waveforms.*[22]

Spencer *et al.* defined intracranially recorded seizure onset as sustained and rhythmic EEG patterns, with frequencies higher than 2 Hz, that are state-independent and different from the background.[7] Such a definition of early ictal patterns precluded assessment of low-voltage fast rhythms in their series, although the authors acknowledged that low-voltage fast activity is a recognized ictal pattern and resection of tissue where such pattern is localized, is associated with a good seizure control prognosis.[23]

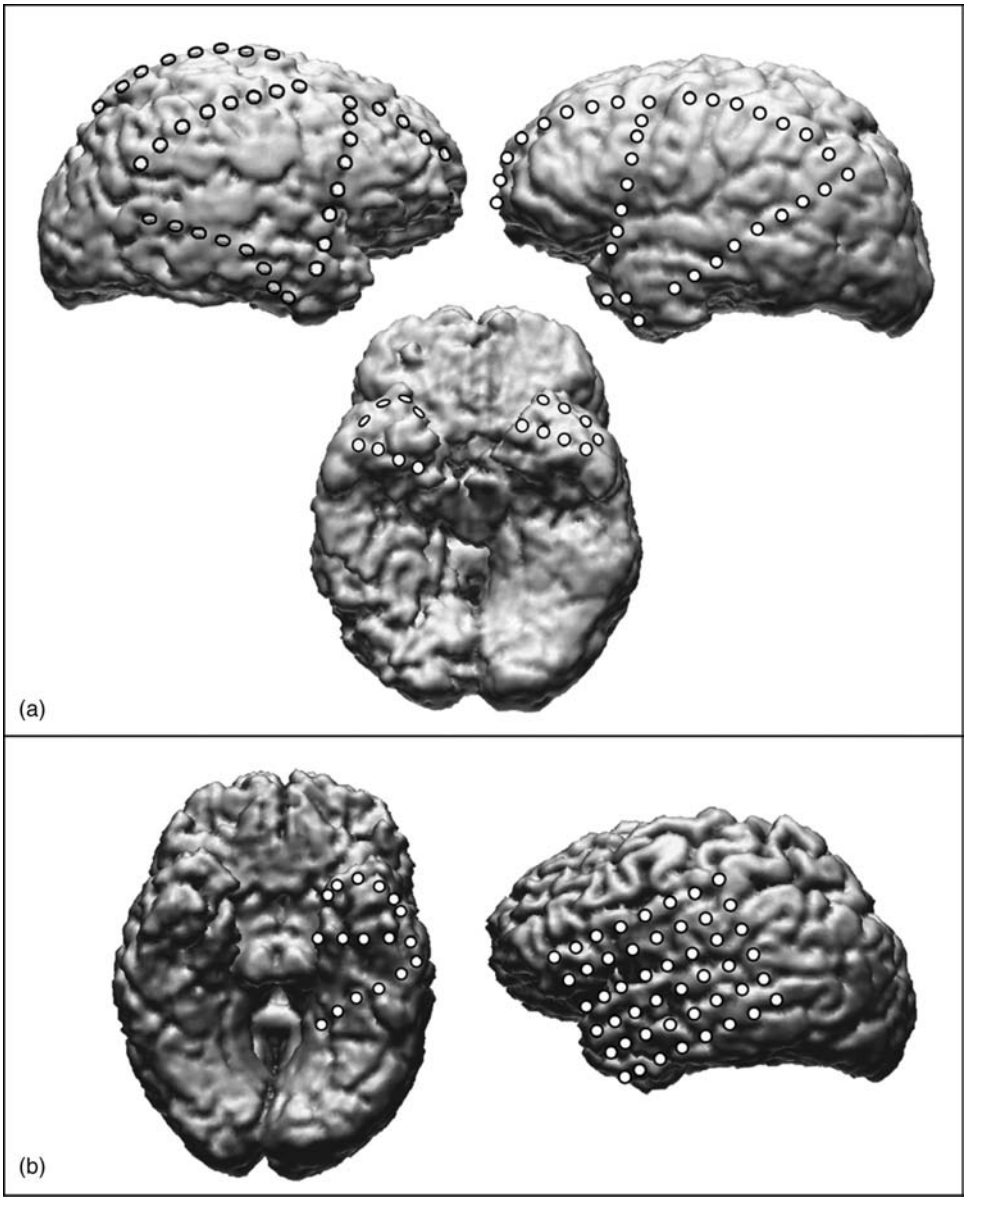


Figure 72.2 Cortical surface rendering of a presurgical volumetric magnetic resonance image (MRI), with the location of subdural electrodes from a postoperative volumetric head computed tomography (CT) scan superimposed. The coregistration (done with Curry software, Compumedics Neuroscan, El Paso, TX) allows three-dimensional visualization of the implanted electrodes in relation to gyral anatomy. a. Bilateral strip electrodes are placed through burr holes in order to help lateralize the seizure focus. Three (left) and four (right) strips are placed through frontal burr holes, and three through temporal burr holes on each side. b. This is a patient whose extracranial EEG showed an ictal discharge in the left frontotemporal regions several seconds after the clinical seizure onset (see also Figure 72.3). Grid electrodes were implanted over the left frontal and temporal lobes with an 8 × 8 grid covering the perisylvian cortex, and three 1 × 6 strips sampling the basal temporal cortex.

Low voltage fast activity

The pioneers of EEG included a gamma band to represent activities higher than 35 Hz, but this band was of very limited clinical use as the analog EEG machines were limited by the response time of the stylus, in addition to using a 'standard' low pass filter of 70 Hz.[9] The first reports of intracranial recordings that associated high frequency activity with ictal electrodecremental pattern on scalp EEG date back to 1950, when Mazars and collaborators performed corticographic recordings of epileptogenic foci before they attempted surgical resection.[24,25] A decade later, Bickford and Klass reported that 19 of 350 seizures started with generalized electrodecrement.[26] This pattern was later associated with tonic seizures, infantile spasms and Lennox-Gastaut syndrome, but some authorities later argued that most partial seizures are initially associated with a low-voltage fast pattern if electrodes are close enough to the seizure focus.[9,27] Morris *et al.* described regional electrodecrement in association with complex partial seizures of temporal lobe origin.[11] The invention of digital EEG, and extraoperative monitoring of patients with implanted subdural electrodes, led to further characterization of high frequency activity as an ictal pattern.[9,18,19,27]

With higher digital sampling frequency and low pass filter, even higher frequency oscillations may be detected that will aid is identifying epileptogenic cortex (see Figure 72.5). Fisher *et al.* recorded seizures with subdural electrodes sampling the EEG at 2000 points per second, and using a 300-Hz low-pass filter.[9] They found that the EEG signal included within the

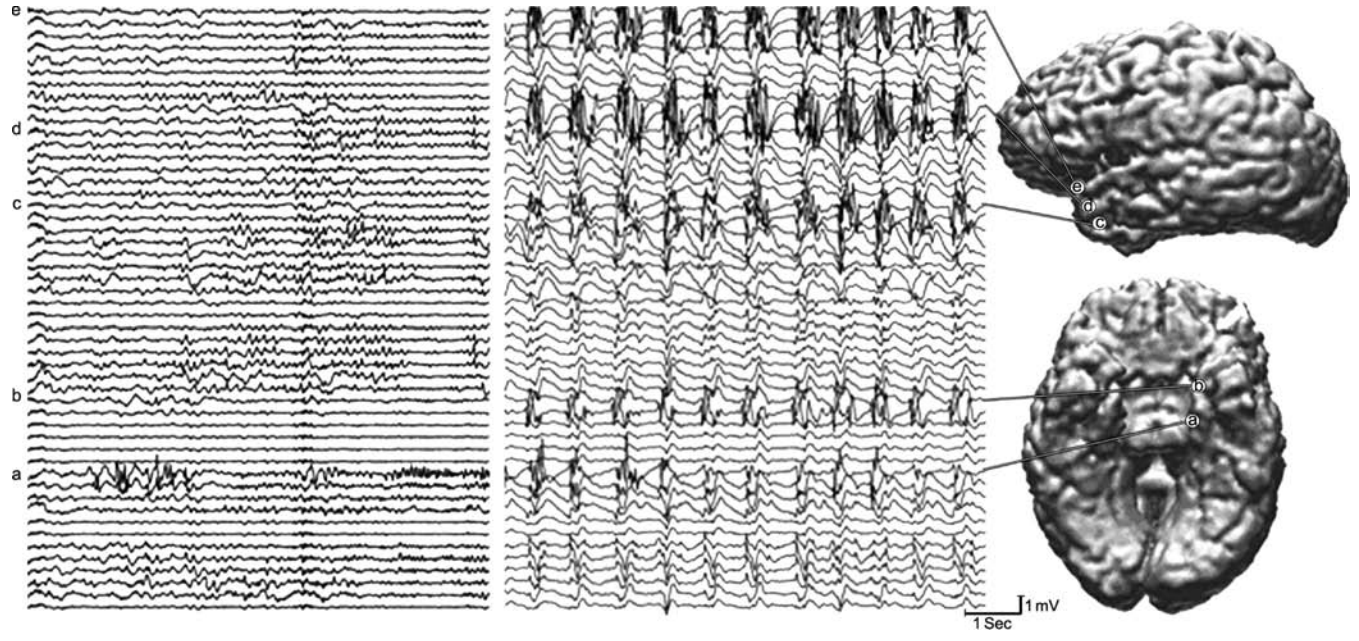

Figure 72.3 Ictal EEG recorded intracranially in the patient whose subdural electrodes are shown in Figure 72.2b. Clinical seizure onset, semiologically identical to what has occurred without discernible scalp EEG changes during prior extracranial monitoring, is now seen in association with an electrographic ictal discharge localized to the left mesial temporal region (first page, electrode a). The second page, approximately 1 minute later, shows a fully evolved ictal discharge, which would have become evident by scalp electrodes at that stage. The locations of the most active electrodes are shown on the brain surface.

ictal electrodecremental pattern consisted of a 'conventionally invisible' high-frequency band, illustrating the importance of high-frequency recordings in localizing seizure foci. At the start of seizures, the 40–50 Hz portion of the frequency spectrum was doubled and the 80–120 Hz portion increased five times in the region of epileptic focus, but not in remote areas. The same authors reported evidence of high-frequency activity originating in one frontal lobe by subdural electrodes when scalp-EEG recording revealed diffuse electrodecrement as an ictal pattern.[27] Semiologically, seizures associated with this pattern were dialeptic, dystonic, tonic, atonic, or a combination of more than one type. Worrell *et al.* found that 62% of neocortical seizures recorded by subdural electrodes were preceded by an increase in high-frequency activity in the 20 min prior to the clinical onset of the seizure.[18]

Alarcon *et al.* used subdural, as well as intracerebral electrodes, to record 78 complex partial seizures.[16] They studied five seizure patterns: electrodecremental events, low-voltage fast, short bursts of irregular sharp waves intermixed with slow activity, regular epileptiform discharges, and rhythmic ictal transformation. In 12 out of 15 patients, electrodecremental events constituted the early ictal pattern. The authors also reported that interictal spectral EEG power was generally below 12 Hz,[16] but ictal changes appeared more complex and not always localized to one area.

A 2006 study concluded that high frequency oscillations occur in epileptogenic areas, both mesial temporal and neocortical, but rarely in areas of seizure propagation.[19] The presence of high-frequency oscillations at seizure onset is considered a measure of proximity of the recording electrodes to the epileptogenic focus, whereas absence of such activity indicates poor localization (see Figure 72.4).

Ictal patterns and specific pathology

Since extraoperative monitoring with subdural electrodes became common use, several studies attempted to correlate locations of the seizure onset zone and ictal patterns, with their pathologic substrates. However, it is unclear whether specific ictal patterns are strictly related to certain tissue pathology, and it appears that the morphology of the ictal discharge is, at least in part, determined by an interaction between the anatomic location and tissue pathology.[28]

Correlation between electrocorticographic data and pathology has been studied most in TLE. A study that used lateral and basal temporal subdural electrodes in patients with intractable TLE demonstrated that epileptogenic lesions were likely located in the immediate vicinity of structural lesions.[11] The authors also found that macroscopic lesions (i.e., ones that could be seen by head CT scan or by the naked eye intraoperatively) were more likely to be lateral temporal, whereas microscopic lesions were basal or mesial. An earlier study in patients with TLE concluded that ictal and interictal EEG recordings yielded different conclusions about the presence and nature of pathology.[29] Other studies related spike-wave discharge or repetitive spikes with cortical dysgenesis,[30] periodic spikes preceding seizure onset with reduced cell count in the CA1 region of the hippocampus, and the latency of the ictal discharge propagating to the contralateral hippocampus with reduced cell count in the CA4 region.[31]

Spencer *et al.* studied the ictal pattern of 166 seizures in 26 patients recorded intracranially with a combination of depth and subdural electrodes, and correlated the morphological manifestations of the ictal pattern with the pathology of the resected tissue.[7] They found that 58% of temporal lobe

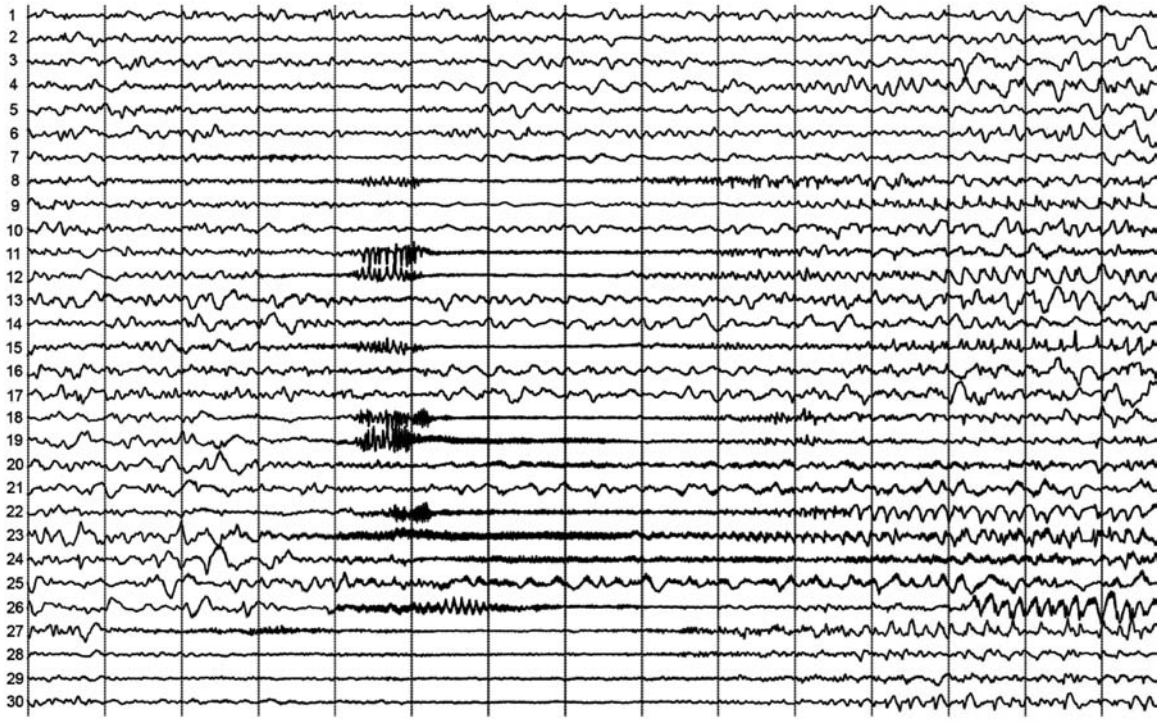

Figure 72.4 Ictal tracing from right occipital lobe subdural grids in a 20-year-old patient with intractable seizures manifesting as elemental visual phenomena in the left hemifield, followed by alteration of awareness, and occasional secondary generalization. This is a bipolar montage with channels 1 through 17 covering the lateral parieto-occipital convexity, and channels 18 through 30 covering basal and medial occipital regions. The digital sampling frequency is 1000 Hz. Notice the regional low voltage, high frequency (approximately 200 Hz) ictal discharge.

seizures with initial ictal discharge frequencies of <13 Hz were associated with positive pathology (including mesial temporal sclerosis), compared with 96% of those with initial frequencies of >13 Hz ($p < 0.00001$). On the other hand, extratemporal seizures with an initial ictal discharge frequency of <13 Hz were significantly associated with abnormal pathology, and those with a frequency of >13 Hz with normal tissue. However, all seizure patterns and frequencies were seen in both mesial temporal and extratemporal seizures, and separate seizures were recorded with discharge frequencies of either greater or less than 13 Hz in half of their patients. Conversely, in patients with extratemporal seizures, abnormal pathological findings were not associated with variability of seizure onset frequency. Temporal lobe seizures are more likely than extratemporal seizures to exhibit variable frequency of the initial ictal discharge in the same patient.

A study in patients with neocortical epilepsy showed that ictal patterns consisting of gamma range activity were likely to be seen in extratemporal locations and tended to be of regional onset.[28] However, beta frequency activity was seen more commonly in temporal lobe seizures and those with more focal onset. Different pathologic substrates were not associated with differences in onset frequency. Of note, seizure freedom was not related to onset frequency or distribution. Another study found no relation between spatial distribution of ictal onset and pathology,[32] but at least two studies[29,33] associated focal onset with reduced hippocampal cell density.

Localizing value of ictal patterns

Localization of the epileptogenic zone can be approximated by the onset of an electrographic seizure, provided it occurs prior to, or at least concomitantly with, the clinical onset. The localizing value of the ictal pattern can be assessed by the surgical outcome, as seizure freedom after epilepsy surgery indicates that the epileptogenic region was included in the resection.

Faster frequencies at the onset of the ictal discharge probably signify that the recording electrodes are closer to the ictal onset zone than those with slower onsets.[28] Slower onset frequencies may represent propagated activity,[34] and regional onset may indicate volume diffusion or spread from a distant generator.[35] This view is corroborated by the good outcomes after epilepsy surgery being associated with low-voltage fast activity at seizure onset,[36] and with focal onset seizures.[29] Some authors, however, found no relation between surgical outcome and the spatial extent of the seizure onset.[28]

Alarcon *et al.* used a combination of depth and subdural electrodes to correlate electrographic patterns with surgical outcome in patients with complex partial seizures.[16] They reported early electrodecremental patterns with frequencies below 40 Hz in the majority of their patients. Whereas localized high-frequency patterns correlated with favorable outcome after epilepsy surgery, diffuse electrodecremental patterns were not associated with poor outcome. The authors argued that diffuse electrodecremental patterns may not be part of the ictal process itself.

Figure 72.5 Ictal tracing from a right perirolandic subdural grid in a 33-year-old patient with intractable daily seizures manifesting as left hand sensory symptoms, which then involve more proximal arm regions and face. At times, this is followed by motor symptoms and occasional secondary generalization. Extracranially recorded EEG has shown no ictal discharge is association with seizures manifesting as mere left hand sensations without further progression. With subdural electrodes, however, there is one-to-one correspondence between the onset of her sensory seizures and bursts of fast (85–90 Hz) activity (upper page and insert). Channel 18, where the fast activity is seen, corresponds to a contact over the hand area of the primary somatosensory cortex (confirmed by electrical stimulation mapping). Note that the fast activity is followed 2–3 seconds later by regional electrodecrement (last 2 seconds of the upper page), and, several seconds later, by a higher voltage rhythmic spike discharge. Digital sampling frequency is 1000 Hz, and the low-pass cut-off frequency is 300 Hz. Decreasing the frequency of the low-pass filter increases the likelihood of missing the initial high-frequency activity which is most localizing to the seizure onset zone. Of note, resecting the cortical tissue corresponding to the initial burst of high-frequency oscillation (electrode 18) resulted in total cessation of seizures.

Limitations

The major limitation of recording with subdural electrodes is that they sample only a limited area of the cortex, which increases the likelihood of missing the epileptogenic region. To maximize the chances of covering the area of ictal onset, epileptologists generally plan the implantation after extensive preoperative testing. Nevertheless, in some patients it may be difficult to determine whether the ictal discharge recorded by a certain subset of subdural electrodes is originating from that area or propagating to it. The initial patterns of local onset and propagating electrographic seizures may be identical, although one study found that rhythmic theta-delta activity may be unique to propagating seizures.[34] In addition, the spatial extent of the ictal onset zone may be difficult to determine if the initial ictal discharge is detected by electrodes at the border of a grid.

Another limitation of recording with subdural electrodes is in patients with deep seizure foci. Although depth electrodes only parsimoniously sample the cortex and cannot be used for mapping of cortical function, they are superior for recording from the mesial temporal structures[37] and from some patients with neuronal migration disorders.[38] Even when subdural electrodes cover the hemispheric convexity, they record activity from only a limited area of the neocortex, and may miss electrical activity in the banks of fissures or sulci. Lüders *et al.* argued that the inability of subdural electrodes to record from cortical infoldings may explain the difficulty of detecting auditory evoked potentials with perisylvian plates,[12] as the auditory cortex is likely probably located deep in the supratemporal plane.[39]

In TLE, subdural electrodes led inadequate or even false localization of ictal onset in two studies using simultaneous subdural with depth electrodes.[40,41] Another study found that lateralization of the seizure onset zone, when detected by subdural electrodes, was always concordant with depth electrode recordings, but subdural electrodes were less sensitive in detecting hippocampal seizures.[37] Other authors showed that concordant lateralization by depth and subdural strip electrodes was seen in the majority of recorded seizures in patients with TLE, although some seizures were falsely localized by subdural electrodes.[42] The authors concluded that accurate localization is achieved by basal temporal subdural electrodes when the parahippocampal region is covered.

73 Stereoelectroencephalography

P Kahane and S Francione

Introduction

In the presurgical evaluation work-up of patients suffering from drug-resistant partial seizures, intracranial EEG has been in use for more than 50 years. This practice not only generated considerable historical and practical information, but also continues to hold an important role in the precise definition of the epileptogenic zone in a consistent percentage of patients. Invasive EEG, indeed, is still performed on 25–50% of patients at most epilepsy surgery centers, depending on the referral population. Among the broad group of invasive procedures, and more especially in the field of 'depth recordings', some conceptual and technical aspects make the stereoelectroencephalography (SEEG) very particular since, from the begining, it has been conceived by Talairach and Bancaud as a comprehensive methodology and not only as a diagnostic tool.

Theoretical basis

Historical background

The basic principle of Bancaud and Talairach approach was to study the seizures themselves, through what they named the 'anatomo-electro-clinical correlations'.[1–3] Under this term, they regarded the chronological occurrence of ictal clinical signs as crucial, reflecting the spatio-temporal organization of the epileptic discharge within the brain. Their clinical analysis of ictal events, beyond a simple description, consisted, on one hand of interpreting the symptoms according to documented cortical topology, and on the other hand of analyzing them chronologically to imagine a logical spatial evolution of the intracerebral discharge. Understanding this temporal dynamic of ictal symptoms with respect to brain anatomy implied that 'ictal electroencephalographic changes must be recorded at the very point where they occur (anatomo-electrical relationships) and that their initial or secondary reverberations on the clinical picture (electro-clinical relationships) must be evaluated as the discharge spread'.[2] Such an approach was rendered technically feasible thanks to the advent of atlases providing the spatial coordinates of most telencephalic structures, as well as the development of neurosurgical techniques that allowed to target and reach such coordinates[4,5] (see Chapter 104). The selection of the structures to be explored was based on a very careful analysis of all the data – notably clinical – collected during the noninvasive presurgical investigations in order to formulate one or several hypothesis concerning the site(s) of seizure onset, and the pathways of preferential ictal spread.[1–3,6–8] The implantation strategy was then 'custom-tailored', and electrodes were placed according to the prior hypotheses, in a way that enabled to interpolate intracerebral EEG activity within the interelectrode space. The underlying concept was therefore very different from other intra-cerebral EEG procedures referred to as 'depth recordings'[9–11] the aim of which was primarily to ensure the side of seizure onset in temporal lobe epilepsies, or to differentiate frontal lobe seizures from temporal lobe seizures. Intracerebral targets were in such cases relatively standardized in order 'to avoid biasing the exploration strategy in favor of one's preferred localizing hypothesis'.[12]

It was clear, when considering the SEEG method, that if the pre-SEEG hypotheses were wrong, the placement of intracerebral electrodes would be inadequate, the interpretation of SEEG findings was likely to be erroneous, and surgical results would be probably poor.[13] Conversely, if the pre-SEEG hypotheses were correct, the resulting implantation strategy would allow to help to identify the amount of brain tissue that must be ideally resected, and to reliably anticipate the patient's postoperative outcome according to the surgical possibilities and limits.

SEEG today

Technically speaking, the SEEG method has evolved with time: 'acute' recordings has became 'chronic', electrodes have been reduced in size, electro-clinical correlations have been improved thanks to the advent of audio-video-EEG monitoring system, and intracerebral targets are currently assessed using MRI. Conceptually, 'the song remains the same', and a SEEG study cannot be performed without having previously hypothesized what the preferential origin and spread of the seizures could be.[13–16]

As for many epilepsy surgery centers, the overall proportion of our patients evaluated by invasive recordings has decreased over the last decade. However, the subset of patients who can benefit from the use of SEEG remains significant and, in our centers, approximately 40% of resective surgical procedures are performed so far after SEEG recordings.[14] Schematically, such recordings are needed when noninvasively obtained data remain insufficiently concordant, when they are discordant or inconclusive, and when they suggest an early involvement of highly eloquent areas, providing that the questions derived from the noninvasive protocol are clear, and that the patient is likely to benefit from surgery.

Implantation strategy

Since there are no standard targets for electrode implantation, the selection of the structures to be explored must be determined individually, mainly on the basis of both clinical and scalp-EEG seizure pattern(s).[1–3,6–8,13–15] This assumption is even true in lesional epilepsies where a SEEG study may remain indicated. In such cases, the presence of a lesion will influence the implantation strategy, as far as the relationships between the lesion itself and the region of seizure generation must be clarified. Nonetheless, the leading principle is still to investigate all the cortical areas, the ictal involvement of which is suspected on the *main* basis of ictal electro-clinical information.

Yields of electro-clinical findings

Today, evidence has accumulated on the diagnostic value of seizure symptoms, and many studies have been – and continue to be – conducted in this way. Most tend to attribute to isolated signs, as well as to clusters or evolution of a few signs, a lateralizing or localizing significance.[17] This kind of clinical analysis, although helpful, remains very different from the working method that Talairach and Bancaud emphasized: in their mind, indeed, ictal clinical symptomatology must be viewed as a whole (this led to the notion of *seizure pattern*). Particularly, it was clear for them that seizure symptoms (and more particularly the 'signal-symptom'), when taken individually, could lead to erroneous interpretation.[1] The emergence of an identical clinical sign may result, indeed, from the ictal disorganization of cortex regions which, even if different, may have common subcortical projections. For instance, an ascending epigastric sensation, 'typically' of (mesio-)temporal lobe origin,[18] may as well translate an ictal involvement of the insular cortex[19] as that of the mesial prefrontal cortex,[20] or be the first manifestation of a discharge circumscribed within a hypothalamic hamartoma.[21] Additionally, symptoms of highly localizing value are rare and, even in such ideal condition, the localizing sign must be integrated chronologically to make an extrapolation of the anatomical origin of the seizure. Focal clonic jerks, for instance, which are the expression of the ictal involvement of motor cortex, will not have the same value at the beginning of an ictal episode initiated by paresthesia in the same body segment (strong probability that the perirolandic region was initially affected), than after the occurrence of auditory hallucinations (propagation of a posterior perisyslvian discharge to the motor strip), or than at the end of a fit beginning with a rising epigastric feeling followed by oroalimentary and gestural automatisms (no localizing value). Finally, the emergence of some signs of relatively poor localizing significance (e.g., gestural automatisms), especially in a late phase of the seizure, may only reflect the simultaneous or sequential dysfunction of several cortical areas – thus probably of several efferent systems – without giving any indication, per se, on seizure origin. A good example is given by the supposedly highly localising significance of 'frontal' hypermotor behavior, which have been recently described during seizures of temporal[22] or insular origin.[23]

Nowadays, ictal clinical patterns are assessed at best by video-EEG monitoring, but careful attention must also be paid to the historical evolution of symptomatology. This latter may have evolved with time, so that auras or focal signs of high localizing significance may have disappeared during the course of the disease, or still exist only in a few occasions but have not been documented during long-term video-EEG monitoring. The cortical areas to which these clinical manifestations refer will have to be taken into account for the adjustment of electrodes positioning.

Although crucial, the localization hypothesis suggested by ictal clinical picture should be confirmed and completed by careful analysis of the concurrent ictal scalp-EEG discharge. This remains essential to confirm the clinical hypothesis when this latter is clear, but above all to improve it when ictal symptoms are ambiguous and fail to indicate a clear-cut localization or lateralization. In that respect, emphasis is put on the identification of the first ictal EEG change that occurs prior to the first clinical symptom, and more specifically on the identification of a well-localized low-voltage fast activity which is likely to reflect an underlying fast-synchronizing intracerebral EEG discharge. As a matter of fact, such a scalp EEG pattern has been recently found to be predictive of a good surgical outcome in frontal lobe epilepsy.[24] However, a low-voltage discharge may not appear on the scalp recording, especially if it is well-limited and located deep in the cortex. In such a case, particular attention must be paid to a well-localized flattening of the EEG trace, or to the disappearance of well-localized interictal EEG abnormalities, which are both good indicators of the region of seizure origin. Altogether, these scalp-EEG patterns of seizure onset are particularly helpful for identifying the core region of the future implantation, but they cannot account for the whole brain area which is involved by the discharge. It is thus of particular importance to also evaluate the cortico-cortical propagation of the discharge, which is at best assessed by a careful analysis of the spatial evolution of the scalp-EEG discharge from the onset of the seizure to its end. Unfortunately, scalp-EEG discharges may quickly be widespread or bilateral, or multiregional, so that the preferential spread pattern may be particularly difficult to define.

The recording of the patients seizures, although crucial, does not exempt one from analyzing interictal EEG abnormalities which may influence in part the final placement of the electrodes, particularly when their distribution does not match with the territories that are suspected to be involved by the seizures, or when ictal recordings are fairly informative due to movement artifacts, as during hypermotor seizures.

Essential rules for electrodes implantation

Although all the SEEG studies are designed, a priori, on the basis of patient's individual characteristics, the analysis, a posteriori, of all our investigations shows that they can be schematically grouped in several implantation patterns, according to the main cortical regions that were targeted[25] (see Chapter 104). However, the exact drawing of electrodes placement is never identical for one patient to another one, and it closely depends on all the noninvasive features previously collected (see below the illustrative case). As a rule, the position and number of intracerebral electrodes (Figure 73.2a) must be designed to address the following issues:

1. Demonstrating that brain regions suspected to be involved in seizure onset and early propagation (the 'epileptogenic zone') show the expected ictal pattern. This requires the suspected brain regions to be implanted (Figure 73.2b).

2. Considering the possibility that this pattern might in fact reflect the propagation of an ictal discharge generated elsewhere. This requires a comprehensive review of such alternative hypothesis, and the intracerebral evaluation of part or all of the corresponding brain structures (depending on the number and the likelihood of these hypotheses) (Figure 73.2c).
3. Delineating the border of the 'epileptogenic zone' as precisely as possible, in order to perform the minimum cortical resection. This requires the placement of intracerebral electrodes in brain structures located outside the theoretical limits of the suspected 'epileptogenic zone' (Figure 73.2d).
4. Assessing whether the removal of the cortical areas involved in seizure generation will be possible or not. This requires the investigation of the eloquent areas that are of interest, relatively to the hypothetical 'epileptogenic zone', and with respect to the possible boundaries of the planned resection (Figure 73.2d).
5. Evaluating the precise relationships between an anatomical lesion (when present) and the 'epileptogenic zone'. This requires to investigate, whenever possible, the epileptogenicity of the lesion itself and in any cases of the surrounding cortex, the number of the 'lesional' electrodes to use depending on the morphology, extent and anatomical location of the lesional process (Figure 73.2b).

Illustrative case

This 32-year-old right-handed patient, without any familial nor personal antecedent of epilepsy, started having seizures at the age of 8 years. During childhood, the fits were initiated by auditory illusions associated with blurred vision, which were followed by a loss of contact and left oculo-cephalic deviation, possible fall, and rare secondary tonic-clonic generalisation. The episodes persisted until the age of 12 years when clobazam was associated to carbamazepine and phenobarbital. Around the age of 17, seizures recurred, beginning with a sensation of nausea in the stomach during which the patient was able to speak, followed by a loss of contact with gestural and verbal automatisms. Since then and despite numerous medications, seizures persisted with a mean seizure frequency of six to nine episodes per month, without any prolonged seizure-free intervals. Ictal symptomatology changed at the age of 21: seizures started with a sensation of pleasure ('a spiritual pleasure'), rarely associated with an epigastric feeling or with a *déjà-vécu* impression. These auras could remain isolated without language disturbances, or could be followed by a global sensation of 'switching off' (lowering of the sounds and visual blurring) as the prelude to the loss of contact, the features of which were not well described.

At the age of 30, the patient came at the C. Munari Epilepsy Surgery Centre for presurgical evaluation. Neurological examination was normal and neuropsychological evaluation demonstrated a deficit in both verbal and visuo-spatial memory functions. The only persisting aura consisted in an inconstant and brief feeling of pleasure, which might precede the loss of contact with staring and a few gestural, verbal and oro-alimentary automatisms; the postical phase was characterized by deambulatory behaviors and complex verbal automatisms. Seizures could also occur in clusters of brief and pauci-symptomatic fits, during which the patient experienced a sort of ecstatic state with a clear spatio-temporal disorientation; he was still able to speak and had an almost correct working and social behaviour.

MRI (Figure 73.1) showed in the right temporo-occipital junction a slightly expansive lesion involving the cortex of the collateral sulcus and the surroundings fusiform and lingual gyri. These gyri appeared thickened with a discrete hyposignal in inversion-recovery sequences and a clear and more widespread hypersignal in FLAIR images. The superior part of the lesion presented with a cystic component of less than 1cm in diameter. The diagnosis of tumor, possibly a dysembryoplastic neuroepithelial tumor, was suggested. No other MRI abnormalities were found, especially concerning the right hippocampus and the temporopolar region.

Video-EEG monitoring showed, interictally, a clear asymmetry of background activity (8–9 Hz, mid amplitude) which appeared more regular and better represented over the left posterior regions. Slow waves and rare spikes were recorded over the right fronto-temporal region. Spikes frequency was increased during sleep, with a phase reversal over F8, but also T4 and T6. Occasionally, left temporal asynchronous spikes were also recorded. Five electro-clinical seizures were recorded during wakefulness. In all, the patient was able to warn and

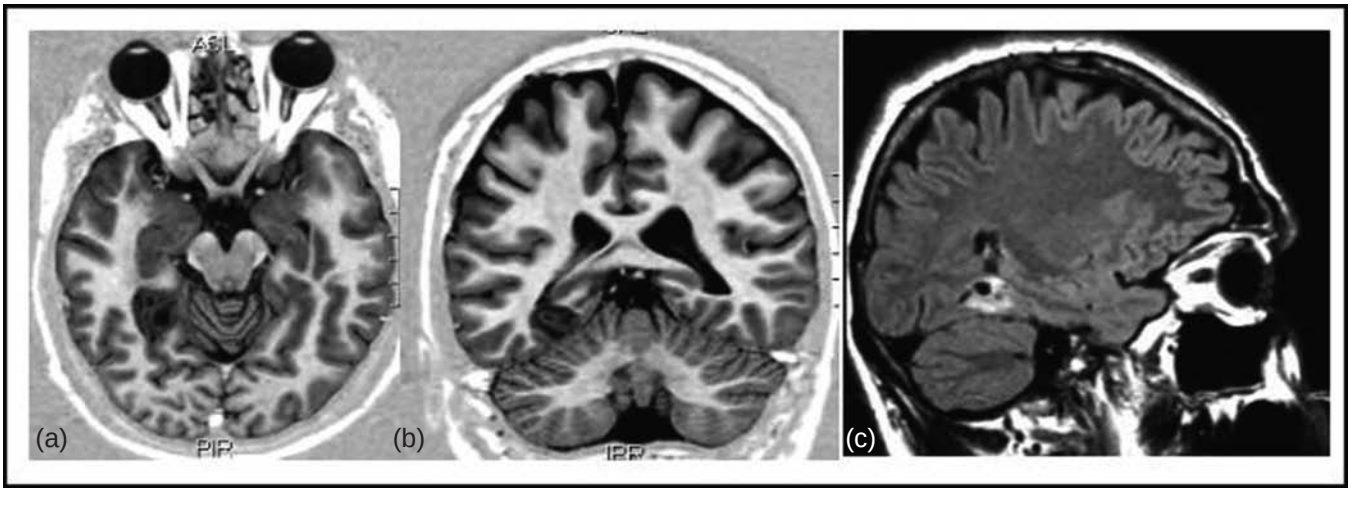

Figure 73.1 Pre-operative MRI (patient of the illustrative case). a: axial view, inversion-recovery sequences; b: coronal view, inversion-recovery sequences; c: sagital view, FLAIR sequences.

dialogue with the observer for the first 10 seconds. Then, the contact was impaired with staring, verbalization of a few stereotyped words, occurrence of a few activities of swallowing and discrete chewing. The episodes lasted less than 1 minute, at the end of which recovery of language function was total within a few seconds. EEG correlate was poor at the initial phase of the fit, but a clear rhythmic theta activity occurred while the patient became unresponsive: this activity mainly involved the right anterior temporal region, with a latter spread over the right parieto-central and left temporal regions.

These anatomo-electro-clinical features led us to propose to the patient a SEEG investigation (Figure 73.2a), the main aims of which were to define the relationships between the lesion with its different components (Figure 73.2b), mesiotemporal lobe structures (Figure 73.2b), and the visual and auditory cortices (Figure 73.2c). The SEEG study aimed also at evaluating how the different parts of the temporal neocortex and the adjacent temporo-parietal and temporo-occipital regions could participate in seizure early spread.

Recording and stimulation procedures

Thanks to many technical progresses such as the advent of long-term audio-video-EEG monitoring systems, most – if not all – SEEG studies are nowadays conducted extraoperatively in chronic conditions. Altough the monitoring systems utilized vary from one center to another, two main technical features are required to provide reliable information: the system must be able to sample the signal at a high frequency rate (at least 256 Hz, but recent work in patterns of seizure onset suggests potential benefit of using at least 512 Hz and even more), and to acquire the signal from at least 64 channels (but it is clear that this is a strict minimum, and twice, or even more, that number is optimal, and currently used). In our centers, we choose one of the contact sites in the white matter as reference and depth EEG activity is displayed using bipolar recordings between contiguous contacts. SEEG activity is

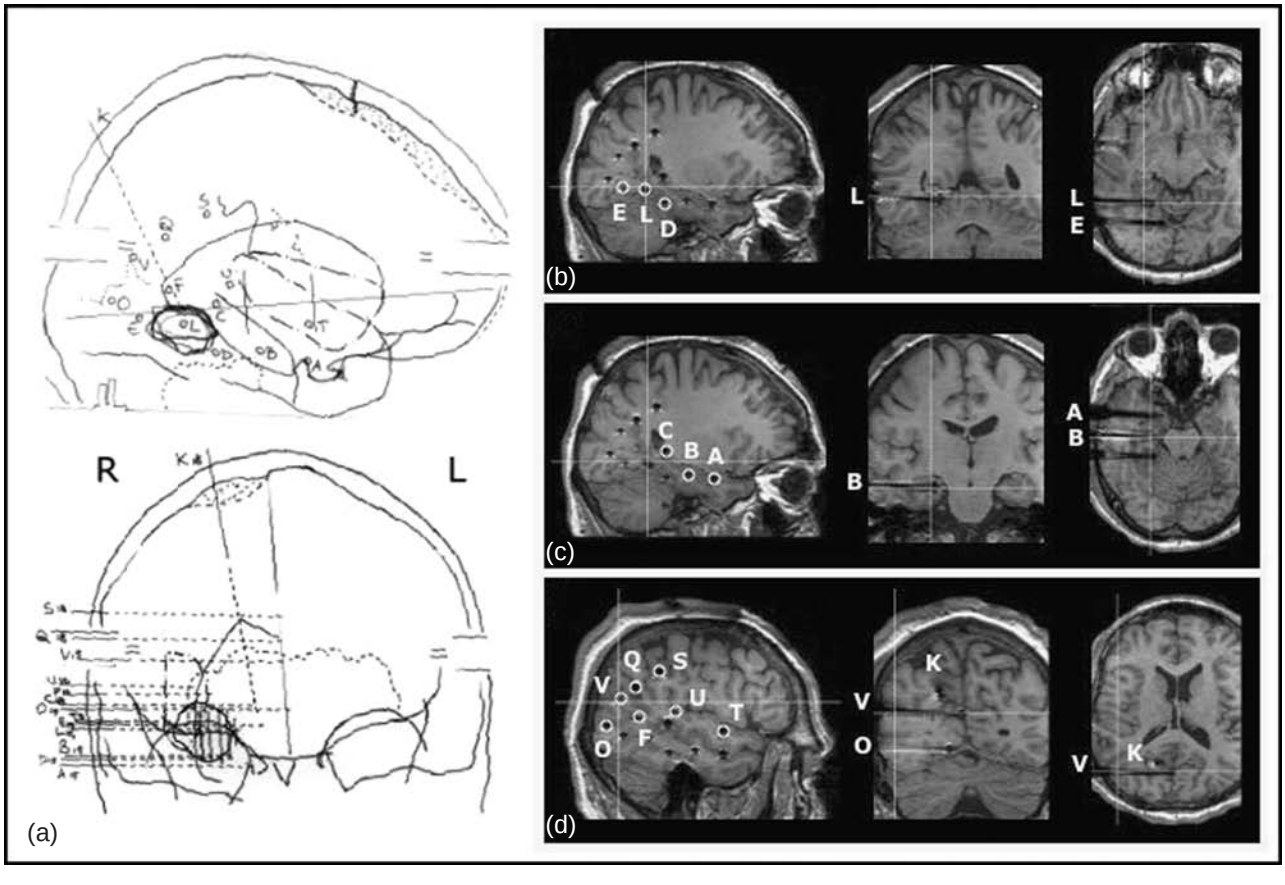

Figure 73.2 Implantation of intracerebral electrodes (same patient as in Fig.1). a: SEEG scheme, lateral and frontal view of the skull; b, c, d: multiplanar reconstructions (sagittal, coronal and axial views) of the MRI performed with the implanted intra-cerebral electrodes. b: position of the electrodes exploring the suspected ictal onset zone, including the lesion (L) and the peri-lesional cortex located anteriorly (D) and posteriorly (E); c: position of the electrodes recording mesial temporal lobe structures (A: amygdala, B: anterior hippocampus, C: posterior hippocampus), the role of which in early propagation (or even onset) of the seizures had to be clarified; d: localisation of the other intra-cerebral electrodes utilised in this case for a complete definition of the cerebral structures involved in the primary and secondary organisation of ictal discharges: i) superior temporal gyrus (electrodes T and U) due to auditory illusions described in the patient's history; ii) visual cortex (internal leads of electrodes F, O, V, K) both for clinical (blurred vision) and functional reasons; iii) lateral cortex of the temporo-occipital and temporo-parietal junctions since in our experience, such 'pauci-symptomatic' fits may result from an the ictal involvement of this extended neocortical region.

often recorded along with a limited number of EEG needle electrodes, the electrocardiogram is systematically monitored, and other parameters such as the electromyogram or the oculogram may at times be assessed.

Recordings are performed under different conditions (waking, after sleep deprivation, or during night sleep when necessary), over a period of 1 to 3 weeks, with a gradual reduction of patient medication when necessary. Patients are continuously observed by a member of the epilepsy team in order to obtain a precise description of subjective patient experience at seizure onset, as well as to test awareness, language, muscle tone and sensory-motor functions. Particularly, attention is focused on the signs and symptoms which cannot be assessed by reviewing retrospectively the videotapes, and more especially on the initial subjective symptoms which may be forgotten at the end of the seizure. In our experience, it is not necessary to capture systematically a predefined number of ictal episodes, but it is mandatory that the fits recorded are similar to the patient habitual seizures, and well documented. Recording of several seizures, however, is usually necessary, particularly in those of patients in whom ictal symptomatology is fairly stereotyped. The aim is to be able to analyze the main elements of the clinical symptomatology before one can establish electro-clinical correlations.

Electrical stimulations are performed for several days under continuous video-EEG control. The goals are the reproduction of the aura, the induction of an electroclinical seizure, and/or the localization of an eloquent cortical area that has to be spared during surgery. Following our standard clinical practice,[26] stimulations are performed at 1 Hz and 50 Hz (depending on the level of excitability and on the type of clinical signs that one expects to elicit by stimulating a given structure) and applied between contiguous contacts at various levels of the electrode axis. Advantages and limits of the stimulation during SEEG procedure is the object of Chapter 71.

Interpretation of SEEG findings

It is not possible to systematize, in this chapter, all the findings provided by a SEEG study, since each investigation is designed for a specific problem, and the number and type of structures evaluated vary according to the problem under investigation. Schematically, the interpretation of a SEEG study aims first at constructing a preoperative composite 'drawing' of the brain area to be removed (what we could call the 'what-to-remove area'), which could be easily followed in the operatory theatre. The determination of this area depends above all on the study of the anatomo-electro-clinical correlations evidenced during the seizures themselves, also taking into account the features of subclinical discharges and of interictal abnormalities, as well as the effects of electrical stimulation.

Seizure analysis

Seizure analysis represents the principal guide of the whole SEEG approach, as it allows to define what the mentors of Sainte-Anne School named the 'epileptogenic zone', i.e., the 'site of the beginning and of the primary organization of the epileptic seizures'.[8] However, what was clear in Bancaud and Talairach's minds from their earliest clinical experiences was that the topographic determination of the epileptogenic zone could not be based only on electrophysiological criteria: it depended on the study of electro-clinical correlations, this term underlining the importance to assess not only the precise anatomical location of the site of origin and early spread of the ictal discharges, but also how these SEEG changes gave rise to the clinical symptoms.

Ictal onset

In SEEG terminology, the ictal onset zone ('site of the beginning ...,) can be defined as the cortical area(s) where the first clear ictal electrical change is recorded. The SEEG assessment of this area, however, depends on the spatial sampling of the SEEG investigation, so that caution is required to ascertain that the site of seizure origin has been unequivocally identified. Nevertheless, it is reasonable to attribute to the first clear ictal electrical change a reliable localizing significance, providing: **(1)** that this change occurs prior to the clinical onset of the seizure, and **(2)** that it manifests by a fast synchronizing discharge (low-voltage fast activity or recruiting fast discharge of spikes), the pattern and frequency of which may differ from one region to another one.[27–29] The lack of one of these two criteria implies an incorrect SEEG investigation, so that the ictal onset zone, as well as the epileptogenic zone (which by definition should include the ictal onset zone), cannot be defined. In such condition, success or failure of surgery, if eventually performed, will not provide any valuable information. Conversely, the coincidence of clinical and relevant ictal electrical findings, and a fortiori the appearance of clinical onset after such ictal SEEG changes, both tend to indicate that the positioning of at least some electrodes is correct (Figure 73.3).

Primary organization of the discharge

The definition of the ictal onset zone, however, only helps in defining part of the epileptogenic zone, the main difficulty being then to evaluate 'how much of the cortex contiguous to the site of origin is recruited into action to produce a clinical seizure'.[30] Bancaud and Talairach assumed that this issue could be answered, at least in part, by considering also the cortical areas participating in early seizure spread ('... the primary organization of the epileptic seizures'). Under this term, particular attention deserves the spatial extent of seizure discharges at the moment where the first clinical sign(s) occurs, as well as the coherence between the localization of the discharge and the (expected?) type of the concomitant symptom(s) (Figure 73.3). Also, attention must be paid on the types of SEEG changes that occur during seizure evolution: once again, emphasis is put on cortex areas that are able to generate fast synchronizing discharge, including not only those recruited successively from the ictal onset, but also those exhibiting such a fast activity *de novo* during the course of the initial discharge (Figure 73.3). In any cases, what must be considered as an 'early' or a 'late' SEEG change cannot be assessed in terms of seconds, or tens of seconds, so the repertoire of ictal patterns are rich and the propagation times variable. This probably explains why Talairach and Bancaud used preferentially the term of 'primary organization of the epileptic seizure' than the term of 'early seizure spread'.

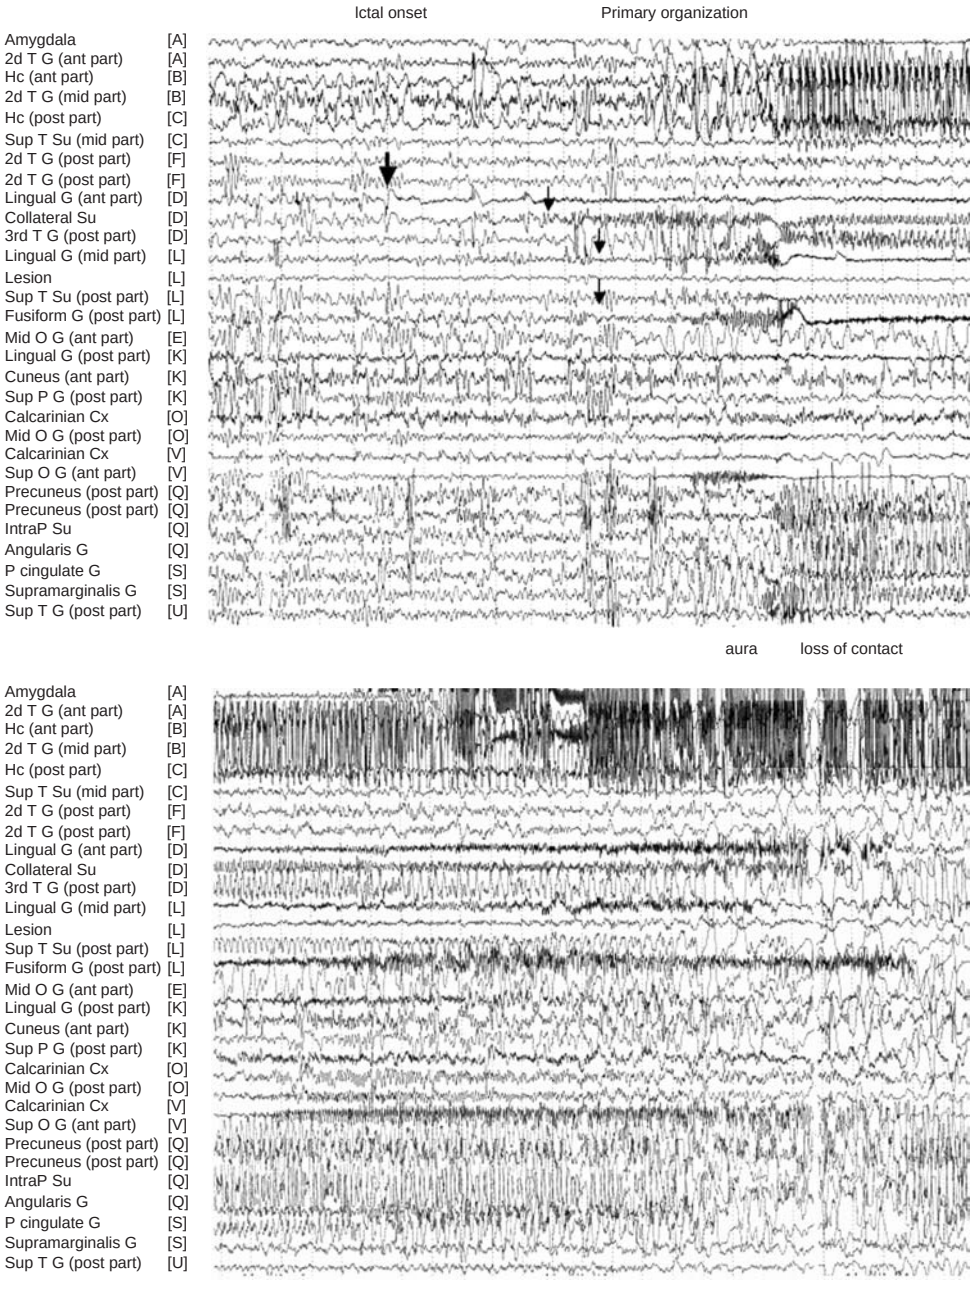

Figure 73.3 SEEG recording of an electro-clinical seizure (same patient as in Fig.1,2).G: gyrus; Su: sulcus; T: temporal; Hc: hippocampus; P: parietal; O: occipital; 1st/2d/3rd: first/second/third; ant/post: anterior/posterior; sup: superior. Letters in brackets refers to the recording electrodes (see Fig.2). a: The seizure starts in the anterior part of the lingual lobule, an immediately peri-lesional structure, with a low voltage fast discharge (first arrow); 4 seconds later, this activity involves, in a slower way, the collateral sulcus, the mid part of the lingual lobule and the posterior part of the fusiform gyrus (small arrows); two seconds after, the fast discharge spread out of the borders of the peri-lesional area, involving the third temporal gyrus as well as the superior and mid occipital gyri. At that time, the hippocampal formation begins to exhibit a spiking activity. During all this period, the patient, who was talking with one of the observers, does not report any symptom but looks like watching around with an interrogative expression. Ten seconds after the ictal onset, he stares for a while before saying: 'I guess I'm having an aura'. Immediately after he stops answering and obeying to the observer, even if he can continue looking at her. The electrical correlate of this sudden clinical modification is easily identified and consists, on one hand, in the abrupt acceleration of the low voltage fast discharge, especially over the lingual and fusiform gyri, and on the other hand in the sudden occurrence of a high amplitude spike-and-wave discharge within the hippocampus which seems to evolve independently. b: During the second part of the fit, the discharge is widely extended, involving almost all the explored structures.

Postictal findings

Early postictal findings, although not clearly specified in Talairach and Bancaud's work, are part of the analysis of any seizures recorded during SEEG investigation. Particular attention has been paid to those cortex areas exhibiting, at seizure termination, major attenuation and/or suppression of their background activity. Insofar, Toussaint *et al.*[31] have recently reported that postictal SEEG suppression accurately localized the seizure onset zone in a majority of frontal lobe cases, while it appeared more widespread in temporal lobe patients, involving both areas of ictal onset and seizure propagation. Postictal spikes were, in this study, of relatively poor localizing significance, in accordance with other works.[32] Certainly, postictal patterns have been neglected in the literature and further work is needed to set their actual role in the surgical decision.

Subclinical discharges

In any cortical location, a rhythmic activity or a fast activity mimicking an ictal discharge may develop focally without any accompanying symptoms. It is reasonable to attribute to such 'subclinical seizure activities' a high localizing significance, in as much as they have been correlated with an excellent outcome after surgery.[33,34] However, even when this kind of paroxysmal activity is present on the traces, the recording of the fully developed electro-clinical seizures remains mandatory. Subclinical discharges, in fact, may differ in terms of morphology and/or location from the clinical ictal discharge, or may appear identical to the early part of a clinical seizure which later involves other cortical structures.[35]

Interictal abnormalities

Lesional area

In SEEG terminology, the *lesional zone* refers to the brain area which is revealed by an abnormal slow-wave activity or, in some cases, by a major alteration of background activity or by an electrical silence.[6,7,13,36] These features, especially when caricatural, presume an underlying macroscopic alteration of the neural tissue, making common the anatomical overlapping of the electrically defined *lesional* zone with the 'epileptogenic lesion' (currently the most often revealed on MRI). Due to this good correlation, when slow-waves are present in the 'negative MRI area', neuroimaging evaluation should be improved in that specific region. However, the topographic distribution of the slow-waves does not always match with a lesion as assessed on pathological specimens. Thus, although the significance of such nonparoxysmals events remains unclear, it seems legitimate to carefully consider the area which exhibit continuous delta wave activity for the final surgical decision, even in the absence of a corresponding MRI anatomical lesion.

Irritative area

One of the cortical zones identified at the end of a SEEG study is the *irritative zone*, which includes the structures mainly involved by spike activity. Due to the abundance of these paroxysms and to their great variability in firing pattern and location, the definition of the irritative zone often represents a difficult diagnostic problem. In particular, the topographic relationships with the 'epileptogenic zone' must always be carefully evaluated since, in many occasions, the two zones can strongly differ in localization or show only a partial overlapping.[13] In a surgical perspective, however, it would be a mistake to ignore the extent of interictal spikes, whether they are focal or not. Indeed, they can provide additional confirmation of localization, but also may even prove of more important localizing value than seizure recording. This is typically the case of Taylor's focal cortical dysplasia (type II), whose peculiar interictal pattern could be considered as a good marker of the extent of the dysplastic cortex that needs removal to abolish the seizures.[37–39] Particular attention has to be paid, moreover, to those spikes that do not disappear at seizure onset; this persistence, indeed, might suggest that they do not depend on a pathophysiological process common to the underlying area(s) of seizure onset, and therefore that they might be part of what Lüders and colleagues named the 'potential seizure onset zone'.[40]

Intracerebral electrical stimulation

Intracerebral electrical stimulations represent a mandatory part of a SEEG study, not only for localizing eloquent cortical areas, but also (and often mainly) for eliciting seizures.[26,41,42] This latter application may prove very helpful in many controversial circumstances: (1) when spontaneous ictal discharges are widely extended from the onset of the seizure; (2) when they apparently arise 'independently' from different brain structures; (3) when regions initially silent at seizure onset seem to activate abruptly during the ictal discharge, showing in the further phases an asynchronous electrical build up that is different in terms of frequency and morphology from the primary seizure discharge. In these cases, induction of a complete and habitual seizure sequence by electrical stimulation militates for the inclusion of the stimulated structure in the surgical plan. Elicitation of auras may also help by identifying relay and subrelay areas that are essential for the final construction of ictal clinical picture, especially when those symptoms have disappeared in the course of the disease, or still exist occasionally and were not documented spontaneously. Even in this figure, however, the correct interpretation of elicited auras has to take into account, according to Talairach and Bancaud, the possibility of the activation of regions (cortical and subcortical) remoted from the stimulation site. Therefore, and mainly when a local ictal discharge has not been concomitantly elicited, caution is required when establishing a causal relation between a stimulated structure and the occurrence of a given symptom.[3] The role of electrical stimulation for defining the ictal onset zone is detailed in Chapter 71.

Surgical implications

Schematically, the 'what-to-remove area', wherever its location may be, can be defined either as focal, regional (lobar), multilobar, or multifocal. Surgery, in any cases, is designed according to the results of SEEG findings so that tailored resections are the rule rather than the exeption (see Chapter 104) (Figure 73.4).

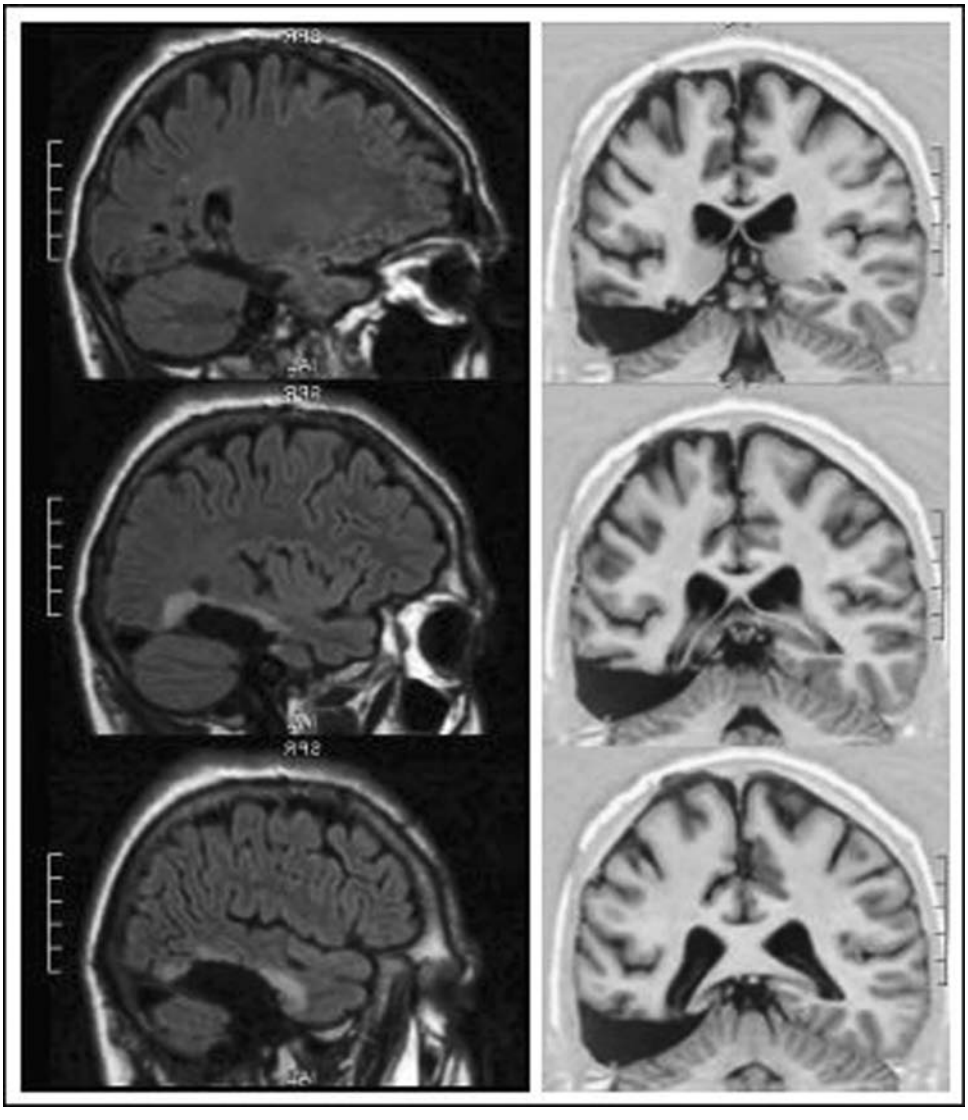

Figure 73.4 Tailored cortical resection (same patient as in Figures 70.1–70.3). Coronal Inversion Recovery (up) and sagittal FLAIR slices from the post-operatory (6 months) MRI study.

Focal discharges

Discharges affecting only a well localized area do exist, showing as many clinical correlates as the combination of topographic and electrical features that one discharge may produce. This is true in temporal lobe epilepsy, where an ictal discharge can remain confined into the amygdala[43] or the hippocampus,[44] the most often without clinical accompaniment; but it is also a common finding in most cortical locations. In fact, one must be sure of the accuracy of the 3D spatial sampling of the SEEG investigation before defining as *focal* such an ictal discharge. As a consequence, very limited cortical resections are uncommonly performed on the basis of SEEG findings. It remains a peculiar finding, which is mainly seen in cases of *focal* epileptogenic lesions. However, small 'epileptogenic zones' may exist even in cryptogenic cases, as recently shown by the therapeutic effect of stereotactic radiofrequency lesion of a very restricted frontomesial epileptogenic 'focus' generating dyskinetic behavior and laughter.[45]

Lobar discharges

In most patients, the area that has to be removed is localized inside the borders of a single lobe, even if ictal discharges may affect initially different structures of the lobe. Therefore, relatively standardized cortical resections can be performed without taking into account some of the subtle variabilities that can be observed in electrophysiological terms and sequential involvement of different structures. This is even true in temporal lobe epilepsy where increasing evidences suggest that the classical subdivision between mesio-temporal and neocortical discharges is an oversimplification.[29,46,47] In extratemporal epilepsies, similar considerations can be done but, due to the more limited experience in this field, the difficulty in the identification of clear cut and reproducible anatomo-clinical patterns is probably greater than in temporal lobe epilepsy.[48–51]

Multilobar discharges

A few years ago, Claudio Munari and colleagues[52] emphasized that in about 20% of patients studied by SEEG, the 'epileptogenic zone' included distinct (but interconnected) regions of different lobes of one hemisphere, and consequently should be defined as 'multilobar'. This condition, though uncommon, has been reported in other studies,[50,51,53–56] and does not represent a purely theoretical discussion: as demonstrated by Munari *et al.*,[52] more than 80% of patients were cured when

the epileptogenic zone was completely (or almost completely) removed, while when the removal was clearly incomplete, the percentage of seizure-free patients dropped to 10%. Thus, the possibility that an epileptogenic zone may extend outside the boundaries of one lobe must be taken into account. For instance, when looking at surgical failures in temporal lobe epilepsy, a consistent percentage of patients are likely to suffer from 'temporal plus' epilepsy (Ryvlin and Kahane),[57] so that identifying this 'multilobarity' might enable to tailor a more extensive corticectomy with a probably better surgical outcome.

Multifocal discharges

In our experience, the indication of depth recordings to understand whether the 'epileptogenic zone' is unifocal or multifocal is rare. In general, patients with electro-clinical evidence of different seizure types are excluded from surgery after the non-invasive phase of the evaluation. However, in a restricted and well-selected number of cases, especially when a lesion is present, the realization of a SEEG may help in establishing whether the different seizure types have a link in between. The results of the SEEG study performed in these conditions may allow to demonstrate that the different seizure types, although multifocal, are in fact part of a widely extended area which can be safely removed.[58] Another striking example of this possibility is represented by patients in whom an hypothalamic hamartoma is associated with multiple seizure types, and in whom SEEG recordings demonstrated that laughing (or crying) attacks, the hallmark feature of the syndrome, were linked to ictal discharges confined to the hamartoma.[21] Such examples are rare enough to be mentioned, so that caution is required whenever different kind of seizures have been clearly documented during scalp-EEG monitoring, and recognized by the patient and/or his family as the habitual seizures. Thus, in our experience, most of the true multifocal epilepsies defined during SEEG procedure are not expected from the non invasive protocol and, as a consequence, the idea of surgery is often abandoned, or eventually dictated by the possible efficacy of surgery on the predominant or more disabling seizure type.

Conclusions

The SEEG is not a presurgical evaluation tool, but a complete methodology which emphasizes the importance to study the spatio-temporal dynamics of seizure discharges (the 'epileptogenic zone'), and not only their starting point (the 'ictal onset zone'). Obviously, it cannot be considered as *the* ideal method for defining the cortical areas that have to be removed to cure the patients. However it has survived the huge development of modern neuroimaging and other noninvasive localizing techniques, and has greatly helped our understanding of ictal clinical symptomatology of partial epileptic seizures. For these reasons, it remains a reliable way to assess the origin and extent of an epileptic discharge within the cortex, even in the absence of any neuroimaging abnormality.

74 DC recordings to localize the ictal onset zone

A Ikeda

Introduction

Interictal epileptic neuronal discharges were expressed as PDS (paroxysmal depolarization shift) and its pathophysiology has been revealed by abnomal channel activity of the cell membrane labeled as channelopathy, or by excitatory amino acid receptor abnormality, and so on. Furthermore, it is also pointed out that the glia performs important roles in buffering functions that help to maintain the uptake of potassium and glutamate, and other aspects of the extracellular circumstances of neurons.[1,2] A change in the microenvironment of the neuron by glial dysfunction could be another important aspect of epileptogenesis.

Since it is most likely that focal cortical epileptogenicity is almost always accompanied by gliosis, i.e., abnormally accumulated normal and abnormal glial cells, except for the functionally determined focal epilepsy such as benign rolandic epilepsy, dysfuction of the glia in epileptic focus could be one of the biggest modulating factors. Ictal direct current (DC) shifts reflect not only epileptic neuronal discharges but also passively depolarized glial activity following depolarization of the epileptic neurons, or the glia plays as an amplifier of the ictal DC shifts, as described below, and thus ictal DC recording could provide very important information about core epileptogenicity in patients with intractable partial epilepsy as surgical candidates.

In this chapter, clinical application of ictal DC recording is described mainly by means of invasive recording techniques, and its usefulness for surgical candidates with intractable partial epilepsy is discussed.

Ictal DC shifts

Generator mechanism and experimental epilepsy

When EEG is recorded with an infinite time constant, slow potentials can be recorded as the DC shifts, which are believed to reflect (1) directly the physiological as well as (2) pathological activity of the central neurons and glia.[3] DC shifts during generalized seizures induced by various drugs in experimental animals were studied by Goldring *et al.*[4] in the 1950s, and clear negative shifts were associated with initial EEG changes consisting of paroxysmal fast activity.

Field potentials recorded during interictal, epileptic activity are transient changes in neuronal membrane potential called PDS occurring in individual neurons.[5,6] As the interictal activity, it starts with steep depolarization which, having exceeded the membrane threshold, triggers a series of action potentials, followed by a plateau for 80 to 100 msec. It is then followed by steep repolarization and further hyperpolarization (Figure 74.1).[7,8]

As the ictal activity, simultaneous recording of intracellular and extracellular (field) potentials in experimental animals revealed that an intense depolarization of neuronal elements in the epileptic focus is associated with the intense DC negative shifts (Figure 74.2)[9], and initially with high frequency discharges. In the 1940s, the experimental model of epilepsy was well developed also by topical application of penicillin, and the observation of slow ictal DC shifts was done by using the DC amplifier in 1965.[10,11] In penicillin-induced seizures, DC negative shifts were associated with tonic seizure showing low-voltage multiphasic pattern. The center of the focus had the surface negative shifts of the highest voltage, and the voltage became gradually smaller with increasing distance from the center. The shifts were positive in the area much further distant from the center.[11] Epicortically recorded negative shifts had no reversal of the polarity beneath the center of focus by microelectrode analysis of the field. Maximum negativity was observed at a depth of 1–1.5 mm corresponding to layer V.[12] Those findings suggest that the intense negative shifts at the center of the penicillin epileptic focus are related to intense depolarization of pyramidal neurons, i.e., PDS, in that area, and that nearly the entire length of the neurons is depolarized with the source of current flow lying in the axons and dendrites. On the other hand, DC shifts in seizures induced by strychnine had a reverse sign of polarity at 400 micron in depth from the surface, suggesting the different epileptogenicity of the pyramidal neurons from those of penicillin focus.[13] The similar DC shifts were also observed in seizures at the hippocampus evoked by electric stimulation.[14]

Role of glia in ictal DC shifts

In addition to intense depolarization of the epileptic neurons, it is also important that glial cell plays a significant role in generating slow cortical shifts.[7] Glial cells are intermingled with neuronal structures, and the glial fibers are electrically coupled by low-resistance electrical junctions to build up an extended functional network as a 'syncytium'.[15] Glial cells do not generate action potentials or postsynaptic potentials. However, glial membrane potentials are not constant, and since action potentials of neurons are associated with the

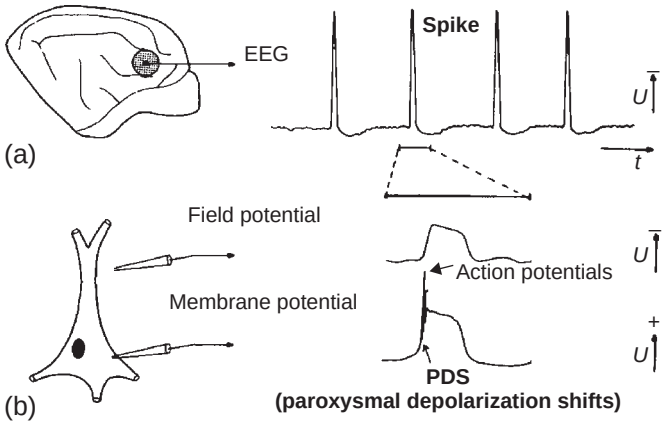

Figure 74.1 EEG (a), and extracellular field potential and membrane potential changes (b) of pyramidal neurons during interictal activity elicited by topical application of penicillin to the cortical surface. The sweep speed in b is five times that in a. (Modified from ref. 7 with permission.)

extracellular potassium concentration increase, it causes depolarization of glial cells (Figure 74.3). If the potassium concentration does not affect the entire glial cell membrane and remains increased only locally, the potential gradients build up along the glial cells, giving rise to intra- and extracellular current flows similar to the ones described in reference to neuronal synaptic transmission. It is also shown that glial, as compared with neuronal, membrane potentials are more sensitive to changes in extracellular potassium concentration in the physiological ranges. Therefore, it is most likely that extracellular field potentials including DC shifts are amplified significantly by glial cells.[16]

Recently, furthermore, in experimentally produced cortical dysplasia (reactive gliosis), astrocytes surrounding the lesion showed a significant reduction in K_{IR} (the activity of inwardly rectifying K^+ channels) and compromised potassium buffering capacity for accumulated extracelluar potassium.[2] It thus may suggest (1) the augmentation of the ictal DC shifts by the abnormal glial function, and (2) possible role of the glia in modulating epileptic activity in the seizure focus.

Recording technique

Clinically, equipments including amplifier and computer hard wares have been currently advanced, and the recent development of epilepsy surgery provided us with the opportunity to investigate ictal DC shifts in human epilepsy.

Practically, the DC amplifier is not necessarily essential for recording slow shifts, but an AC amplifier with long time constant could be allowed to record slow shifts as long as the following three conditions are carefully considered from the methodological point of view: 1) the kind of metals used for the electrode, (2) the size of recording surface, and (3) input impedance of the amplifier.

With regard to the property of the metal of which electrode is made, a nonpolarized or reversible electrode is essential to minimize electrode potentials which could distort slow potential signals. Currently available nonpolarized electrodes are made of Ag/AgCl. However, nonpolarized metals including Ag/AgCl are toxic to the brain tissue. Therefore, when used as intracranial electrodes, the only metals available are polarized or nonreversible ones, such as stainless steel, platinum, and gold. Each metal has its own electrode capacity as demonstrated by Cooper. (Figure 74.4)[17] Among the nonreversible electrodes, platinum is better than either gold or stainless steel to slow potentials.

Since the recording electrode could be represented by a series of resistance and capacitance (R-C circuit), it has the property of a low-frequency filter. Capacitance of electrodes, also combined together with the input impedance of the amplifier, acts as a low-frequency filter (LFF). Since the capacitance is proportional to the recording surface of the electrode, the large electrode surface such as subdural contacts minimally attenuates slow potentials; namely, LFF becomes open. On the contrary, depth electrodes which have a small contact surface may hardly record slow potentials.

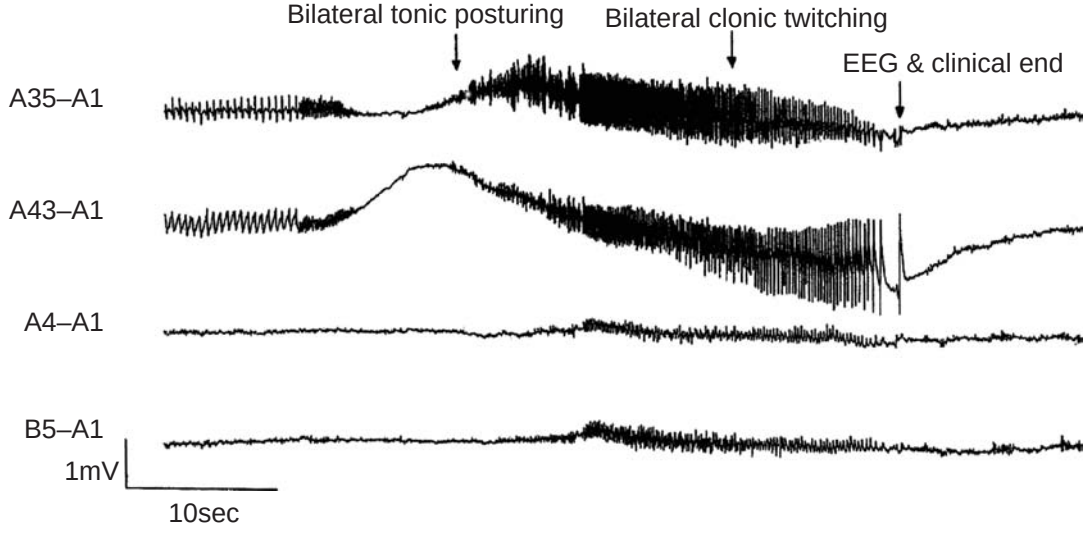

Figure 74.2 Subdurally recorded ictal DC shifts with the setting of time constant of 10 sec in a 48-year-old patient (right parietal lobe epilepsy). 2–3 Hz rhythmic activity at the A42 and 43 are suddenly replaced by high-frequency, low-amplitude activity and 4 sec later by electrodecremental pattern. A slow negative shift is selectively observed at A43 at that time, and then spread to A35 and B5. (Modified from ref. 18 with permission.)

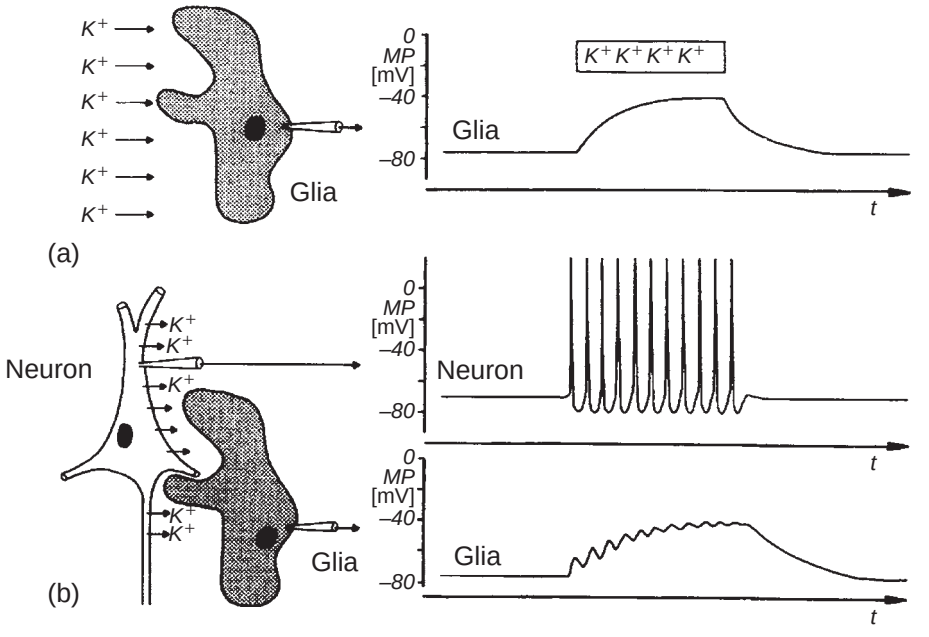

Figure 74.3 Functional linkage between neuronal and glial activities. Increased potassium concentration in the extracellular space close to the glial cell passively depolarizes glial membrane potentials (a). The similar situation in (a) for glial cells is produced by repetitive firing of neurons, and it leads to a sustained depolarization of the neighboring glial cell (b). (Cited from ref. 7 with permission.)

Previously, amplifiers used to have relatively small input impedance less than 1 Mohm, as in Cooper's experiment in 1963 in Figure 74.4. Huge input impedance of more than 50 Mohm is currently available, which minimizes the effects of electrode potentials. Therefore, under the current recording conditions using an AC amplifier, platinum electrodes can record slow cortical potentials provided that widely-opened LFF, with huge input impedance of more than 50 Mohm, and large electrode contact surface are used. Since stainless steel electrodes recorded slow potentials as well as platinum electrodes in our previous study,[18] the difference electrode capacitance of metals can be overcome by the other factors described here. Therefore, Figure 74.5 represents the property of the metals under the recording condition adopted at that time, i.e., small input impedance (750 kohm) of the amplifier and wire electrodes with a small recording surface.

Nevertheless, especially when attempts are made to record with scalp electrodes, the artifact contamination-like movements and galvanic skin responses are still always carefully taken into account, as mentioned later.[19–22]

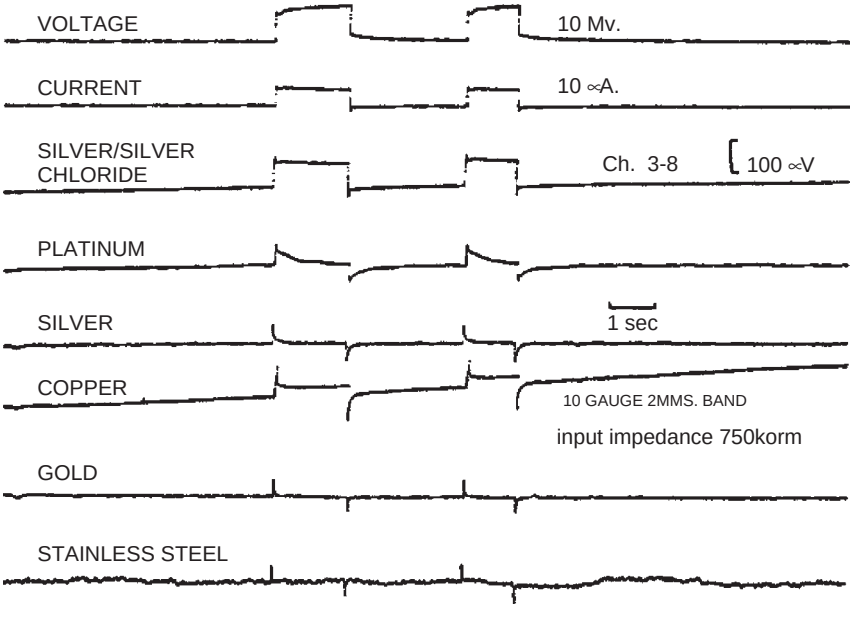

Figure 74.4 Characteristics of various metallic electrodes to reproduce a 10 mV, 10 microA square wave input. It was recorded by using a DC amplifier with an input impedance of 750 kohm and electrodes of wire type. (Cited from ref. 17 with permission.)

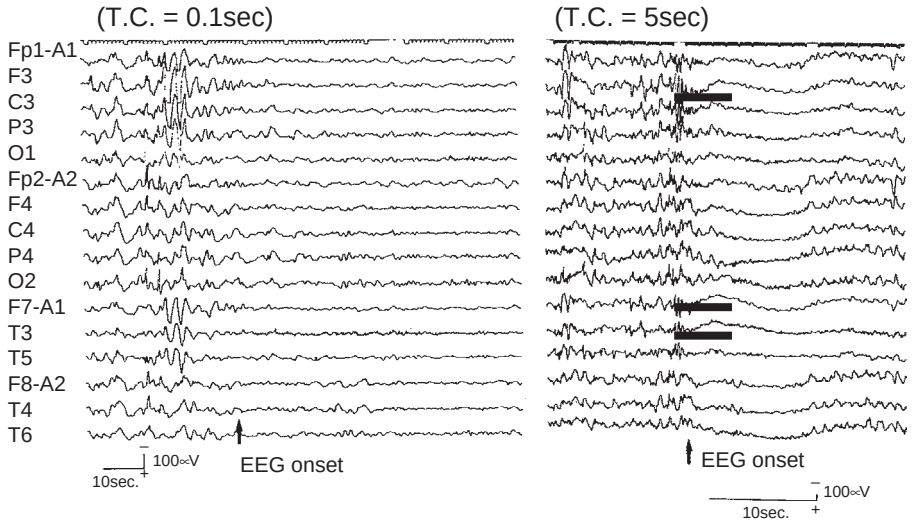

Figure 74.5 Left: Ictal EEG pattern displayed with the conventional LFF setting of 1.0 Hz (time constant of 0.1 sec) recorded by scalp electrodes in a 9-year-old patient with intractable temporal lobe epilepsy. Background activity is first suppressed and a diffuse electrodecremental pattern occurs (as shown by an arrow labeled as EEG onset). Right: Ictal EEG pattern of the seizure shown on the left is displayed with the LFF setting of 0.03 Hz (time constant of 5 sec). A clear negative shift (shown by thick, short bars) started occurring exclusively at F7, F3 and T3, exactly at the time when the diffuse electrodecremental pattern appeared (as shown by an arrow labeled as EEG onset). The peak amplitude of the negative shifts is −300 μV. (LFF = low frequency filter.) (Cited from ref. 19 with permission.)

Scalp-recorded DC shifts in human focal epilepsy

Usually scalp-recorded ictal DC shifts are not successfully recorded, because movements during clinical seizures could cause significant artifacts mainly due to the fluctuation of electrode potentials. Recent trials of scalp recording of ictal DC shifts in patients with focal epilepsy suggest its usefulness, although the degree of sensitivity varied between the studies.[19–21] We recorded slow ictal negative shifts in four patients (three with neocortial epilepsy and one with temporal lobe epilepsy) who had more than ten seizures per day and thus, the incidence rate of ictal DC shifts were calculated. Scalp-recorded ictal DC shifts were observed in 14–40% of all the recorded seizures and were restricted to 1–2 electrodes, very closely related to the onset of high frequency, low-voltage ictal activity (electrodecremental pattern) (Figure 74.5). Those seemed to be absent when the seizures were less intense among many recorded seizures.[19,20] It was thus suggested that scalp-recorded ictal DC shifts were highly specific, but the low sensitivity was to be taken into account in clinical applications. Another group also demonstrated that scalp-recorded ictal slow DC shifts were always recorded in 35 recorded seizures from five patients with intractable mesial temporal lobe epilepsy (MTLE), using Ag/AgCl electrodes employing a DC amplifier,[21] although their group pointed out the significant effects of non-neuronal generators for scalp-recorded slow shifts at the same time.[22]

For generalized epilepsy, slow shifts associated with spike and wave complexes were previously observed,[23–25] mainly in patients with petit mal. Chatrian *et al.*[26] carefully investigated slow negative shifts and concluded that these shifts occurred during the spike and wave complex paroxysms, and that they were generally unrelated to galvanic skin responses and were not generated by potential changes due to eye movements. The slow negative shifts never preceded the appearance of spike and wave activity in the EEG, but occasionally would outlast the paroxysm for a brief time.

Ictal DC shifts with invasive electrodes in human partial epilepsy

Subdural electrodes

Currently invasive recording with subdural grid electrodes is widely used in epilepsy surgery in order to delineate an epileptogenic zone by analysis of ictal and interictal activity, and to map the eloquent zone by electric stimulation or various, sensory evoked potentials.

When recording ictal activity in patients with extratemporal lobe epilepsy, intracranial ictal recordings often reveal diffuse or ill-defined ictal patterns, which make localization of the ictal onset zone difficult.[27]We have investigated ictal DC shifts accompanying clinical seizures from subdural electrodes chronically implanted in patients with intractable partial seizures mainly from the neocortical area. We concluded that, in addition to a careful interpretation of the conventional ictal EEG recording, an analysis of the ictal DC shift could be useful to better localize the ictal onset zone. In our laboratory, ictal DC shifts were investigated from more than 30 patients (mainly neocortical epilepsy and MTLE) with chronically implanted subdural grid electrodes in our laboratory (Figures 74.2, 74.6–74.9).[18, 20, 28–31]

Commercially available subdural grid electrodes of 3 mm in diameter and 1 cm center-to-center interelectrode distance were used. Electrodes made of platinum were used in all of the patients except for one (Patient 1 in Ikeda *et al.*, 1996)[18] in whom ones made of stainless steel were employed. For recording slow EEG shift, instead of DC amplifiers, AC amplifiers having an input impedance of 200 or 80 Mohm were used with a long time constant of 10 sec and high frequency filter

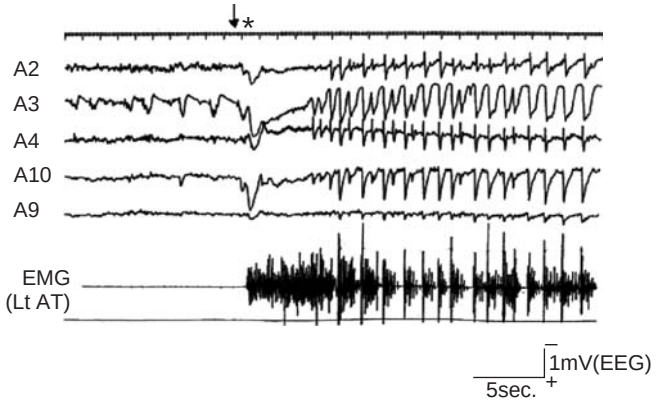

Figure 74.6 Subdurally recorded ictal DC shifts associated with a simple partial seizure (supplementary motor seizure clinically) in a patient with intractable right frontal lobe epilepsy. Just after a large transient positive activity at the time of clinical seizure onset, as demonstrated by tonic EMG discharges from the tibialis anterior muscle (Lt. AT), negative shifts are localized exclusively at A3 and A10. These two electrodes belonged to the ictal onset zone defined by the conventional ictal EEG changes (high amplitude spiking in the later part of ictal period). An arrow indicates the ictal EEG onset, and an asterisk indicates the clinical onset in this figure and also in Figures 74.7–9. EEG is displayed with LFF setting of 0.016 Hz, also in this figure and Figures 74.7–9. (Cited from ref. 20 with permission.)

(HFF) of 100 Hz, and all signals were digitized and stored at a sampling rate of 200 Hz per channel. All subdural electrodes were referenced to one subdural electrode placed over the lateral convexity which, on stimulation, did not elicit any symptoms or show any ictal or interictal epileptiform discharges.

As the results, with long-term follow-up of surgical outcome after surgery in our patient group, we analyzed ictal DC shifts in 24 patients with intractable partial epilepsy (19 of them with more than 1 year of follow-up period, mean of 3.9 ± 2.1 years) (16 with neocortical epilepsy and eight with MTLE). The DC shifts were recorded in 23 out of 24 patients (96%) and were observed in 87% of recorded seizures on the average in each patient. The DC shifts predominantly occurred associated with electrodecremental pattern (11 patients: 48%) and with 10–15 Hz rhythmic fast activity (10 patients: 44%). Simple partial seizures associated with 2–4 Hz spike discharges were not associated with slow shifts except for one patient. The slow shifts were mainly negative in polarity. They occurred at or before the clinical onset in 16 patients (70%), and followed in seven patients (30%), most patients of the latter group had the diagnosis of MTLE. It was invariably located in a more restricted area as compared with the epileptogenic zone defined by conventional EEG finding. As seizure control among the 19 patients with more than 1 year of follow-up, 11 patients (58%) were for Class I (Class Ia: 7, Class Ib: 4), 6 (32%) for Class II, and 2 (11%) for Class III. Out of two patients in Class III, one (FLE) with four years of follow-up, belonged to Class I in the first 2 years, and another (PLE) with 3 years of follow-up, belonged to Class Ib in the first year. It was concluded that 1) subdurally recorded ictal DC shifts in humans were almost invariably recorded regardless of underlying etiology or epilepsy type, and that 2) the more restricted localization can aid in delineating ictal onset zone before surgery. Most of them had a good seizure control without surgical deficits probably because of resection of core epileptogenic zone by means of DC shifts, but some of them had a good seizure control only during initial 1 to 2 years. It may imply that 1) real, core epileptogenic zone was not detected in spite of DC recording, or that 2) those patients newly developed epileptogenicity after surgery.[30]

Another institute also provided the similar conclusion based on the suddurally recorded ictal DC shifts from the parahippocampal gyrus in five patients with MTLE.[32]

Judging from the basic experiments as described above, the ictal DC shifts seem to have a close relationship with the electrodecremental pattern seen in conventional EEG recording. These periods are frequently associated with paroxysmal

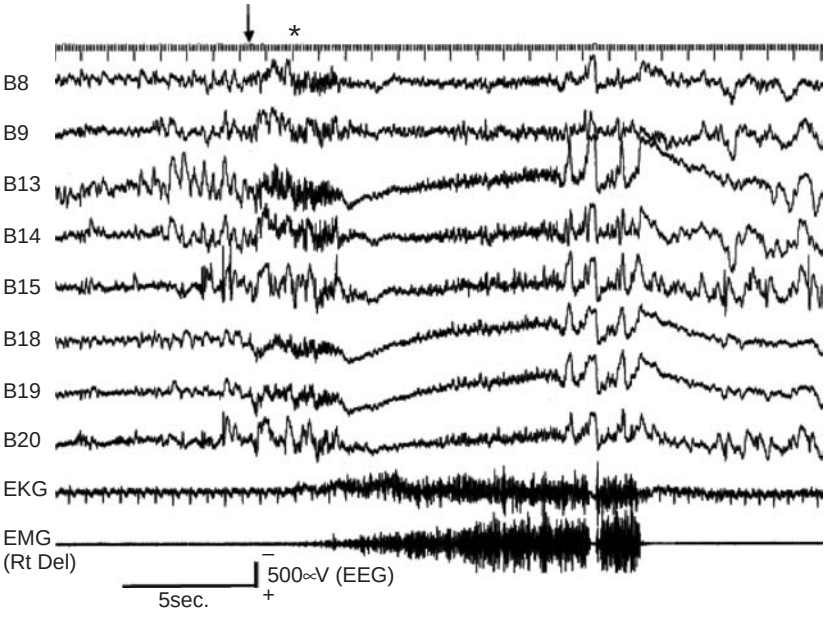

Figure 74.7 Ictal DC shifts were observed at B13,18 and 19 where conventional low amplitude fast activity occurred just 1–2 sec before the onset of DC shifts. It was recorded from a patient with left frontal lobe epilepsy. (Cited from reference 29 with permission.)

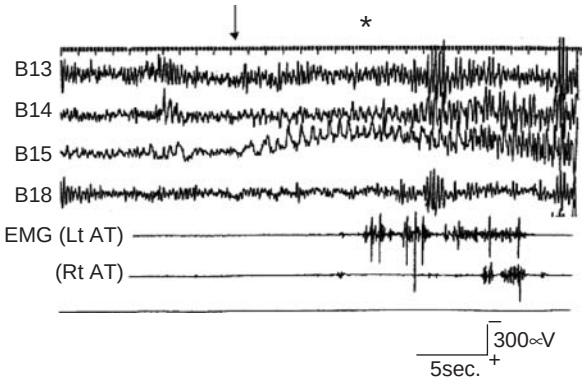

Figure 74.8 Ictal DC shifts were observed associated with about 1 Hz rhythmic activity in the conventional ictal pattern, but this occasion was less popular. It was recorded from a patient with right frontal lobe epilepsy. (Cited from ref. 19 with permission.)

low-amplitude, fast activity and usually they are also related with a very fast spreading of the ictal activity. Therefore, it is most likely that DC shifts seen with subdural electrodes in human epilepsy is an expression of highly synchronized PDSs of the pyramidal cells which occur in association with maximal intensity and rapid spreading of the ictal activity, leading to rapid involvement of extensive cortical areas. This highly synchronized PDSs of the pyramidal cells may occur relatively early during the ictus but may also occur later. DC shifts occur in close temporal relationship with this sudden seizure spread that could also be associated with a diffuse electrodecremental pattern. The fact that the DC shift is apparently more localized than the electrodecremental pattern and that these electrodecremental patterns in the conventional subdural EEG recording not infrequently occur just at the beginning of the seizures, especially in neocortical epilepsy, and also at least in the middle course of the ictal period at the parahippocampal gurus of MTLE, suggest that the DC shifts could greatly assist us in localizing the epileptogenic zone in human epilepsy.[28]

Other invasive electrodes

Wieser *et al.*[33] successfully recorded the ictal slow negative shifts from foramen ovale electrodes in patients with MTLE. (The size of input impedance of the amplifier was not described.) In their results, DC records with foramen ovale electrodes were satisfactory during the initial ictal period if the beginning of the clinical seizure was not accompanied by gross movements of head or trunk, and a slow shift was observed even in cases in which spiking was restricted to a small volume of mesio-basal limbic structures and therefore not clearly visible in the simultaneous AC mode record (Figure 74.10).[34] Therefore, they concluded that negative epicortical DC shifts recorded by the foramen ovale electrode are a sensitive indicator of epileptic activity within the underlying deeper structures, and that it is clinically useful at least to decide the side of ictal onset.

Depth and epidural electrodes failed to record slow ictal DC shits in four patients with the LFF setting of 0.01 Hz on an AC amplifier with an input impedance of 20 Mohm, when they employed stainless steel electrodes with a small recording contact.[35] However, recently, ictal slow shifts were investigated (LFF of 0.1 Hz) by means of depth electrodes placed in the hippocampus in 32 seizures of five patients with MTLE, and 84% of the seizures were associated with localized positive slow shifts at ictal onset, ranging from 1.5–11.5 sec. They concluded that ictal slow shifts at the onset of depth-recorded seizures is an excellent visual aid for localizing the epileptogenic focus.[36]

Clinical significance

Ictal DC shifts represent sustained PDSs occurring in epileptic neurons, and thus reflect the nature of the neurons and adjacent glial cells in the epileptogenic area. When recorded in human epilepsy, especially, for presurgical evaluation by means of subdural grid electrodes, negative shifts were observed by currently available equipment: platinum electrodes using an AC amplifier with a very high input impedance (>50 Mohm) and opened LFF (< 0.016 Hz). The recorded slow cortical potentials can aid to delineate an epileptogenic area with high sensitivity and specificity, and thus provide additional information to the conventional ictal EEG findings. However, invasive recording with either depth or epidural electrodes may not record reliable slow shifts probably because recording conditions for DC shifts are not fulfilled technically.

In patients with intractable partial epilepsy, especially of neocortical origin, cortical malformation including cortical

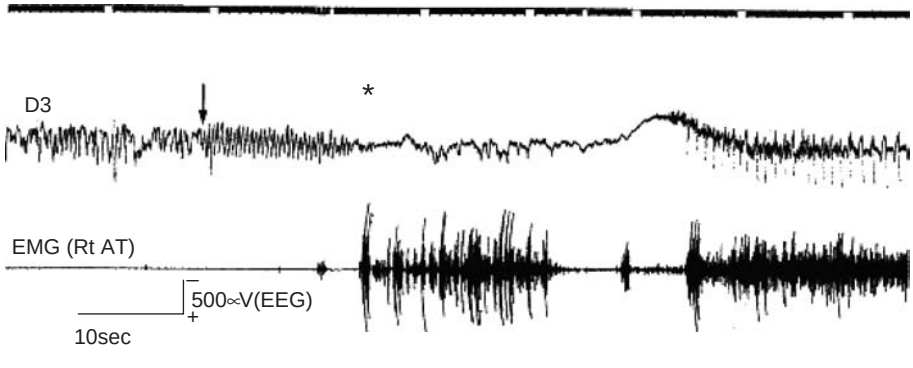

Figure 74.9 On rare occasion, ictal DC shifts were observed much after the onset of clinical and conventional ictal EEG pattern. It simply reflects that ictal DC shifts occur once a large population of neurons simultaneously discharge, and if it occurs later after the clinical onset, the onset of ictal DC shifts are then observed much after the clinical onset as shown in this figure. It was recorded from a patient with right parietal lobe epilepsy. (Cited from ref. 19 with permission.)

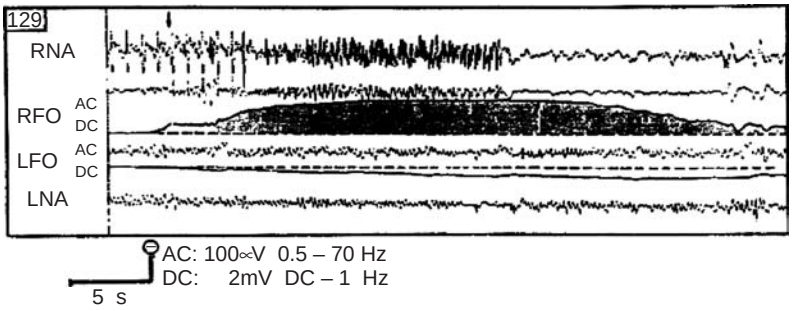

Figure 74.10 AC and DC recordings with right- and left foramen ovale electrode (RFO, LFO) together with stereo-EEG from the right and left amygdalar nucleus (RNA, LNA) during a seizure induced by repetitive, single-pulse electrical stimulation of the right hippocampus in a patient with mesiobasal temporal lobe epilepsy. The arrow indicates the onset of seizure characterized by an olfactory aura. (Cited from ref. 34 with permission.)

dysplasia is one of the most prevalent and disabling causes. Cortical dysplasia or cortical malformation has been relatively well delineated by MRI FLAIR image recently, but frequently it is not visible even by the most powerful machine. It was recommended that the whole area of cortical dysplasia as revealed by MRI should be resected to obtain the best seizure control. Recently, it was shown that resection guided by MRI does not always stop seizures in these patients. Namely, the MRI negative area is also a very important zone for seizure generation in patients with focal cortical dysplasia.[37,38] Usually, cortical dysplasia can generate very frequent interictal spikes that mimic ictal discharges because of its long-lasting repetitive discharges.[39] In addition, some areas of cortical dysplasia generated scanty spikes or just irregular slow activity.[40,41] Since epileptic spikes can reflect the dipoles generated in the cortical layers, cortical dysplasia would not always generate convenional spikes or dipoles, but only ill-defined ones, presumably depending on the degree of distortion of the cortical layers. Ictal DC shifts would be well defined even in cortical dysplasia where cortical layers were distorted, as long as epileptic firing neuronal pools and surrounding gliosis are preserved. In our patient series with subdural electrodes, only one patient so far who showed no ictal DC shifts had cortical dysplasia located within the white matter but not on the cortical surface at all.

Ictal DC shifts usually provide information of epileptogenicity which is equally as useful as conventional ictal EEG changes, being thus regarded as redundant information in surgical candidates with very clear seizure focus. However, ictal DC shifts could provide very important information to delineate core epileptogenicity, especially in patients having cortical dysplasia invisible to MRI.

In scalp recording in human focal epilepsy, little clinical application has been done so far. From the viewpoint of clinical practice, with currently available equipment as mentioned above, scalp-recorded ictal DC shifts were not sensitively recorded, but once recorded, high specificity may aid in localizing the epileptogenic zone even in scalp-recorded data for presurgical assessment.

High frequency ictal/interictal activity

Since highly synchronized PDSs of the pyramidal cells occur at the beginning of seizures or relatively early during the ictus, DC shifts occur associated with an electrodecremental pattern, i.e., low-amplitude very fast ictal activity. High-frequency repetitive discharges of more than 100 Hz can also delineate the ictal onset zone in patients with neocortical epilepsy by means of invasive recording.[42] Furthermore, discrete burst oscillation between 100 and 500 Hz (such as ripple for 100–200 Hz, and fast ripple for 250–500 Hz) was identified as interictal activity in the epileptogenic area mostly in animal experiments.[43] Recently, in patients with both MTLE and neocortical epilepsy, this high frequency activity (100–200 Hz) was well defined in the primary seizure focus or very discrete focus, near the time of seizure onset, and thus it would delineate core epileptogenicity and common property of epileptogenicity regardless of etiology.[44] Opening of an analysis window to both extremely slow and fast activity would be very important to add clinically useful information in invasive presurgical recording.

Summary and prospects

Ictal DC shifts have been observed in the animal epilepsy experiments, and whose physiological significance was well suggested previously. However, clinical applications or studies in human focal epilepsy was infrequently done until recently, mainly because of the limitation of equipment, including amplifier and computer hardware, especially digital EEG systems.

As suggested by animal experiments, at the beginning of seizures, ictal DC shifts most likely occur together as an expression of highly synchronized PDSs of the pyramidal cells which occur in association with maximal intensity and rapid spreading of ictal activity.[5,6,10] It also strongly reflects glial function and dysfunction, i.e., passive depolarization as the result of massive depolarization of the epileptic neurons with accumulated extracellular potassium, and its impaired buffering function, respectively. Currently recording techniques have been advanced, and the recent development of epilepsy surgery provides us with the opportunity to investigate. On the other hand, new ictal EEG analysis techniques are required because conventional ictal EEG findings at times fail to localize an epiletogenic zone as seen in cortical dysplasia. Careful analysis of ictal DC shifts will lead us to valuable information with regard to epileptogenicity in human focal epilepsy.

Although great technical advances enable us to record and analyze ictal DC shifts in patients having intractable

partial epilepsy, the condition is not optimal for possible artifacts and unstable electrode potentials even in invasive recording situations, and much more in scalp recording. More suitable recording electrodes and relevant amplifier circuits for DC shifts would enhance clinical usefulness in the near future.

75 fMRI in the evaluation of the ictal onset zone

K Hamandi and JS Duncan

Introduction

Functional MRI (fMRI) encompasses the study of neural activity by measurement of alterations in the MRI signal caused by neuronally driven changes in blood oxygenation levels. Magnetic resonance spectroscopy (MRS) whilst also providing information on neuronal function is reviewed elsewhere (Chapter 88).

fMRI has a number of advantages over other functional imaging techniques. (1) it is noninvasive, allowing repeated studies in the same patients, (2) the temporal resolution is such that a response to brief neural events can be captured, and (3) spatial resolution is of the order of a few millimetres. This allows the mapping of neural correlates of interictal discharges seen on surface EEG, i.e., the irritative zone during simultaneously acquired EEG and functional MRI (see Chapter 60). Imaging the ictal onset zone however may provide added insights into seizure generation and propagation.

Major practical limitations exist. For robust analysis a seizure needs to be captured in its entirety during a scan session and subject motion is a serious confound in fMRI analysis.[1,2] Nevertheless, a number of studies have been carried out in individual patients with frequent partial seizures.

Methodological considerations

The increases in regional cerebral blood flow in response to neural activity, that forms the basis of many current functional imaging techniques, were recognized over a century ago.[3] The extensive blood-flow increase during epileptic seizures was first described after direct visualization of macroscopic changes peroperatively.[4,5] This can be captured with SPECT,[6] PET,[7] and gadolinium-enhanced MRI.[8]

The rate and spatial extent of the neuronally-driven blood flow increase greatly exceeds that of local oxygen consumption, resulting in a regional decrease in venous deoxyhaemoglobin levels. Oxy- and deoxyhaemoglobin have different magnetic properties.[9] A time series of whole-brain images that are sensitive to changes in deoxyhemoglobin levels can be acquired using a fast image acquisition sequence–echo planar imaging (EPI).[10] Each brain image or volume is typically acquired in approximately 3 sec. The haemodynamic response reaches a peak at around 5 sec from the onset of neural activity and returns to baseline over 20–30 sec and can be captured in its entirety with fMRI; thus providing an endogenous contrast agent, termed the Blood Oxygen Level Dependent (BOLD) response.[11] The terms 'activation' and 'deactivation' are operationally defined as increases or decreases in BOLD response, directly linked to neural activity.

The signal-to-noise ratio in fMRI is low, a few percent at 1.5 Tesla. BOLD fMRI cannot be used to detect low-frequency state-related changes because of large intersessional variability and scanner noise characteristics. Together with a slow hemodynamic response function (HRF) relative to neural activity, the detection power of fMRI is limited to the narrow frequency band within which most conventional fMRI paradigms operate, i.e., active and rest states alternating, or events occurring, every 20–30 sec. Most commonly fMRI is used to map neural responses to a particular experimental task or stimulus. This is presented either as brief events or blocks, repeated over the course of an fMRI session (typically of 10- to 20-minute duration) to improve signal to noise. Advances in statistical analysis packages and computer processing power allow complex regression analyses to look for areas of significant correlation between the task or stimulus and the fMRI signal time course. A thresholded statistical map (the statistical parametric map or SPM) is used to show the spatial distribution of significantly correlated voxels. Clearly the experimental paradigms used in conventional fMRI studies are not possible in the study of ictal events with fMRI.

Early reports of ictal fMRI used a number of exploratory analysis methods. These include visual inspection of image time series, cross-correlation analyses and variance maps; however these lack the robustness of a formal statistical framework. More sophisticated exploratory techniques are being developed, that do not rely on the statistical correlation of an experimental paradigm. These have not yet been applied to imaging seizures. They include principle component analysis (PCA) and independent component analysis (ICA) of fMRI data.[12,13]

Sources of noise in fMRI include subject motion, respiratory and cardiac effects, scanner noise (low-frequency drifts) and neuro-physiological confounds from changes in the subject's resting state. Of these, subject motion will cause the greatest change in MRI signal. The type and timing of the motion with respect to the event of interest can have a greater effect than the actual extent of motion. Sudden motion, i.e., jerks, even on the submillimeter scale is sufficient to contaminate data and lead to false-positive activations if it is correlated with the event of interest.[2] Similarly changes in heart rate or respiration that can accompany seizures can also affect MRI

signal and confound data.[14] Examination of voxel time series for temporal maxima, known as temporal clustering analysis, has been proposed as a means of identifying fMRI changes to interictal activity.[15] However a close temporal relationship between subject motion as measured by realignment parameters (the six linear transformations used to realign successive scans to the same space) and the time points of voxels reaching their maximum temporal clusters has been shown.[16]

The spatial extent of fMRI activations is influenced by the voxel size, and spatial smoothing used during preprocessing to maximize signal to noise ratios. Typical voxel sizes are of the order of 3–5 mm, with smoothing of 6–10 mm. BOLD fMRI measures changes on the venous side of the circulation, such that large draining veins can result in false activations at a distance from the true neuronal activity.[17,18] In the surgical setting errors in co-registration between functional and structural images can occur, in part due to the different distortions inherent in EPI and T1-weighted volumetric acquisitions.[19] Where statistical analyses are used, the extent of an 'activation' is also influenced by the threshold at which the image is viewed. Finally the spatial extent of the decrease in deoxyhaemoglobin greatly exceeds that of the neural activity driving the haemodynamic changes, 'watering the garden for the sake of one thirsty flower'.[20]

Comparison with PET, SPECT, and SEEG

Notwithstanding the limitations outlined above, fMRI has a relatively high spatial resolution, of the order of several millimeter's resolution, and a temporal resolution of several seconds. The correlates of brief neurological events can be captured in a way that is not possible with other neuroimaging techniques.

Measuring changes in glucose metabolism or cerebral blood flow with PET has little to offer in directly imaging the ictal onset for the following reasons. For blood flow PET, the radioisotope $H_2{}^{15}O$ has a very short half-life, of around 2 min, such that only seizures occurring by chance at the time of prearranged scans could be captured. Glucose metabolism is measured with[18] flouro-deoxy-glucose (^{18}FDG). Although the half-life of the isotope[18] FDG is around 2 hours, the brain uptake of tracer can take 30 to 45 minutes such that acquired images after injection made at seizure onset will be made up of an amalgam of ictal and postical activity, which compromises localizing value.[7]

SPECT (Chapter 79), despite its lower spatial resolution has significant advantages over both PET and fMRI in imaging seizures, and at the present time is the only potentially clinically applicable method of imaging seizure onset.[21] The most commonly used SPECT tracers, ^{99m}Tc-hexamethylproplenamine (^{99m}Tc-HMPOA) and ^{99m}Tc-ethyl cysteinate dimmer (^{99m}Tc-ECD) are stable for several hours. The patient is monitored on the telemetry unit with an intravenous cannula in place and arrangements for isotope injection at the onset of a seizure. The isotope forms a stable bond once it crosses the blood–brain barrier. Patients can then be scanned some hours after the seizure when it is medically safer, and they are better able to lie still in the scanner. Any delay to tracer injection, and the time taken for tracer binding results in activations in areas of seizure propagation rather than onset.[22,23] The relatively low temporal and spatial resolution of SPECT necessitate a careful interpretation of results, taking into account delay to tracer injection from seizure onset, seizure duration, underlying pathology that may affect perfusion, as well as processing strategies used in analysing the images. Subtraction of ictal from interictal scans and coregistration with MRI (Subtraction Ictal SPECT Coregistered with MRI (SISCOM)) improves accuracy.[21]

EEG remains the optimum modality in studying seizure onset and propagation. However the distance of surface electrodes from the site of seizure onset, the filtering effects of skull and scalp and the lack of a unique solution due to the inverse problem, and rapid propagation of discharges confound dipole source localization.[24] Intracranial recordings can overcome this,[25] however they are highly invasive compared to functional imaging or surface EEG, and coverage is limited to the immediate vicinity of the implanted electrodes such that clear hypotheses regarding the location of the ictal onset zone are needed before their use.[26] The search for a noninvasive imaging modalitiy that can identify the site of seizure onset for surgical resection, or better inform the placement of intracranial electrodes therefore continues.

Ictal fMRI studies

Focal epilepsies

A total of five case reports of fMRI of ictal activity in humans have been published (Table 75.1), in addition to a study using fMRI to image the preictal state. These are detailed below.

Jackson *et al.* [27] used single-slice fMRI to obtain BOLD sensitive images in a 4-year-old child with Rasmussen's encephalitis, and frequent motor seizures involving the right face. Images were obtained every 10 s from a single slice in blocks of 10 min. Images were analyzed by subtracting baseline images from those acquired during seizures. Analysis was by way of visual inspection. No motion correction or formal statistical analysis was applied. Signal increases were seen in left hemisphere gyri in five clinical seizures. A similar change was also seen during a period that was not associated with a clinical seizure, felt to be subclinical activity. Whilst this case showed the potential of fMRI to detect seizure activity, the contribution of motion effects, caused by the single slice moving in and out of the imaging plane leading to the detected signal changes, remain a possibility.

Detre *et al.*[28] described fMRI activation with suspected subclinical seizure activity. The patient had right focal motor seizures, affecting the face. There was no simultaneous EEG recording during fMRI and there was no clinical evidence of seizure activity. Scans were acquired every 4 sec for 11 min. After standard preprocessing with realignment and spatial smoothing, images were displayed as an animated cine loop and inspected visually. Focal signal-intensity changes were seen in the posterior left frontal lobe, which correlated in both duration and spatial localization with ictal activity on EEG. The patient went on to intracranial implantation and surgery. A 1 cm^2 area of cortex identified on corticography was resected; pathologic examination revealed chronic gliosis. The resected area, as seen on postoperative structural MRI, showed close spatial concordance with the area of fMRI

Table 75.1 Summary of case reports of ictal fMRI studies summarising patient details, data acquisition and analysis methods used and main findings

Reference	Clinical data	Seizure detection	Functional MRI	Analysis	Main ictal fMRI finding
Jackson *et al.*[27]	4 year old male: right sided partial motor seizures of body and face **Etiology** Rasmussen's encephalitis **MRI** L hemisphere thickened cortex with abnormal signal in grey matter **Routine EEG** Interictal: Widespread slow and occasional L parietal spikes. Ictal: Irregular slow waves over anterior frontotemporal regions preceded by twitching **Sedation** IV Diazepam	Facial movement	**Scanner** 1.5T Siemens SP4000 **Sequence** Multi shot FLASH (TE/TR 60/85ms, matrix 62×128. FOV 230mm, flip angle 40°	Visual inspection of subtraction images and time courses extracted from subsequently selected areas	L hemisphere cortical signal increase
Detre *et al.* [28,29]	25 yr old male: R focal motor seizures of face **Etiology** cryptogenic **MRI** widespread left hemisphere atrophy **Routine EEG** Interictal: Increased theta during wakefulness Ictal: No definite ictal findings	Clinical observation	**Scanner** 1.5T GE signa **Sequence** Single shot GE-EPI (TE/TR 50/4000 ms, 64×64 matrix, FOV 240mm, 16×5 mm slices no gap). **Coverage:** whole brain **Time resolution:** 4s	Visual inspection of thresholded percentage change images and time courses extracted from selected cluster. Concordant areas with 3-4% signal increases	Area focal signal increase concordant with subsequently identified region on corticography
Krings *et al.* [30]	62 yr old female, Jacksonian march L leg **Etiology** glioblastoma multiforme **MRI** R central space occupying lesion **Routine EEG** Ictal and interictal EEG normal	None	**Scanner** 1.5T Phillips Gyroscan **Sequence** Multishot GE-EPI (TE/TR 35/2200ms Voxel size 3×5×5mm flip angle 35°) **Coverage:** Whole brain **Time resolution:** 2.2s	Visual inspection of thresholded percentage change images and time courses from selected clusters	2 perilesional areas of signal increase and one of decrease, starting 60 seconds before the onset of the seizure
Salek-Haddadi *et al.* 2002[31]	47 year old male, left fronto-temporal electrographic seizure. **Etiology** cryptogenic **MRI** normal **Routine EEG** Interictal: Left fronto-temporal spikes	Concurrent EEG	**Scanner:** 1.5 GE signa **Sequence:** GE-EPI (TE/TR 40/3000 64×64 matrix, FOV 240, 21×5mm interleaved slices) **Coverage:** Whole brain **Time resolution:** 3 seconds	SPM99 according to the general linear model. Modeling of ictal event as boxcar with motion parameters as nuisance covariates	L fronto-temporal signal increase with subsequent prolonged undershoot before return to baseline
Morocz *et al.* 2003[33]	48 yr old female, music induced complex partial seizures **Etiology** cryptogenic **MRI** normal **Routine EEG** Interictal: normal Ictal: left temporal theta and high frequency	Self reporting by button press	**Scanner** 1.5T Philips Gyroscan **Sequence** Gradient echo PRESTO TE/TR 35/5000ms, 3.75×3.75mm, slice thickness 3.5mm flip angle 30°	SPM99, boxcar of inducing music versus non-seizure inducing music; and seizure sessions versus non-seizure sessions	L temporal signal increase during music induced seizures.

activation. Further cross-correlation analysis was used to examine time-dependent alterations in regional signal intensity that correlated with signal-intensity changes from this cortical seizure focus.[29] Signal changes in the left ventrolateral thalamus showed a high degree of temporal correlation with signal changes in the left frontal cortical seizure focus, suggesting functional connectivity between the thalamus and the cortical focus.

Krings *et al.*[30] reported on a patient with a right frontal glioma. She was experiencing up to five events an hour at the time of the study. A 33-sec Jacksonian march involving the left leg with 'calf shaking' was imaged with fMRI. One hundred and two scans were acquired with a temporal resolution of 2.2 sec per scan, i.e., around 3 min of scanning. An automated image realignment algorithm was used to minimize the effects of interimage motion-related artifacts. For each voxel, the percent change in T2* signal fluctuations was calculated for each time point, against a baseline (mean of MR signal of the first 20 images of a given voxel). These were color coded on a thermal scale, overlaid onto an anatomical image and visualized by scrolling through the functional images in an animated loop. Only voxels exhibiting percentage signal changes larger than 1.5% from baseline were visualized to minimize random MR signal noise.

Three perilesional areas with signal intensity changes related to seizure activity were seen with signal changes of between 2.2–3.5%. The temporal evolution of signal change in each of these regions differed, beginning at 60 seconds before (an increase of up to 2.2%), 30 sec before (a decrease of up to 3.5) and at the onset of the seizure (an increase of up to 3.1%). The last region was in the left foot area as determined by previous motor fMRI. It is not clear from the report whether changes of similar percentage changes were seen elsewhere in the brain at other times during scanning. A temporal resolution of 2.2 sec is too slow to allow imaging of the propagation of electrical activity. The authors conclude:

> the identification of cortical areas with different types of hemodynamic seizure-related changes may help in delineating seizure generators from areas with propagated activity, even if the propagation time is too fast to be detectable with fMRI.

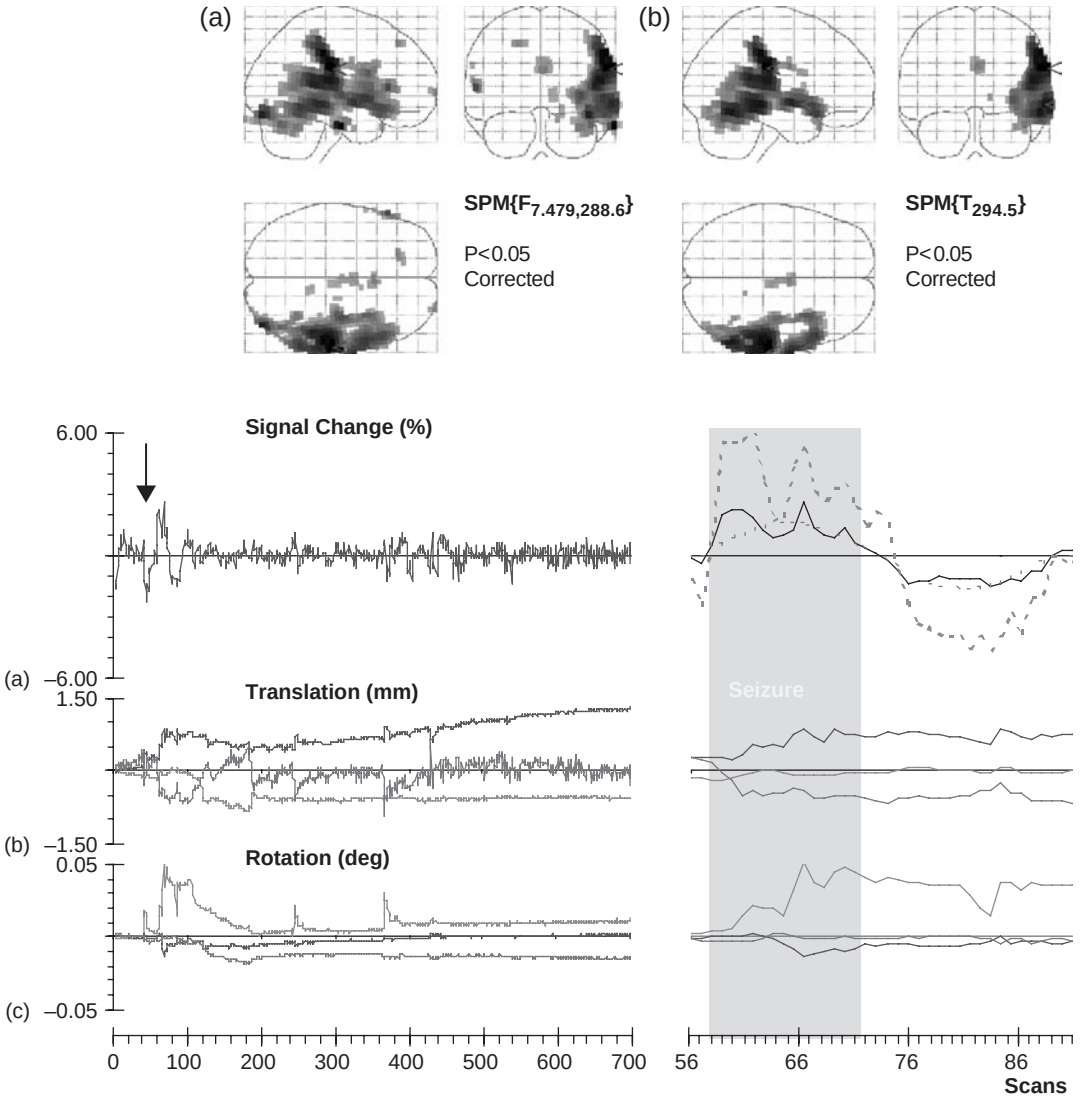
Salek-Haddadi reported a case of ictal fMRI based on an electrographic seizure recorded on simultaneous continuous EEG.[31] The simultaneous recording of EEG during fMRI being necessary to fully correlate ictal activity with fMRI measures. A 47-year-old man with frequent partial and secondarily generalized seizures was scanned with continuous EEG and fMRI (EEG-fMRI) for 35 min (700 scans), as part of a study of interictal epileptiform discharges. An electrographic seizure, with a focus at F7/T3 of approximately 40 sec occurred early into the study. Images were realigned to the same space and spatially smoothed. fMRI data was analyzed according to the general linear model, with the recorded seizure as an effect of interest and the realignment parameters as nuisance covariates. An extensive area of activation was seen extending posteroinferiorly from the left insular gray matter, through the temporal lobe insula, along the superior and middle temporal gyri to the left fusiform gyrus; anteriorly to the left inferior frontal gyrus; and superiorly up to the left inferior parietal lobule. A smaller cluster was also evident within the gray matter of the ipsilateral cingulate gyrus. The mean signal rise was 2.5% (maximum 5.5%) with a prolonged undershoot (Figures 75.1–3). The undershoot most likely represented more prolonged oxygen consumption, following the peak in blood flow response, than is seen in the normal physiological HRF. The authors stress the importance of a robust statistical framework for the analysis of ictal fMRI.

Reflex epilepsies

The reflex epilepsies[32] although rarely, if ever considered for resective epilepsy surgery provide unique opportunities to study the epileptogenic zone with fMRI, given that ictal events can be induced during fMRI scanning; once appropriate ethical considerations and consent have been addressed.

Morocz *et al.*[33] studied a 48-year-old woman with music induced complex partial seizures. Scanning took place in blocks with previously identified 'epileptogenic' music alternating with music that was known not to induce seizures. Statistical analysis revealed two patterns of BOLD signal change, one related to the actual triggering of music-induced seizures in the left anterior temporal lobe, the right gyrus rectus and ventral frontal lobes, and the other related to exposure to the specific epileptogenic music in the orbitofrontal lobes only. The authors speculate that emotional processing of music in the orbito-frontal areas may have initiated the seizure cascade.

Reading epilepsy is characterized by brief jaw jerks associated with EEG spikes when reading specific texts. Generalized seizures can follow if reading persists in the face of increasing jaw jerks. Archer *et al.*[34] studied two patients with spike triggered fMRI and reading epilepsy. Subjects read text back projected onto a screen during fMRI scanning. EEG was recorded continuously and scanning was triggered 2.5 sec after the occurrence of an EEG spike to acquire one brain volume. An identical 'rest' volume was acquired after a 20-sec period of no spikes. fMRI of a standard reading task was also acquired using a 30-sec block design of reading text versus fixating on a cross hair. Spike versus rest scans were compared by means of an unpaired t-test. Reading-related spike activity was seen bilaterally in the inferior precentral gyrus, central sulcus, basal ganglia, and globus pallidus. Signal change of 2.5% in cortex and 1% basal ganglia was seen in association with jaw jerks and spikes. Koepp and Salek-Haddadi (unpublished work) studied nine patients with reading epilepsy using an MR-compatible system for scalp-EEG, submental EMG, left-handed button press, and online audio recording to detect reading-induced orofacial myocloni (ORM). Language and motor (hand/mouth) mapping did not show any abnormalities, compared to normal subjects. One patient had abundant ORM in association with left-frontal spikes occurring on silent reading. In a further five patients, symptoms were only elicitable on reading aloud so events were selfindicated. Induced spikes or jaw jerks were associated with consistent activation patterns within left motor and premotor areas in five of these six patients, in Brodman area (BA) 47 in 2/6, in the striatum (4/6) and thalamus (2/6). Taken together these studies demonstrate the potential cortical and subcortical circuitry involved in reading induced seizures.[35]



Figures 75.1 and 75.2 fMRI signal change during electrographic seizure captured during EEG-fMRI recording session. Fig 75.1 a) SPM {F}: the SPM 'glass brain' display shows areas of significant correlation to the EEG recorded seizure, these results were obtained using a Fourier set of basis functions, spanning the seizure event, and (b) results obtained using a single sine wave regressor spanning the seizure. Realignment parameters were included as confounds. The statistical maximum is shown in red. Fig 75.2. (a) Regional time series. On the left, the first eigenvariate is shown as extracted from the principal cluster of the SPM {F} for the entire experiment. Seizure onset is indicated by the arrow. On the right and rescaled, the maximum signal change is also shown (green) along with the sine wave regressor (red). The seizure interval is shaded in grey. Percentage changes are with respect to the grand session mean. (b,c) Realignment parameters. The X, Y, and Z translations in units of millimeters are shown in red, green, and blue, respectively, and the corresponding rotations given underneath in degrees. (reproduced from Salek-Haddadi *et al*. 2002, with permission from the publisher). (See Color plates.)

The Preictal state

Mathematical analyses of EEG frequency components suggest the presence of a preictal state.[36] Federico *et al.*[37] studied the fMRI signal changes minutes prior to a seizure in three patients with frequent sleep onset seizures. Patients were sleep deprived for one night and scanned the following morning under close supervision, until a seizure occurred. There was no concurrent EEG monitoring. Images were analysed by comparing fMRI signal between two 1-minute blocks–at one minute before seizure onset compared with in one case, 3 and the other two, 5 min before the seizure. The full signal time course of regions of interest based on differences detected in this comparative analysis was examined. Two patients showed BOLD activations ipsilateral to the site of presumed seizure onset, whilst the other had contralateral changes. The significant fMRI signal changes were attributed to altered neuronaly driven hemodynamics in the preictal state; although without EEG it is possible that changes in sleep–wake cycle that preceded the seizures may have also been captured. Comparing similarly spaced 1-minute blocks at other points in the time series would have given some indication of the specificity of their findings, and other possible confounding effects in the data. The use of concurrent EEG, and possibly some form of independent motion detection would be advantageous in these studies.

Animal studies

Capturing seizures during the scan session, and lack of independent knowledge of the seizure focus limit the study of ictal activity with fMRI in humans. Animal models are commonly

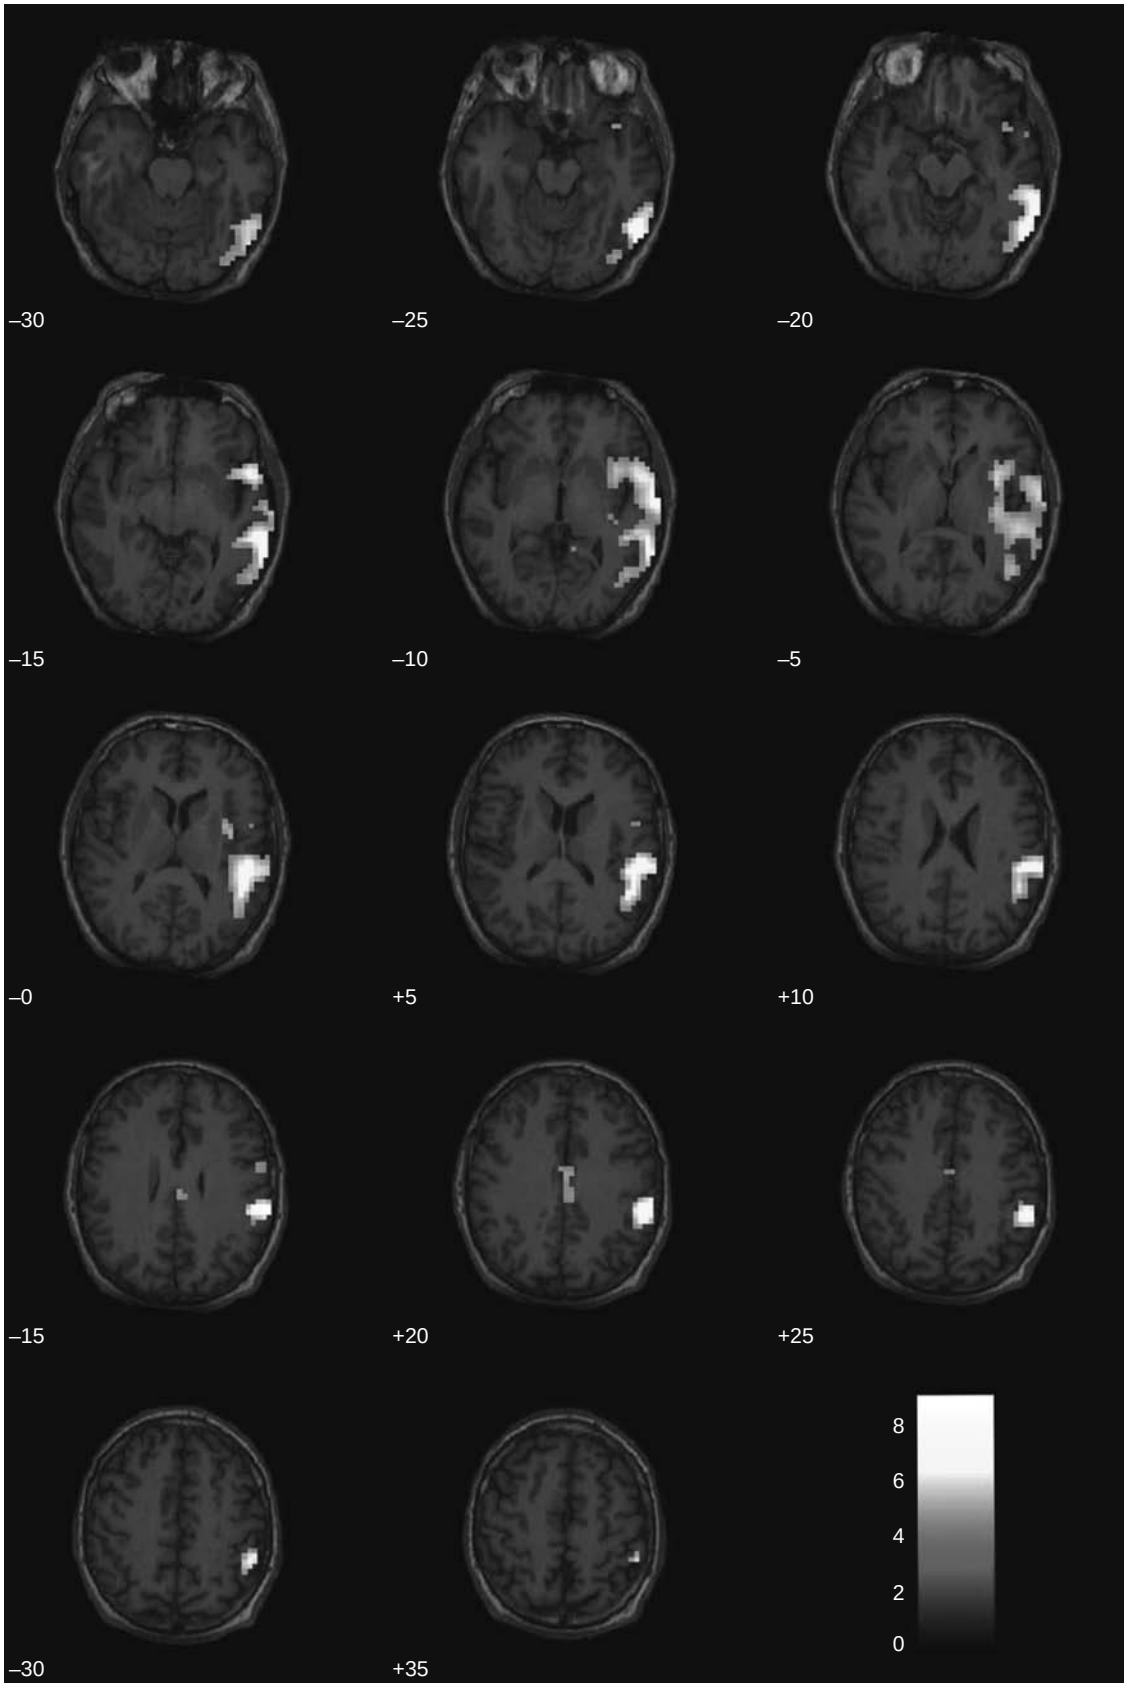


Figure 75.3 Anatomical overlay. The seizure related activation obtaining from Figure 75.2b is shown overlaid onto consecutive slices of a co-registered T1-weighted scan. (Reproduced from Salek-Haddadi *et al*. 2002, with permission from the publisher).

used in the development of antiepileptic drugs, neurophysiological and histochemical studies. Well established models include the penicillin and kindled seizure models, and genetic epilepsy models.

Opdam *et al.*[38] developed a sheep model of penicillin induced focal seizures specifically for the purpose of studying ictal activity measured with fMRI and simultaneous intracranial EEG. An intracranial EEG probe was placed on the cortical surface with a penicillin delivery port. EEG acquisition was interleaved with MRI scanning. Data was analysed by means of the variance of the time series of each voxel. These variance maps were overlaid onto the raw images for anatomical localisation. Areas of greatest variance, which included the injection site and the ipsilateral amygdala were considered to be part of a cortical–sub cortical circuit in seizure propagation. This study demonstrated a proof of principle, the main outcome being the development of a large animal model that could be studied with fMRI. Their observations of BOLD changes were preliminary. More sophisticated analysis, for instance modelling the EEG with fMRI according to the general linear model, would be more robust to signal to noise issues and may yield clearer spatio-temporal localizations.

Future applications and conclusions

fMRI of ictal activity has been limited to a few cases. A number of analytical techniques have been used. Many of these deviate from an accepted dogma in fMRI analysis of rigorous statistical correlations that include the whole time series from whole brain. Using fMRI to image the ictal onset zone is doubly confounded in that scanning needs to take place during a seizure and that motion correlated with the event of interest makes interpretation of fMRI data very difficult. Most paradigm-related fMRI studies set a threshold for subject motion above which data sets are discarded, something ictal fMRI studies cannot afford to do.

The spatiotemporal resolution of fMRI is much higher than the other imaging modalities of PET and SPECT. Nevertheless the BOLD response, peaking at 5 sec and spread over around 30 sec makes the study of seizure progression difficult, this is probably best summed up by Salek-Haddadi *et al.*:

> Sampling of an inherently noisy fMRI time series at low temporal resolution concealing a single relatively brief, undefined, and sluggish BOLD fluctuation would not permit inferences regarding the spatiotemporal cascade. Similarly the relative length of an HRF in relation to the ictus prohibits any meaningful subdivision of the epoch for modeling as other than a single event without prior knowledge of subtle interactions and nonlinearities for instance. Moreover, even were sequential activation to be evincible, any extrapolation of temporal relationships to the underlying neural activity would be hampered by interregional variability within the HRF'.

A more direct and quantitative measure of rCBF can be obtained using perfusion or arterial spin labeling (ASL) MRI. ASL-MRI uses magnetically-labeled in flowing arterial blood as an endogenous tracer for measuring CBF.[39] This is achieved by modifying the magnetization of arterial H-protons proximal to the tissue of interest. This elicits a local change in longitudinal magnetization of subsequently perfused tissue that is proportional to inflowing blood. Subtraction of sequentially acquired images, with, and without arterial spin-labeling (tag and control images) provides a measure of this inflowing blood. Like BOLD fMRI, this can detect evoked changes in blood flow correlated with neural activity of a task or stimulus.[40,41] An advantage of ASL over BOLD is that low-frequency state-related changes can be imaged, and between-session comparisons are valid.[40] Furthermore ASL-MRI images the arterial side of circulation and is therefore not confounded by false activations in draining veins. A submillimeter spatial resolution has been demonstrated with ASL-MRI.[42]

With current methods ictal fMRI is unlikely to be a useful tool in 'routine' presurgical work-up. Advances in scanner hardware with higher field strength will increase both temporal and spatial resolution. Algorithms for motion correction in frequency space prior to the reconstruction of raw images although not currently available for BOLD fMRI could greatly reduce the problems encountered with subject motion.[43] Appropriate MR physics and data analytical expertise is crucial.

Ultimately functional imaging is used to make inferences about brain function, rather than giving a direct measure of that function. In the context of epilepsy surgery ictal fMRI could allow inferences to be made about lateralization and localization of epileptogenic foci, and generate hypotheses for the placement if intracranial EEG electrodes. Functional imaging findings need to be considered with results of other investigations, and awareness of the methodological limitations of any technique fully appreciated, particularly if findings are used to plan surgical interventions.

76 Ictal SPECT in the definition of the seizure onset zone

GD Cascino and D Lachhwani

Introduction

Partial or localization-related epilepsy is the most common seizure disorder in the patient being considered for surgical treatment.[1] The majority of patients with adult-onset recurrent seizures have partial epilepsy.[2–4] Individuals with partial epilepsy experience focal seizures that variably are associated with altered awareness, automatisms, localized or lateralized neurological deficits, or secondarily generalized tonic-clonic seizures.[3–4] Most patients present with more than one seizure-type. The presence of the neurological symptoms at seizure onset may be used to localize the epileptogenic zone, i.e., site of seizure onset and initial seizure propagation.[1,2] Approximately 30–40% of newly diagnosed patients with epilepsy will experience medically refractory seizures that are physically and socially disabling.[3–6] Most individuals with a pharmacosensitive partial seizure disorder respond to the first or second antiepileptic drug (AED) medication.[3–6] Less than 10% of patients who fail to respond to the initial AED therapy will be rendered seizurefree with subsequent pharmacotherapy.[3–6] Polypharmacy with the concomitant use of three or more AEDs has not been shown to increase the efficacy of therapy in patients with medically refractory seizures, but may significantly increase dose-related adverse effects.[4–6] A seizure disorder is often considered intractable when the neurological illness is medically, socially or physically disabling.[2–6] The combination of AED neurotoxicity and recurrent focal seizures may significantly alter the quality of life of the individual. The goals of treatment include rendering the individual seizurefree, avoiding additional morbidity, and allowing the patient to become a participating and productive member of society.[1,7–10]

Surgical treatment of epilepsy

Epilepsy surgery is an effective and safe therapy for selected patients with intractable localization-related epilepsy.[1,2,7–12] Surgically remediable epileptic syndromes have been identified that assist in the selection of operative treatments for intractable partial epilepsy.[10] These individuals usually experience a significant reduction in seizure tendency associated with an improvement in quality of life following a focal corticectomy.[2,7,8] Patients with medial temporal lobe epilepsy and partial seizures related to foreign-tissue lesional pathology may be highly favorable candidates for epilepsy surgery.[7,11–14] The superior efficacy of surgical treatment compared to AED medication in patients with temporal lobe epilepsy has been demonstrated.[8] The efficacy of anterior temporal lobectomy in patients with mesiobasal limbic seizures arising from the amygdalohippocampal complex has been confirmed.[7,8,12–14, 16–18] The majority of patients with medial temporal lobe epilepsy have pathological findings consistent with focal hippocampal neuronal loss and astrogliosis.[12–14,16–18] Patients with a lesional epileptic syndrome may have an underlying tumor, vascular anomaly or malformations of cortical development (MCD) as the etiology of a medically refractory partial seizure disorder.[10,11,14,15,18,19] The common tumoral surgical pathologies encountered in patients with lesional epilepsy include low-grade glial neoplasms, gangliogliomas, and dysembryoplastic neuroepithelial tumors.[7,14–18] The vascular anomalies include cavernous hemangiomas, and angiographically identified or occult arteriovenous malformations.[10] The MCD present in patients with a localization-related epilepsy include focal cortical dysplasia, polymicrogyria, hamartoma, and schizencephaly.[10,19] Other focal structural abnormalities, such as encephalomalacia related to prior trauma, hemorrhage or stroke, also may develop an intractable seizure disorder and be considered for surgical treatment.

Individuals with medial temporal lobe epilepsy and lesional epilepsy frequently have an abnormal structural magnetic resonance imaging (MRI) study that demonstrates with a high sensitivity and specificity the underlying epileptogenic pathology.[2,10,12,13,17–20] Patients with focal structural neuroimaging abnormalities may be classified as having *substrate-directed* partial epilepsy.[20] MRI has proved essential in the selection and evaluation of patients for surgical treatment of an intractable partial seizure disorder.[7,10,12,13,16–18] The MRI study is almost invariably abnormal in patients with primary brain neoplasms and vascular anomalies.[20] The sensitivity and specificity of the MRI is more variable in patients with microscopic MCD such as focal cortical dysplasia.[19] A comprehensive presurgical evaluation is conducted in patients with MRI-identified structural abnormalities, e.g., changes consistent with mesial temporal sclerosis or a foreign-tissue lesion (Tables 76.1 and 76.2). The EEG-identified ictal onset and initial seizure propagation, i.e., epileptogenic zone, in conjunction with other neurological studies is used to establish a relationship between the MRI findings and the underlying the epileptic brain tissue [12,13,15–18] (Tables 76.1 and 76.2). The demonstration of concordance between the pathological substrate and the ictal onset zone indicates a highly favorable

Table 76.1 Surgically remediable epileptic syndromes

Selected epileptic syndromes	MRI	SISCOM	Pathology
Substrate-directed			
Medial temporal lobe epilepsy	> 90%	–	MTS
Lesional epilepsy: tumor	100%	–	Ganglioglioma, glioma, DNET
Lesional epilepsy: vascular anomaly	100%	–	Cavernous hemangioma, AVM
Lesional epilepsy: malformation of cortical development	80–90%	–	FCD
Non substrate-directed			
Neocortical (extrahippocampal)	0%	75%	Gliosis, focal cell loss, none

MTS = mesial temporal sclerosis; DNET = dysembryoplastic neuroepithelial tumor; AVM = arteriovenous malformation; FCD = focal cortical dysplasia.
Adapted from Cascino GD. Advances in neuroimaging: surgical localization. Epilepsia 2001;42:3–12.

operative outcome in selected individuals.[2,7,11,13–16,18] The most common and effective operative strategy in patients with a substrate-directed partial epilepsy involves a focal cortical resection of the epileptogenic zone with excision of the surgical pathology.[10,11] The extent of lesional pathology extirpation is of significant prognostic importance in these individuals.[1,2,9] Postoperative MRI findings are important to assess the anatomical resection, and to evaluate the presence of residual or recurrent lesional pathology.

MRI Methodology

The MRI seizure protocol at the Mayo Clinic includes: (1) sagittal T1-weighted imaging with minimum echo time (TE) and 500 msec repetition time (TR) required for whole-head coverage with 5-mm thick contiguous sections; (2) whole-head coronal three-dimensional volumetric spoiled gradient-echo (SPGR) acquisition is performed with minimum full TE and TR, 192 views, one repetition, 1.5 mm section thickness with 124 partitions, 22 cm field of view, and 45°flip angle; and (3) coronal spin-echo (SE) imaging is performed with TE of 30 and 80 msec, TR greater than 2000 msec, 20 cm field of view, 4 mm section thickness and 2 mm intersection gap, and 192 views with one repetition.[12,13,18] An oblique-coronal fluid attenuated inversion recovery (FLAIR) sequence is also obtained.[13] The FLAIR sequence allows the pathological signal change to be differentiated from the physiological signal alteration related to cerebrospinal fluid.[13] An enhanced study will be performed if a space-occupying lesion is detected in the unenhanced study. Currently studies are performed on a 1.5 Tesla or 3 Tesla scanner.

Nonsubstrate-directed partial epilepsy

MRI studies that do not reveal a focal structural pathology that is the putative etiology of the medically refractory focal seizures are classified as nonsubstrate-directed partial epilepsy.[20] This would include individuals with a normal MRI study or the presence of nonspecific findings, e.g., diffuse atrophy and T2-weighted signal changes, that do not indicate the pathology underlying the epileptogenic zone. Patients with nonsubstrate-directed partial epilepsy have neocortical or amygdalohippocampal seizures.[18,20] The pathology in these patients at the time of epilepsy surgery includes gliosis, hippocampal cell loss, focal cortical dyspalsia or no histopathological alteration.[18,20] Approximately 50–60% of patients with a normal MRI study are seizurefree following an anterior temporal lobectomy.[18] Unfortunately, less than 50% of patients with nonsubstrate-directed epilepsy with neocortical and extratemporal seizures are rendered seizurefree following

Table 76.2 Presurgical evaluation

Performed Invariably	Performed variably	Performed selected centers
History and examination	Video-EEG (intracranial)	SISCOM
Routine EEG	Electrocorticography	MRS
MRI head	FDG-PET	PET receptor studies
Video-EEG (extracranial)	Interictal-ictal SPECT	Functional MRI
Neuropsychology	Sodium amobarbital study	MRI hippocampal volumetry

Performed invariably: almost always obtained prior to epilepsy surgery.
Performed variably: available at most epilepsy centers, used in selected candidates.
Performed selected centers: not widely available.
MRI: magnetic resonance imaging.
PET: positron emission tomography.
SPECT: single photon emission computed tomography.
SISCOM: subtraction ictal SPECT co-registered to MRI.
MRS: magnetic resonance spectroscopy.

surgical treatment.[12,15,18] An estimated 20–30% of these patients with frontal lobe epilepsy will enter a seizure remission following a focal cortical resection.[15,18] An important reason for the unfavorable operative outcome in patients with nonsubstrate-directed partial epilepsy is the inherent difficulty in localizing and even lateralizing the epileptogenic zone.[15,18] The potential limitations of interictal and ictal extracranial EEG monitoring in patients with partial seizures of extrahippocampal origin have been welldefined.[15,18] The anatomical region of seizure onset may represent a continuum in these patients that lends itself to an incomplete resection of the epileptogenic zone. Advances in imaging have assisted the evaluation and treatment of operative candidates with nonsubstrate-directed partial epilepsy.[21–26]

Single photon emission computed tomography

Single photon emission computed tomography (SPECT) is the preferred functional neuroimaging technique for peri-ictal imaging in patients with partial epilepsy being considered for surgical treatment.[21,25,29–39] Interictal SPECT studies involve cerebral blood-flow imaging using radiopharmaceuticals, principally either technetium-99m-hexamethylpropylene amine oxime (^{99m}Tc-HMPAO) or ^{99m}Tc-bicisate, that have a rapid first-pass brain extraction with maximum uptake being achieved within 30–60 sec of an intravenous injection.[21,29–31,36] These studies may produce a 'photograph' of the peri-ictal cerebral perfusion pattern that was present soon after the injection.[31] The SPECT images can be acquired up to 4 hours after the termination of the seizure so that the individual patient can recover from the ictus prior to being transported to nuclear medicine. SPECT studies have an important clinical application in the potential identification of the epileptogenic zone.[31]

Peri-ictal SPECT studies have been confirmed to be useful in patients with temporal lobe epilepsy to identify a region of focal hyperperfusion.[25] The rationale for interictal SPECT imaging at present is to serve as a reference for a baseline study for the interpretation of ictal SPECT images. The diagnostic yield of ictal SPECT has been established to be superior to interictal SPECT in patients being considered for surgical ablation procedures. The recent development of stabilized radiotracers that do not require mixing immediately before injection, such as ^{99m}Tc-bicisate, has made ictal SPECT more practical in patients with extratemporal seizures that often are not associated with an aura and may have a shorter seizure duration.[36]

Subtraction ictal spect co-registered to MRI (SISCOM)

The imaging paradigm using computer-aided subtraction ictal single photon emission tomography (SPECT) co-registered to MRI (SISCOM) has been used in patients with intractable partial epilepsy.[31–42] The protocol was introduced by O'Brien and colleagues at Mayo Clinic.[31,32] (Figures 76.1–3). SISCOM represents an innovation in neuroimaging that may be useful in the evaluation of patients with focal seizures being considered for surgical management. Other methodologies including ictal SPECT using statistical parametric mapping has also been shown to have a high diagnostic yield in localizing the site of seizure onset.[43] The localized blood flow alteration demonstrated using SISCOM may be intimately associated with the epileptogenic zone.[31] Subtracting normalized and co-registered ictal and interictal SPECT images, and then matching the resultant difference image to the high resolution MRI for anatomical correlation has been shown to be a reliable indicator of the localization of the epileptogenic zone in patients with localization-related epilepsy [32–35] (Figures 76.1–3). SISCOM in a series of 51 patients had a higher rate of localization (88.2 vs. 39.2%, $p < 0.0001$), better inter-observer agreement, and be a better predictor of surgical outcome than visual inspection of the interictal and ictal images.[31] The study demonstrated the inherent problems with visual interpretation of either peri-ictal or interictal SPECT studies alone.

The methodology used for SISCOM involves co-registering of the interictal to the ictal SPECT study by matching the surface points on the cerebral binary images of the two procedures[32,35,36] (Figure 76.1). The normalized interictal image is subtracted from the normalized ictal image to derive the difference (subtraction) in cerebral blood flow related to the partial seizure (Figure 76.1). Thresholding of the subtraction image to display only the pixels with intensities greater than two standard deviations above zero is performed. Finally, the images with intensities of more than two standard deviations are co-registered onto the structural MRI (Figures 76.1–3). Following implantation of subdural electrodes for chronic intracranial EEG monitoring the electrode positions can be segmented from a spiral CT scan and co-registered with the SISCOM image[33] (Figure 76.1). This allows the determination of the relationship between the localized peri-ictal blood flow alteration and the ictal onset zone.

The SISCOM region of blood flow alteration is a surrogate for the localization of the epileptogenic zone independent of the pathological finding.[38] The clinical parameters that are signficant in determining the diagnostic yield of SISCOM include the duration of the seizure and the length of time of the injection from ictal onset.[21,31] The seizure should be at least 5–10 sec in duration and the time from seizure onset should be less than 45 sec.[31] The SISCOM findings also correlate with the operative outcome. Patients with a SISCOM alteration concordant with the epileptogenic zone are most likely to experience a significant reducation in seizure tendency if the focal cortical resection includes the region of peri-ictal blood-flow change.[31,38] The disadvantages of a SISCOM study include the need for hospitalization and long-term EEG monitoring, the use of radioisotopes for two imaging procedures, and the required presence of habitual seizure activity. The indications for SISCOM in patients undergoing a presurgical evaluation include: nonsubstrate-directed partial epilepsy and conflicting findings in the noninvasive evaluation (Figures 76.2 and 3). SISCOM may be use to identify a 'target' for placement on intracranial EEG electrodes.[33] The presence of a SISCOM alteration may obviate the need for intracranial EEG recordings in selected patients. For example, patients with nonsubstrate-directed partial epilepsy of temporal lobe origin may not require chronic intracranial EEG monitoring if the extracranial ictal EEG pattern and peri-ictal SPECT studies are concordant. SISCOM also improves the diagnostic

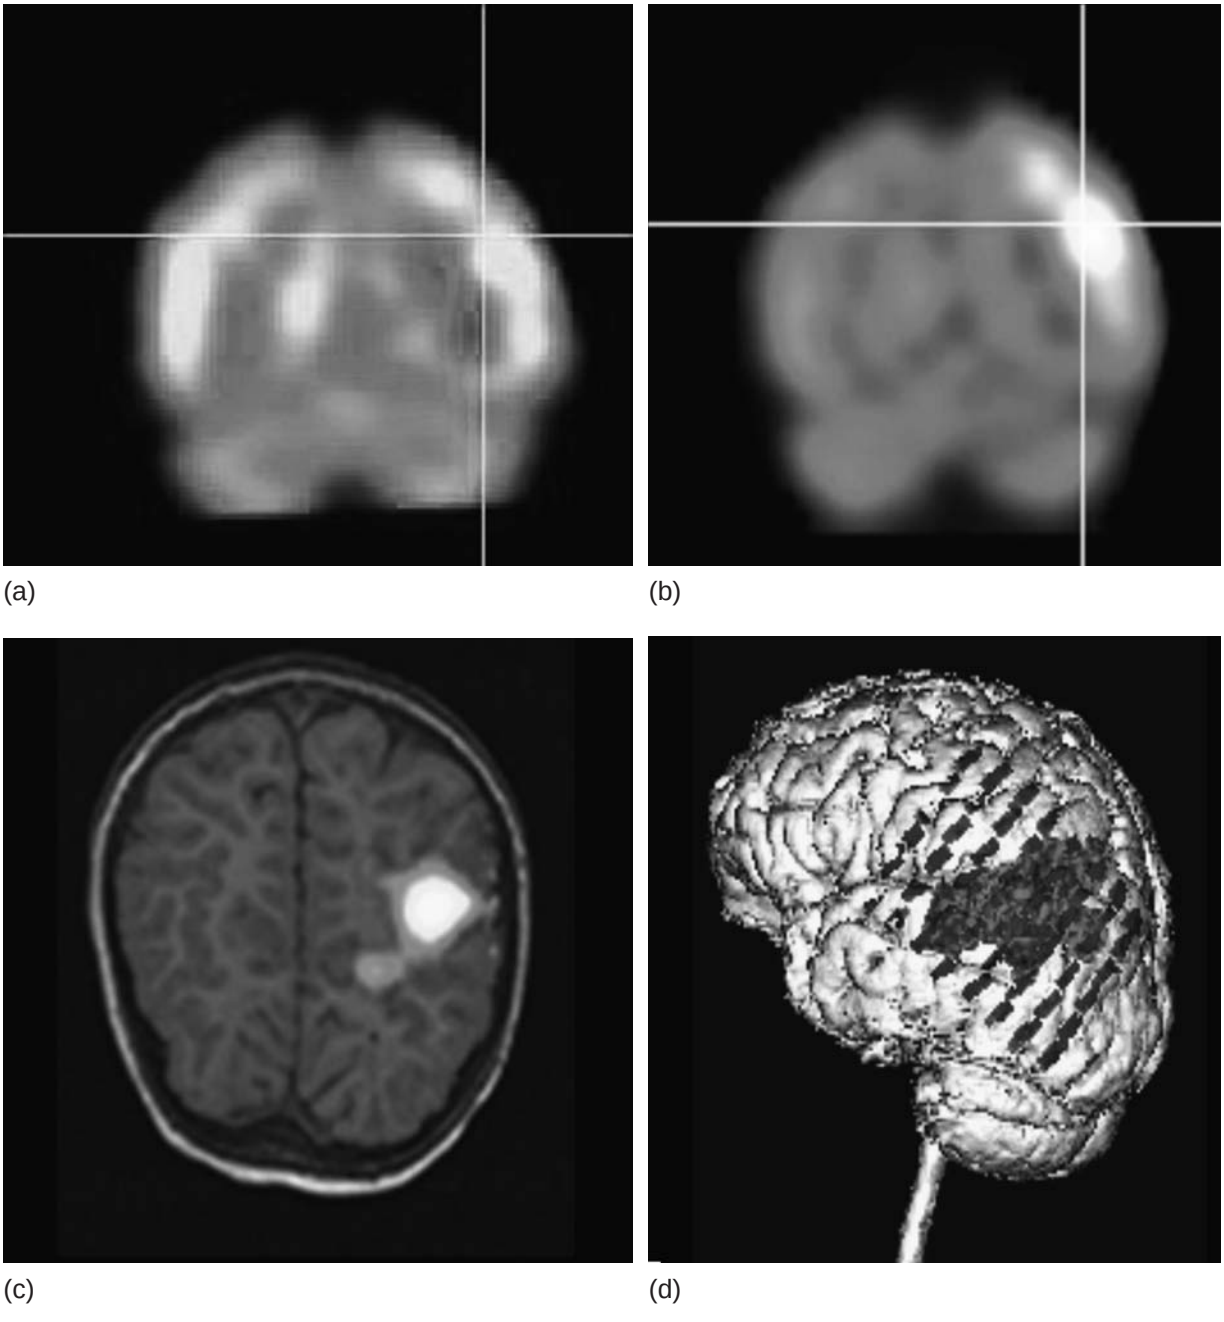

Figure 76.1 Subtracted peri-ictal SPECT co-registered to structural MRI (SISCOM) in a patients with intractable partial epilepsy and an ill-defined MRI abnormal in the left partietal lobe region. On visual inspection the interictal (a) in the oblique-coronal plane shows no obvious abnormality. The ictal (b) SPECT images suggest a left hemisphere region of ictal hyperperfusion. The subtracted study (c) reveals a localized abnormality. The SISCOM *focus* (d) is present in the left partietal lobe. The placement of a subdural grid was superimposed over the region of ictal hyperperfusion. Pathology demonstrated focal cortical dysplasia. (Note: The left side of the brain is on the right side of the figure.)

yield of postictal studies in patients with intractable partial epilepsy.[34]

The superiority of SISCOM in localizing the epileptogenic zone, particularly in extratemporal epilepsy, has been previously demonstrated.[38] The prognostic importance of the SISCOM *focus* in patients undergoing a focal cortical resection for partial epilepsy of extratemporal origin has been evaluated[38] (Figures 76.2 and 3). The operative outcome was assessed in 36 patients with extratemporal epilepsy who had a preoperative SISCOM study.[38] The presence of a localizing SISCOM alteration concordant with the epileptogenic zone was a favorable predictor of an excellent surgical outcome ($p < 0.05$).[38] Eleven of 19 patients (57.9%) with a concordant SISCOM *focus* and three of 17 patients (17.6%) with a nonlocalizing or discordant SISCOM, respectively, were rendered seizurefree or experienced only rare seizures. Approximately three-quarters of the patients with a localized SISCOM abnormality had a normal structural MRI. In addition, this study demonstrated that the extent of resection of the SISCOM *focus* was also of prognostic importance ($p < 0.05$).[38] Failure to resect the neocortical region intimately associated with the localized blood-flow change concordant with the ictal onset zone was a predictor of an unfavorable operative outcome.[38]

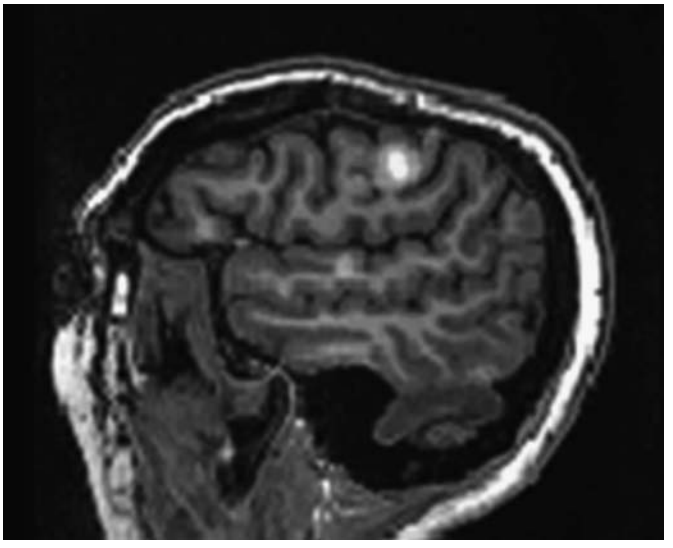

Figure 76.2 Subtracted peri-ictal SPECT co-registered to structural MRI (SISCOM) in the sagittal plane in a patient with right posterior mesial frontal lobe seizures. MRI study was normal. The surgical pathology revealed focal cortical dysplasia. (Note: The right side of the brain is on the left side of the figure.)

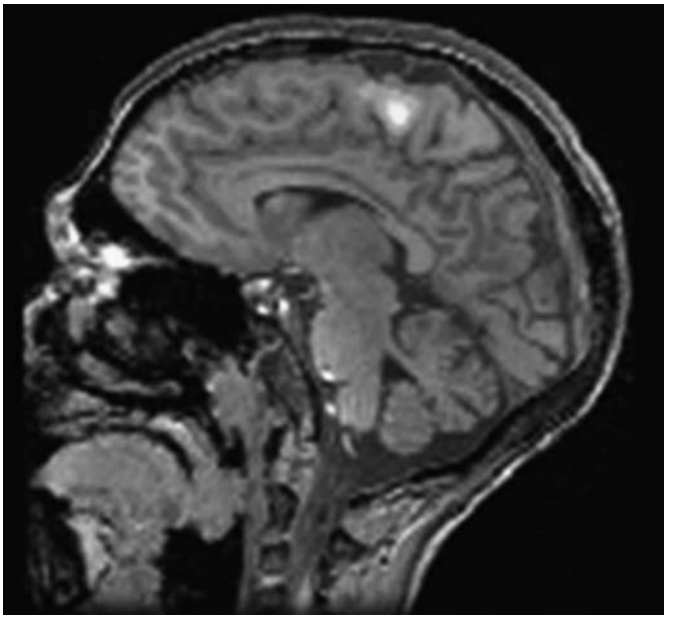

Figure 76.3 Subtracted peri-ictal SPECT co-registered to structural MRI (SISCOM) in the in a patient with a left frontal lobe seizures. MRI study was normal. The patient had focal motor seizures involving the right upper extremity. Pathology revealed only mild gliosis. (Note: The right side of the brain is on the left side of the figure.)

The diagnostic yield of SISCOM has also been examined in patients with focal cortical dysplasia.[41] As previously noted, these individuals may have unremarkable structural MRI studies and present with intractable partial epilepsy of neocortical origin. SISCOM images were localizing in 19 of 22 patients (86%); including eight of ten individuals with normal MRI studies.[41] SISCOM localization was concordant with MRI in 91%, scalp ictal EEG in 93%, and intracranial ictal EEG in 100%. The presence of a localizing SISCOM image also correlated with a lower postoperative seizure frequency score ($p < 0.05$).[41]

SISCOM has also been evaluated in the identification of the ictal onset zone in patients being considered for reoperation.[44] These individuals were 'surgical failures' and continued to experience an intractable seizure disorder. Fifty-eight patients were evaluated for reoperation.[44] The average age of the patients was 31 years (range, 2–56 years). The SISCOM study revealed a hyperperfusion localized alteration in 46 of 58 patients (79%). Thirty-three of 46 (72%) imaging abnormalities were adjacent to the previous surgical site, e.g., posterior to the margin of resection, and eight of 46 (17%) were remote but in the ipsilateral cerebral hemisphere. The hyperperfusion focus was in the contralateral hemisphere in the five of 46 patients (11%). The SISCOM study was indeterminate in 12 patients (21%). The site of the scalp-recorded ictal-EEG onset zone was concordant with the SISCOM focus in 32 of 46 patients (70%). The SISCOM finding was concordant with both the ictal-EEG pattern and MRI site of the previous resection in 28 of 46 patients (61%). The ictal-SPECT studies were correlated with the localization of the seizure onset zone in the 15 patients who underwent chronic intracranial EEG monitoring. The SISCOM abnormality correctly lateralized the site of seizure of seizure onset in 12 of 15 patients (80%).[44] The localized imaging alteration was concordant with the ictal onset zone in seven of 15 patients (47%). In five patients (33%) the SISCOM finding was ipsilateral, but remote, from the site of seizure onset. In three patients (20%) the SISCOM study was either indeterminate ($N = 2$) or revealed a localized abnormality contralateral to the epileptic brain tissue ($N = 1$). Twenty-six of the 31 patients (84%) were followed 6 months or longer after reoperation. The seizure outcome at 1 year or longer postoperatively could be determined in 24 of the 26 patients. Only one of the 26 patients (4%) had a MRI-identified pathological substrate prior to reoperation. Eleven of the 26 patients (42%) had a favorable operative outcome and five individuals (19%) were rendered seizurefree. The predictive value of SISCOM was assessed in 23 of the 26 patients with a localized hyperperfusion alteration who underwent reoperation. The SISCOM-identified abnormality was concordant with the epileptogenic zone in 20 of 23 patients (87%). The results of the ictal SPECT study in this group of patients, however, did not achieve statistical significance ($p = 0.23$). The effect of SISCOM findings on operative outcome was also not significant when patients with indeterminate findings were included with individuals with discordant findings ($p = 0.19$).[44]

77 Automatic detection of epileptic seizures

FT Sun, TK Tcheng, EH Boto, BM Wingeier, TL Skarpaas, and MJ Morrell

Overview and scope

Automatic seizure detection, the method of using computers to detect epileptic seizures based on recorded electrographic signals, has made significant advancements over the past three decades. While the field started with simple detection algorithms based on the shape of the electrographic waveform, it has matured to incorporate advanced signal processing methods and classification algorithms such as wavelet transforms and support vector machines. The motivations for seizure detection have evolved from off-line processing of electrographic data for further review by the clinician to completely implantable systems that provide electrical stimulation in response to detected seizure activity. In this chapter, we first discuss the motivations, algorithm design considerations, and limitations of automatic seizure detection. We then review different computational algorithms and address the advantages and disadvantages of the different approaches. Finally, we discuss the algorithms that are implemented in commercially available systems as well as the current state-of-the-art, automatic seizure detection in an implantable device.

Before proceeding, it is important to understand the differences between seizure detection, spike detection, and seizure prediction. The earliest computer algorithms for parsing electrographic data focused on the detection of specific electrographic features such as spikes and sharp waves.[1–4] Spike detection algorithms were developed to relieve the clinician from the tedious task of counting spikes, and also to provide a more consistent and automated evaluation of electrographic data. However spike detection algorithms are not effective in detecting all types of seizures because of the large variation in electrographic seizure patterns.[5] Therefore, seizure detection has developed into a separate class of electrographic analysis. Seizure detection is also distinguished from seizure prediction. Seizure prediction attempts to forecast probable seizures or determine the probability of a seizure well in advance of a seizure onset (by minutes or hours) based on electrographic of physiological changes. While seizure prediction may provide an early indication of a probable event, seizure prediction algorithms do not identify the actual onset or time of the seizure. Because the goals and motivations for spike detection and seizure prediction are not the same as for seizure detection, they are not discussed in this chapter. The reader is referred to Gotman *et al.*[6] and Brown *et al.*[7] for a review of various spike detection algorithms and to Litt and Echuaz[8] and Mormann *et al.*[9] for a review of seizure prediction algorithms.

Background

Motivation for seizure detection

The conventional clinical use of automated seizure detection algorithms is to identify abbreviated epochs of interest out of a typically large and unabridged electrographic dataset, for example, as acquired during long-term monitoring of an epileptic patient. When used to monitor on-line electroencephalographic (EEG) activity, the detection systems can be configured to trigger an auditory or visual signal to alert the attending clinician or caregiver of the event. When used off-line, detections can also be used as markers to identify epochs for further review, thus reducing the time and effort needed to review EEG records. While human visual analysis of the data is still considered the gold standard for identifying seizures, seizures can often be missed. Because of the often-limited human resources and the improvement of commercially available seizure detection algorithms, epilepsy monitoring units are relying more heavily on computer-aided systems for seizure detection.[5]

Early seizure detection algorithms were developed during an era of relatively limited computational power and primarily for off-line EEG analysis. Advancement in computer technologies over the past three decades has allowed for the development of more powerful seizure detection algorithms, real-time computation, and ambulatory detection systems. These developments have expanded the range of applications for seizure detection. Among these applications are ambulatory seizure warning systems designed to alert the patients to an imminent seizure,[10,11] and responsive therapy delivery systems that may provide electrical or pharmacological therapy in response to a detected event.[12–14] With the miniaturization of computer processors, a completely implantable device that performs seizure detection and delivers responsive electrical stimulation has been developed (NeuroPace, Inc., Mountain View, CA).*[15]

*The NeuroPace® RNS™ system is currently in clinical trials for the treatment of refractory epilepsy.

Seizure warning systems and responsive therapy applications are practicable in cases such as partial onset or focal seizures, where an electrographic onset may be observable seconds or minutes before the first clinical sign,[16,17] or before progression to a more serious complex partial seizure or generalized seizure. This early electrographic onset may provide a window where a warning can be delivered, or electrical, chemical, or other treatment applied in order to interrupt progression to a more generalized event. Such applications have been proposed by several authors,[10,12,13] but are not yet common due to the technological barriers involved.

Algorithm design considerations

In each of the seizure detection applications discussed above, there are a number of considerations that shape the detection algorithm. The sensitivity and specificity of an algorithm determine its performance in detecting seizures (correct positives), missing seizures (false negatives), and incorrectly detecting seizures (false positives). In the case of diagnostic seizure identification, a false positive may be more tolerable than a false negative. For example, a false positive may still provide valuable information for localizing the epileptogenic zone; moreover a neurologist can quickly discard false detections upon review.[18] On the other hand, a false negative may lead to a misinformed diagnosis. If the missed seizure is representative of a secondary event, an overly specific detection algorithm may result in a missed seizure type or epileptogenic zone.[19] Other applications, such as seizure counting or responsive therapy systems, may require that detection be set conservatively, so that seizures are counted, or therapy delivered, only when detection of the event is certain. Frequent false positives in a seizure warning system may render the system ineffective, as alarms will eventually be ignored.

Detection timing also plays a meaningful role in algorithm development. In the case of diagnostic seizure identification or seizure counting, detection at any time during the event may be adequate. However, early seizure detection is critical for seizure warning or responsive therapy systems. In these applications, detection at the earliest electrographic onset may be able to provide a warning or deliver therapy before the seizure becomes widespread or generalized, and potentially even before the patient becomes aware of the seizure.[20] Early detection can also be important for facilitating localization during ictal imaging procedures, such as single-photon emission computed tomography (SPECT), where the timing between the seizure onset and injection of a radiotracer at the start of the procedure is critical for identifying the true onset region; delayed injections may result in visualization of secondary foci or seizure spread.[10]

Another consideration for seizure detection algorithms is whether or not 'future' data may be used to further specify detection. In other words, detection algorithms may detect seizures based on either causal methods, which use past and present data, or acausal methods, which use past, present, and future data. Real-time systems that must respond as early as possible to a seizure onset usually operate on causal data only. Off-line seizure detection systems may employ more accurate acausal signal processing methods.[19] When acausal algorithms are used in on-line applications, they detect seizures with a time lag due to their reliance on future data. Diagnostic seizure identification and seizure counting are examples of applications that can benefit from the increased accuracy of acausal methods.[19] In comparison, seizure warning and responsive therapy systems must operate in real-time using causal methods because of their need for rapid response.

Most seizure detection algorithms allow user input to adjust detection performance. This may be either manual adjustment of sensitivity parameters, or more involved user-directed training of the algorithm.[10,20,21] For example, the clinician may need to annotate the first few seizures, select parameters specific to the patient's seizures (e.g., frequency range or type of electrographic onset), or provide feedback of false detections. The added input may greatly improve the accuracy, specificity, and possibly early detection of seizures, however, the increased time required to personalize the detection algorithm and the additional burden on the clinician may make these techniques practicable only in long-term applications, such as in implantable technology.

There are a number of other considerations that influence the development of seizure detection algorithms, such as whether the electrographic data are from intracranial or surface electrodes, the age of the patient (neonatal, pediatric, or adult), and the available computational resources (implantable device versus external device). All of these issues need to be addressed for each application of a seizure detection algorithm.

Limitations

A fundamental limitation to the accuracy of seizure detection systems is the quality of the electrographic data and the conditions under which they were acquired. Electrode location is a critical variable in seizure detection, since seizures may be missed if electrodes are not positioned appropriately. This may be particularly relevant in the case of focal seizures and/or under the conditions of scalp recording.[16,22] Temporal resolution is also an issue in seizure detection. Due to computational and data storage limitations, early electrographic data were sampled at 200 Hz or less. Moreover, data were often filtered to exclude frequencies above 40 Hz based on the understanding of epileptic discharges at the time.[18] Even now, high frequency sampling is not common, despite the recent literature and interest in high frequency oscillations involved in epileptogenic localization, and seizure generation and onset.[23–29] Scalp monitoring and intracranial recording may also be susceptible to artifacts. A patient's movement during a seizure can obscure the electrographic onset of the event. In the past, electrographic epochs affected by artifacts were often excluded. A number of groups are currently developing algorithms to continue to improve signal quality.[30,31]

Electrographic features of seizures

Clinical versus electrographic seizures

Before reviewing seizure detection algorithms, one must consider what an electrographic seizure is and how it relates to clinical or behavioral seizures. Gotman[5] dissociates these two terms, describing a 'behavioral' seizure as the behavioral manifestation of an epileptic seizure, and an 'electrographic' seizure as an abnormal paroxysmal EEG pattern. In most cases, the behavioral and electrographic events can be

observed concomitantly. However, a behavioral seizure can be observed in the absence of an electrographic correlate. If the seizure was a true epileptic event, it may be assumed that abnormal activity is present in the brain, but was not recorded due to the limitations in recording technology. Conversely, if an electrographic seizure is observed with no behavioral correlate, the seizure may be referred to as a 'pure electrographic seizure' or a 'subclinical' seizure. In many situations, detection of subclinical events is still meaningful for seizure localization[32–35] or for responsive therapy.[36,37] Moreover, the lack of overt behavioral manifestations does not preclude a clinical event; some clinical symptoms are negative, such as speech arrest, aphasia, amnesia, neglect, and motor arrest, and can only be observed under specific conditions.[33,38–40]

Ictal morphology

One of the most challenging aspects of automated or computer-aided seizure detection is that seizure morphology is so varied, from patient to patient, within a patient, and within a seizure. Electrographic onset patterns for partial epileptic seizures have been described as low-amplitude desynchronization, polyspike activity, low-voltage fast, rhythmic waves, rhythmic spike, spike-wave, or sharp-wave, and possibly even nondescript.[23,41–44] As seizures progress, the morphology can evolve into a different electrographic pattern.[41] The earliest computerized seizure detection algorithms focused on a single feature of the electrographic signal.[45–47] These algorithms were effective in identifying high-amplitude events such as those associated with generalized tonic-clonic seizures. However, because they were feature-specific, they often failed to detect seizures with different morphologies.

The spectral and electrographic appearance of ictal activity depends on whether the EEG was acquired on the scalp or intracranially. While scalp electrographic recordings are most common, intracranial ictal electrocorticography is thought to provide the most reliable information for localizing seizure foci.[48] Electrographic data acquired from intracranial electrodes may contain higher frequency information and different electrographic features as compared to scalp recordings.[42] For these reasons, algorithms have been developed specifically for seizure detection based on intracranial data.[11,12,48–50]

Neonatal seizure detection also forms a distinct class from adult seizure detection. Electrographic features during both the baseline and ictal periods differ between neonates and adults. Neonatal seizures are characterized by narrow band rhythmic discharges, repetitive spiking and very slow rhythmic discharges.[51] In fact, some features that are considered to be ictal in an adult may be normal in the infant, and vice versa.[52] Although this chapter focuses on adult seizure detection, a number of papers have been published that focus on neonatal seizure detection algorithms. The reader is referred to Faul *et al.*[53] for review.

Methods for automatic seizure detection

Trending-based seizure detection algorithms

Many successful seizure algorithms rely on comparing the features of the current period of time to earlier 'background' data in the same EEG record. These detection algorithms are referred to as 'trending' algorithms because the current epoch of interest is compared to a continually-updating background trend. Trending algorithms are sensitive to rapid or paroxysmal changes compared to the background activity, and typically require minimal user input or training since detections are based on historical electrographic data from the patient. Continuously updating the background trend allows for consistent detection around the clock, since the current epoch is always being compared to a relative baseline. For instance, during sleep, the background might be very different than during active wake, but paroxysmal events are detected in both states because these algorithms look for relative changes compared to a recent baseline. If a detector is used to mark events for future visual inspection, the timing of detection relative to the onset of the electrographic event is not critical. For this application, the delay from the electrographic onset to detection may be quite long (e.g., > 20 seconds),[20] and a relatively high false positive rate (e.g., 1/hour) is tolerable.[19,48]

The detection algorithm described by Gotman[18,19] was one of the first successful trending seizure detectors. It has been tested on both scalp and intracranial EEG recordings, and is now commercially available (see Stellate Section). Gotman noted that the majority of seizures contained paroxysmal, sustained rhythmic activity with a fundamental frequency between 3 and 29 Hz at some point during the event.[18] Thus, the detection algorithm focused on detecting paroxysmal rhythmic activity within those frequencies. First, the EEG signal is low-pass filtered and decomposed into half-waves (elemental segments that are representative of the amplitude and frequency of the signal). Aggregate measures of the half-waves within an epoch, such as the average amplitude, average duration, and coefficient of variation of the duration are extracted for each epoch. A detection occurs when the average half-wave amplitude in the current epoch is significantly greater than the background, and the coefficient of variation and average half-wave duration are within a specified range, indicative of rhythmic activity. The current epoch is defined by a short window (e.g., 2 seconds) and the background is defined by an extended window (e.g., 16 seconds, ending 12–20 seconds prior to the current epoch).

This algorithm was further extended in 1990 to include a second 'background' segment after the current epoch (e.g., 8 seconds).[19] The second background was included to reduce the number of false detections due to short events. Qu and Gotman (1993)[21] later extended the algorithm again by incorporating false seizure detections from earlier monitoring sessions of an individual patient to further reduce the false-positive rate during subsequent sessions of the same patient. However, the limitation of all of these detection algorithms is that seizures consisting of irregular EEG with mixed frequencies as well as low-voltage fast events that are not followed by high-amplitude rhythmic activity can be missed.

A similar trending seizure detection method was developed specifically for intracranial EEG recordings.[48] This algorithm was designed to detect both high-frequency and high-amplitude activity. The absolute magnitude of sample-to-sample differences is calculated, where a large magnitude is indicative of a steep slope or rapid change in the signal. Within each 5-second epoch, the number of large magnitude differences is counted. A seizure is detected when a segment has an increased count compared to the running average counts of

the background. The advantage of this system is that it detects high frequency activity very well. However, it may be insensitive to some low frequency events.

Another implementation using the trending approach was reported by Osorio *et al.*[12] This algorithm was developed specifically to detect seizures in real-time. In this algorithm, the signal is first filtered using a wavelet transform that is sensitive to power changes between 5 and 45 Hz. Then the signal is filtered using a non-linear median filter to rapidly detect changes while overlooking very brief signal changes. The final step compares the median power of the current epoch (2 seconds) to a background (30 minutes, smoothed with exponential forgetting). This algorithm results in earlier detection[54] and shorter detection latencies (3.6–5 seconds)[37] than the algorithms discussed above. It also includes several manually-adjustable parameters associated with frequency band, filter percentile, background length, and patient-specific optimization. However, atypical seizures will still go undetected, which is a problem for patients who do not have a stereotyped electrographic seizure onset. Also, seizures that contain frequencies outside of the frequency range specified can go undetected.[37]

Preclassification-based seizure detection algorithms

A second category of seizure detection algorithm leverages statistics derived from previously classified EEG to properly sort novel EEG into seizure and non-seizure categories. These prior data are used either to train a classification algorithm, such as an artificial neural network, or to provide a prior distribution for Bayesian methods. Preclassification-based algorithms differ from each other in two main facets: (1) the extracted EEG features used for detection and (2) the method used to classify the EEG.

Feature extraction

As with trending-based detection, the first step in a preclassification-based algorithm is to identify a feature or set of features upon which detection is determined. Relevant features can include statistics describing temporal features of the data, such as RMS amplitude,[55] or measures of the frequency content.[55–57] Three types of frequency analysis are commonly used in feature extraction: the Fourier transform, wavelet transform, and matching pursuit decomposition. Frequency analysis methods involve a tradeoff between time and frequency resolution. This tradeoff governs the method's robustness to transient noise, ability to represent rhythmic behavior, and to some extent detection response time. The Fourier transform and its derivatives (e.g., short-term Fourier transform and fast Fourier transform) have long been used to analyze EEG frequency content.[58] The Fourier methods are efficient and easy to implement. However, they are subject to broadband spectral interference in response to abrupt frequency changes because the time resolution is uniform across the frequency spectrum. This property negatively affects accurate characterization of EEG frequency in the presence of fast transients such as spiking.[58,59]

Wavelet-based frequency analysis provides excellent time resolution at higher frequencies and good frequency resolution at lower frequencies. Unlike Fourier analyses, where the signal is decomposed into sine and cosines, in wavelet analyses, segments of the signal are decomposed using a family of finite functions called 'wavelets'. In a family of 'wavelets', the primary waveform or 'mother' wavelet is scaled and shifted to form the 'daughter' wavelets, thus allowing for increased temporal resolution at higher frequencies. This property minimizes the broadband distortions due to brief spiking or sharp-wave transients seen in Fourier-based analyses. The discrete, wavelet transform is commonly used for EEG frequency analysis.[10,60,61] Khan and Gotman[62] compared a discrete wavelet-based trending detector to a prior Gotman trending detector, attaining equivalent sensitivity with an 86% decreased false-positive rate.

Finally, the matching pursuit algorithm, a similar non-linear signal decomposition method (further discussed in the Persyst Reveal Section), provides extensive flexibility in managing the time-frequency resolution trade-off, even within a single frequency band.[55] The matching pursuit algorithm is robust against sharp transients and shows good frequency resolution within seizure EEG.[55,57] Wilson *et al.*[55] use matching pursuit in their commercialized Reveal algorithm, reporting satisfactory improvements in both accuracy and false-positive rate as compared to their previous fast-Fourier transform (FFT)-based detector.[63]

Classification

The second step of preclassification-based seizure detection algorithms is to categorize novel EEG data based on the features of preclassified EEG. Three approaches are commonly used for classification: artificial neural networks (ANNs), support vector machines (SVMs), and Bayesian methods.

Artificial neural networks describe a class of methods where 'neural networks' are trained to categorize EEG epochs as either seizure or non-seizure based on a manually preclassified set of EEG examples. The training or learning phase is typically an iterative process that generates rules to minimize the cost function or error. After the initial training, new EEG data are classified based on the rules created during the initial learning phase. Thus, the examples used in the training set are critical to the success of an ANN approach.[64,65] In the Reveal algorithm, matching pursuit-based feature vectors are processed through both ANN-generated and hypothesis-driven rules. The algorithm achieved competitive sensitivity with exceptionally low false-positive rates.[55] ANNs have also been used heavily in other automated seizure detectors over the last decade.[63,65–68]

Support vector machines use preclassified data to calculate a border that maximally separates the boundary cases of non-seizure EEG and seizure EEG. Novel data are then classified by where they fall relative to the defined border. In a patient-specific study, Shoeb *et al.*[10] combined this classification method with a wavelet-based analysis to achieve competitive true-detection rates for novel EEG data with a relatively low false-detection rate. The group noted their SVM classifiers' robustness to class-imbalanced training data, a property highly applicable to seizure detection due to the usual scarcity of seizure EEG relative to non-seizure EEG. Other theoretical advantages of the method include robustness to over-fitting, a guarantee of global optimization, and relatively low increase in model complexity with increasingly large feature vectors.

The Bayesian method of seizure detection described by Saab and Gotman (2005)[11] classifies novel EEG epochs by calculating the likelihood of the epoch being seizure data given prior probabilities from preclassified EEG data. This calculation assumes

that the features in the data are independent, characterized by Gaussian distribution, and differentiable by class (e.g., have different mean and/or variance in seizure versus non-seizure EEG). When a novel EEG epoch is introduced, the formulation uses Bayes' theorem to calculate the probability that an epoch belongs to the seizure class. If a measure based on that probability crosses an arbitrary threshold, it is classified as a seizure. This method also provides controls for balancing detector sensitivity against false-detection tolerance. The group observed sufficiently improved sensitivity to a previous method,[19] and sufficiently fast execution time to merit further exploration of the classification method in real-time seizure detectors.

Advantages and disadvantages

Preclassification-based seizure detection algorithms offer certain advantages relative to trending-based algorithms. When employing the right technologies in a patient-specific context, excellent detector performance can be achieved at a low false-positive rate.[10,55] Moreover, establishing these classification-based algorithms may require less manual manipulation of parameters than some trending-based detectors (e.g., half-wave), as rule and threshold development can occur mostly in the machine-based classifier.

This family of methods also has disadvantages relative to trending algorithms. Shoeb *et al.*[10] found that their preclassification-based detector performed poorly when used in a general clinical setting due to dissimilarity between training examples and new patient EEG data. Although this could also occur with most trending-based detection algorithms, the latter can be corrected by quickly altering trending parameters and thresholds whereas preclassification-based detectors may require training on possibly hours of data for each new patient, depending on their seizure rate. One group controlled for this effect by exclusively extracting normalized EEG features.[11] Another disadvantage of these methods is that they can only detect those seizure types that have been previously observed and hand-classified in a training set, requiring additional training in the case of a patient's newly observed seizure type.

State-based algorithms

A third category of seizure detection algorithms identifies a seizure state, irrespective of the recent background activity or previously categorized seizures. These algorithms are not dependent on the relative changes in the signal; rather they measure the absolute state of the current epoch and compare that state to a non-seizure state, which is either defined previously or acquired from the data. State-based detection algorithms operate by identifying the one feature or set of features (often non-linear) of the electrographic activity that is most representative of the seizure state. Several such features have been identified in the literature, including total energy, power, or variance,[49,69] Lyapunov exponents,[70] Kolmogorov entropy,[71] and minimum description length.[72] With this class of detection algorithms, detection may often occur seconds to minutes before the electrographic onset (as identified by the epileptologist). Therefore the distinction between seizure detection and seizure prediction becomes less clear, and these techniques are sometimes referred to as methods for 'early' seizure detection, seizure anticipation, or preseizure state detection.[73]

The earlier methods to detect a change in state were based on the power or variance of the signal, either within a specific frequency band or across all frequencies. This method of detection is simple and requires minimum computational power. Detection occurs when power within a frequency band is above a threshold.[69,74] In some cases changes in the accumulated energy occurred as early as 50 minutes before the electrographic onset.[74]

More elaborate state-based methods make use of non-linear dynamics for seizure detection.[70,75,76] These techniques focus on the change in the predictability or chaos of the neural system prior to or during the seizure. Iasemidis *et al.*[70] proposed the use of the short-term Lyapunov exponent, a measure of the short-term predictability in a non-linear dynamic system. They found that during a seizure, the maximum short-term Lyapunov exponent is reduced, indicating decreased chaos and increased predictability of the system. The Kolmogorov entropy, another measure of the complexity of a dynamic system, describes the level of uncertainty about the future state of the system. As with the Lyapunov exponent, the Kolmogorov entropy has been shown to decrease prior to a seizure with detection of a trend as early as 40 minutes before the electrographic onset.[71] Minimum description length is yet another way to define the complexity of the signal by estimating the minimum number of bits needed to describe the data.[72] This method has been proposed for neonatal seizure detection, where seizures are typically very rhythmic, and therefore defined by a low minimum description length. Other similar measures such as correlation dimension[73] and multidimensional probability evolution[77] have also been proposed.

For all of these non-linear dynamic methods, the main drawback is that they often require a large amount of stationary data to estimate parameters, and the computational complexity may be difficult to implement in real-time, particularly for ambulatory or implantable applications.

Clinical implementations

Commercial seizure detection algorithms

There are two major commercially available seizure detection systems; they are provided by Stellate Systems, Inc. (Montreal, Quebec, Canada), and Persyst Development Corporation (Prescott, Arizona). Stellate offers five different specialized seizure detectors: (1) a seizure onset detector, (2) a seizure pattern detector, (3) Icta-S for scalp EEG, (4) Icta-D for intracranial recordings, and (5) a newborn seizure detector. In addition to these stand-alone seizure detectors, several companies have incorporated Stellate algorithms into their EEG monitoring systems. Persyst offers their Reveal seizure detection algorithm. These commercially available algorithms employ a combination of the techniques and methods discussed above. All of these seizure detection algorithms can be run either on-line or off-line.

Stellate

The detection algorithms that are available in the Stellate package are summarized here; they are described in detail in several prior publications.[11,18,19,51,78]

The Stellate seizure and onset pattern detector algorithm evaluates each EEG channel individually by comparing a brief (2 seconds) epoch sliding window with a background sliding window (15–16 seconds). The epoch and background windows are separated by a gap (12–20 seconds).[19] The EEG signal is decomposed into half-waves and subsequent analysis is based on these half-waves. The seizure detector is triggered when several conditions are met:

1. The epoch amplitude must exceed the background amplitude by a specified value.
2. A candidate detection must occur in the same or the following epoch on a specified number of channels.
3. The frequency of the candidate seizure must exceed a specified value.
4. The coefficient of variation within the epoch, which is inversely correlated with rhythmicity, must be below a specified value.

The Icta-S algorithm is optimized for scalp EEG recordings. This algorithm is based on Bayes' formula and uses features and probabilities developed from a training data set to probabilistically determine whether a seizure has occurred. Epochs of 2 seconds are compared with a 30-second baseline period, separated by 1 minute.[11] Epochs with a high seizure probability affect the seizure probability of the following two epochs. As with the seizure and onset pattern detectors, amplitude, frequency, and coefficient of variation are used to identify candidate seizure epochs.

The Icta-D algorithm is optimized for intracranial recordings, which contain more variability in patterns, amplitudes and frequencies. It differs from the Icta-S algorithm in that epochs of 4 seconds are compared with 2-minute baseline periods.[78] Also, it was trained on intracranial data instead of scalp EEG.

The neonatal seizure detector combines three detection algorithms: (1) detection of rhythmic discharges, (2) detection of multiple spikes, and (3) detection of slow rhythmic discharges. A spectral analysis method is used to detect rhythmic discharges of 0.5–10 Hz using overlapping 10-second epochs compared to 20 seconds of background, separated by a 60-second gap. Multiple spikes are identified within high-pass filtered, 10-second epochs. Only spikes above a specified threshold are counted and the number of spikes within a 10-second epoch must exceed a minimum value. Slow rhythmic discharges less than 0.5 Hz are detected using low-pass filtered EEG data and the same half-wave and trending-based analysis method as described in Gotman (1990),[19] using overlapping 10-second epochs compared to a 20-second background, separated by a 60-second gap.[51]

Persyst Reveal

The Persyst Reveal algorithm is described in detail by Wilson *et al.* (2004)[55] and summarized here. In this algorithm, EEG data are filtered and downsampled to 32 Hz, restricting the maximum frequency analyzed to 16 Hz. Each channel of the data is segmented into 2-second epochs with a 1-second overlap. A matching pursuit decomposition is applied resulting in a set of Gabor 'atoms', describing the time-frequency evolution of each 2-second epoch; only the first two atoms are selected for the analysis. Epochs are also described by total RMS amplitude, maximum amplitude excursion, and summed duration of amplifier saturation. Epochs containing excessive artifact, based on amplifier saturation and maximum amplitude excursion, are rejected. Several hand-coded and data-trained neural net functions are used to identify rhythmicity and seizure events based on features of the atoms and epochs. Additionally, a clustering function is applied to a moving 60-second window to group consecutive epochs based on similarity into background, seizure and offset sections. These functions are described below.

1. A hand-coded function computes a 'rhythmicity' value for each atom that is maximized when the atom half-wave-amplitude, atom-half-wave-slope, atom-half-wave-count, and atom-duration are maximized.
2. A neural net function computes a 'distinguished-from-window' value that indicates how well an atom is distinguished from the window based on atom-amplitude, atom-duration, and atom-frequency.
3. A hand-coded function computes a 'seizure-score' for the epoch that is maximized when the previously computed rhythmicity and distinguished-from-window values are maximized.
4. A neural net function calculates a 'seizure-candidate' value based on seizure frequency and the seizure score.
5. A neural net function calculates a 'seizure-is-perceived' value based on the candidate seizure duration, the seizure-candidate value, and the absence of exceptionally high maximum amplitudes, indicative of artifacts.
6. A neural net function calculates a 'composite-seizure-is-perceived' value based on the first- and third-best channels seizure-is-perceived values, as well as the amplitude and frequency differences between successive epochs.

NeuroPace® RNS™ system

The NeuroPace RNS System is an implantable system capable of performing real-time seizure detection and responsive electrical stimulation (Figure 77.1, Figure 77.2). At this time, the system is being evaluated in clinical trials to assess the safety and efficacy of responsive neurostimulation for the treatment of medically intractable partial-onset epilepsy. The implantable components of the system include (1) a neurostimulator, which senses and stores electrographic activity, performs detection, and delivers electrical stimulation; and (2) chronically implanted depth and strip leads, which are used to sense and provide stimulation. The external components include (1) a Programmer, used to program detection and stimulation settings and retrieve stored information (e.g. electrographic activity) from the neurostimulator; and (2) a wand, which allows wireless communication between the neurostimulator and the Programmer. A patient data transmitter is also provided, to allow uploading and monitoring of device data between clinic visits. These data are uploaded via the Internet to a central patient data management system, and may be reviewed by physicians.

Detection algorithm

The detection algorithms implemented in the RNS Neurostimulator are designed to be computationally efficient and highly optimized in order to perform real-time seizure detection within the constraints of currently available

Figure 77.1 Schematic illustration of the implanted RNS Neurostimulator, depth lead and cortical strip lead. The RNS Neurostimulator (inset) is designed to match typical skull thickness and curvature, and is intended for implant in a ferrule, or socket, placed in a craniectomy. Up to two leads may be used with the system; each may be a depth lead or cortical (subdural) strip lead, and each has four electrode contacts, which are used for sensing and providing stimulation. In order to provide early seizure detection and delivery of focal electrical stimulation, leads are positioned using standard neurosurgical techniques as close as possible to the seizure focus or foci.

implantable technology, such as limited power and processing capabilities. Three fundamental detection algorithms (or tools) are provided, which are based on the half-wave, line length, and area features extracted from the EEG. The detection tools are highly configurable and can be adjusted by the physician to optimize the sensitivity and specificity trade-off for each individual patient. The tools can also be combined to yield even more specific detection.

The half-wave algorithm used in the RNS System is similar to that of Gotman (1982),[18] and is used to detect spikes and rhythmic activity occurring in specific frequency ranges. The neurostimulator segments the EEG at local minima and maxima (excluding deviations smaller than a programmed threshold), resulting in half-waves the amplitude and duration of which are representative of the amplitude and frequency components of the EEG. Half-waves that exceed a physician-programmed amplitude and duration are counted; the number of these half-waves occurring within a given window length must exceed a certain threshold for detection to occur.

The line length algorithm, described by Esteller *et al.* (2001),[79] is similar to fractal-dimension measures and is used to identify changes in both amplitude and frequency. The line length is defined as the average of absolute sample-to-sample differences within a window. A short-term sliding window average is compared to a long-term sliding window average. The short-term window and long-term window durations can be configured to optimize detection of specific features. A detection occurs when the short-term measurement exceeds an absolute or relative threshold (Figure 77.3). A negative threshold can also be used to detect decreases in line length, which may represent a period of electrodecrement or decreased frequency.

The area feature,[80] is similar to an energy or power measurement[81] and is used to identify changes in overall signal energy without regard for frequency. Area is defined as the average absolute area-under-the-curve within a window. As with line length, a short-term window average is compared to a long-term background window average, and detection occurs when positive or negative threshold is exceeded (Figure 77.3).

The output of the half-wave, line length and area tools from the same or different EEG channels may be combined to identify specific electrographic events. In addition, the output of a tool may be assigned a persistence duration to facilitate detection of events in sequence. For instance, a seizure onset consisting of a series of spike-wave events followed by elevated gamma might be identified by a half-wave spike detector, given several seconds of persistence and a line-length detector sensitive to the increase in frequency.

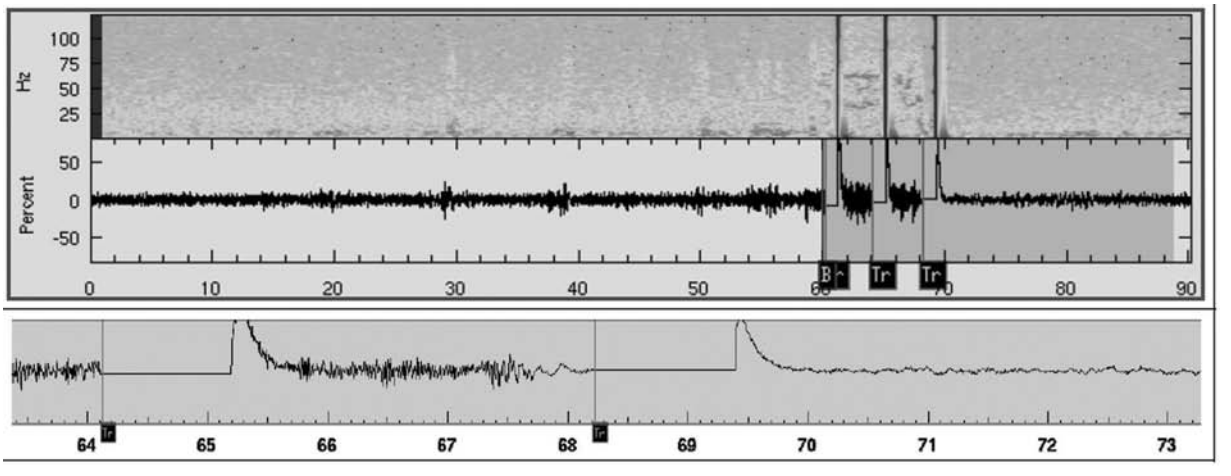

Figure 77.2 Example of a possible seizure termination by responsive stimulation. The upper panel shows the FFT spectrogram and time series for a single cortical EEG channel. The lower panel shows a close-up of the time series around the time of termination. In the time series plots, detection is indicated by the vertical blue line and the 'B' label, and responsive stimulation is indicated by the vertical red lines and the 'Tr' labels (the first is partly obscured by the 'B' label). (See Color plates.)

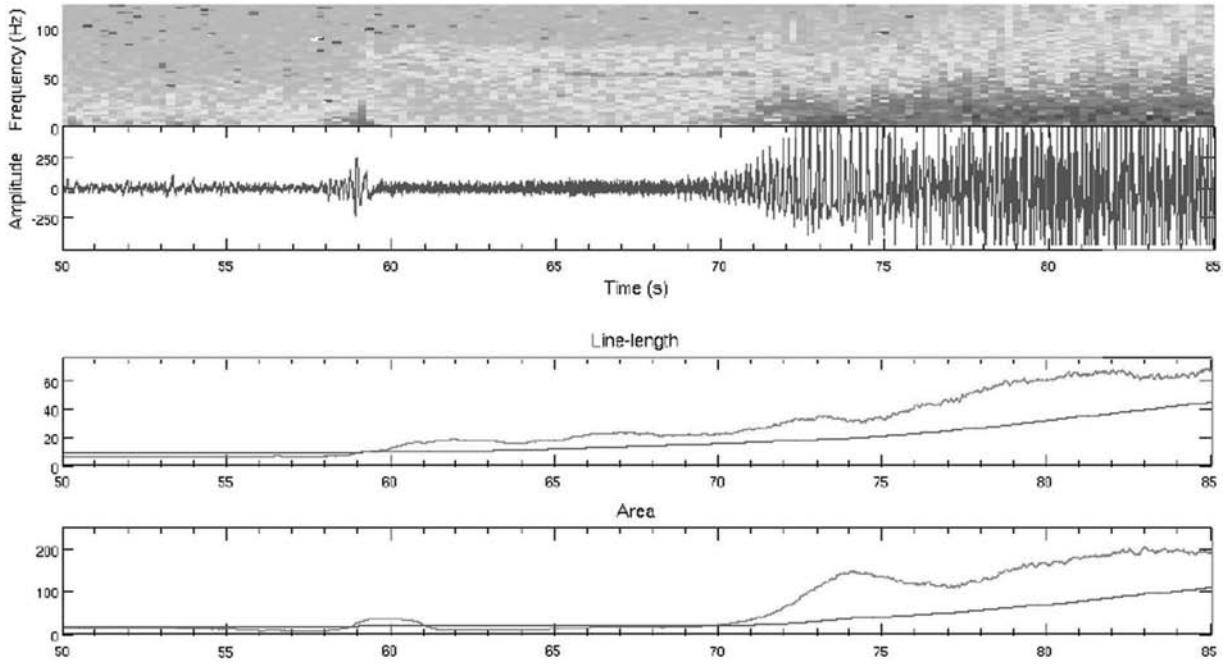

Figure 77.3 Demonstration of the line-length and area algorithms. The upper panel shows the FFT spectrogram and time series of a single cortical EEG channel at a seizure onset. The middle panel displays the data represented by the short-term (red) and long-term (blue) line length features. In this example, the short-term window is 2 seconds and the long-term window is 30 seconds. Detection occurs when the short-term trend exceeds the long-term trend (e.g., at ~59 seconds). The bottom panel displays the detection using the area algorithm. As with the line-length algorithm, detection occurs at ~59 seconds and redetection occurs at 70 seconds. Note that the line-length detection is sensitive to both changes in frequency and amplitude, whereas the area detection is sensitive to amplitude. (See Color plates.)

Advantages

Implantable systems have the unique advantage of operating on a chronic, continuous and relatively artifact-free stream of electrographic data from an ambulatory subject. This information is valuable to both the clinician and researcher, and has been used to study such topics as circadian variation in the intracranial EEG.[82] These data can be further used to optimize seizure detection for a given patient, or to control responsive stimulation delivered by the implantable device. In addition, bipolar signals recorded and analyzed by an entirely-implanted device are particularly resistant to external noise.

Limitations of implantable technology

These advantages do not come without limitations; at present implantable seizure detection is technologically constrained in comparison with methods proposed for off-line or non-implantable applications. This is due to many factors, including limited power, computational restrictions, and limitations in electrode placement. An implantable device must either be rechargeable or possess a battery life on the order of years. In either case, the power available to perform seizure detection is strictly limited. This manifests as a limit on clock speed for the implantable microcontroller. Whereas current desktop computers may perform more than 10^9 operations per second, an implantable device may be constrained to fewer than 10^6 operations per second. Detection tools are constrained to those that may be reasonably implemented in low-power digital hardware. This may require discrete approximations to complex methods, such as line length for fractal dimension. Moreover, the complexity of a device increases drastically as more channels are added. While in-hospital epilepsy monitoring may use grids of 64 or more contacts, implantable devices are currently limited to far fewer contacts and channels. This means that localization must be determined with some accuracy before use of an implantable device.

It is expected that these boundaries will expand greatly as technology advances; however, implantable applications of seizure detection will always be constrained by the resources available in a small, chronically implanted device.

Conclusions

Automated seizure detection is a rich problem area for signal analysis. A range of algorithms have been developed for this purpose. Each of the approaches has its own strengths and weaknesses, owing to the complexities of seizure waveforms, tradeoffs between sensitivity and specificity, tradeoffs between accuracy and latency, and platform constraints. In this chapter, we have reviewed a number of computational algorithms for seizure detection. While the field has grown in leaps and bounds over the past three decades, there is still no single solution to the complex problem of automated seizure detection, and there may never be. As the field continues to develop along with the acceleration of computer technology, we expect advancement in the area 'state-based' or early seizure detection algorithms as well as significant progress in ambulatory and/or implantable detection systems. These developments will be invaluable to the understanding and treatment of epilepsy.

78 'Preictal' predictors of epileptic seizures

F Mormann, K Lehnertz, and CE Elger

Outline of the chapter

Our understanding of the mechanisms that lead to the occurrence of epileptic seizures is rather incomplete. If it were possible to identify preictal precursors from the EEG of epilepsy patients, therapeutic possibilities could improve dramatically. First attempts to predict the occurrence of seizures from EEG time series were started in the 1970s. Studies on seizure prediction have since then advanced from preliminary descriptions of preictal phenomena and proof of principle studies via controlled studies to studies on continuous multi-day recordings. Following the mostly promising early reports, the recent years have witnessed a debate over the reproducibility of results and suitability of approaches. The current literature is inconclusive as to whether seizures are predictable by prospective algorithms. Prospective out-of-sample studies including a statistical validation are missing. Nevertheless, there are indications of a superior performance for approaches characterizing interactions between different brain regions by means of quantifying relations between signals from different recording sites. Prediction algorithms must be proven to perform better than a random predictor before prospective clinical trials involving seizure intervention techniques in patients can be justified.

In this chapter we will critically review the literature from the emerging field of seizure prediction and discuss the problems and pitfalls associated with the design and evaluation of seizure prediction algorithms.

Introduction

To epilepsy patients for whom complete seizure control can not be achieved, e.g., by medical or surgical treatment, it is the sudden, unforeseen way in which seizures strike 'like a bolt from the blue' that represents one of the most disabling aspects of the disease. Apart from the risk of serious injury, there is often a severe feeling of helplessness that has a strong impact on the everyday life of a patient. It is obvious that a method capable of predicting the occurrence of seizures could significantly improve the therapeutic possibilities[1] and thereby the quality of life for epilepsy patients.

A question of particular interest is whether apart from clinical prodromi, which are found only in some patients,[2,3] characteristic features can be extracted from the continuous EEG that are predictive of an impending seizure. If it were possible to reliably predict seizure occurrence from the EEG of epilepsy patients, therapeutic concepts could move from preventive strategies (e.g., long-term medication with AEDs) towards an on-demand therapy, e.g., by excretion of fast-acting anticonvulsant substances or by electrical or other stimulation in an attempt to reset brain dynamics to a state that will no longer develop into a seizure.

In principle there are two different scenarios of how a seizure could evolve: It could either be caused by a sudden and abrupt transition in which case it would not be preceded by detectable dynamical changes in the EEG. Such a scenario would be conceivable for the initiation of seizures in primary generalized epilepsy. Alternatively, this transition could be a gradual change (or a cascade of changes) in dynamics which could in theory be detected. This type of transition could be more likely in focal epilepsies.[4]

Several seizure-facilitating factors are known. In the context of his 'reservoir theory', Lennox[5] has defined seizure facilitation as the input of sensory, metabolic, emotional, or other yet unknown factors that '… fill up some reservoir until it overflows', which in turn results in a seizure. Among others, state of consciousness, sleep deprivation, stress, disturbances of electrolytes and acid-base balance, sensory stimulation and exposure to drugs are factors known to facilitate seizures.[6] Apart from the rare exception of sensory-evoked or reflex epilepsies, however, these factors are rather unspecific and highly variable since they depend on individual habits, susceptibility, and daily routine. Clinicians who care for patients with epilepsy have long known that individual patients can identify periods when seizures are more likely to occur, though they can rarely specify an exact time when seizures will happen. Reported prodromal symptoms include mood changes, irritability, sleep problems, nausea, and headache.

There are also physiological studies in small numbers of patients, usually collected serendipitously before seizures, that support the existence of a preictal period. Weinand and co-workers[7] detected a significant increase in blood flow in the epileptic temporal lobe starting 10 min before seizure onset that spread to both temporal lobes 2 min before seizure onset. Similarly, Baumgartner and colleagues[8] demonstrated increased blood flow in the epileptic temporal lobe in two patients, 11 and 12 minutes respectively, before seizure onset. Using near-infrared spectroscopy in three patients, Adelson and co-workers[9] reported an increase in cerebral oxygen availability that began more than 13.5 h, and was identified as early

as 1.5 h, before documented seizure onset. Preictal changes in other variables, such as R-R interval on the ECG[10–12] may also have predictive value, perhaps as epiphenomena related to seizure precursors, in some types of epilepsy. More recently, functional magnetic resonance imaging has demonstrated changes in perfusion prior to seizure onset.[13]

Knowledge about basic mechanisms leading to seizures has mainly been derived from animal experiments. Although there is a considerable bulk of literature on the topic, the underlying electrophysiological and neurobiochemical mechanisms are not yet fully explored. Moreover, it remains to be investigated to which degree findings from animal experiments can be transferred to human epilepsies. During recent years, a variety of potential ictogenic (seizure generating) mechanisms have been identified in experimental models of focal epilepsy, including alterations in synaptic and cellular plasticity and changes in the extracellular milieu. It is still a matter of debate, however, whether these mechanisms can be regarded as specifically ictogenic, apart from their critical role in normal brain function. On the level of neuronal networks, focal seizures are assumed to be initiated by abnormally discharging neurons (so-called bursters;[14–18] see Yaari and Beck[19] for an overview) that recruit and entrain neighboring neurons into a critical mass. This build-up might be mediated by an increasing synchronization of neuronal activity that is accompanied by a loss of inhibition, or by processes that facilitate seizures by lowering the threshold for excitation or synchronization. In this context, the term 'critical mass' might be misleading in the sense that it implies an increasing number of neurons that are entrained into an abnormal firing pattern. This mass phenomenon would be easily accessible to conventional EEG analysis which, to date, has failed to detect it. Rather, the seizure initiating process might better be visualized as a process in which an increasing number of critical interactions between neurons in a focal region and connected units in an abnormal functional network unfold over time.

Based on these concepts, a number of studies have aimed at characterizing this collective neuronal behavior from the gross EEG in order to allow definition of a transitional preictal phase. In this chapter we will give an overview of the literature on this topic and the current state of this rather young research field and critically discuss some of the methodological problems and pitfalls involved in the design and testing of seizure prediction algorithms.

The history of seizure prediction

For a better understanding of the practical problems in this field, in this section we categorize the literature on seizure prediction according to methodological standards. A chronological overview is given in Table 78.1.

Early approaches

After some early work on the predictability of seizures dating back to the 1970s,[65] attempts to extract seizure precursors from the EEG were carried out by different groups using mostly linear approaches such as spectral analysis[66–68] or pattern detection by analyzing spike occurrence rates.[69–73]

Preictal phenomena

Following the advent of the theory of nonlinear systems in the 1980s, time series analysts became aware of seizure prediction as a potential field of application. In the early 1990s, Iasemidis and co-workers[74] calculated the so-called largest Lyapunov exponent from the intracranial EEG of epilepsy patients by means of a moving window analysis and reported a decrease of this measure minutes before an epileptic seizure. Some years later, a French group of researchers reported a preictal decrease of a measure termed correlation density prior to seizures in a large group of patients.[22] The same group developed another measure named dynamical similarity index, which quantified changes in dynamics relative to a constant reference window at the beginning of a preictal recording. They found changes in dynamics prior to seizures in both intracranial[23,24] and scalp EEG recordings.[28]

Common to all these studies is that their focus of interest was entirely limited to the preictal period and that they did not include evaluation of interictal control recordings (i.e., periods from the seizure-free interval other than the presumed preictal period). By thus neglecting the issue of specificity, these studies rendered an incomplete evaluation of the investigated measures' suitability for seizure prediction.

Proof-of-principle studies

Another group of studies tackled the issue of specificity by comparing preictal changes in dynamics to interictal control recordings, although the findings reported in these studies remained on an exemplary level. Navarro *et al.*[36] used selected examples of five of their patients to show that drops in their similarity measure occurred more frequently before seizures than during the interictal EEG. In 2000, Mormann *et al.*[25] reported changes in synchronization between different brain areas before seizures that were not found in exemplary seizure-free recordings. In two reviews of their own work, Le Van Quyen and co-workers[31,32] referred to a submitted study including eight patients with neocortical epilepsy that seemed to confirm these findings. In 2003, Chávez *et al.*[42] published exemplary results using phase synchronization analysis after band-pass filtering of the EEG and reported preictal changes in synchronization to occur predominantly in the beta band.

Controlled studies on predictability

In the first *controlled studies* comprising defined groups of patients with preictal *and* interictal control recordings, measures like the correlation dimension,[20,21] dynamical entrainment[29] (defined by the authors as the convergence of largest Lyapunov exponents in certain selected channels), accumulated signal energy,[30,52] simulated neuronal cell models,[37] or phase synchronization[38,39] were shown to be suitable to distinguish interictal from preictal data. These studies were followed by a number of studies (mostly carried out on more extensive data bases) that found a substantially poorer predictive performance than presumable from earlier reports for the correlation dimension,[47] the similarity index,[46] and accumulated energy.[51] Whether these measures performed at all better than random could not be answered by these studies since the statistical validation scheme applied did not include corrections for testing of multiple channels and seizures

[a] Selected out of a group of 10 patients.
[b] Results listed are those obtained for out-of-sample testing data after in-sample optimization on training data.
[c] Only from five selected patients.
[d] Algorithm designed to run prospectively, but results are reported for training and testing data together.
[e] Various predefined prediction horizons were analyzed.
[f] Uncorrected false-positive rate including preictal periods.
[g] Separate results reported for two different patients.
[h] Separate results reported for two different measures.
[i] Inconclusive validation: surrogate seizure times are not treated in the same way as original seizure times.

(cf. Schelter *et al.*).[75] Around this time a controversy evolved regarding both the reproducibility of earlier studies[40] and the problems and pitfalls associated with nonlinear measures used to characterize EEG time series.[76–78]

Continuous multiday recordings

Around the turn of the millennium when mass storage capacity became more widely available, epilepsy centers were able to store the complete data acquired during presurgical monitoring without the necessity to select sample recordings. In 2005 a series of studies from different groups was published that were carried out on a set of five continuous multiday recordings provided by different epilepsy centers for the First International Collaborative Workshop on Seizure Prediction[79] held in Bonn in April 2002. The aim of this workshop was to have different groups test and compare their methods on a joint data set. Results from the different groups for the most part showed a poor performance of univariate measures.[53–55,58,60] A better performance was reported for bivariate measures.[56,59,60] One of these studies found a discriminative power for interictal and preictal amplitude distributions for certain measures of synchronization that was shown to be significant using a rigorous statistical validation, while many univariate measures, including the correlation dimension, the Lyapunov exponent, and the signal energy, were not able to discriminate the preictal from the interictal period above chance level.[60]

Prospective studies

The first attempts to test seizure prediction algorithms in a prospective manner were carried out by Iasemidis *et al.*[45] and D'Alessandro *et al.*[53] The sensivity and specificity rates obtained were unacceptable for clinical implementation. Whether the performance of the algorithms was at all better than random was not investigated. A recent study by Chaovalitwongse *et al.*[63] attempted such a validation based on a method proposed 2 years earlier,[80] but the authors did not apply the exact same analysis procedure to the seizure times surrogates as to the original onset times so the results must be regarded as inconclusive.

Summary

During the 1990s, a number of studies raised a high optimism about seizure prediction becoming feasible for clinical application in the near future. The focus of these studies, however, was limited to analyzing short and selected data segments, and numerous methodological caveats were disregarded. In the past 5 years many studies were published that questioned both the validity and reliability of these findings by showing that earlier optimistic results could not be reproduced.

For the field of seizure prediction to advance towards clinical applications, it is inevitable that future studies on seizure prediction place a strong emphasis on sound methodology and include a rigorous statistical validation. In the next two sections of this chapter we will therefore address some of the methodological issues and caveats involved in the designing and testing of seizure prediction algorithms before pointing at possible future developments.

Conceptual issues

This section addresses issues that need to be resolved prior to designing a study on seizure prediction.

Prediction, forecasting, or anticipation?

In the strict sense of the words, prediction or forecasting of an event means the ability to determine in advance the time of its occurrence with a certain precision. The term anticipation on the other hand implies an uncertainty as to when exactly an event will occur. This latter concept better fits the design of seizure prediction algorithms which usually assume a seizure to occur within a certain time period after an alarm is issued without knowing its exact onset time. Throughout the literature, however, the three different terms are for the most part used interchangeably.

The type of EEG: intracranial or surface recordings?

While the majority of seizure prediction studies to date have been carried out on intracranial recordings, some studies have also used surface recordings (cf. Table 78.1). Intracranial recordings bear the advantage of a higher signal-to-noise ratio and a better spatial resolution, and the data can be considered mostly artifact free. They also bear the potential advantage of allowing to record directly from the seizure-generating region. Surface recordings on the other hand are less invasive and could in principle be used in an ambulatory setting to monitor a patient's seizure situation in his/her usual environment. This would, however, require a high compliance on part of a patient due to the impairment of constantly wearing an EEG cap.

Furthermore, if seizure anticipation algorithms proved to be successful, they would most likely be implemented in an implantable, closed-loop warning or intervention system. The feasibility of such systems has already been proven by intracranial brain stimulation devices that are currently being tested in clinical trials for their ability to reduce seizure frequency. The usefulness of scalp EEG recordings for studies on seizure anticipation can therefore be regarded as rather limited compared to intracranial recordings.

The events to be predicted: clinical or electrographical seizures?

Another important issue is the selection of the ictal events that should be predicted by an algorithm.[79] While the benchmark for clinical application would clearly be the forecasting of clinical seizure events, subclinical seizures today are mostly regarded not as a different entity, but as a milder variant of the same dynamical event that constitutes a clinical seizure. It is therefore arguable whether it is reasonable to exclude subclinical ictal events in a prediction algorithm. Nevertheless, most studies so far have restricted themselves to the analysis of clinical seizures.

Similarly, the onset time of a seizure can be determined either from the first clinical signs or from the first visible EEG changes. Since there is often some uncertainty in the assessment of clinical symptoms, particularly in complex partial and absence seizures, it is reasonable to determine the seizure

onset electrographically, especially if intracranial recordings from the seizure onset zone are available.

Algorithms that aim at an early detection of the electrographical seizure onset, which may occur several seconds before the first clinical symptoms should not be regarded as seizure prediction algorithms, but rather as early seizure detection algorithms (e.g., Osorio *et al.*).[81]

Data requirements and data completeness

While it is on the one hand desirable to use data sets for analysis that contain a large number of seizures, it is also desirable to have a sufficient time interval between consecutive seizures, so they can be regarded as independent events. If seizures are too closely spaced (clustered seizures) it becomes difficult to separate the postictal period from a presumed preictal state (cf. Jouny *et al.*)[58] as the exact duration of either of the two is unknown.

Note in this context that the average seizure frequency in a monitoring unit of up to three events per day[82] is about 30 times higher than a typical seizure frequency of three per month under normal circumstances.[83] If a false prediction rate obtained in the epilepsy monitoring unit corresponded to a situation where every other alarm is a false alarm (positive predictive value of 50%), then the same false prediction rate under normal circumstances would result in only one out of 60 alarms being a correct warning (positive predictive value of 1.7%) (cf. Winterhalder *et al.*).[46]

EEG recordings used for studies on seizure prediction should ideally comprise EEG data recorded continuously over several days. Recording gaps due to diagnostic procedures during the presurgical work-up (e.g., structural MRI to verify electrode placement) are usually unavoidable and are not considered a major drawback. Since during the presurgical monitoring, patients are constantly undergoing changes that could have a confounding influence on characterizing measures of the EEG (e.g., tapering of medication), it is advisable to use all interictal control data available since a restriction to, e.g., the first 24 h of EEG could introduce a confounding bias.

Assessing the performance of a prediction algorithm

In this section we will discuss some of the problems and pitfalls involved in the evaluation of an algorithm for seizure prediction.

Moving window analysis

In order to judge the relative merit of the different studies on seizure prediction published to date, it is necessary to realize how the performance of a seizure prediction technique is assessed. Most of the prediction techniques published up to now have certain common features: They use a moving window analysis in which some (linear or nonlinear) characterizing measure is calculated from a window of EEG data with a predefined length, then the subsequent window of EEG is analyzed, etc. The duration of these analysis windows usually ranges between 10 and 40 sec. Depending on whether the employed measure is used to characterize a single EEG channel or relations between two or more channels, it is referred to as a univariate, bivariate or multivariate measure, respectively. The moving window analysis thus renders *time profiles* of a characterizing measure for different channels or channel combinations.

Statistical vs. algorithmic approaches

The study design used to evaluate these time profiles in a next step can be either statistical or algorithmic (cf. Table 78.1). A *statistical* design is retrospective by nature and usually compares the amplitude distributions of the characterizing measures from the interictal with those from the *assumed preictal period* in one way or another. The temporal structure of the time profiles is usually not preserved in this type of analysis. Such a design can be useful to investigate and compare the potential predictive performance of different characterizing measures under different conditions.

An *algorithmic* analysis on the other hand uses a design that produces a time-resolved output, i.e., an output for every point of a time profile. With respect to practical application, the algorithm should ideally be prospective, i.e., its output at a given time should be a function of the information available at this time. Prediction algorithms usually employ certain thresholds. If the time profile of a characterizing measure crosses the threshold, the algorithm produces an alarm. This alarm can be either true or false, depending on whether it is actually followed by a seizure or not. For this distinction, it is necessary to define a *prediction horizon*, i.e., the period after an alarm within which a seizure is expected. If an alarm is followed by a seizure within the prediction horizon, it is classified as a true alarm (true positive), otherwise it is regarded as a false alarm (false positive). In addition, it may be useful to require a minimum time interval between an alarm and a seizure occurrence in order to count this alarm as a successful prediction if the algorithm is to be used for seizure prevention. This *minimum intervention time* can be introduced as an additional constraint. (Note that in the literature, sometimes different definitions are used for these quantities, e.g., one group has used the term 'seizure occurrence period' instead of prediction horizon and 'seizure prediction horizon' instead of minimum intervention time.)[46,47,51] In studies that employ a statistical instead of an algorithmic design, the prediction horizon corresponds to the assumed preictal period.

Sensitivity and specificity

If a seizure is not preceded by an alarm within the prediction horizon, this will be counted as a false negative. A less trivial question is how to quantify true negatives. In principle, every single window of the moving window analysis that is outside the duration of the assumed preictal period (i.e., one prediction horizon prior to a seizure) and does not produce an alarm could be counted as a true negative. However, since *sensitivity* is usually quantified as the number of seizures with at least one alarm within the preceding prediction horizon divided by the total number of seizures, it is reasonable to define *specificity* based on the prediction horizon, too. If, for instance, the prediction horizon is 3 h, the sensitivity quantifies the fraction of correctly classified preictal 3-h segments, while the

specificity measures the fraction of correctly classified (consecutive) interictal 3-h segments.

In order to avoid any ambiguity in statistically quantifying the specificity of a prediction algorithm, most studies have instead reported specificity rates measured as false predictions per hour. Unfortunately, also for false prediction rates, different definitions are found in the literature. Several groups have determined false prediction rates by counting all false positives and dividing this number by the total duration of the analyzed recording.[41,45,54,56,63] This definition ignores that for each seizure contained in the recording, there is a preictal period (i.e., the prediction horizon) during which every alarm is counted as a true prediction, and false predictions cannot occur by definition. Other groups have therefore used corrected false prediction rates that were calculated only for the interictal period.[38,39,46,47,51]

In this context it is important to realize that a reported false prediction rate cannot be judged independent from the prediction horizon since in a prospective prediction algorithm a false alarm will leave the patient mistakably awaiting a seizure for the duration of the prediction horizon. It is only after this duration that the patient will know if the alarm was a false warning or not.

Consider as an example[56] an algorithm with a 2-h prediction horizon that yields a sensitivity of 9/11 = 82% of predicted seizures and an uncorrected false prediction rate of 6/41h = 0.15/h. If we take into account that the uncorrected false prediction rate includes the preictal periods during which no false prediction can occur by definition, the corrected false prediction rate (assuming the preictal periods are nonoverlapping) is 6/19h = 0.32/h, thus more than twice as high. If we consider furthermore that after each false prediction, the patient needs to wait for 2 h before knowing if it was indeed a false prediction, the performance of our example (assuming that false predictions are not spaced closer than the prediction horizon) may leave a patient $6 \times 2/19 = 63\%$ of the interictal period waiting for a seizure that will not occur while still failing to anticipate every fifth seizure. An algorithm yielding the same results for a prediction horizon of 10 min would instead leave the patient in futile expectation of a seizure only in 3% of his/her seizure-free time. This example shows that a prediction rate should be judged in view of the prediction horizon used by the algorithm and that it is the product of these two quantities that should be compared across studies.

A better way to assess the specificity of a prediction algorithm would be to report the portion of time from the interictal period (i.e., the interseizure-interval without the preictal period) during which a patient is not in a state of falsely awaiting a seizure.

In general any algorithm can be tuned (e.g. by varying the alarm threshold) to yield a higher sensitivity at the cost of a lower specificity and vice versa. For a closed-loop intervention system, the desired relation between these two quantities will depend on the invasiveness of the intervention technique under consideration. If the intervention does not impair the patient, a higher false prediction rate will be tolerated up to the point where a constant intervention (such as a duty-cycle stimulation from implantable deep brain stimulation devices, cf. Vonck *et al.*)[84] is possible that could be performed without a prediction algorithm.

The problem of in-sample optimization

Another important issue in the evaluation of a prediction algorithm is the use of *a posteriori* information. For a prospective prediction algorithm, this type of information is not available. Two typical cases of using *a posteriori* information are found in the literature: (1) in-sample optimization of parameters of the algorithm and (2) *a posteriori* selection of one or more channels with optimum performance.

In-sample optimization or training of parameters is present whenever parameters used for the calculation of the characterizing measure of the EEG or of the prediction algorithm itself are adjusted to produce optimal performance of the algorithm for a given set of data. Such an optimization is likely to result in an overestimated performance that will not be reproducible when applying the algorithm to other, out-of-sample testing data that was not used in the optimization process. In order to assess the true performance of a prediction algorithm, it is therefore inevitable to test it on out-of-sample data.

Another way of using *a posteriori* information relates to the selection of channels that are able to discriminate an interictal from a preictal state. The great majority of studies have shown that out of the available number of recording channels, only a limited number carry information that can actually be used for the detection of a preseizure state, while the remaining channels are likely to increase the number of false detections without contributing to the detection sensitivity of an algorithm. The task at hand is to decide in advance which channels are best suited for the purpose. While many early studies reported preictal changes in channels within or close to the seizure onset zone,[20–24] more recent ones found channels in more remote, in some cases even contralateral, areas to carry the relevant information.[44,63,64,59,60]

Several studies have attempted to tackle this problem by using the first few seizures to select the appropriate channels and/or parameters for the algorithm before trying to detect precursors of the seizures that follow.[44,53,54,59] Such a procedure implies that the spatio-temporal dynamics preceding a seizure do not change from seizure to seizure. Iasemidis *et al.*[45,56] designed an algorithm using a selection of channels that is readjusted after every seizure such that it would have been optimal for the seizure that has just occurred. Such a procedure is based on the implicit assumption that preictal dynamics change to a certain degree from seizure to seizure, but that the preictal dynamics of a seizure still depend on the dynamics of the previous one. If these algorithms reliably proved to be better than a random prediction, they could, in addition to being beneficial for patients, provide valuable clues for new theories on the mechanisms involved in ictogenesis.

The need for statistical validation

If an algorithm is designed to run prospectively, its quasi-prospective out-of-sample performance can be tested retrospectively on continuous long-term recordings that were not previously used for parameter optimization or channel selection. Once this quasi-prospective performance (in terms of correct alarms and false alarms with respect to the given prediction horizon) has been assessed, it remains to be tested whether it is indeed superior to that of an algorithm working with random prediction. For this aim, Winterhalder and

collegues have designed a framework to assess the performance of such a random predictor.[46,75]

In retrospective statistical studies on predictability, however, it may be desirable to investigate and compare the potential predictive performance of different characterizing measures for various thresholds and parameters. In this case the use of a random predictor for statistical validation would require Bonferroni corrections for multiple testing that can be difficult to perform. Here the concept of seizure time surrogates as introduced by Andrzejak *et al.*[80] can provide a means for statistical validation. In this process, artificial seizure onset times are generated by randomly shuffling the original inter seizure-intervals. Using these surrogate seizure onset times instead of the original onset times, the EEG data is then subjected to the same algorithm or prediction statistics that was used for the original onset times. Only if the performance of the algorithm for the original seizure times is better than the performance for a number of independent realizations of the surrogate seizure times, can the null hypothesis, namely, that a given algorithm cannot detect a preseizure state with a performance above chance level, be rejected. The advantage of this type of statistical validation is that it can be applied to any type of analysis, algorithmic or statistical. A modification of this surrogate test has recently been proposed based on a constrained randomization of the time profile of the characterizing measure.[85]

Future perspectives

Prospective out-of-sample algorithms with statistical validation

The next problem that needs to be tackled by seizure anticipation algorithms is to design algorithms to run (quasi-) prospectively on unknown, out-of-sample data. If the algorithms require a training phase in which some seizures are used to adjust patient-individual parameters and perform a feature or channel selection, the requirements on the individual data sets increase since a larger number of seizures per individual data set will be needed. Performance results should be reported only for the testing data.

Before addressing the question whether an obtained performance might be sufficient for clinical application, it needs to be tested whether a performance is at all better than chance. To this aim, methods for statistical validation are inevitable. These methods can be based either on bootstrapping techniques[38,57,60,80,85] or on the performance of a random prediction process[46,75] derived analytically.

Mechanisms of ictogenesis

While many studies on seizure prediction placed their emphasis on algorithmic prediction, their primary focus of interest was not directed towards the underlying mechanisms of seizure generation. A number of recent studies have attempted to increase our understanding of the dynamics of ictogenesis. Both in temporal lobe and neocortical epilepsies, high frequency oscillations were found to play a role in the initiation of epileptiform potentials and seizures.[86–88] In another recent study on patients with temporal lobe epilepsy, the so-called phase demodulation of intracranial EEG recorded interictally during intermittent electrical stimulation was found to yield important clues for possible dynamical scenarios that lead to seizure onsets.[61] Schiff and coworkers[89] successfully used canonical discrimination analysis to search for dynamically distinct stages of epileptic seizures in humans. A further promising approach is to model EEG signals to gain a better understanding of the mechanisms of ictogenesis.[90,91] For an excellent and detailed review on recent findings in quantitative EEG analysis, refer to Stam.[92]

Given the rather poor performance of the seizure prediction algorithms designed to date, it is likely that a better understanding of the mechanisms involved in seizure generation may stimulate the design of improved methods and algorithms.

Confounding variables

Another key to the improvement of algorithms could be a better understanding of the interictal period and all of its confounding variables that may influence the characterizing measures used in the algorithms and may thereby decrease the algorithm's sensitivity or specificity. Studies on continuous multiday recordings have identified distinct circadian fluctuations of synchronization measures.[85] Particularly different vigilance state, e.g., slow-wave sleep, seem to have a substantial influence on these measures. A further confounding influence on characterizing measures has been described for the blood levels of carbamazepine.[93] Little is known to date about the influence of different cognitive or emotional states.[94] Once the influence of these confounding variables is better understood, it can be taken into account by an algorithm to increase its predictive performance.

Conclusions

The more rigorous methodological design in many recent seizure prediction studies has shown that many of the measures previously considered suitable for prediction perform no better than a random guess.[55,60] On the other hand, evidence has accumulated that certain measures, particularly measures quantifying relations between recording sites as a correlate of interaction between different brain regions, yield a promising performance[56,59,60] that ranges above chance level, as evidenced by rigorous statistical validation.[60]

The few studies that have used prediction algorithms in a quasi-prospective manner (i.e., without the use of *a posteriori* information) either did not include a statistical validation[45,53,56] or did not apply it correctly.[63]

The design and evaluation of prospective seizure prediction algorithms involves numerous caveats that need to be regarded. The current literature allows no definite conclusion as to whether seizures are predictable by prospective algorithms. To answer this question, future studies need to rely on sound and strict methodology and include a rigorous statistical validation.

The next necessary step in the field of seizure prediction will be to test on long-term recordings whether the prediction algorithms devised to date are able to perform better than a random predictor in a quasi-prospective setting on out-of-sample data. This step is an indispensable prerequisite to justify prospective clinical trials involving invasive seizure intervention techniques based on prediction algorithms such as electrical brain stimulation in patients.

79 Effect of anticonvulsant withdrawal on seizure semiology and ictal electroencephalography

CT Skidmore and MR Sperling

Introduction

Prior to performing epilepsy surgery, an intensive evaluation process is conducted to define the boundaries of the epileptogenic region. Characterizing seizure semiology and the EEG pattern of habitual seizures is a key component of this process. This is typically accomplished through monitoring in a video-EEG unit. It is important to ensure that all relevant seizure types are captured to ensure an accurate diagnosis. Moreover, it is important to make certain that the observed seizures have been accurately assessed, and that the observed EEG and behavioral characteristics are reliable. While the optimal number of seizures that should be recorded is uncertain, many strive to capture at least three typical seizures during hospital admission. This figure, however, depends upon the quality of the EEG recordings, results of other diagnostic testing, number of clinical seizure types, and other factors. While video-EEG monitoring can be accomplished during a brief hospital stay in many patients, those who have less frequent seizures (less then weekly) would require prolonged hospital stays. Since prolonged hospitalization can be emotionally taxing and injurious to patient finances, it is desirable to attempt to minimize hospital length of stay. In addition, there are external pressures from insurance companies for efficient monitoring stays, and the number of available video-EEG monitoring beds is limited. Therefore, any method that can shorten the length of stay can benefit patients, reduce the cost of presurgical investigations, and improve health care access.

For these reasons, various techniques have been utilized in an attempt to temporarily increase seizure frequency, thereby shortening the hospital stay. The most common provocation maneuver is antiepileptic drug (AED) withdrawal. This is generally a safe and effective means for provoking seizures. This chapter will review the data regarding its effect on seizure semiology and ictal EEG.

Effect of AED withdrawal on seizure frequency

Before assessing the effect of AED withdrawal on seizure semiology and ictal EEG, one must determine whether withdrawal truly provokes seizures. Marks *et al.*[1] found a significant increase in seizure frequency when AED levels were subtherapeutic or absent in a study of 35 patients. Marciani *et al.*[2] reported the effects of AED withdrawal on seizure frequency in patients who were monitored on and off AEDs. In 12 of 17 patients who had no seizures on AED therapy, seizures were provoked by AED withdrawal, and in 16 of 23 patients who had baseline seizures there was a clear increase in seizure frequency. So and Gotman[3] reported the seizure rate in three controls and in eight patients whose AEDs were withdrawn. They found a clear increase in seizure frequency during AED withdrawal in comparison with controls, whose seizures occurred less frequently. Several studies demonstrate that carbamazepine (CBZ) withdrawal increases both seizure frequency and the rate of occurrence of secondarily generalized seizures.[4–9] Bromfield *et al.*[10] demonstrated an increase in seizure frequency during phenytoin (PHT) withdrawal, Zhou *et al.*[7] noted no change in seizure frequency during valproate (VPA) withdrawal, and Wang-Tilz *et al.*[11] found an increased seizure frequency during lamotrigine (LTG) withdrawal. Based on these studies and many other reports in the literature, it seems apparent that AED withdrawal increases seizure frequency.

Effect of AED withdrawal on seizure semiology and ictal EEG

Spencer *et al.*[12] reported results in 25 patients who had intracranial EEG monitoring. They compared seizure semiology and ictal EEG before and after the withdrawal of AEDs. They identified four patients who had atypical semiology or ictal EEG onsets during the withdrawal phase; however these patients were already determined to have multifocal or bilateral epileptogenic zones during the baseline phase. One patient had atypical semiology and multifocal onsets, which was different from the baseline phase, however this patient failed surgery after excision of the region from which typical seizures emanated. He was found later to have seizures emanating from the contralateral hemisphere. They concluded that AED withdrawal successfully provoked typical seizures in the majority of patients, and that atypical seizures may suggest a latent multifocal predisposition that may not be surgically remediable. However, after this report Engel and Crandall[13] reported a single patient who had an intracranial bitemporal

implant for seizure localization who had typical seizures emanating from the right temporal lobe and atypical seizures arising from the left temporal lobe. Based on the scalp evaluation and intracranial data he underwent a right temporal lobectomy and was seizure free for 4 years at the time of the report. They cautioned that atypical seizure semiology and ictal EEG data may be secondary to distant hyperirritability secondary to the primary epileptogenic focus or possible direct irritation from the implantation of the depth electrode. In addition to this patient they also commented on four additional patients who had atypical ictal EEG who 'benefited from surgery' and while atypical data is a poor prognostic sign, it should not be an absolute contraindication. Marciani and Gotman[14] reported data from 14 patients who had typical seizures recorded with intracranial EEG while taking stable doses of medication and during drug AED withdrawal. Only one patient had a clinical seizure with altered semiology and ictal EEG onset compared to their baseline seizures. However, this seizure occurred after an insignificant change in a single AED dose and the patient then had several typical seizures during aggressive drug withdrawal. In the remaining patients, seizure semiology and ictal onset in the EEG were not affected by AED withdrawal, even during seizure clusters and secondary generalization. Marks *et al.*[1] reported that five out of 35 patients had atypical clinical seizures during drug withdrawal. Two of these patients were thought to have multifocal disease, and the other 3 had atypical seizures both during the baseline and withdrawal phase, so AED withdrawal was probably not responsible for changes in ictal EEG findings. Seventeen of their patients had intracranial ictal data recorded while taking AEDs and during AED withdrawal. One patient who had a right temporal lesion had a diffuse ictal onset with the first seizure during drug withdrawal, but four other seizures recorded after this had focal onset. One patient missed several doses of clonazepam, apparently by mistake, which resulted in simultaneous neocortical and hippocampal onset. However, once the clonazepam was restarted all the remaining seizures had focal onset in the hippocampus. Bardy[15] reported no change in seizure semiology in 11 patients undergoing AED withdrawal for video-EEG monitoring, and So and Gotman[3] reported that while eight patients with intracranial EEG had more frequent and severe seizures during AED withdrawal, a variety of measures including latency of interhemispheric spread, seizure duration for a given seizure type (i.e., complex partial seizure), and localization were not affected.

Based on these studies, it appears that the overwhelming majority of seizures occurring during AED withdrawal display typical semiology and ictal EEG. However, as noted by Engel and Crandall,[13] the existence of atypical seizures should not necessarily prevent surgery from being carried out. Atypical seizures may signal the presence of a latent epileptogenic focus, but they may either be dependent upon the primary focus or be amenable to AED therapy should it persist after surgery.

Effect of specific AEDs on seizure semiology and the ictal EEG

Most published data address the effect of withdrawal of older AEDs on seizure semiology and the ictal EEG. They do not address how withdrawal of most newer AEDs influence these features. With these constraints in mind, we will attempt to review the information available for each individual AED.

Carbamazepine

Duncan *et al.*[9] and DeToledo *et al.*[6] reported no new seizure types provoked by withdrawal of CBZ. These studies were limited though since they were based on clinical follow-up and not video-EEG monitoring. Zhou *et al.*[7] studied 20 patients taking CBZ and undergoing video-EEG monitoring. They analyzed the presence of hypermotor features, oroalimentary automatisms, hand automatisms, ictal speech, and secondary generalized tonic and/or clonic signs before and after the withdrawal of CBZ, and noted an increased frequency, duration, and intensity of most ictal signs with CBZ withdrawal. However, the scalp ictal onset and initial seizure semiology was not altered by CBZ withdrawal. Spencer *et al.*[12] evaluated eight patients with intracranial EEG before and after the withdrawal of CBZ. Three of these patients were determined to have multifocal or bilateral EEG onset in the baseline and CBZ withdrawal phases. None of the patients with unilateral focal onset had atypical clinical semiology or EEG onset. However two of the patients with multifocal disease had atypical EEG onset captured during drug withdrawal.

Valproate

Duncan *et al.*[9] reported no new seizure types in 25 patients undergoing VPA withdrawal. However, this was an outpatient study without video-EEG correlation. Zhou *et al.*[7] evaluated 13 patients taking VPA with video-EEG monitoring. They found no effect on seizure frequency or seizure intensity, but seizure duration was increased. They did report that the amounts of hypermotor components of the seizures were increased, but initial ictal signs and EEG onset were unchanged.

Phenytoin

Duncan *et al.*[9] reported no new seizure types in 22 patients withdrawn from phenytoin (PHT) as outpatients. Spencer *et al.*[12] reported two patients who were studied with intracranial EEG before and after PHT withdrawal. One patient had multifocal EEG onset and the other had bilateral EEG onset during baseline and withdrawal phases. Although new seizure types were not captured during the withdrawal phase, the patients did not have unilateral focal disease, and it is difficult to assess the effect of PHT withdrawal on ictal EEG and semiology.

Phenobarbital/primidone

Spencer *et al.*[12] evaluated four patients on phenobarbital (PB) and one patient on primidone (PMD) with intracranial EEG before and after AED withdrawal. One patient on PB had focal ictal EEG onset and clinically typical seizures before and after withdrawal of PB. A second patient had a typical clinical seizure with EEG onset in the right temporal lobe in the baseline phase, but had atypical clinical and electrographic

seizures during PB withdrawal. This patient was later found to have seizures emanating from the left hemisphere, as described previously. The other two patients had multifocal or bilateral disease and both had atypical seizures on EEG compared to the baseline phase. One of the patients also had atypical clinical seizures during drug withdrawal. Only one patient had seizures during the baseline and withdrawal phases on PMD, and this patient did not have any atypical seizures or ictal EEG onsets.

Lamotrigine

Wang-Tilz *et al.*[11] noted an increased seizure severity and duration with LTG withdrawal, but no definite increased frequency of secondary generalized seizures. The ictal EEG onset and initial seizure semiology was not altered by LTG withdrawal.

Risks associated with AED withdrawal

The concern about quality and character of seizures observed during drug withdrawal is more than matched by a concern about safety. If drug taper provokes more frequent and severe seizures, it may be associated with an increased risk of complication. Several possibilities exist, including secondary generalized tonic-clonic seizures, status epilepticus, neuronal injury, cognitive impairment, and bodily injury.

Status epilepticus perhaps raises the most concern, but its incidence during controlled AED withdrawal in a hospital setting is apparently quite low. In several studies of patients monitored with video-EEG before and after AED withdrawal, there were no reported cases of status epilepticus.[2,7,11,16,17] This could be due to the existence of protocols to treat seizure clusters and prolonged generalized tonic-clonic seizures early in their course, or due to under-reporting of status epilepticus. There are numerous reports of an increased incidence of seizure clusters during AED withdrawal, and some of these might fulfill criteria for status epilepticus. The incidence of clusters varies from study to study as do the definitions of a seizure cluster. Marks *et al.*[1] defined seizure clusters as >3 seizures within a 48-hour period. They reported seizures clusters in four patients on stable AED therapy and in 18 patients during AED withdrawal of 35 patients. Yen *et al.*[16] defined seizure clusters as >3 per 24-hour period, and reported that approximately 50% of their patients (n=102) experienced at least one seizure cluster during video-EEG monitoring with aggressive AED withdrawal. In our experience, status epilepticus can occur during drug taper, and the incidence ranges between half and one percent. We have observed tonic-clonic, tonic, complex partial, and absence status during drug withdrawal. In part, distinguishing between a seizure cluster and status epilepticus can be difficult, but when a series of seizures occur without full return of neurological function between the seizures,[18] it is reasonable to diagnose status epilepticus. Hence, it is our belief that some patients who have been reported as having had seizure clusters probably had brief bouts of status epilepticus.

Secondarily generalized seizures may either occur de novo or increase in frequency during drug withdrawal. These have the potential of causing morbidity such as lacerations and other trauma, bone fractures, aspiration, and cognitive impairment. It is particularly concerning when patients with no prior history of secondarily generalized seizures or who have only rare secondarily generalized seizures have them during the evaluation. Most studies report an increase in the frequency of secondary generalized seizures during AED withdrawal.[2,7,11,16] This appears to be especially true for CBZ withdrawal,[2,4,7,8,11] but is also reported for phenytoin.[2,4,10] The occurrence of new secondarily generalized seizures or the re-emergence of secondary generalized seizures in patients who had them rarely occurred in 9% of patients studied by Yen *et al.*[16] and in 3/20 patients studies by Wang-Tilz *et al.*[11] There is no data documenting that lamotrigine, valproate, or primidone withdrawal increase the frequency of secondarily generalized seizures,[2,7,11] but it seems intuitive that it must happen at times; indeed, we have occasionally seen this phenomenon with these drugs at our institution. In contrast, Swick *et al.*[17] found no correlation between AED withdrawal and the occurrence of secondary generalized seizures, and found that the only predictor of their occurrence was a prior history of secondary generalized seizures. However, this does not comport with the rest of the literature, nor our experience.

Other complications are infrequent, but have occurred on occasion. We have observed a brachial plexus injury with persistent limb paresis after a de novo secondarily generalized seizure in one patient, several bone fractures, a few shoulder dislocations, bruising, and many severe tongue and cheek bites. In addition, after secondarily generalized seizures or clusters of complex partial seizures, many patients have reported memory defects that have lasted for up to several weeks. On the other hand, patients occasionally experience injury as a consequence of seizures when AED doses have not been altered. Therefore, how much drug taper increases risk cannot be known without a randomized study, which has never been performed and likely never will be done.

Conclusion

AED withdrawal is an effective means of temporarily increasing seizure frequency in epilepsy monitoring units to ensure that an adequate number of seizures are recorded for diagnostic purposes. Drug withdrawal generally seems to lead to seizures that can be confidently analyzed as part of the presurgical evaluation process. Concerns that drug taper may provoke atypical seizures appear largely unjustified, and most data suggest that this phenomenon, if it occurs, is rare. Data regarding the effects of drug withdrawal is needed for many AEDs that came into use in the 1990s and afterward, but our clinical experience suggest that there is probably no difference compared with older drugs. The major disadvantage appears to be the provocation of seizure clusters and secondarily generalized seizures, which pose risk to the patient. Risk can be averted or reduced when epilepsy monitoring units employ clinical protocols for aggressive medical treatment when an unusual number of seizures or unusually severe seizure occurs. This may prevent the development of status epilepticus or injury. We advise that treatment be implemented automatically. Physicians should place orders in the hospital chart to initiate therapy once a certain predetermined seizure threshold is

reached in advance of problems developing, so that effective treatment is not delayed. Depending upon the type of seizure and how frequently seizures occur, one of several options can be used. Either one can prescribe a large dose of the oral agent that was being tapered, give an oral dose of a benzodiazepine, or administer an intravenous dose of a benzodiazepine.

80 Zone of electrical stimulation induced seizures in subdural electrodes

R Schulz

Definition of zone of electrical stimulation induced seizures

Electrical stimulation of the cortex can elicit afterdischarges (ADs), subclinical EEG seizure patterns, auras (SIA), and clinical seizures (SIS). Auras and clinical seizures can occur with nonhabitual or habitual symptomatology. Electrical stimulation takes place extraoperatively with implanted electrodes (subdural grid electrodes or depth electrodes), or intraoperatively by the neurosurgeon using stimulation electrodes. The area of responses can be defined as the zone of electrical stimulation induced seizures (ZESIS). The actual ictal onset zone as defined by spontaneous seizures is not always congruent with ZESIS so that ZESIS also includes cortex which is potentially epileptogenic, e.g., after the surgical removal of the actual seizure onset zone or pacemaker zone.

From a historical perspective, SIA and SIS have been important in cortical localization since Fritsch and Hitzig discovered the irritability of the cortex using electrical stimulation in animals.[1] Seizures were induced by electrical stimulation, by mechanical palpation of the brain during surgery, by local or systematic application of drugs, and by peripheral stimulation (e.g., photic stimulation). During the first decades stimulation concentrated on the motor cortex. Cortex outside the central region was mostly disregarded. Fritsch and Hitzig stimulated the motor cortex and elicited epileptic seizures with increased stimulation intensity. They strongly influenced Jackson who focused his studies on the semiology of unilateral motor seizures. Jackson argued that local symptoms like cloni of an arm imply a local lesion of the brain. Jackson also coined the term 'variety of epilepsy' for seizures characterized by 'dreamy states'.[2] Krause used the term 'petit mal' for seizures lasting only a few seconds regardless of the semiology, including auras, tonic seizures, and absences.[3] Cushing assumed that the epileptogenic zone could be identified through auras elicited by electrical stimulation of the cortex when he wrote that in the future it would be possible 'to pick out with an electrode areas of the brain from which the sensory aura of a focal convulsion has originated' and speculated that this methodology would eventually lead toward 'operative localization of subcortical irritative lesions of the immediate postcentral field.' When mentioning subcortical lesions he was referring to lesions which cannot be detected by intraoperative inspection.[4]

Foerster was the first to use extensive stimulation outside the central cortex and reported on somatosensory, auditory, olfactory, gustatory, visual SIA, and prefrontal SIS.[5] Foerster and Penfield reported the provocation of habitual seizures and auras by mechanical irritation and by stimulation with faradic current in a summery of 12 cases.[6] In their stimulation studies, they carefully documented responses from the primary sensory and motor area and the occurrence of SIA and SIS. Furthermore, they outlined the visible epileptogenic lesion and the borders of the resections. In six of 12 cases (50%) the patient's habitual seizure or aura was elicited by electrical stimulation. In two patients the cortical area with SIA or SIS was located within the epileptogenic lesion, in four patients the cortical area with SIA or SIS lay close to the epileptogenic lesion (1 cm or less). In all six patients the cortical area from which a habitual aura or seizure was elicited was resected together with complete removal of the epileptogenic lesion. Apparently Foerster assumed that the area with SIA was part of the epileptogenic zone which had to be resected to achieve seizure freedom.

The initiative to develop epilepsy surgery further was taken by Penfield after the foundation of the Montreal Neurological Institute in 1934. In a study relating the Montreal experience, intraoperative stimulation reproduced habitual auras in 44 out of 80 patients (55%) with nontumoral parietal lobe epilepsy, in ten out of 25 patients (40%) with tumoral parietal lobe epilepsy[7], and in 37% of 29 patients with occipital lobe epilepsy.[8] Some of the patients with SIA are illustrated in detail in Penfield and Jasper's compendium 'Epilepsy and the functional anatomy of the human brain'.[9]

Penfield and Jasper[9] considered SIA to be an important criterion for delineating the limits of resection: 'Electrical stimulation is the original method of initiating focal cortical epileptic discharge, and is still one of the best.' They carefully adjusted the stimulus intensity to initiate local discharges in a very restricted area of cortex: 'Areas most susceptible to afterdischarges, especially if associated with the aura or onset of the patient's seizure, indicate a hyperirritable cortex which may be the focus of spontaneous epileptic seizures.' Penfield and Jasper also commented on SIA/SIS after spread from a distant source, suggesting that the SIA/SIS zone rarely leads to false assumptions about an epileptogenic region in silent cortex: 'Volleys of nerve impulses arriving in a hyperirritable area of the cortex from different distant sources may serve to initiate epileptiform discharge in a manner similar to the direct stimulation of a hyperirritable cortex.' In one of their

documented cases, they commented that 'distant stimulation had its effect by means of neuronal conduction along connecting pathways.' But they mostly found a convergence of irritative and SIA/ SIS zone: 'In the majority of cases, however, there is a close correlation between a spike focus and the area of susceptibility to prolonged afterdischarges. … There is also fairly good correspondence between the area of prolonged afterdischarges and the site from which the aura or onset of the attack was reproduced by electrical stimulation.' In most cases the SIA zone was resected.

In summary, Penfield and Jasper already discussed the present opinion of hyperirritable cortex – as documented by SIA/ SIS, afterdischarges, and interictal spikes – which in a minority of cases can also be triggered over a distance via connecting pathways of propagation.

In 1954 Foerster, Penfield, and Jasper had used and had further developed the diagnostic means of the EEG in epilepsy surgery. Since that time brain imaging has considerably changed the diagnosis of the epileptogenic lesion so that preoperative, noninvasive detection is now possible in most cases in contrast to the previous reliance on EEG and, during surgery, inspection, electrocorticography, and assessment of SIA/ SIS.[10,11] On the other hand, depth electrodes and subdural grid electrodes were essential in further contributing to the evolution of EEG and they now permit prolonged extraoperative evaluations with assessment of interictal and ictal EEG, mapping of functional cortex, and systematic registration of SIA, ADs, and SIS.

Defining ZESIS with subdural grid electrodes

The technology and evaluation with subdural grid electrodes (SDE) in general have been outlined in Section 7 of this book. SIA and SIS occur as a by-product of electrical cortical stimulation for functional mapping. The stimulation current is increased in steps of 0.5–2 mA up to the maximum intensity of 15 mA or to the occurrence of functional responses, SIA or SIS. To discern accidental auras or seizures we usually only include SIA/SIS which occur more than once. To avoid eliciting a seizure after the first SIA at a given electrode we usually reduce the following stimulation current by 1 mA and stop the stimulation at this electrode after occurrence of the second SIA. SIA/SIS should occur without afterdischarges to exclude the triggering of remote cortical regions and make localization as precise as possible. On the other hand, the facilitation of pathways to a more distant pacemaker zone for auras and seizures indicates the irritability or epileptogenicity of all neurons involved.

The threshold of afterdischarges (ADs) is low, especially in the primary motor and primary sensory areas (M1, S1),[12] with easy triggering of a nonhabitual seizure semiology.[13] The delineation of ADs and subclinical EEG seizure patterns is often not possible. Indeed, the EEG glossary of the International Federation of Clinical Neurophysiology defines ADs as EEG seizure patterns induced by electrical stimulation.[14] Inoue and co-workers presented the EEG example of right temporal repetitive ADs with decreasing frequency, of 70 s duration, accompanied 30 s later by a contralateral, left temporal EEG seizure pattern and a habitual clinical seizure in a patient with left mesial temporal lobe sclerosis.[15] In this case, the morphology of the EEG pattern with large-amplitude, low-frequency epileptiform discharges (similar to PLEDS), immediately after stimulation suggests ADs; the evolution of the frequency, however, suggests an EEG seizure pattern. The left temporal EEG seizure pattern was identical to the EEG pattern in spontaneous habitual seizures, clearly different to ADs. Obviously, there are gradual shifts in the epileptogenicity from ADs to clear-cut EEG seizure patterns. The threshold of ADs varies from day to day and even from stimulation to stimulation.[16] To minimize ADs, antiepileptic medication is kept at a high level and often benzodiazepines are used.

Afterdischarges, subclinical EEG seizure patterns, SIA, and SIS contribute to ZESIS. To our knowledge, systematic studies about the diagnostic value of ADs and stimulation-induced subclinical EEG seizure patterns in defining the epileptogenic zone do not exist.

In a retrospective and prospective study of 31 patients, we evaluated the value of SIA in defining the extent of the epileptogenic zone.[17] Sixteen of 31 patients (52%) had SIA. The epilepsy syndromes were classified as follows: frontal lobe epilepsy eight, parieto-occipital lobe epilepsy three, temporal-lobe epilepsy three, perirolandic epilepsy one, and nonlocalizable focal epilepsy one. In three patients the habitual first subjective sign of the seizure was not an aura in the strict sense of the term but a sensation of movement of an eye, a sensation of clonic jerks on one side of the mouth, or the inability to speak (aphasic seizure). SIA were elicited at one to 20 electrodes per patient (mean 4.8). SIA occurred on stimulation above the epileptogenic lesion in 75% of the patients (12 out of 16), in three patients 1 cm from the lesion, in one patient 2 cm from the lesion. The zone of SIA overlapped with the EEG seizure onset zone in 75% of the patients (12 out of 16); in three patients the EEG seizure onset zone was 1 cm away, and in the other patient SIA were located on the convexity of the cortex whereas the EEG seizure onset was on the mesial plate adjacent to the opposite limits of the lesion. Overlap of the SIA zone with the irritative zone of interictal spikes was observed in only 50% of the patients (eight out of 16).

Relating surgical outcome to complete or incomplete resection of the epileptogenic lesion, the EEG seizure onset zone, the SIA zone, and the irritative zone of interictal spikes we found a significant correlation of surgical outcome only with the total removal of the epileptogenic lesion. Complete or incomplete resection of the EEG seizure onset zone, the SIA zone or the irritative zone did not permit prediction of the surgical outcome. However, the value of resecting the other zones in addition to the lesion could not be established because the number of patients was too small for statistical analysis with stepwise logistic regression.

De Salles and co-workers reported a small series of 12 patients with invasive diagnosis using subdural strip electrodes. In eight patients cortical stimulation was performed.[18] The authors argued that

> confirmation that with intracranial recordings was important for the final decision of resection, especially for the patient who experienced speech arrest, usual seizures and aura during cortical stimulation. …

Cortical stimulation confirmed the seizure focus by inducing the usual seizures or aura in 75% of the patients undergoing electrical stimulation.

Surgical results were not mentioned in this study.

Defining ZESIS intrasurgically

Although extensive intrasurgical stimulation of the cortex for cortical mapping of eloquent areas was standard procedure in earlier days of epilepsy surgery, it is the exception nowadays and mostly confines itself to a definition of the language areas (Broca, Wernicke) or the primary motor cortex. The registration of SIA requires stimulation while the patient is awake. Anesthesia is demanding for both the patient and physician under these circumstances and as a consequence is applied only when the insertion of subdural grid electrodes is not possible and when functional mapping of language is necessary.

The stimulation parameters are largely identical to extraoperative stimulation. We usually start at a current intensity of about 7 mA and increase in steps of 1–2 mA up to 15 mA. Instead of stimulation tweezers we use subdural strips so that the registration of ADs is also possible. After the occurrence of ADs stimulation is stopped to avoid the risk of SIS of the wakeful patient during surgery. The stimulation protocol has to take place within 1 hour or less, resulting in considerable time pressure so that SIA only rarely occur.

Conclusions

The definition of ZESIS in SDE is usually a by-product of cortical mapping for language areas. The mapping of somatosensory and motor cortex is mostly done by SSEP and MEP during surgery and under considerable time pressure so that SIA/SIS rarely occur. Consequently only small evidence exists about the relative value of ZESIS versus other zones (e.g., lesion zone, irritative zone of interictal spikes or ictal EEG onset zone) with regard to postoperative seizure prognosis. Electrical stimulation is not undertaken merely for the definition of ZESIS because of possible complications of the implantation of SDE. On the other hand, neurologists and neurosurgeons will take the knowledge gained about a ZESIS together with other relevant information into consideration to delineate the borders of resection. A ZESIS in close vicinity to an epileptogenic lesion, with good convergence of the irritative and ictal onset zone, will be resected in most cases. A ZESIS with some distance to the epileptogenic lesion raises the doubt of propagation within a hyperconnective epileptogenic network and will often not be resected.

SECTION 8

The epileptic lesion

81 The epileptogenic lesion: general principles

HM Hamer and S Knake

Concept of the epileptogenic lesion

The most common cause of focal epilepsies is a morphological brain abnormality, the epileptogenic lesion. The concept of the epileptogenic lesion, however, is not without difficulties. Any alteration of the brain that can be identified by the pathologist could be considered an epileptogenic lesion but for the purposes of clinical practice, an epileptogenic lesion usually refers to a cerebral abnormality detected by invivo neuroimaging or by the surgeon. This concept was established with the introduction of CT scans but the development of magnetic resonance imaging (MRI) had the greatest impact on neuroimaging in epilepsy. The most frequent pathologies identified in partial epilepsy are hippocampal sclerosis (HS), vascular malformations, tumors, and malformations of cortical development (MCD). MCD constitute a large group of cortical malformations with distinct histopathological abnormalities revealing variable degrees of epileptogenicity.

Establishing the etiology early in the course of epilepsies helps defining the prognosis and has the advantage to determine the possibility or even necessity of surgical treatment in the future. A potentially epileptogenic lesion detected by neuroimaging is predictive of good surgical outcome in frontal as well as in temporal lobe epilepsies.[1–3] However, imaging of epilepsy patients can be challenging, since epileptogenic lesions frequently are small and difficult to detect. Moreover, their extent may be underestimated by MRI studies which is especially true in patients with MCD.[2,4]

Relationship between epileptogenic lesion and epileptogenic zone

The presence of a structural lesion on imaging of epileptic patients usually implies that the epileptogenic zone comprises the lesion or lies in its immediate vicinity. However, the relationship between a lesion seen on imaging studies and the epileptogenic zone may be complex. Cortex extending far beyond the epileptogenic lesions seen on MRI studies, such as MCD or post-traumatic gliotic lesions, may appear normal on imaging but abnormal at a microscopic level and may be part of the epileptogenic zone. In noninfiltrating lesions, such as vascular malformations, the epileptogenic zone includes frequently the adjacent cortex. In cavernous hemangiomas, the main underlying mechanism for seizure generation is most probably pathologic changes in the surrounding tissue due to hemosiderin deposits. On the other hand, postencephalitic lesions demonstrated by MRI were often widespread and even discordant to the seizure onset zone.[5,6] This supports the observation that even incomplete removal of an assumingly epileptogenic lesion rendered a minority of patients seizure free.[7]

Not every lesion detected on structural imaging necessarily represents the epileptogenic lesion (Figure 81.1) and there is no definite way to predict by structural imaging to which extent the lesion identified on MRI overlaps with the epileptogenic cortex. Therefore, detailed video-EEG monitoring is required to establish the relationship between the structural lesion seen on imaging studies and the irritative and seizure onset zone. In selected cases, invasive recordings are necessary to achieve this goal. As a rule, the lesion can be considered epileptogenic, when irritative and seizure onset zone are overlapping with the lesion or are in the immediate neighborhood.

If cortical areas which harbour the seizure onset zone but extend beyond the lesion are included in the resection, a better postoperative outcome was found as compared to simple lesionectomy.[8] This confirms studies which showed that pure lesionectomy is associated with poorer outcome than 'epilepsy surgery' in a variety of etiologies.[9] However, there are no convincing data to assume that the pathophysiology of epilepsy is the same for all different epileptogenic lesions nor is there reason to expect the postoperative prognosis to be the same.

Magnetic resonance imaging (MRI)

MRI is clearly the most important imaging modality to detect structural cerebral abnormalities. Imaging strategy, quality and image interpretation have a major impact on the likelihood of detecting a lesion. Prior clinical and test information can assist in defining the possible location of the epileptogenic zone and should guide the MRI examination. Patients in whom a focal neocortical epilepsy is suspected should be imaged with a protocol that includes whole head thin-sectioned high-resolution 3D T1-weighted and T2-weighted images and should also comprise a gradient echo T2 sequence. If mesial temporal epilepsy is suspected, the protocol should include high-resolution images scanned perpendicularly to the axis of the hippocampus to detect primary and secondary signs of hippocampal sclerosis. T1-weighted, T2-weighted and FLAIR sequences are usually employed.

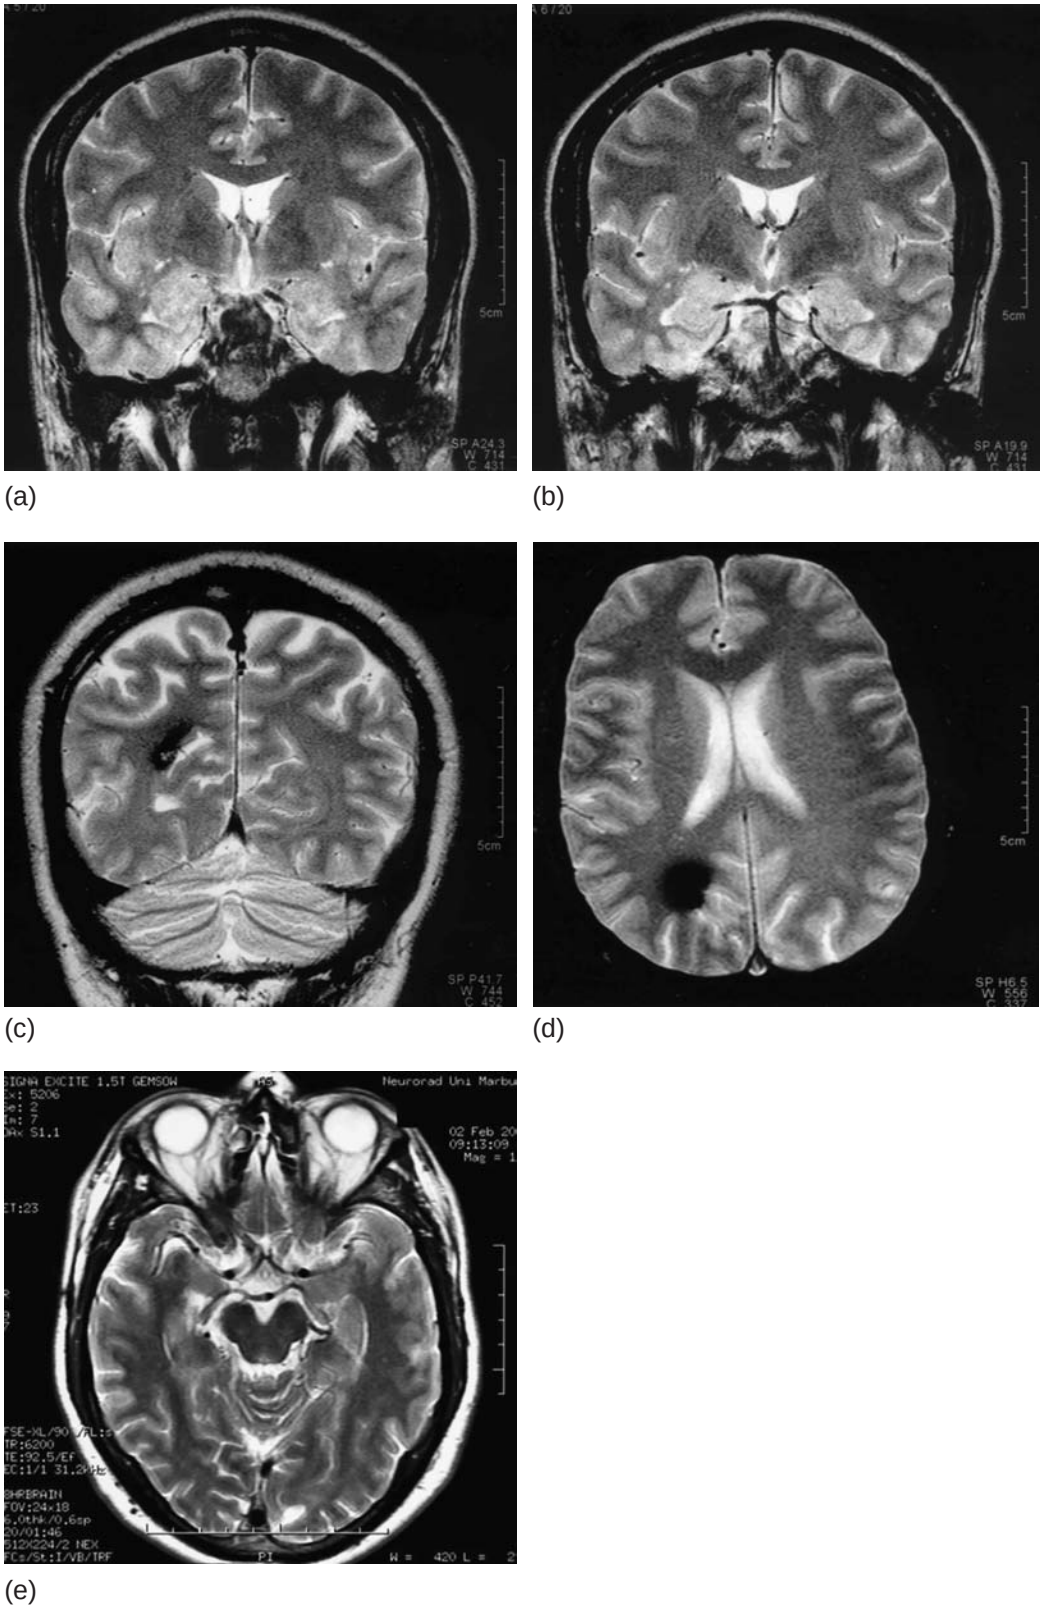

Figure 81.1 35-year-old patient with medically refractory right hemispheric epilepsy leading to automotor seizures. Dual pathology was seen on MRI (hamartoma in the right amygdala (a, b), which was not detected on the first routine MRI and right parietal cavernous hemangioma (c, d). Video-EEG monitoring revealed right anterior temporal seizure patterns and interictal sharp waves exclusively recorded maximal in the right sphenoidal electrode which localized the seizure onset and irritative zone to the hamartoma. The patient remained seizure free after selective removal of the hamartoma (e).

Scans through the rest of the brain should be analysed carefully to rule out dual pathology.

Recent improvements in MRI have greatly increased the preoperative ability to identify epileptogenic lesions and to define their extent and nature. Image quality is generally enhanced by increasing the signal to noise ratio (SNR) available in a given scan time. The SNR can be improved in MRI by replacing the standard quadrature head coil by phased array (PA) surface coils and by going to field strengths higher than 1.5 T (Figure 81.2).[10] These improvements increased lesion detection in patients with focal epilepsy.[11] Phased array studies should particularly be considered in patients with focal epilepsies and medically refractory seizures.

Additional developments in MRI techniques and image sequences, such as magnetisation transfer imaging,[12] or double inversion recovery,[13] have enabled further identification of abnormalities in patients in whom conventional MRI did not isolate a cause for focal seizures.[14] Presurgical detection of brain lesions permit estimation of the spatial relationship of epileptogenic cortex to eloquent cortex and, if necessary, allow a more targeted placement of intracranial electrodes.[11] Besides, the use of modern MRI in conjunction with stereotactic neurosurgery provides the opportunity to correlate the operating field with rendered views of the images acquired preoperatively and, thus, helps to tailor the resective procedure.

However, there is still a subset of patients whose focal lesions will not be detected even by best quality neuroimaging and an experienced reader. Imaging research is directed to such patients. Advanced techniques in postacquisition processing analysis such as diffusion tensor imaging,[15,16] cortical thickness analysis,[17] automated subcortical volumetry, cortical parcellation or statistic parametric mapping[18–20] are innovative techniques whose potential to better define areas of structural brain abnormalities especially in so far 'nonlesional' patients is currently explored.

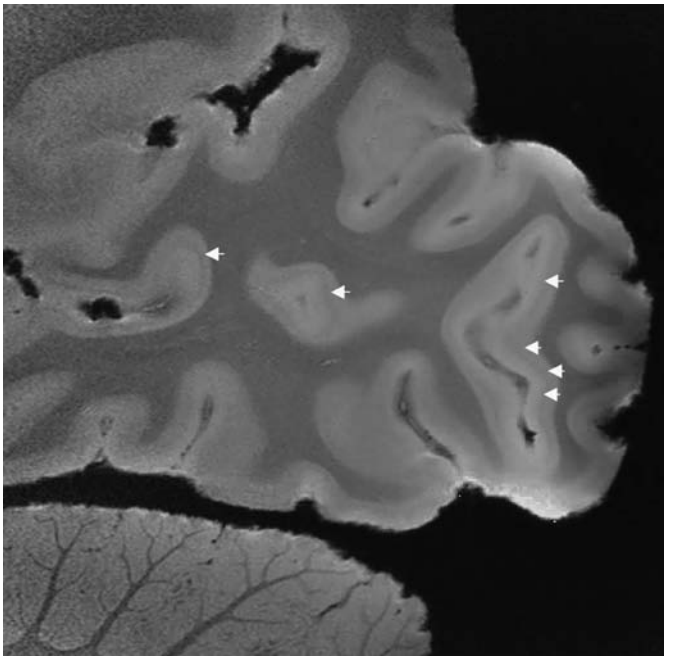

Figure 81.2 Ex vivo MRI of a healthy human brain, scanned at 7T using a 5-cm 1-channel surface-coil. The image is an average of four 1-hour runs of a 3D flash sequence (320 × 512 × 512, 120 µm isotropic voxel, TR/TE/flip 30 ms/4.5 ms/10 ms). The occipital pole and the superior part of the cerebellum are shown in great detail. In the occipital cortex, the stria of Gennari can be seen (arrowheads). The image quality and details give an outlook about future imaging possibilities, making it possible to detect even subtle pathologies. (Image courtesy of Lawrence L. Wald, PhD, A. A. Martinos Center for Biomedical Imaging, Massachusetts General Hospital, Dept. of Radiology, Charlestown, MA.)

Electroencephalography

In general, the EEG plays only an ancillary role to identify the nature of the epileptogenic lesion. There is one report that found interictal epileptiform discharges in patients with mesial temporal lobe epilepsy due to hippocampal sclerosis to be highly restricted to the anterior temporal region while patients with mesial temporal tumors showed more widespread interictal discharges.[21] There is also evidence that continuous, rhythmic spiking on a slow background activity which is not associated with behavioral changes is characteristic although not pathognomonic for focal intrinsically epileptogenic cortical dysplastic lesions.[2,22,23]

Electroencephalography, however, is an essential tool to proof the epileptogenicity of a lesion seen on MRI (Figure 81.1). As mentioned above, the existence of a MRI-visible lesion in a patient with epilepsy does not proof its epileptogenicity. Video-EEG monitoring is necessary to demonstrate this relationship. Seizure semiology has to be consistent with the location of the lesion and the EEG defined irritative and seizure onset zone are usually required to overlap with the lesion or the immediate neighborhood. The same methodology is used when two or more lesions are detected in neuroimaging (Figure 81.1), such as patients with multiple cavernous hemangiomas or tuberous sclerosis. In selected cases invasive recordings are necessary to define the epileptogenicity of a lesion or the exact borders of the epileptogenic zone if the extent of the lesion is difficult to define by neuroimaging, such as in patients with MCD, or if it is unclear to what extent the adjacent cortex is responsible of the focal epilepsy.[24]

Magnetic resonance spectroscopy (MRS)

Magnetic resonance spectroscopy investigates cerebral metabolites, pH and some neurotransmitters. MRS provides an indirect, noninvasive tool to measure the integrity and function of neuronal tissue. Most clinical studies use ^{1}H-MRS at 1.5 T scanners with spatial resolutions between approximately 1 and 8 cc depending on whether multivoxel or single voxel techniques are applied. ^{1}H-MRS provides biochemical information about neuronal function (N-acetyl aspartate), membrane turnover (choline), total energy stores (creatine) as well as the presence of cerebral lactate.[25] The sensitivity and specificity of pathological findings in MRS in patients with temporal lobe epilepsy ranges from 60[26] to 90%[27] with higher spatial resolution spectroscopic imaging techniques reporting greater sensitivity and specificity.[28] Especially in patients with unremarkable structural imaging, MRS may be helpful to

delineate the epileptogenic lesion. However, it has been reported, that the ^{1}H-MRS signal may also be modified by recent seizure activity,[29,30] by antiepileptic medication or by metabolic interventions such as the ketogenic diet.[31,32,32] Therefore, results should always be interpreted with caution and in the clinical context. The usefulness of MRS in the presurgical evaluation has not yet been fully determined and its clinical application is still very limited.[25]

Positron emission tomography (PET)

Positron emission tomography using desoxyglucose (FDG-PET) demonstrates areas of reduced glucose metabolism, which are characteristic for the interictal state of the epileptogenic zone but usually extend beyond it.[33] It may be useful in temporal lobe epilepsy for lateralization. However, results in extratemporal lobe epilepsy have been less favorable.[4] FDG-PET has been applied as an ancillary technique to identify the epileptogenic lesion in a certain subset of patients, such as patients with MCD or tumors unseen by MRI at its present state.[34]

More promising than FDG-PET may be PET studies which explore various neurotransmission related with epileptogenesis and thus, delineate better the extent of the epileptogenic zone. Benzodiazepine receptor ligands, such as flumazenil (FMZ), are found to be reduced in the epileptogenic zone and FMZ-PET images were more sensitive than FDG-PET to define the epileptogenic zone.[4,35,36] FMZ-PET allowed lateralisation and localisation of seizure onset in MRI negative patients suffering from frontal lobe epilepsy.[37] Tryptophan PET was reported in one study to differentiate between epileptogenic and nonepileptogenic tubers in patients with tuberous sclerosis.[35] However, the lack of large multicentric and controlled studies, evaluating the impact of PET, represents a major limitation to a better understanding of the clinical role and utility of PET in epilepsy.[38]

Conclusions

MRI is generally the imaging technique of choice for identifying the structural basis of focal epilepsies. This is important for the diagnosis of focal epilepsies, the determination of therapeutic options and the prognosis in general[39] as well as in respect to epilepsy surgery.

Clinical and electrographic information on the possible location of the epileptogenic zone often helps to target imaging studies properly. Recent developments in MRI techniques and advanced postacquisition processing techniques further improved the sensitivity of MRI but there is still a subset of patients with focal epilepsy and unremarkable MRI.

Not every lesion seen on imaging studies is epileptogenic and the relationship between the structural abnormalities on MRI and the epileptogenic zone can be complex. Therefore, correlation with clinical and electrophysiological data is mandatory. In addition, MRS and PET can help to define this relationship. The usefulness of novel MRI, MRS and PET techniques for assessment of patients MRI-negative with standard techniques is not clear yet because only few studies have directly compared the different imaging techniques in large samples or related the findings to postoperative outcome.

Currently, a combination of different imaging modalities tailored specifically for each patient appears to be most appropriate to improve postoperative seizure control and reduce postoperative impairment through more accurate identification of the epileptogenic lesion, surrounding eloquent cortex, the epileptogenic zone, and vital connections between cortical areas. In addition to their use in the presurgical planning, these methods may reduce the need for invasive techniques in the future.

82 Magentic resonance imaging in epilepsy: mesial temporal sclerosis

GD Cascino

Introduction

Partial or localization-related epilepsy is the most common seizure disorder.[1–3] Over 90% of the incident cases of epilepsy in adults experience partial seizure activity.[1,2] The most frequently occurring seizure type in the adult patient is a complex partial seizure of mesial temporal lobe origin.[1–3] Approximately 45% of patients with partial epilepsy will experience medically refractory seizures that are physically and socially disabling.[1] A minority of patients who fail to respond to first-line antiepileptic drug (AED) therapy will be rendered seizure free with newer medical treatments introduced in the past decade.[4–6] Less than 10% of patients will have a medically responsive seizure disorder if habitual seizures persist with the initial two or three AED medications. Epilepsy surgery is an effective and safe alternative form of therapy for selected patients with intractable partial epilepsy.[1,2,7–12] Patients with medial temporal lobe epilepsy and lesional epilepsy may be favorable candidates for epilepsy surgery and have a surgically remediable epileptic syndrome.[2,7,8] Surgical treatment compared favorably, i.e., more effective in reducing seizure tendency, to AED medication in a randomized controlled trial evaluating medical and surgical therapies in 80 patients with temporal lobe epilepsy. The majority of these patients experience a significant reduction in seizure tendency following surgical ablation of the epileptic brain tissue.[7–16] The hallmark pathology of medial temporal lobe epilepsy is mesial temporal sclerosis (MTS).[17,14,16–18] The surgically excised hippocampus in these patients almost invariably shows focal cell loss and gliosis.[13,14,16–18] This entity is also referred to as hippocampal sclerosis, although, the pathological findings characteristically extend to the amygdala, subcortical white matter, and entorhinal cortex. Patients with lesional epilepsy may have a primary brain tumor, vascular anomaly or malformations of cortical development (MCD).[10,11,14,15,18] The common surgical pathologies encountered in patients with lesional epilepsy include a low-grade glial neoplasm, gangliogliomas, dysembryoplastic neuroepithelial tumors (DNETs), cavernous hemangioma and focal cortical dysplasia.[10,11] Individuals with mesial temporal sclerosis and lesional pathology usually have an abnormal structural magnetic resonance imaging (MRI) study and the seizure types are classified as substrate-directed partial epilepsy.[2,10,18–20] Other MRI-identified structural abnormalities that may indicate the localization of the epileptic brain tissue include focal encephalomalacia related to a prior traumatic brain injury, cerebral infarction or intracranial hemorrhage. The MRI in these individuals may detect a specific intra-axial structural abnormality that may suggest the likely site of seizure onset and the surgical pathology.[20] MRI has a pivotal role in the selection and evaluation of patients for alternative forms of therapy.[7,10,13,16–18] The rationale for the presurgical evaluation is to identify the site of ictal onset and initial seizure propagation, i.e., epileptogenic zone, and determine the likely pathological findings underlying the epileptic brain tissue.[12,13] In patients with an MRI-identified foreign-tissue lesion or unilateral mesial temporal sclerosis the purpose of the electroclinical correlation is essentially to confirm the epileptogenicity of the structural abnormality.[13,15,16,18] The demonstration of concordance between the pathological substrate and the ictal onset zone indicates a highly favorable operative outcome in selected individuals. Approximately 80% of patients with a ganglioglioma, dysembryoplastic neuroepithelial tumor or cavernous hemangioma are rendered seizure free following surgical treatment.[2,7,11,13–16,18] The operative strategy in these individuals usually includes excision of the foreign-tissue lesion and the epileptogenic zone. Over 90% of patients with these pathological findings will experience an excellent surgical outcome, i.e., auras only or rare nondisabling seizures.[7] The operative outcome is distinctly less favorable in individuals with focal cortical dysplasia and other MCD.[19] The most common operative strategy in patients with intractable partial epilepsy involves a focal cortical resection of the epileptogenic zone with an excision of the surgical pathology.[10,11] The goals of surgical treatment are to render the individual seizure free and allow the patient to become a participating and productive member of society.[1,2,9]

This chapter will discuss the use of MRI in the evaluation of patients with medial temporal lobe epilepsy who are being considered for surgical treatment.

Magnetic resonance imaging

MRI has been demonstrated to be the most sensitive and specific structural neuroimaging procedure in patients with partial or localization-related epilepsy.[2,7] Importantly, MRI is a noninvasive technique that has no known biological toxicity and does not involve ionizing radiation.[18] The presence of an MRI-identified structural abnormality may suggest the localization of the site of seizure onset.[4–8] The high diagnostic yield of MRI to delineate foreign-tissue lesions, e.g., tumor or vascular malformation, has been confirmed.[13] MRI findings have

Table 82.1 Surgically remediable epileptic syndromes

Selected epileptic syndromes	MRI	SISCOM	Pathology
Substrate-directed			
Medial temporal lobe epilepsy	> 90%	–	MTS
Lesional epilepsy: tumor	100%	–	Ganglioglioma, glioma, DNET
Lesional epilepsy: vascular	100%	–	Cavernous hemangioma, AVM
Lesional epilepsy: malformation	80–90%	–	FCD
Non Substrate-Directed			
Neocortical (extrahippocampal)	0%	75%	Gliosis, focal cell loss, none

Adapted from Cascino GD. Advances in neuroimaging: Surgical localization. Epilepsia 2001; 42:3–12.

been used to select favorable candidates for epilepsy surgery, tailor the operative resection, and confirm the extent of corticectomy postoperatively.[16]

The sensitivity and specificity of MRI in patients with localization-related epilepsy has been confirmed.[13] The high diagnostic yield of MRI to 'reveal' the common pathological alterations, e.g., post-trauma, vascular malformation, tumor, MCD has been demonstrated in patients undergoing epilepsy surgery. The optimal technique in adult patients with partial epilepsy must include coronal or oblique-coronal images using T1-weighted and T2-weighted sequences.[15,16] The most common imaging alteration in the adult with intractable partial epilepsy is medial temporal lobe atrophy with a signal intensity change.[15,16] Fluid attenuated inversion recovery (FLAIR) sequences have been shown to increase the sensitivity of MRI to indicate a signal change (personal communication: Dr Clifford Jack). Both magnetic resonance spectroscopy (MRS) and positron emission tomography (PET) have a high diagnostic yield in patients with temporal lobe epilepsy. These techniques may be most useful in patients with indeterminate structural MRI studies, e.g., no intra-axial abnormality of bilateral hippocampal atrophy.

Patients with lesional epilepsy may have a primary brain tumor, vascular anomaly or a malformation of cortical development (MCD). The common surgical pathologies encountered in patients with lesional epilepsy include a low-grade glial neoplasm, cavernous hemangioma and focal cortical dysplasia. Individuals with mesial temporal sclerosis and lesional pathology almost invariably have an abnormal structural magnetic resonance imaging (MRI) study and the seizure-types are classified as substrate-directed partial epilepsy. The MRI in these individuals may detect a specific intra-axial structural abnormality that may suggest the likely site of seizure onset and the surgical pathology.

The MRI seizure protocol at the Mayo Clinic Rochester includes:

1. Sagittal T1-weighted imaging with minimum echo time (TE) and 500 msec repetition time (TR) required for whole-head coverage with 5-mm thick contiguous sections;
2. Whole-head coronal three-dimensional volumetric spoiled gradient-echo (SPGR) acquisition is performed with minimum full TE and TR, 192 views, one repetition, 1.5 mm section thickness with 124 partitions, 22 cm field of view, and 45° flip angle; and
3. Coronal spin-echo (SE) imaging is performed with TE of 30 and 80 msec, TR greater than 2000 msec, 20-cm field of view, 4-mm section thickness and 2-mm intersection gap, and 192 views with one repetition. An oblique-coronal fluid attenuated inversion recovery (FLAIR) sequence is also obtained. The FLAIR sequence allows the pathological signal change to be differentiated from the physiological signal alteration related to cerebrospinal fluid. An enhanced study will be performed if a space-occupying lesion is detected in the unenhanced study.

Table 82.2 Presurgical evaluation

Performed invariably	Performed variably	At selected centers
History and examination	Video-EEG (intracranial)	SISCOM
Routine EEG	Electrocorticography	MRS
MRI head	FDG-PET	PET receptor studies
Video-EEG (extracranial)	Interictal-ictal SPECT	Functional MRI
Neuropsychology	Sodium amobarbital study	MRI volumetry

Performed invariably: almost always obtained prior to epilepsy surgery.
Performed variably: available at most epilepsy centers, used in selected candidates.
Performed selected centers: not widely available.
MRI: magnetic resonance imaging.
PET: positron emission tomography.
SPECT: single photon emission computed tomography.
SISCOM: subtraction ictal SPECT co-registered to MRI.
MRS: magnetic resonance spectroscopy.

Medial temporal lobe epilepsy

The three major categories of symptomatic partial epilepsy are as follows: (1) medial temporal lobe epilepsy; (2) lesional epilepsy; and (3) nonlesional neocortical epilepsy.[1] Approximately 80% of patients with partial epilepsy have temporal lobe seizures.[6] The epileptogenic zone in the temporal lobe involves the amygdalohippocampal complex in nearly 90% of patients.[21] The pathological hallmark of medial temporal lobe epilepsy is MTS.[5,7] Surgically excised pathology in approximately 65% of patients with intractable partial epilepsy is MTS associated with focal neuronal loss with or without gliosis.[5,7] A structural lesion underlying the epileptogenic zone is identified in approximately 30% of patients undergoing epilepsy surgery. Lesional pathology includes primary brain tumors, vascular malformations, and MCD.

Mesial temporal sclerosis

MRI findings in patients with MTS include hippocampal formation atrophy (HFA) and an increased mesial temporal signal intensity[5,7,11,13–15] (Figures 82.1–82.3). Inspection of MRI will allow detection of 80–90% of the cases of MTS.[5,7,11,13-15] The HFA atrophy is most obvious using the T1-weighted image in the oblique-coronal plane.[5,7] The signal intensity alteration can be identified using T2-weighted imaging or the FLAIR sequence in the oblique-coronal plane. The coronal or oblique-coronal planes are useful for MRI studies in patient MTS because of the capability to compare the two hippocampi for any side to side asymmetry.[5,7,11,13,14] Potential limitations of visual inspection of the MRI in patients with suspected MTS includes the following: head rotation, symmetrical bilateral HFA, subtle unilateral HFA or signal intensity alteration. Most importantly, visual inspection is a subjective determination that is strongly dependent on the inspector's expertise for appropriate interpretation. Three-dimensional SPGR images are helpful since they are reformatted into true anatomic coronal plane.

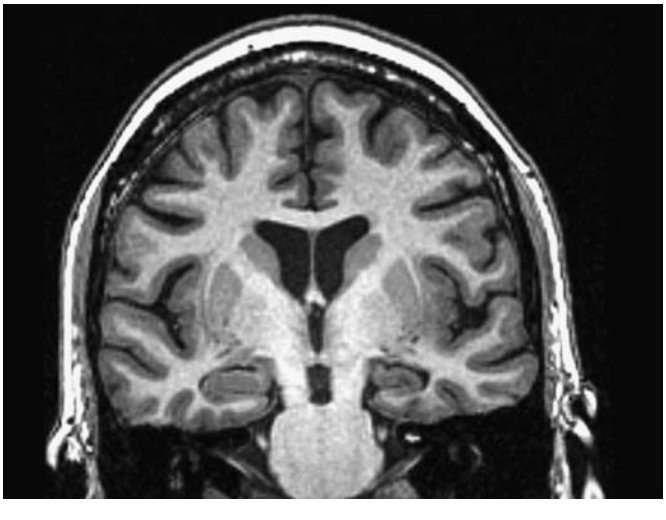

Figure 82.1 MRI head: 3-Tesla T1-weighted pulse sequence in the oblique-coronal plane revealing atrophy of the left hippocampus. The pathological findings showed hippocampal neuronal loss. (Note: the left hippocampus is on the right side of the figure).

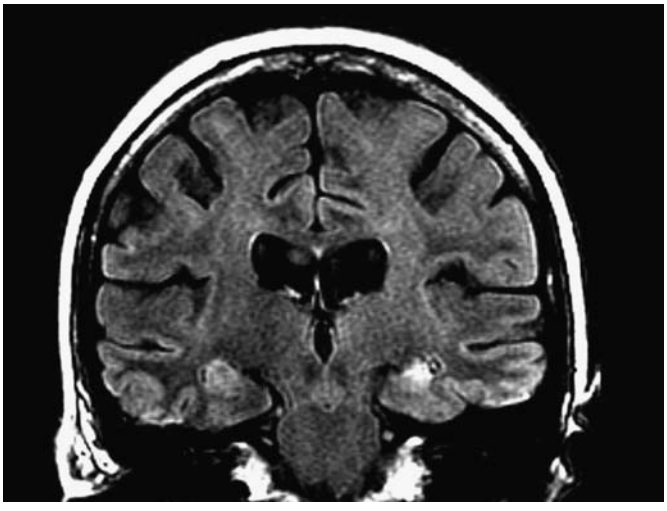

Figure 82.2 MRI head: 3-Tesla fluid attenuated inversion recovery sequence (FLAIR) in the oblique-coronal plane revealing a signal intensity alteration in the left hippocampus. The pathological findings showed severe gliosis. (Note: the left hippocampus is on the right side of the figure.)

MRI-based hippocampal formation volumetric studies have been developed to objectively determine the degree of hippocampal volume loss in patients with MTS.[13,14,16–18] Absolute hippocampal volume measurements are performed using a standardized protocol with the results being compared to age-matched normal controls to assign abnormal values.[13] A unilateral reduction in hippocampal volume has been shown to be a reliable indicator of the temporal lobe of seizure origin in patients with medically refractory partial epilepsy. Jackson *et al.* described T2 relaxometry to objectively determine the medial temporal lobe signal intensity.[17] Quantitative MRI studies have limited clinical application because of the high diagnostic yield of visual inspection. The most important use of hippocampal formation volumetry and T2 relaxometry is for research studies. HFA correlates with an early age of seizure onset, a history of a febrile seizure of childhood, and

Figure 82.3 MRI head: 3-Tesla heavily T2-weighted pulse sequence in the axial plane shows unilateral hippocampal formation atrophy and a signal intensity alteration in the left hippocampus. The pathological findings showed hippocampal neuronal loss and gliosis. (Note: the left hippocampus is on the right side of the figure.)

Table 82.3 MRI and surgical pathology

	MRI				
Pathology	**T1**	**T2**	**FLAIR**	**HF atrophy**	**Gad-DTPA**
Tumor	+	++	+++	–	++/–
AVM	++	++	++	–	+/–
MCD	–	+/–	+	–	–
MTS	–	+/–	+	++	–

T1: T1-weighted imaging sequence.
T2: T2-weighted imaging sequence.
FLAIR: fluid attenuated inversion recovery sequence.
HF atrophy: hippocampal formation atrophy or volume loss.
Gad-DTPA: gadolinium enhanced study.
Tumor: primary brain tumor.
AVM: vascular malformation.
MCD: malformation of cortical development.
MTS: mesial temporal sclerosis.

Table 82.4 MRI and mesial temporal sclerosis

MRI Techniques	Sensitivity
T2-relaxometry	79%
IR	86%
Visual atrophy	90%
IR + visual atrophy	93%
Hippocampal volumetry	97%

Kuzniecky *et al.*, 1997

the diagnosis of medial temporal lobe epilepsy.[13,14,16–18] A history of a neurologic illness in childhood, e.g., febrile seizure, head trauma, or meningitis, appears to be an important risk factor for the development of MTS.[16] The duration of epilepsy and age at the time of surgery have not correlated with volumetric results in most studies.[13,14,16]

The identification of MTS in the surgically excised temporal lobe has been a favorable prognostic indicator of seizure control following epilepsy surgery.[12] Nearly 90% of patients with unilateral hippocampal atrophy have been rendered seizure free.[16] MRI is now recognized as being predictive of neurocognitive outcome in patients undergoing an anterior temporal lobectomy.[18] Patients with normal left hippocampal volumes are at greater risk for experiencing a significant decline in cognitive performance following a left medial temporal lobe resection than those with left HFA.[16–18]

Magnetic resonance spectroscopy

Proton (^{1}H) MRS has been shown to be a reliable indicator of the temporal lobe of seizure origin in patients with medial temporal lobe epilepsy.[28,29] ^{1}H MRS is highly sensitive in the lateralization of temporal lobe seizures by revealing a reduction in N-acetylated compound (NA) concentrations or abnormalities in the creatine (Cr)/NA or NA/choline ratios.[28,29] The underlying pathogenesis for the metabolic changes are likely to be complex and may relate to focal neuronal loss, gliosis, or a functional alteration intimately associated with the frequency of seizure activity. The diagnostic yield of MRS is similar to structural MRI in patients with medial temporal lobe epilepsy related to MTS[28]. The detection of metabolic abnormalities by ^{1}H MRS also correlates with the outcome following temporal lobectomy for intractable partial epilepsy.[28,29] Preoperative metabolic abnormalities in the contralateral temporal lobe were predictive of operative failure. ^{1}H MRS may be of particular benefit in patients with medial temporal lobe epilepsy and normal structural MRI studies.[28,29] Proton spectroscopy may also lateralize the epileptic temporal lobe in patients with bilateral hippocampal formation atrophy. There is limited information regarding the diagnostic yield of ^{1}H MRS in patients with neocortical, extrahippocampal, seizures. The potential benefits of proton spectroscopy in patients with nonlesional extratemporal seizures remain to be determined. At present, ^{1}H MRS is an investigative diagnostic tool that is restricted to only selected epilepsy centers. Despite observations of focal metabolic abnormalities in selected patients with nonlesional extratemporal seizures, it is doubtful that this diagnostic innovation will have widespread use to demonstrate a localized abnormality in patients with nonsubstrate-directed partial epilepsy.

Conclusions

The presurgical evaluation in patients with substrate-directed partial epilepsy is designed to determine the epileptogenicity of the neuroimaging alteration. The rationale for the electrophysiological studies is essentially *confirmatory* in patients with unilateral MRI-identified mesial temporal sclerosis or an isolated foreign-tissue lesion. Video-EEG monitoring is performed in these individuals to confirm the diagnosis of a partial seizure disorder, establish the seizure-type, and determine the disabling effect of the ictal behavior. Functional neuroimaging procedures may not be necessary in patients with medial temporal lobe epilepsy or lesional epilepsy in the presence of a structural MRI abnormality that is concordant with the remainder of the presurgical evaluation. Both MRS and PET have a high diagnostic yield in patients with temporal lobe epilepsy. These techniques may be most useful in patients with indeterminate structural MRI studies, e.g., no intra-axial abnormality of bilateral hippocampal atrophy. In patients with nonsubstrate-directed partial epilepsy there are significant concerns regarding the localization of the epileptogenic zone. Chronic intracranial EEG monitoring may prove necessary in these patients, especially with extratemporal epilepsy. Identification of a localized SISCOM *focus* may be a reliable indicator of the ictal onset zone. SISCOM may reveal a localized region of cerebral hyperperfusion or hypoperfusion in up to 80% of patients with intractable partial epilepsy. The SISCOM findings are also predictive of operative outcome. Ultimately, a decision regarding surgical treatment must be based on a convergence of the neurodiagnostic evaluation. Electrophysiological studies invariably need to be performed to localize the ictal onset zone in these patients. Resection of the SISCOM *focus* may be necessary to significantly reduce the seizure tendency in patients with a localized abnormality that is concordant with the epileptic brain tissue.

83 Magnetic resonance imaging in neurocutaneous syndromes

D Moon and A Gupta

Introduction

Neurocutaneous syndromes are commonly associated with epileptogenic brain lesion(s) that could be surgically resected for relief from refractory epilepsy. Their clinical recognition is of critical importance before surgical epilepsy planning for several reasons. First, recognition of a specific neurocutaneous syndrome will help to anticipate the pathological nature of the epileptogenic lesion(s) such as hamartomas in tuberous sclerosis complex (TSC) or a leptomeningeal angiomatosis in Sturge Weber syndrome (SWS). Additionally, a possibility of multiple bilateral lesions, that may be subtle, could be recognized and special MRI protocols may be done to fully appreciate the extent of brain lesions and scalp EEG findings. Second, screening for other organ and system involvement may be necessary before epilepsy surgery. For example, patients with SWS may have glaucoma, choroid angioma and chronic visual loss that may impact surgical planning of a brain lesion that is usually in the posterior quadrant. Third, some neurocutaneous disorders are familial, and genetic counseling is of paramount importance. Fourth, basic science studies using characteristic pathological substrates on the resected brain tissue from patients with neurocutaneous disorders have enhanced our understanding of the epileptogenesis. Most neurocutaneous syndromes are identifiable by physical examination, and brain MRI helps in confirming the presence of anticipated lesion(s). In this chapter, we will focus on brain MRI and important clinical findings in neurocutaneous disorders that are commonly associated with epilepsy.

Sturge-Weber syndrome (SWS)

Sturge-Weber syndrome (SWS) or Sturge-Weber Dimitri syndrome is also known as encephalotrigeminal angiomatosis or encephalofacial angiomatosis. The majority of cases are sporadic mutations, and there is no clear inheritance pattern. Familial cases in which siblings have phenotypic presentation of SWS exist, but is estimated that these types of cases comprise less than 10% of all cases.[1] Prevalence of SWS is estimated in one study to be 1 in 50 000.[2] There is no known race or sex predilection. Seizures occur in 80% of SWS patients. Seizures usually begin in the first year of life, and are the most common presenting symptom of neurological involvement. Common clinical features include a facial capillary angioma (nevus flammeus or port-wine stain) suggesting a possibility of an underlying ipsilateral leptomeningeal angioma and ocular choroidal angiomas.

Skin findings in SWS

The facial capillary angioma is in the cranial nerve V distribution. Usually it is in theV1 distribution with variable V2 and V3 involvement. Patients with V1 involvement are at risk for neuro-ocular lesions. Some experts feel that facial angioma is not a sine qua non, and up to 5% of patients with SWS do not have facial angiomas.[3] In a minority of cases facial angiomas may be bilateral. Even when facial angiomas are bilateral intracranial involvement tends to be unilateral or dominant to one side.[4]

Eye findings in SWS

Glaucoma is diagnosed in 15% of SWS patients at birth, 61% in the first year of life and 72% by the age of 5 years.[5] Developmental anomalies in the anterior chamber and increased episcleral venous pressure are felt to be the inciting factors for glaucoma in SWS.[6] Dilated episcleral and retinal vessels are present with V1 involvement. There is increased incidence of retinal detachment secondary to hemorrhages from the choroidal hemangiomas. Eye involvement may result in acute or chronic or acute on chronic visual loss that may not be readily apparent in a young infant without an opthalmological examination by an expert.

Brain findings in SWS

Key neuroimaging findings are cortical calcification (Figure 83.1), cerebral hemiatrophy with patchy parenchymal gliosis, choroid plexus hyperplasia, and leptomeningeal angiomatosis. Facial angioma and intracranial lesions are usually ipsilateral.[7] The cortical calcifications show a gyriform pattern on unenhanced brain CT (Figures 83.1 and 83.2). This gyriform pattern, sometimes also referred to as 'tram line calcification', is best appreciated on bone window settings (Figure 83.1). In the normal brain windows the calcifications often appear as amorphous dense lesions (Figure 83.2).

On brain MRI, calcified lesions are best visualized on gradient or susceptibility sequences where they exhibit gyriform susceptibility artifact (low signal areas Figure 83.3) similar to the pattern seen on brain. T1 images (Figure 83.4 and 83.5) show encephalomalacia in the area of the lesions. On administration

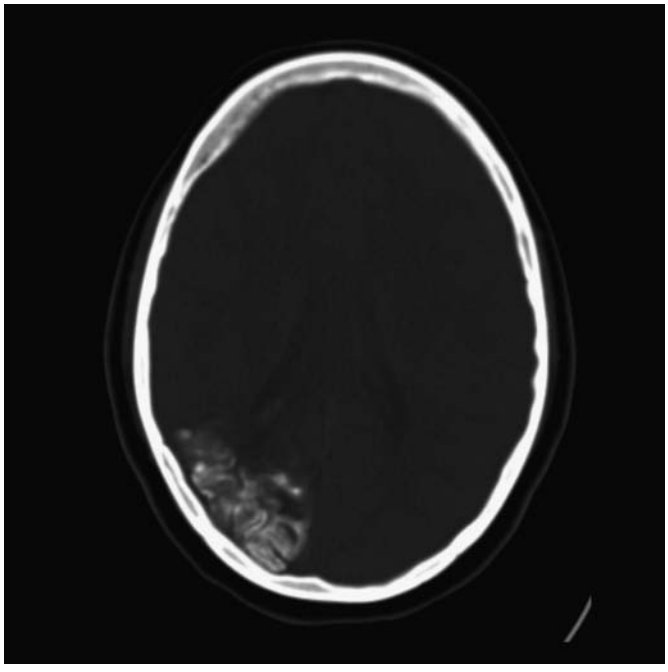

Figure 83.1 Dense occipital cortical calcifications on head CT, bone window in a child with SWS.

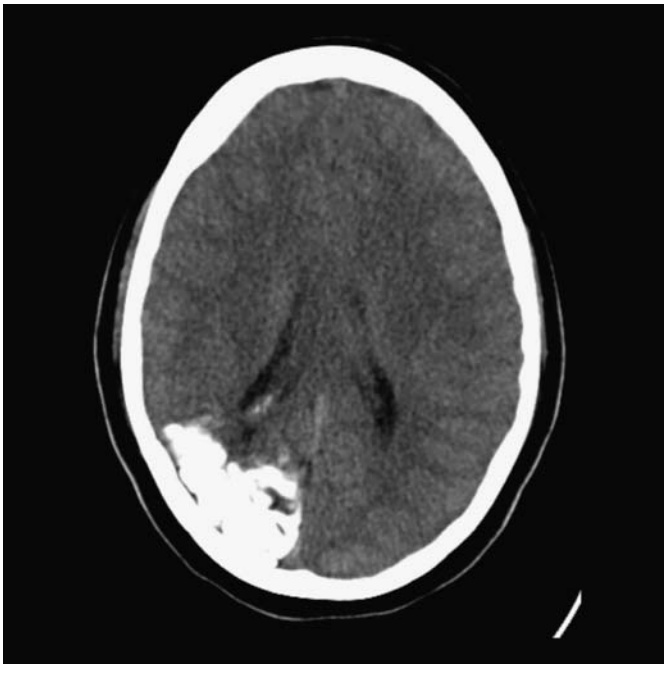

Figure 83.2 Dense cortical calcifications in same SWS patient on head CT, parenchymal window. Note that this is the same image as 86.1 but shows the appearance of more extensive calcifications because of windowing.

of the intravenous gadolinium, T1 contrast images shows enhancement in this area reflecting the underlying venous anomaly, and of the hyperplastic chroid plexus in the ipsilateral atria of the lateral ventricles. Contrary to what might be anticipated intuitively, neither MR venography or MR angiography is helpful in assessing SWS (Figures 83.6–83.8).

Neurological findings include hemianopsia that may not be appreciated or present at birth but tends to be recognized later in life. A subtle clue in a young infant may be gaze preference or ignoring the visual hemifield contralateral to affected size.[8] In SWS, seizures may be followed by prolonged or persistent hemiparesis in the postictal period, suggesting the diagnosis of transient ischemic attacks or cerebral stroke.[9] Fixed hemiparesis may develop. Hemianopsia is usually apparent by the time of hemiparesis.[10] Intracranial angioma may also be bilateral, but one side tends to be dominant. Also SWS patients have angiomas of visceral organs such as kidneys, spleen, ovaries, intestine, adrenals, thyroid, pancreas, heart, thymus, lungs, and extremities. The latter with hypertrophy of the limbs is similar to or may be a subset of Klippel-Trenaunay-Weber syndrome.

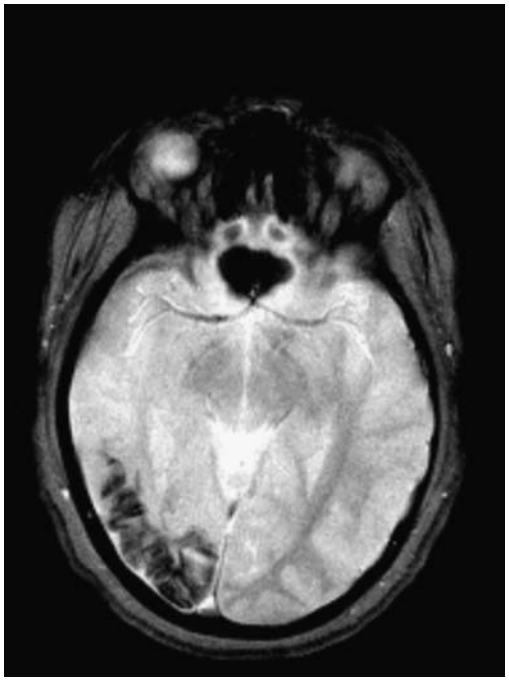

Figure 83.3 Cortical susceptibility artifact reflecting MRI appearance of calcifications in the same SWS patient as 86.1 on MRI gradient echo sequence.

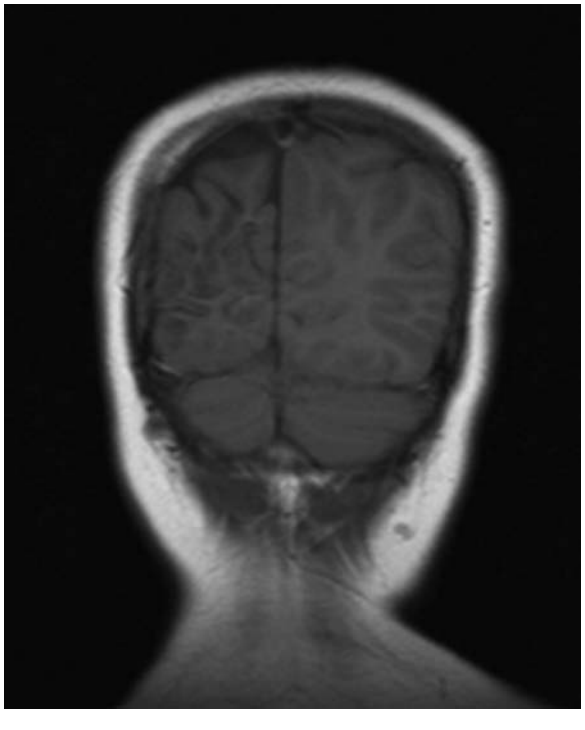

Figure 83.4 Noncontrast T1 weight coronal MRI in a child with SWS showing volume loss in the underlying brain parenchymal in the affected right parietal and occipital lobes.

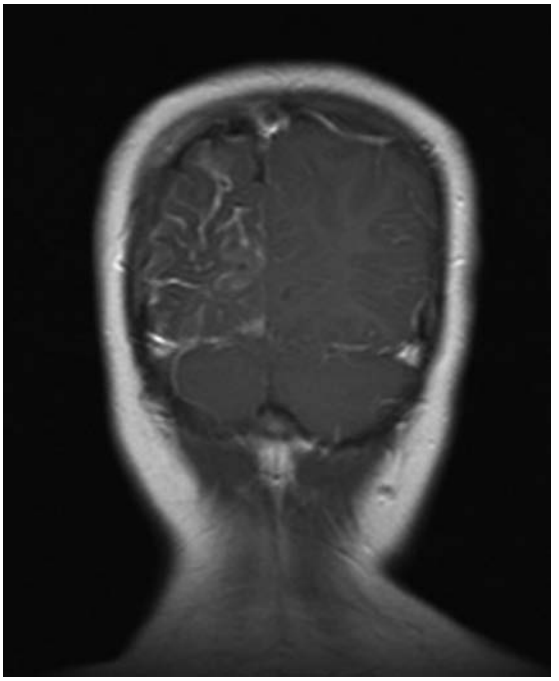

Figure 83.5 Post contrast coronal T1 images showing enhancing right pial angioma in the same patient as 86.4.

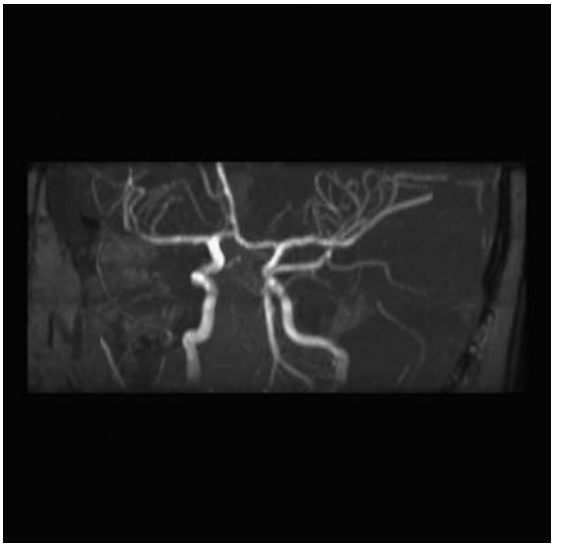

Figure 83.6 MRA maximum intensity images (MIP) shows no abnormal signal to suggest vascular abnormality.

Pathophysiology in SWS

The intracranial lesion is felt to be due to proliferation of leptomeningeal angioma in the subarachnoid space which causes shunting of blood away from brain tissue. Shunting and stasis of blood causes chronic ischemia resulting in gliosis, volume loss and calcification.[11,12] Leptomeningeal angiomas could be bilateral in up to 14% of patients in one series from Mayo Clinic.[13] Absence of superficial cortical veins and thrombosis of SSS has also been reported.[14]

Leptomeningeal angiomatosis is more obvious on gadolinium enhanced MRI than on a contrast enhanced CT.[15] Xenon-133 studies show decreased blood flow in the brain lesion even in patients without neurologic deficits suggesting chronic ischemia.[16] Calcification in SWS is intracortical and noncontrast CT can be used to evaluate cortical calcifications in the later stages. Plain films show the classic 'tram track' pattern on calcification outlining the cortical gyri usually by the age of 2 years. Angiography usually shows enlargement of the deep cerebral veins, decreased or absent cortical veins, or early filling in 82% of patients.[17]

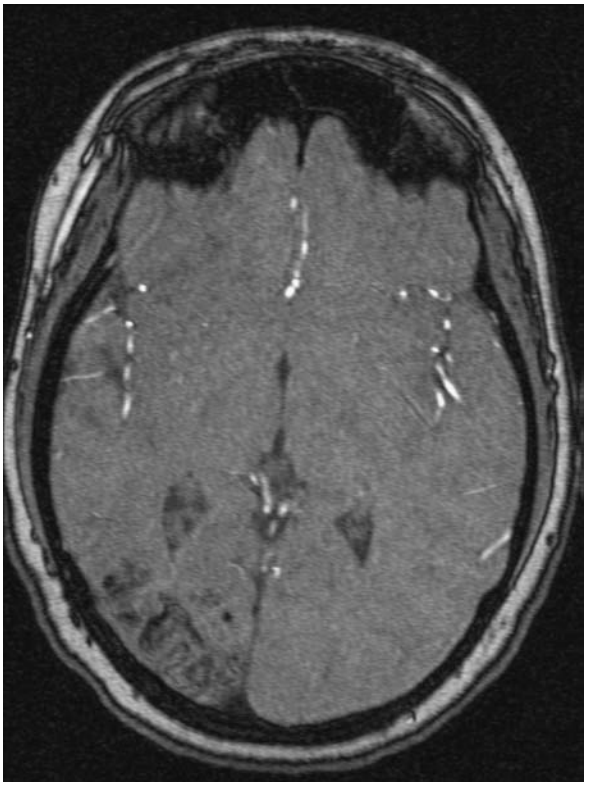

Figure 83.7 MRA individual source image shows no abnormal flow related enhancement (high signal) in the area of affected brain. There is susceptibility artifact in the area where there are gyriform cortical calcifications similar to the ones seen on the susceptibility scans.

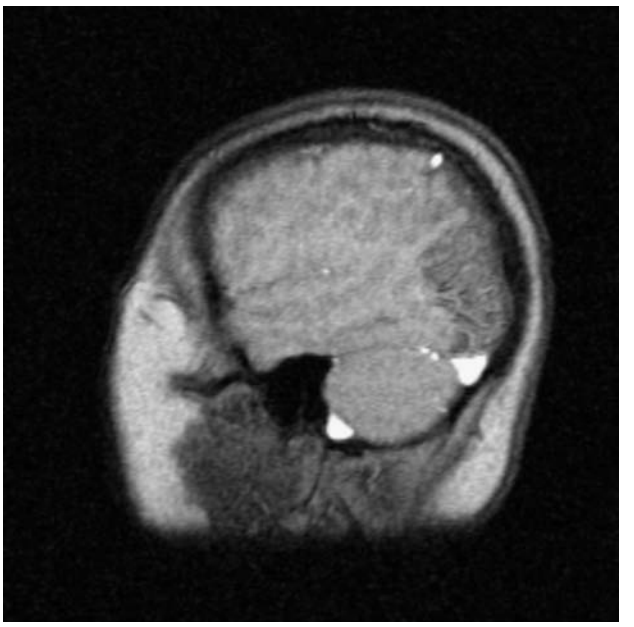

Figure 83.8 2-D time of flight MR venogram individual slice shows no abnormal flow related enhancement in the expected location of the cortical calcification in contrast to the normal high signal (bright) dural venous sinuses.

Neurological morbidity in SWS

Patients with SWS are more likely to have behavioral, social and intellectual issues than nonaffected siblings.[18] Of SWS patients, 60–80% have some degree of mental retardation, and 47–60% are reported to have severe mental retardation in two studies.[19,20] Bilateral hemispheric involvement usually shows increased severity of mental retardation.[21] Intensity of seizures rather than age of onset or hemiparesis as correlated with the presence and severity mental retardation.[22]

Seizures are also very common in SWS, and various studies quote the incidence of seizures to be 75–90% in children with SWS.[23–26] Of those SWS patients who will eventually have seizures, 75% develop seizures by the first year of life, and almost all by the age of 5 years. Only rarely, seizures may first present even in the second decade of life, as in a case report of one patient who presented with seizures at the age of 23 years.[27] Bilateral hemispheric involvement increases risk of seizures.[28] Seizures are usually partial motor (hemiclonic, hemitonic, or myoclonic) or secondarily generalized. Partial seizures involve contralateral extremeties to the intracranial (and usually the facial) lesion. A small number of patients may have primarily generalized tonic-clonic seizures. Some patients may experience a period of seizure remission but seizures may relapse later in life with increased frequency.[29] In one study, there is a 50% incidence of prolonged seizures or status epilepticus.[30]

Epilepsy in SWS is usually difficult to treat. There are some data to suggest that prophylactic antiepileptic drug therapy is useful, even before the patients present with seizures.[31] A trial of at least two antiseizure medications is usually given by most epileptologists before seizures are considered refractory.[32] In SWS with refractory epilepsy, surgical options are usually promising. Presurgical evaluation should be promptly done in these patients. Surgical options include lesionectomy with removal of tissue including generous margins around the lesion or hemispherectomy type procedure of patients of SWS, 70–80% may be seizure free or significantly improved with rare aura or brief seizure after surgery. Lesionectomy is usually reserved for SWS patients who have no motor deficits (hemiparesis), who show a unilateral well-demarcated angiomatous lesion in the parieto-occipital region posterior to the perirolandic region on the brain MRI, and the scalp EEG shows epileptogenicity over the lesion.[33] Hemispherectomy is usually recommended in patients with pre-existing severe hemiparesis that may be progressive, usually with an extensive lesion involving the sensory motor cortex on the brain MRI. The role of invasive recordings to salvage eloquent cortex or perform a more restricted surgery is controversial. Due to predominant posterior quadrant location of the lesions, a comprehensive eye examination and counseling for irreversible anticipated visual deficits is of great importance. Timing of surgery is important. A clinical course with worsening seizures, progressive hemiparesis, and relentless cognitive decline may occur in some patients with SWS. Early surgery is generally recommended for relief from catastrophic epilepsy and ensued encephalopathy from seizures and toxic doses of multiple antiepileptic medications.[34] There is also a possible positive effect on cognitive development with early surgery.[35]

Tuberous sclerosis complex (TSC)

Tuberous sclerosis complex (TSC) (Bourneville disease) is a multisystem genetic disease that is transmitted in an autosomal dominant pattern. Seizures are one of the most common presenting symptom in TSC, and most patients with TSC develop life-long refractory epilepsy. The prevalence is reported to be 1 in 10 000.[36,37] There is no race or sex predilection and spontaneous mutation rate is 60%.[38] Mutations in two genes have been identified in patients with TSC. TSC1 is located at chromosome 9q34 and encodes a protein called hamartin. TSC2 is located at chromosome 16p13.3 and encodes a protein called tuberin.[39] Although located on different chromosomes, the two genes appear to code two proteins that work in the same biochemical pathway involved in cell differentiation and proliferation. Although most patients have mutations localizable to either TSC1 or TSC2, 15% of patients in a study by Dabora *et al.* did not have a lesion localizable to either gene.[40] Sporadic mutations are more common in the TSC2 gene. TSC1 seems to have less severe phenotypic expression. Specifically, TSC1 patients appear to have fewer seizures, fewer intracranial lesions, and less severe mental retardation.[41] Those patients in Dabora's study who did not have a mutation localizable to either TSC1 or TSC2 had even a milder phenotypic presentation than the TSC1 patients.

The classic Vogt triad of mental retardation, seizures, and adenoma sebaceum is only found in only 29% of TS patients.[42] Diagnostic criteria for clinical diagnosis of TSC have been developed and are listed in Table 83.1. Interestingly, 7% patients with TSC1 or TSC2 mutation do not meet diagnostic criteria for TSC, and 15% of patients who meet the criteria for TSC do not have mutation in TSC1 or TSC2.[43]

Table 83.1 TS diagnostic criteria revised[44]

Major features
- Facial angiofibromas or forehead plaque
- Nontraumatic ungual or periungual fibromas
- Hypomelanotic macules (≥ 3)
- Shagreen patch (connective tissue nevus)
- Multiple retinal nodular hamartomas
- Cortical tuber
- Subependymal nodule
- Subependymal giant cell astrocytoma
- Cardiac rhabdomyoma, single or multiple
- Lymphangiomyomatosis
- Renal angiomyolipoma

Minor features
- Multiple randomly distributed pits in dental enamel
- Hamartomatous rectal polyps
- Bone cysts
- Cerebral white matter radial migration lines
- Gingival fibromas
- Nonrenal hamartoma
- Retinal achromic patch
- Confetti skin lesions
- Multiple renal cysts

Diagnosis
- Definite tuberous sclerosis complex is diagnosed by the presence of either two major features or one major feature plus two minor features.
- Probable tuberous sclerosis complex is indicated by one major feature plus one minor feature.
- Possible tuberous sclerosis complex is indicated by either one major feature or two or more minor features.

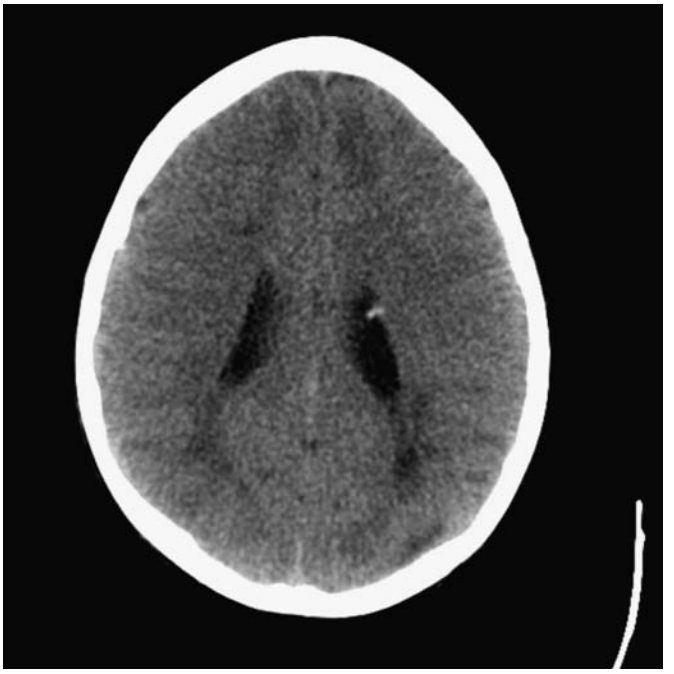

Figure 83.9 Unenhanced brain CT of an 11-year-old child with TSC. Cortical tubers and white matter changes are seen in the left parietal lobe.

Brain involvement and neuroimaging in TSC

This is associated with a variety of brain lesions, and these are: cortical tubers, white matter lesions, subependymal nodules (SEN), and subependymal giant-cell astrocytomas (SEGA).

Figure 83.10 Same child as in Figure 83.9. Ventral cuts on unenhanced brain CT show subependymal nodules and subcortical calcification in the left posterior frontal lobe. Additional cortical and white matter lesions are seen in the right parietal and frontal lobe. Hypodense nature of cortical and subcortical white matter lesions in TSC may be mistaken for remote insult, however the presence of multiple lesions and associated calcified SEN usually clarify the diagnosis.

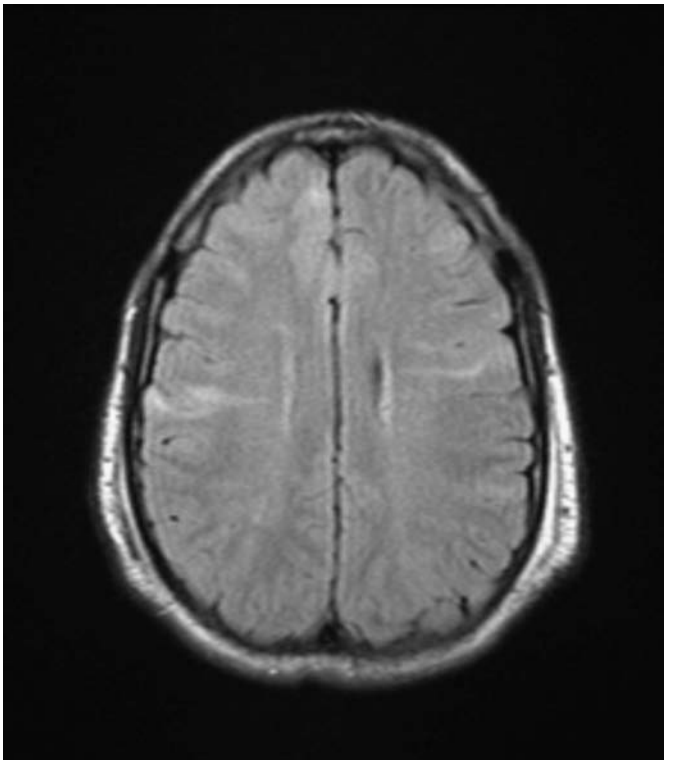

Figure 83.11 Brain MRI FLAIR sequence in a young adult with TSC showing multiple hyper-intense cortical tubers and linear and wedge-shaped white matter lesions.

Histologically, each of the four types of intracranial lesions are composed of clusters of giant cells with varying degrees of neuronal and astrocytic differentiation, and presence of cells that are transitional forms between these two types.[45]

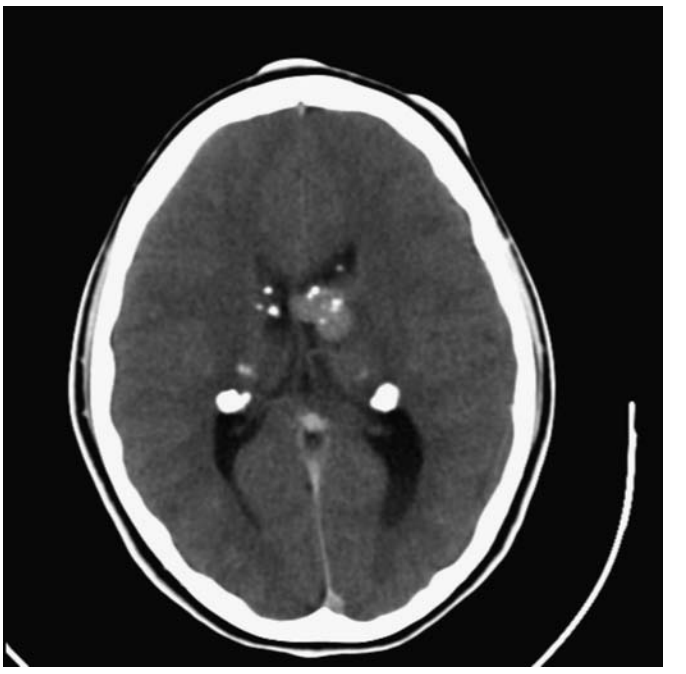

Figure 83.12 Brain CT after administration of contrast in a 16-year-old boy with multiple calcified subependymal nodules (SEN). In the left hemisphere, in addition to the calcified SEN, an enhanced soft tissue mass (SEGA) near the foramen of Monroe is seen. Note the lack of edema surroundings the intracranial masses. Also note the plaque-like areas of increased attenuation in the skin over the frontal bone compatible with cutaneous lesions.

While brain CT is helpful in noticing calcified lesions in TSC, brain MRI is recommended as the neuroimaging procedure of choice to elicit the extent of all lesions. Cortical tubers are hyperintense on T2 and FLAIR sequences, and hypointense on T1 sequences in patients with mature myelination. In newborn and infants with immature myelination, the tubers are hyperintense to unmyelinated white matter on T1 sequences and appear hypointense on T2-weighted images. This effect of immature myelination on the brain MRI findings in infants with TSC is felt to be secondary to the increased water content in unmyelinated regions of the brain.[46] Frontal lobe propensity for cortical tubers has been reported.[47] Cortical tubers usually show decreased uptake of radioactive agent on Tc99mHMPAO interictal SPECT imaging.[48] Similarly, there is hypometabolism on FDG (18-fluorodexy) brain PET.[49] Brain PET may not be as reliable in infants due to normal low glucose metabolism in the brain.[50] There is evidence to suggest that cortical tuber count and location is associated with increased risk of infantile spasms.[51] There also appears to be a correlation between increased number of tubers, development of early seizures, and developmental delay.[52] Magnetic resonance spectroscopy (MRS) shows decreased NAA/Cr ratio, increased choline to creatine ratio, increased myoinositol to creatine ratio, as well as lactate peak.[53]

There are three types of white matter lesions in TSC. These are, in the order of common occurrence; thin linear bands extending radially from the ventricular surface to cortical tubers, wedge-shaped bands with apices near ventricles, and amorphous lesions in the deep white matter. The white matters lesions also show predominance in frontal lobes.[54]

Subependymal nodules (SEN) are often near the caudate head or caudo-thalamic groove. They are variable in appearance. They do not usually obstruct CSF flow, but may uncommonly do so by mechanical pressure against the foramen of Monro. SEN may rarely enhance on gadolinium administration in a nodular or ring-like fashion, and enhancement is better appreciated at higher signal strengths.[55] SEN are better seen on CT than MR because of the presence of calcification.[56]

SEGA are slow growing tumors. They are typically located near the foramen of Monroe and are believed to originate from SEN or tubers.[57] However, rarely SEGA may also appear in other locations in the brain.[58,59] Typically, there is no edema in the brain parenchyma adjacent to the SEGA. Most SEGA are benign, although there are rare cases of malignant degeneration. The symptoms of SEGA are mainly due to their location. TSC patients with SEGA often present with acute or chronic increased intracranial pressure suggesting chronic or intermittent obstruction at the level of the foramen of Monroe. Incidence of SEGA in various studies on TSC is reported to be 1.7–26%. A recent series in a moderate sized group of patients reported 8.2%.[60] SEGA are generally iso- to hypo-intense to brain parenchyma on T1 and hyperintense on T2-weighted images. SEGA are heterogeneous in appearance. Flow voids may be identified within these lesions. They often have internal susceptibility artifact reflecting hemorrhage or calcification. They do show contrast enhancement, and in fact, SEGA should be suspected and periodic screening scans are indicated if SEN show enhancement.

Nonneurological lesion in TSC

Patients with TSC have many visceral lesions including: cardiac rhabdomyomas, phakomas in the eyes (retinal hamartoma), renal cysts and angiomyolipomas, hepatic cysts and pulmonary leioangiomyomatosis. TSC patients may also have a multitude of cutaneous lesions such as hypomelanic macules (ash leaf spots), adenoma sebaceum (facial angiofibromas), forehead plaques, shagreen patches, and ungul or subungual fibromas.

Epilepsy and neurological manifestations in TSC

Seizures are one of the most common presentation in TSC, and occur in up to 80% of patients with TSC.[61] Most patients of TSC with seizures tend to present early in life, and 70% TSC patients develop epilepsy by the age of one year.[62] Infantile spasms are most common type of seizures in infants with TSC. Depending on the location of the epileptogenic tuber(s), other types of seizures such as focal motor, grand mal, complex partial, and atypical absence seizures may occur.[63] Most infants with infantile spasms progress to complex partial to generalized tonic-clonic seizures later in life.[64] In rare TSC patients who develop seizures in later in teenage years or adulthood, partial seizures are most common.[65] Seizures in TSC patients are often difficult to control.

Of TSC patients, 50–65% have mild to moderate mental retardation. IQ appears to be bimodally distributed in patients with tuberous sclerosis.[66] On the good side of the spectrum are a few patients who have no, or infrequent, seizures beginning after infancy with no, or mild, learning disabilities and an IQ that is lower than siblings without TSC. On the guarded side of the spectrum are TSC patients who present with infantile spasms or catastrophic epilepsy with onset before 12 months of age who end with moderate to severe mental retardation.[67] Autism is commonly described in TSC patients, and is reported in 25–50% of patients.[68,69] Patients with TSC also have other neuropsychiatric morbidity in the form of a high frequency of hyperactive and aggressive behavior, and, rarely, self mutilation.[70] SEGA may grow and obstruct the CSF flow requiring tumor excision with or without placement of a ventriculo-peritoneal shunt.

The first line treatment for seizures is antiepileptic medication. Vigabatrin has been found to be especially effective in the treatment for infantile spasms in TSC.[71] There is a question whether it is more effective than ACTH treatment in the treatment of infantile spasms.[72] While ACTH has acute and chronic steroid-related side-effects, Vigabatrin may cause irreversible peripheral field visual defects after long-term use.[73] Besides other antiepileptic medications, ketogenic diet may be helpful in cases of otherwise intractable epilepsy.[74] Vagal nerve stimulation has also been used in a few refractory patients who are not candidates for surgery.[75] Surgery has proven to be an effective and promising option in many refractory cases of TSC. Detection of the solitary or predominant epileptogenic tuber(s) remains a challenge in patients with multiple closely located lesions, and is best achieved by carefully considering seizure semiology, scalp-EEG, and correlating with the brain MRI. Brain PET and ictal SPECT are less informative, although special radioactive PET agents have been touted to increase the yield to detect epileptogenic tuber(s).[76,77]

Epidermal nevus syndrome (ENS)

This is a sporadic neurocutaneous disorder without any known familial cases. Somatic mutation is postulated as the underlying genetic mechanism. The defining cutaneous features of ENS are congenital epidermal nevi that are usually raised skin lesions that may be band-like, round, oval, or linear in configuration. Cutaneous lesions may be subtle to detect due to their skin like color and velvety appearance in infancy, however, they may become verrucous orange or brown later in life. A wide variety of epidermal congenital lesions have been linked to ENS, such as linear sebaceous nevus (of Jadassohn), nevus verrucosus, ichthyosis hystrix, nevus unius lateris, and inflammatory linear verruous epidermal nevus. The cutaneous lesions may differ somewhat in histology.[78] Characteristically, the dermis is not involved, and there is thickening and hyperkeratosis of the epidermis with hyperplasia of the sebaceous glands.

Besides cutaneous manifestations, there is a wide spectrum of clinical presentation involving multiple organs and systems.[79] Pathogenesis of brain involvement is postulated to be vascular dysplasia and migrational anomalies.[80,81] There is no consistent relationship between side of nevus and CNS abnormality.[82] ENS patients may also have ocular, dental, and skeletal abnormalities.

Epilepsy in ENS

Various types of brain malformations and migration abnormalities are reported, however, classical involvement of the brain is in the form of hemimegalencephaly (17 out of 60 patients in Pavone's study).[83] Seizure onset is usually within the first year of life. Seizures in infancy are associated with significant hemispheric abnormalities.[84] Seizures are usually daily, catastrophic, and fail to respond to medical treatment. Hemispherectomy is the treatment of choice in patients with hemimegalencephaly. Important considerations before epilepsy surgery in ENS patients include careful examination and investigations to elicit the clinical severity and organ/system involvement in a given patient, scalp-EEG and MRI to locate epileptogenic zone and also look for evidence of bilateral brain involvement, parental counseling, and weighing benefits/risks of early surgery, whenever possible. A case of ENS with pictures is described in Chapter 170.

Neurofibromatosis 1 (NF1)

Unlike SWS and TSC, only a small percentage of patients with NF1 (Von Recklinghausen's disease) have seizures. The prevalence of seizures in NF1 varies from 4.2–7%.,[85,86] The lower figure is just twice the prevalence in the general population. Seizures were due to tumors (hamartomas), cortical malformations and mesial temporal sclerosis.[87] Other studies of NF1 patients with seizures report no structural lesions identified.[88] Mental retardation is often present in those NF 1 patients who have seizures. Age of presentation varied from 4 days to over 20 years.[89] There are occasional reports of seizures in NF2 patients which are likely due to the presence of localized effects of supratentorial meningiomas and meningioangiomatosis which occurs in NF2 patients.[90,91]

Neurocutaneous melanosis (NM)

This is a rare disorder in which patients have congenital cutaneous nevi and leptomeningeal melanosis leading to CNS manifestations. Precise incidence figure are unavailable, however, a 2.5% risk of developing NM with CNS involvement is quoted in patients with large congenital melanocytic nevi.[92] This disease may be lethal early in life but some patients survival into their 20's.[93,94] Most common MR findings in NM patients is T1 shortening (increased signal) in the temporal lobe and infratentorial brain on noncontrast examinations.[95] There is variable ventriculomegaly and there may be thickening of leptomeninges of brain and spine as demonstrated on contrast enhancement.[96] Leptomeninges may appear to be normal on T1- and T2-weighted sequences. Usually there is leptomeningeal enhancement, however cases have been described without the leptomeningeal involvement.[97] There may also be pachymeningeal (dural) involvement.[98] Dermatologically, patients have multiple congential nevi, the largest of which typically measures greater than 5 cm. NM patients usually present with seizures or increased intracranial pressure. Cranial nerve palsy, hemiparesis, myelopathy, or psychiatric disorders may coexist. NM is believed to be a sporadic neurocutaneous disorder, and is not transmitted as a single gene disorder and does not have any sex predilection.

84 Magnetic resonance imaging in epileptogenic neoplasms

J Tamraz and Y Comair

Introduction

Refractory epilepsy is a consistent health problem worldwide, affecting almost 1% of the population from which more than a quarter present a medically refractory form. Since the preliminary essays of in vivo magnetic resonance (MR) performed 25 years ago, its efficiency took an increasing major role in the diagnosis and the management of intractable epilepsy demonstrating the underlying structural abnormalities.[1–3] Even in the idiopathic form of generalized epilepsy brain imaging may show related abnormalities. The Commission on Neuroimaging of the International League Against Epilepsy (ILAE) recommends[4,5] that '… the ideal practice is to obtain structural neuroimaging with MRI in all patients with epilepsy, except in patients with a definite electroclinical diagnosis of idiopathic generalised epilepsy or benign epilepsy of childhood with centrotemporal spikes'. It also recommends that '… epilepsy surgery should never be contemplated without an MRI examination'.

MR is actually a mature imaging technique and stands as the most accurate neuroimaging modality for the diagnosis of structural abnormalities related to epilepsy and the presurgical evaluation due to its inherent specific characteristics. In fact, MR due to its multiplanar ability allows the exploration of the patient in any oblique plane with a high-contrast resolution premitting to obtain an accurate differenciation of gray and white matter. The absence of beam hardening artifacts from bony structures such as those generated at the skull base vicinity, favors the exploration of tumoral processes located in the orbitofacial or temporal regions. The absence of ionizing radiation makes it the modality of choice for follow-up examinations, particularly in pediatric patients or post surgery or radiation therapy. MRI is a multiparametric technique that largely depends upon operator skills. It is an epilepsy specialist study. The choice of the appropriate pulse sequences contribute consistently to the final diagnosis. A minimum of T1- and T2-weighted sequences and a 3D-T1w volume acquisition with reformations and volume renderings are mandatory and recommended by the ILAE. The need for contrast administration, such as the paramagnetic Gadolinium chelates, is relatively limited usually restricted to the evaluation of intra-axial neoplastic processes and the leptom eningeal seeding and may be of some help in the differential diagnosis or in tumor grading.[6] The search for an optimal cost/efficiency ratio requires the prescription of the most informative examination. The well-established sensitivity of MRI in detecting structural abnormalities in refractory epilepsy averages (95% as compared to 32% for CT).[7] MR is superior for identifying both the focus and the histopathologic substrate found at surgery. A combined approach may be needed for the detection of minute calcifications. However, CT remains useful in patients presenting absolute contraindications to MR exams as patients with pacemaker, vascular clips, neurostimulators, or other ferromagnetic devices.

More sophisticated techniques, recently implemented on most available systems, may be used in addition to morphologic imaging: diffusion-perfusion to assess perfusion measurements and evaluate neovascularisation, diffusion tensor imaging (DTI) to obtain white matter tractography, functional imaging (fMRI) for mapping of brain functions, and in vivo spectroscopy (MRS), which may reveal subtle underlying biochemical abnormalities representing the effects or cause of the epileptic disorder. Note that fMRI activation is more widely available and of much higher spatial resolution than other functional techniques, improving particularly on higher field systems (3 Tesla magnets) and tend to become the powerful functional tool to detect metabolite disorders even supplanting PET for the localization of eloquent cortex most useful in the presurgical planning process.[8–20] In apparently normal MR exams, functional imaging techniques such as ictal SPECT and/or interictal FDG-PET may show regional dysfunctions.

Neuroimaging technique of brain tumors

In order to identify and recognize the underlying structural abnormality responsible for intractable partial epilepsy, a good knowledge of brain anatomy and the nature of the lesional processes that may potentially cause seizures, is necessary.[21–25] These lesions are frequently subtle and may be easily overlooked or misdiagnosed.[26] High spatial and contrast resolution thin coronal MR cuts off the brain and the temporal lobes should be performed on high field systems (1.5 or 3 Tesla).

Brain referentials essential for neuroimaging

Any precise topographical analysis of brain structures ought to be performed according to judicious and definite cerebral reference lines, based on reliable cutaneous, cranial and brain landmarks.[22] In order to facilitate the neuro-anatomical

approach and optimize biometrical studies using MRI, two brain reference lines, the horizontal chiasmato-commissural line (Ch-Cp line) and the vertical commissural-obex line (Cp-Ob line) perpendicular to the previous, are routinely used. These orthogonal reference planes suitable for multimodality imaging are used in brain imaging with highly reproducible anatomical results.[22,27,28,31] The anatomical landmarks defining these reference lines are very easily found on a mid-sagittal MR scoutview (Figure 84.1a).

The horizontal reference Ch-Cp line is defined as the line tangential to the superior border of the chiasmatic notch (Ch) anteriorly to join the inferior border of the posterior commissure (Cp) posteriorly. The consistency of the angle between this line and the bicommissural line serves to validate the choice of this pivotal line situated as it is at the mesodiencephalic junction. This plane has been shown to be truly horizontal oriented parallel to the parallel sulcus and consequently to the lateral fissure materializing a sylvian plane orientation of the brain cuts.[27,28]

The vertical reference Cp-Ob plane is defined as the line tangential to the anterior border of the posterior commissure (Cp) and joining the obex (Ob) at the caudal extremity of the calamus scriptorius on floor of the fourth ventricle (28) (Figure 84.1b). This Cp-Ob line materializing the great vertical axis of the brainstem has been demonstrated as the most reliable referential to obtain reproducible coronal cuts of the brain using MR.[27,31] Coronal cuts are therefore best obtained with the Cp-Ob reference plane due to its perpendicularity to Ch-Cp plane and thus to the anterior-posterior axis of the first temporal and the lateral sulci, becoming particularly most suitable for the coronal study of the temporal lobes, the inferior frontal gyri and the perisylvian speech areas.

Imaging protocol and methodology

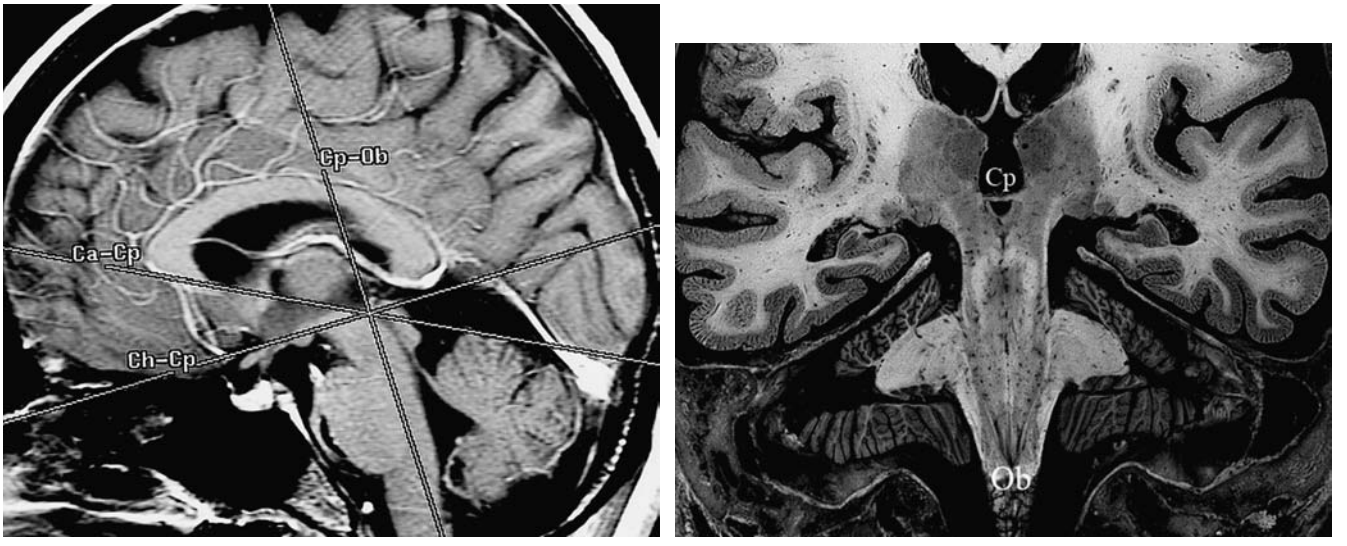
Accurate and reproducible brain reference planes as achieved using the Cp-Ob reference plane have to be used. The imaging protocol must include at least three pulse sequences: a sagittal T1-weighted gradient echo sequence useful for a morphological screening approach and for subsequent landmarking, followed by a coronal-oblique fast fluid attenuated inversion recovery (FLAIR) sequence according to PC-OB line and a 3D-T1 weighted volumetric acquisition with 128 partitions and 1.8 mm slice thickness. The near isotropic small voxel size obtained allow mutiplanar reformations and volume renderings with adequate spatial resolution. Additional T2-weighted and/or T2*-weighted pulse sequences in the axial or the coronal planes may be performed in special conditions.[32] Beyond the routine examination protocol, more sophisticated and powerful imaging modalities available may be used to improve sensitivity in the diagnosis and the staging of primary intracranial tumors and to optimize the presurgical planning. Post-surgical follow-up of resected tumors and evaluation of the effects of adjuvant radiotherapy or chemotherapy are also promising.

Functional aspects of MR

Functional imaging applies to any technique that acquires time dependent imaging data. This includes flow, diffusion, perfusion, brain activation and MR spectroscopy.[33–34] When combined and added to conventional MR technique these functional tools may increase the specificity of the positive diagnosis of brain tumors. A multifunctional approach may help to suggest the tumor grade, evaluate the tumor extension and the therapeutic response and precise the area to biopsy.[35–39]

Diffusion (DWI) and diffusion tensor imaging (DTI)

While MR angiography and flow measure the movement of spins from voxel to voxel, MR is capable of measuring microscopic translational motion within each voxel. This motion can be the molecular diffusion of water and the microcirculation of blood in the capillary network, referred to as perfusion.



(a) (b)

Figure 84.1 Cephalic reference planes suitable for neuroimaging. (a) Horizontal and vertical reference lines are used as referential coordinates for routine brain imaging: the chiasmatico-commissural line (Ch-Cp) joining the Chiasmal point to the Commissura posterior and the commissural-obex (Cp-Ob) line joining the Commissura posterior to the Obex, respectively. Both orthogonal orientations are compared to the bicommissural plane (Ca-Cp). (b) Anatomical correlation as obtained in the Cp-Ob coronal reference plane.

Diffusion is the process by which molecules and other particles mix and migrate due to their random thermal motion. DWI is acquired using a specific bipolar gradient with very high strength to detect the slow molecular diffusion in the body. This bipolar gradient will cause a signal loss in the diffusing spins which depends on the diffusion coefficient and the B value. The B value is determined by the strength and duration of the gradients. High B values can eliminate the T2 effect and improve the visualisation of the white matter fibers. It is therefore possible to obtain maps of diffusion in the three different orthogonal directions or combine the three images into a single map of overall diffusion. With specific research software it is possible to calculate the diffusion tensor and deduce the actual direction of the diffusion and even obtain the direction of the neuronal axons.

Diffusion is increased in area containing free water such as in edema and is decreased in case of hypercellularity as in solid tumors or in viscous necrotic areas found in an abcess, for instance. Increased diffusion appears as dark areas on DW images and as very bright on the ADC map. DTI may be useful to localize a tumor and evaluate its extent. This may be achieved either by the identification of an increase in diffusivity or a loss of anisotropy.[40–42] Interpretation of tractography is improving due to advances in technology and could be more reliable on higher-resolution images as obtained on higher field systems (3 T). The need to compare between normal and diseased hemispheres is helpful.[43] More work is still needed and the results are still debatable.

Perfusion imaging

Perfusion is the study of the net transport of magnetization into a volume of tissue. It can be performed either with endogenous or exogenous contrast agents.[33] One way of achieving this is by injecting a bolus of contrast agent like Gadolinium (Gd) and acquiring rapidly, usually with EPI a series of slices through the region of interest, and then repeating the multislice acquisition at a rapid rate of the order of one per second. This repetition is performed from before the injection until about 30 seconds after the arrival of the bolus. The images are then analysed to look for variations in the arrival of the contrast agent between the pathological and normal regions. The analysis can be made in several ways: the negative enhancement integral which produces a map of the susceptibility effect caused by the flow of blood containing contrast; the mean time to enhance which produces a map based on the time of arrival of the contrast in different regions; and the positive enhancement integral which produces a map of the contrast enhancement rates based on the increase in SNR due to increased concentration of contrast material.

Highly vascular high-grade gliomas usually show increased blood volume and blood flow with respect to normal brain. Conversely necrotic or cystic portions of the tumor show a decrease if not absence of perfusion.[44,45] Reduced perfusion is also found in the peritumoral edema. Although lacking specificity, perfusion imaging may help in some circumstances to approach tumor grade. Low-grade astrocytomas may also show increased blood volume.

Brain activation (fMRI)

Brain activation can be studied either by direct methods, those that measure directly the electrical activity of neurons like EEG (electrical effect) and MEG (magnetic effect), or by indirect methods, those that measure the hemodynamic response to the neuronal electrical activity, like ^{15}O PET (blood flow) and fMRI (BOLD effect).[33] The indirect method used by fMRI can be understood by following the chain of physiological events that describes it. When a set of neurons fire there is a local increase in glucose consumption which, in turn; produces an increase in oxygen consumption. This induces an increase in regional cerebral blood flow (rCBF) and an increase in regional cerebral blood volume (rCBV) with a consequent increase in blood velocity. In the blood there is a decrease in oxygen extraction fraction producing an increase in oxyhemoglobin and a decrease in deoxyhemoglobin. In this sequence of events the most common approach used in fMRI is the blood oxygen level dependent (BOLD) contrast. The decrease in deoxyhemoglobin, because of its high paramagnetism, produces a decrease in local microscopic field gradients which in turn produces an increase in T2*. This corresponds to an increase in signal which is measured by the MR equipment. The ideal sequence to use is a rapid sequence with T2* sensitivity which detects changes in magnetic field, usually a gradient echo EPI. fMRI has its own limitations both in spatial resolution and temporal resolution. To achieve optimal functional imaging it is important to have the highest possible magnetic field (1.5 T or 3.0 T), powerful and fast gradients and a powerful computer with adequate software to manipulate the image.

Magnetic resonance spectroscopy (MRS)

For almost two decades, in vivo magnetic resonance spectroscopy (MRS) has been a revolutionary technique in biomedical research. Today, it is a powerful tool in neurosciences giving noninvasive access to the chemistry of the human brain in health and in disease.[34] MRS is a unique and powerful technique that has been applied to a number of brain diseases. It can be correlated with imaging and other clinical data for confirmation. It enables tissue characterization on biochemical levels. It is useful in the diagnosis and prognosis of diseases and mostly in the evaluation of the noninvasive monitoring of the response to treatment.[46]

The spectroscopy technique routinely used to assess brain tumors is the multivoxel acquisition modality, performed both with an intermediate TE of 144 ms which evaluates the choline level, the major metabolic abnormality in brain tumors, and with a short TE of 30 or 35 ms in order to detect myoinositol which may help tumor grading.[51] The most salient findings are a decrease in NAA and Cr peaks and NAA/Cr ratio and an increase of Cho, lipids and lactate as well as Cho/Cr and Cho/NAA.[49,50] Both ^{31}P and ^{1}H MRS have been used for diagnosis and therapy monitoring of brain tumors.[47] Studying changes in tumor-type-dependent metabolites is an area of active research.[48–51] Lipids and lactate peaks correlate well with necrotic tumors.

In vivo MRS is a complex technology that requires the simultaneous optimal adjustment of multiple parameters during an examination. The most critical task in MRS, however, is not spectral aquisition but rather spectral analysis. This latter is time demanding and necessitates appropriate know-how in order to interprete the results, eliminate artifacts and quantitate data often by complex procedures and finally, statistically analyze the findings. The precise role of many identified metabolites is still unclear.

Neuroimaging of developmental tumors

Tumors are represented most frequently by gliomas of the astrocytic predominantly fibrillary but possibly protoplasmic type or of the oligodendroglial type, followed less commonly by the mixed neuronal-glial or neuronal tumors such as the ganglioglioma, gangliocytoma, and the dysembryoplastic neuroepithelial tumor (DNET). The majority of patients with DNETs or gangliogliomas are less than 20 years old. Tumor recurrence after surgery is usually low.

Dysembryoplastic neuroepithelial tumors (DNET)

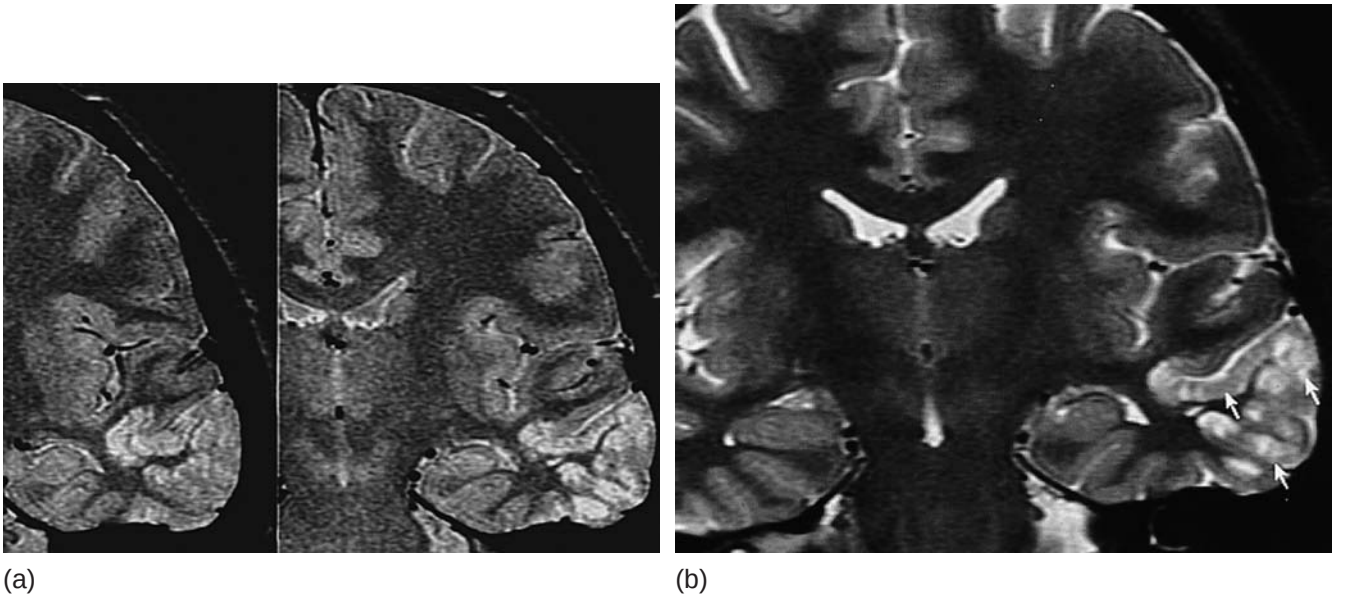
Described in 1988 by Daumas-Duport[52] and accepted into the 1993 WHO revision,[53] DNETs show characteristic histologic features consisting of three cell lines: neuronal, astrocytic, and oligodendroglial. These uncommon tumors are highly associated with long-standing intractable epilepsy with onset in early childhood, before the age of 15 years in 85% of cases,[20] with an average age of 9 years.[54,55] DNET has been indicated in about 20% of medically refractive epilepsy in children and adolescents.[52,56] Males are affected more than females. Diagnostic criterias include partial seizure activity before age of 20 with no associated focal neurologic deficits or congenital deficit, and a cortically-based tumor.

DNETs are benign hemispheric mixed glial-neuronal tumor, predominantly cortical, very rarely deep in location, causing seizures as their earliest manifestations. They correspond to WHO gradeI lesions. These tumors are relatively rare with more than 300 cases reported. All reported cases are supratentorial.[57,58] More than 60% of DNETs are found in the temporal lobes and involve the mesial structures preferentially and about 30% in the frontal lobes. Few are located in the parietal or occipital lobes, the basal ganglia, brainstem or cerebellum.

Morphology and imaging

Morphologically, these tumors are very superficially located, always involving and expanding the cortex despite a concurrent involvement of the subjacent white matter. The tumor gives rise to a macrogyriform aspect rather typically associated with a scalloping of the inner table of the skull vault in more than 50% of the cases.[59,60] These neoplasms are heterogeneous with a multinodular microcystic appearance (Figure 84.2), but true intratumoral cystic formation is uncommon. Actually two varieties may be differenciated, a 'macrogyric or megagyric' form that causes gross expansion of the cortical ribbon and a 'multinodular' form. In the case of associated subcortical extension the tumor appear triangular in shape on coronal cuts.[61] Associated edema is lacking and there is no mass effect. Calcifications are found in about 1/3 of the patients on CT.[54] DNETs show many of the features of gangliogliomas and oligodendrogliomas. DNETs may be associated with adjacent cortical dysplasias and may occasionally occur in neurofibromatosis type I. Because of its benign nature, total resection with complete cure may be obtained.

Hypodense to white matter on noncontrast CT, DNETs are hypointense to cortex on T1-weighted sequences on MR, becoming/hyperintense to adjacent cortex on PD-w and remaining hyperintense on T2-w and FLAIR, due to increased water content, but show no vasogenic edema. The characteristic microcystic architecture is demonstrated in almost 40% of cases on high resolution images using very long T1-w and T2-w sequences at high fields.[62] Cortical analysis and evaluation of DNETs and eventually associated cortical dysplasias may be highlighted using IR-T1-weighted sequence due to its higher contrast resolution. Subcortical extent of the lesion is observed in 30% of the cases.[60] DNETs usually do not show contrast enhancement in more than 2/3 of the cases and show a patchy pattern in 20–40% of the cases.[61] Peritumoral edema is almost absent. The differential diagnosis includes ganglion cell tumors and low-grade gliomas.[63]



(a) (b)

Figure 84.2 Dysembryoplastic neuroepithelial tumor. Coronal cuts showing a cortically based tumor involving the lateral temporal gyri and displaying highly suggestive multinodular appearance due to the presence of intracortical multiple tiny cysts (arrows), hyperintense to gray matter on PDw (a) and T2-w (b) images. The lesion expands the cortex with mild erosion of the inner table of the calvarium. There are no obvious mass effect, neither associated edema. No contrast enhancement was evidenced.

Gangliocytomas and gangliogliomas

Also called ganglioneuromas, most of these uncommon slowly-growing benign tumors are found in patients younger than 16 years old, affecting children and adolescents, but have been reported in patients ranging in age from a few months to 80 years old.[64] Their incidence is slightly higher in males.[65] The diagnosis is usually made in 80% of the cases before age 30 (20–30 years old) in patients presenting a long–standing epilepsy, most commonly partial complex seizures.[65,66] In the pediatric population, the average age at diagnosis is 10 years old with seizures as the most frequent presenting symptom.[65,67] Complete resection of the tumor usually cure seizures.[67,70]

Gangliocytomas are very rare mixed neuronal-glial tumors formed of neoplastic mature ganglion cells (WHO grade I). Gangliogliomas show the presence of mature ganglion cells with neoplastic glial cells (WHO grade I or II). The astrocytic component is either diffuse or pilocytic in nature. They represent together 1.3% of all brain tumors. The tumors may occur anywhere but are most commonly found in the temporal lobes and tend to spare the lateral neocortex.[66,69–71] The other lobes involved are the parietal, the frontal, and the occipital lobes. When superficially located, the tumor may cause thickening of the cortical ribbon and cause a scalloping of the calvarium. Although benign, an aggressive behavior is found in about 10% of gangliogliomas which may undergo malignant degeneration.[72,75] Association with cortical dysplasia may be found in 50% of the patients.

Morphology and imaging

Gangliogliomas and gangliocytomas are usually well-circumscribed small masses, solid or partly cystic in 25% of cases or almost cystic in about 50%. Intratumoral cysts are often multiple. There is usually no obvious mass effect and no or very mild, peritumoral vasogenic edema. In gangliogliomas, the tumor may involve the leptomeninges and the glial component of this mixed tumor may contribute to give a slight infiltrative appearance of the brain-tumor interface. Calcifications are common found in 40% of cases, sometimes of bizarre shape,[70] but remain less frequent than in oligodendrogliomas but more than in juvenile pilocytic astrocytomas or in pleomorphic xanthoastrocytomas.[70,71] It seldom presents as a brain 'stone' without associated soft-tissue neoplasm. They may be associated with mesial temporal sclerosis when located anteriorly. Peripheral tumors may erode the inner table of the skull as reported in about 5% of cases.[74] The tumors may be associated with mesial-temporal sclerosis. Differential diagnosis between gangliogliomas and gangliocytomas is made on histopathology.

Gangliogliomas are hypointense to cortex on T1-w sequences, but their cystic component may be isointense due to a high protein content. On PD-w images the solid portion of the ganglioglioma is hyperintense to the cortex with variable SI of the cystic component which may be even more hyperintense due to its high protein content. On T2-w images the solid portion of the gangliogliomas is mildly hyperintense to brain, less or equally to the cystic component and may show mild peritumoral edema (Figure 84.3). Calcifications may appear as areas of shortened T1 relaxation. IR-T1w sequence, due to its high contrast resolution, is a sensitive sequence, very useful in the investigation and the evaluation of cortical dysplasias, mesial temporal sclerosis and superficial tumoral conditions such as gangliogliomas or gangliocytomas. Cortical analysis is highlighted. On CT, the solid portion of the tumors are isodense or hypodense showing calcifications in about 30% of the cases and a variable contrast uptake.[75] Enhancement of at least the solid portion of gangliogliomas is variable either homogeneous or heterogeneous, usually mild and found in roughly half the cases, except in the case of malignant degeneration.[65,69–71] The wall of the cystic component may show contrast enhancement. In peripherally developed tumors, differential diagnosis with DNETs and oligodendrogliomas may be difficult.

Desmoplastic neuroepithelial tumors

The desmoplastic infantile gangliogliomas (WHO grade I) and the desmoplastic astrocytomas of infancy are tumors encountered in infancy and early childhood, mainly in boys, and presenting similar features. Histopathologically these tumors are composed of both ganglionic and astrocytic cells with a desmoplastic stroma.[76] Clinically, patients present with macrocephaly and partial complex seizures.[76–78] These tumors show a benign clinical evolution and their complete excision may be curative.[79]

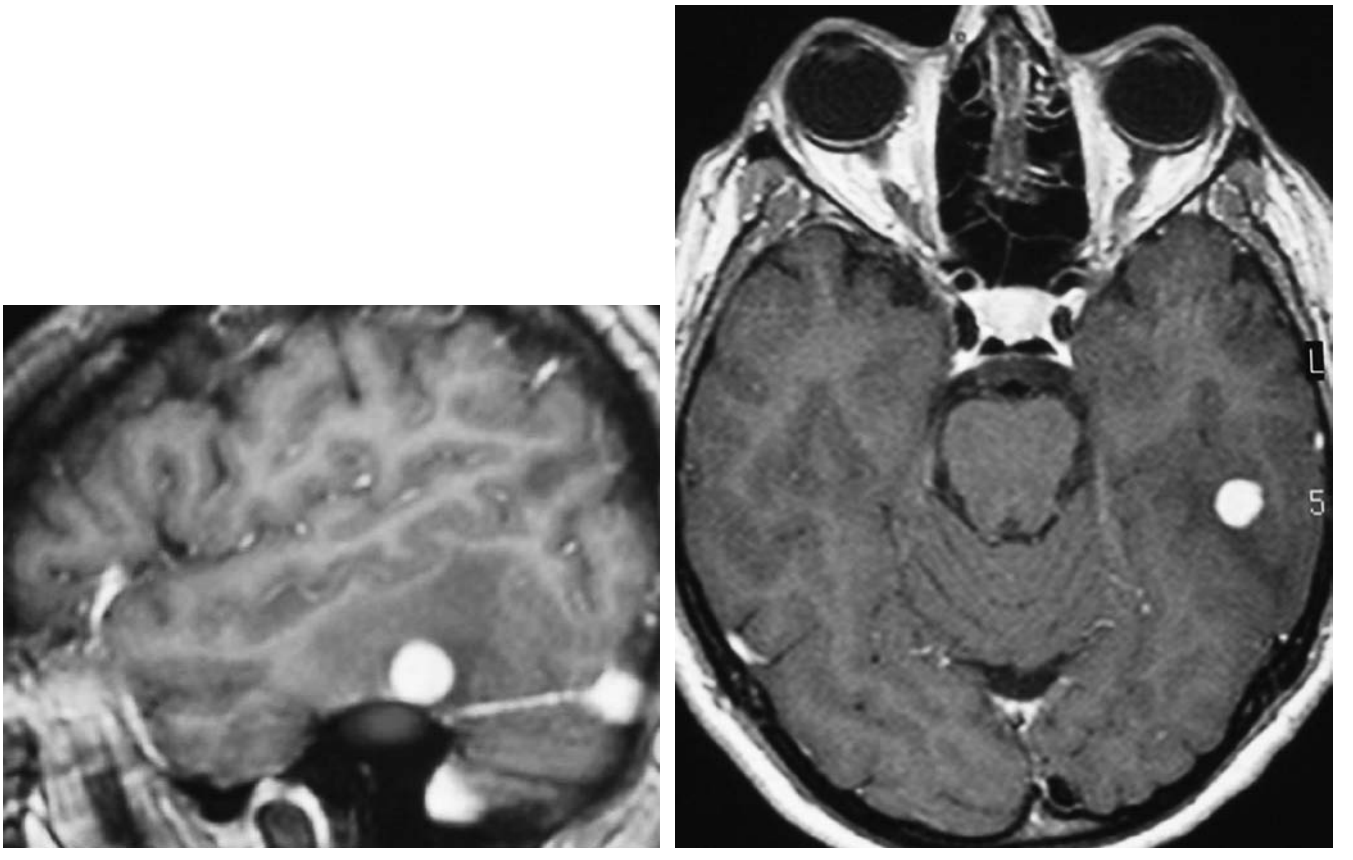
Morphology and imaging

On imaging, the tumor presents as a usually very large cyst with an associated solid component adjacent to the leptomeninges containing the desmoplastic tissue.[76,79,80] The mass shows a predilection to the frontal or the parietal lobes and tends to spare the occipital.[81,82] The solid portion is iso- to hyperdense to gray matter on CT and is isointense to gray matter on T1-w and T2-w images on MR, enhancing intensely after contrast infusion, except for the walls of the cystic component.[82] Desmoplastic neuroepithelial tumors should be differentiated from cystic astrocytomas and pleomorphic xanthoastrocytomas, the latter presenting similar imaging features but being found most frequently in adolescents and young adults, peripherally in the hemispheres and usually in the temporal lobe. Cystic astrocytomas are differentiated by the hypodense appearance of its solid component on CT and its long T2 signal intensity on MR.

Hypothalamic hamartomas

Hypothalamic or tuber cinereum hamartomas, are benign rare congenital slow-growing processes. Composed of disorganized heterotopic neuroepithelial cells, they are considered as non-neoplastic heterotopias. Found inferior to the hypothalamus originating usually from the tuberal region between the pituitary stalk and the mamillary bodies, or from the mamillary bodies.[83] There is no sex predilection.[84,86]

The clinical presenting signs, usually present when tumor size exceeds 10 mm, are most frequently isosexual precocious puberty observed before age 2, whose pathogenesis is unclear, and less commonly gelastic epilepsy and hyperactivity.[83,86–89] The characteristic gelastic seizures, although infrequent, result in spasmodic laughter. Many other types of seizures may be observed, partial complex, partial motor, atypical absences or even infantile spasms. Seizures would be mostly encountered with intrahypothalamic masses.[88,90–92] Interconnections



(a) (b)

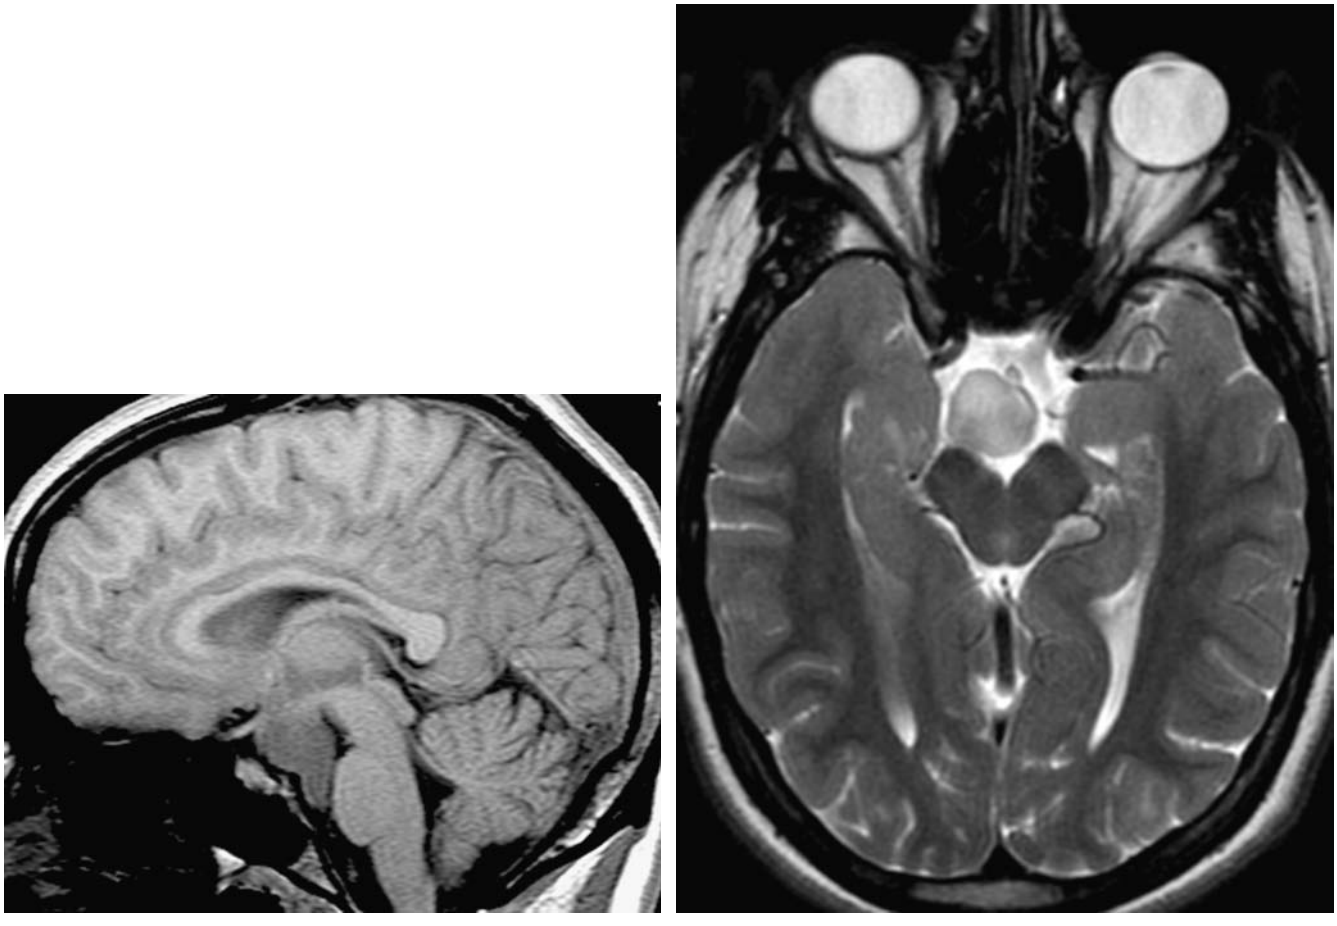
Figure 84.3 Ganglioglioma. Young adolescent male showing a well-demarcated rounded cortical-subcortical process involving the fusiform and inferior temporal gyri. The mass is homogeneously enhanced after contrast administration (a, b). Mass effect and edematous associated changes are mild (a) limited to an aspect of moderately expanded gyri with adjacent sulcal effacement.

between hamartomatous neurons to the limbic lobe could be one of the underlying causes generating seizure activity.[85] Precocious puberty was present in 2/3 of patients and almost 50% presented gelastic or generalized seizures and behavioral disorders.[83,87,89,92] Mental retardation is often associated in children.[86] Diabetes insipidus, growth hormone secreting pituitary adenomas and obesity may be associated.[83,93] Facial anomalies, heart defects or Laurence-Moon-Biedl syndrome have been reported as additional associated malformations. Presence of postaxial polydactyly suggests an autosomal dominant disorder, Pallister-Hall syndrome.[94,95] Tumoral excision may improve patients with medically refractory seizures.

Morphology and imaging

Hypothalamic hamartomas are solid well–demarcated neoplastic processes of neuronal tissue, attached to the floor of the third ventricle posterior to the pituitary stalk. They are usually pedunculated, best shown on coronal cuts or sessile demonstrated on midsagittal cuts. They usually extend toward the suprasellar or the interpeduncular cisterns. They vary in volume from several millimeters to few centimeters. Very rarely the mass appear calcified but show no intratumoral hemorrhage.[99] Typically the neoplasm does not infiltrate the adjacent neural tissues. Associated brain abnormalities may be found in the pediatric population such as callosal dysraphism, heterotopias, polymicrogyri.[86,87] A clinical-topographical classification proposed, with a type I (a and b) concerning small pedunculated masses attached to the tuber (Ia) or the mamillary body (1b), usually asymptomatic or presenting with precocious puberty, and a type II (a or b) in sessile hamartomas, larger than 1.5 cm associated with gelastic epilepsy.[100]

Axial CT usually fails to depict small sessile hamartomas attached to the floor of the third ventricle. Those visible are isodense to brain and well demarcated.[96] Sagittal and coronal cuts using MR improve the diagnostic capability even in very small tumors. MR shows more characteristic imaging features (Figure 84.4). The hypothalamic mass is well delineated, round or ovoid, attached to the floor of the third ventricle or extending into its cavity. Its signal intensity is roughly similar to gray matter. Hypothalamic hamartomas are homogeneously isointense to gray matter on SE-T1w sequences becoming slightly more hypointense on GE-T1w images with IR-preparation. The tumors appear slightly hyperintense to brain on PDw sequences. On T2-w images hamartomas are moderately hyperintense or may remain isointense to brain in about 1/3 of the cases.[85,98] The mass may appear heterogeneous, showing a hypointense central area on T1-w images and a hyperintense central area on T2-w images, surrounded by an isointense peripheral rim. MR spectroscopy tends to show a slight increase of the myoinositol peak and a small decrease of NAA peak, lower than within the thalami.[98] Large cystic formation may infrequently be found. Calcifications may be found. Hypothalamic hamartomas as a rule do not enhance.)[85] Hypothalamic glioma should be considered in the differential diagnosis.



(a) (b)

Figure 84.4 Hamartoma of the tuber cinereum. Huge well-delineated and pedunculated hypothalamic mass attached to the tuberal region of the floor of the third ventricle, between the pituitary stalk and the mamillary bodies as evidenced on the midsagittal T1-w cut (a) and developing within the interpeduncular and the upper prepontine cisterns. The tumor is homogeneous and roughly isointense to gray matter on T1-w (a) and slightly hyperintense on T2-w (b) sequences. The mass did not show any contrast enhancement.

Cortical hamartomas

Corticosubcortical hamartomas are formed of mature but disorganized ganglion and glial cells. Discovered in patients presenting epilepsy but with a normal neurological examination. Usually solitary, brain hamartomas are commonly located in the mesial temporal lobe and may involve the hippocampal formation or in the frontal lobe. They are well-circumscribed masses with no mass effect on the adjacent cortex or sulci. Cortical dysplasia is often associated.[17,18] The main differential diagnosis is the ganglioglioma. On MR imaging the lesion is usually homogeneous, isointense to gray matter on T1-w images, iso- to slightly hyperintense on T2-w images and becomes more or less hyperintense to gray matter on FLAIR sequences. A rim of hypointensity may be observed on T2-w surrounding the hyperintensity.[99] The tumors generally do not enhance.

Developmental cysts

Arachnoidal mesial temporal cysts of developmental origin are usually found incidentally and infrequently in patients referred for seizures. These smoothly marginated cysts are commonly found within the choroidal fissure which appear enlarged. The size of the cystic mass is variable and may be associated with variable mass effect upon the hippocampus. The cyst is well-delineated, ovoid in shape, fluid-filled, showing an homogeneous isointense signal intensity to CSF on all sequences. It never shows any peripheral contrast enhancement (Figure 84.5) but must be differentiated from cystic tumors arising in the mesial temporal lobe.

Neuroimaging of primary brain gliomas

The overall incidence of intracranial tumors is estimated to reach 5 individuals per 100 000 population per year. The rate of brain tumors is much higher in older patients reaching roughly 40% per year per 100 000 population after age 80. Primary brain tumors represented by the gliomas correspond to almost half of all primary intracranial tumors in adults and roughly two-thirds of these in children less than 15 years old. Metastatic tumors, rare in childhood, represent in adults roughly 1/4 of all intracranial tumors in autopsy series. There is a topographic difference between intracranial tumors found in adults, and children. Almost 70% of brain tumors are supratentorial in location in adults, whereas roughly 70% are found in the posterior fossa in children.

Elements of histopathology and classification

Gliomas may be divided into astrocytomas, oligodendrogliomas, and ependymomas corresponding respectively to the three types of glial cells, the astrocytes, oligodendrocytes, and the ependymal cells. Almost 5% of these neuroglial tumors are of a mixed type or 'mixed gliomas'.

Astrocytic tumors or 'astrocytomas' may be subdivided into five clinicopathological categories: 1) Diffuse astrocytomas representing more than 60% of all primary brain tumors are subdivided into three groups: low-grade diffuse astrocytomas (WHO grade II), anaplastic astrocytomas (WHO grade III), and glioblastomas multiforme (WHO grade IV); 2) Pilocytic astrocytomas (WHO grade I) found in childhood and usually circumscribed; 3) Pleiomorphic xanthoastrocytomas (WHO grade II) but showing some 'malignant' features on conventional criteria and usually circumscribed; 4) Desmoplastic astrocytomas, mixed neuronal-glial tumor, found in infancy; and 5) Subependymal giant cell astrocytomas typically found in tuberous sclerosis and usually circumscribed. The relationship with the neuroimaging aspect is critical as high grade astrocytomas show an enhancing core that may be necrotic centrally with surrounding edema. The enhanced part of the tumor correlates with neovascularity, hypercellularity and mitotic activity. Tumoral cells are found within the surrounding edematous area at least over 2 cm from the enhancing tumoral margin.

Oligodendroglial tumors or 'oligodendrogliomas' are subdivided into: (1) oligodendrogliomas (WHO grade II) and (2) anaplastic oligodendrogliomas (WHO grade III).

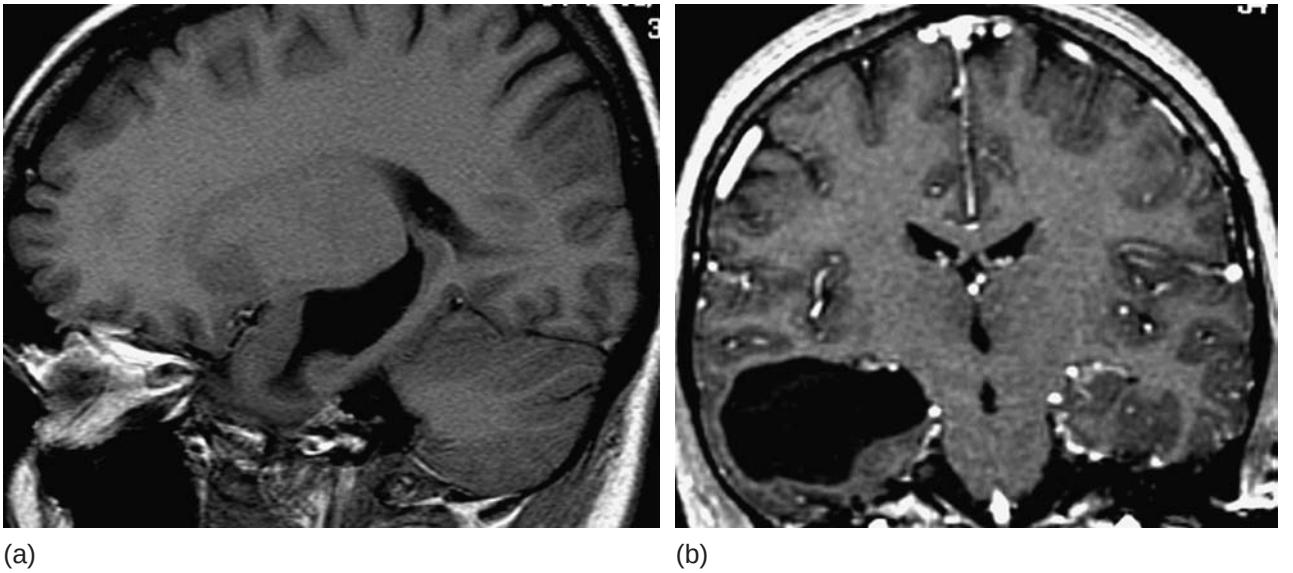
Mixed gliomas correspond to tumors showing a mixture of neoplastic astrocytic and oligodendroglial components. This pathological entity may be subdivided into two groups: (1) oligoastrocytomas (WHO grade II) more frequent of both varieties and (2) anaplastic oligoastrocytomas (WHO grade III).

Signs and symptoms

Patients with brain tumors may present variable neurological syndromes such as: generalized impairment of intellectual function with variable mental changes including emotional lability, inertia, psychomotor reduction, disturbance of memory, spatial disorientation and behavioral disorders; syndrome of increased intracranial hypertension with headaches usually mild, nocturnal and/or worse in the morning and of the pulsatile type, commonly bifrontal and bioccipital, accompanied by vomiting in almost 1/3 of the cases; generalized or focal seizures found in 20–50% of cases with the presence of an aura being suggestive and occurring most frequently in more than 2/3 of cases in slow-growing tumors as compared with fast-growing tumors in 30% of cases; specific neurological syndromes suggestive of specific tumors and localizations.

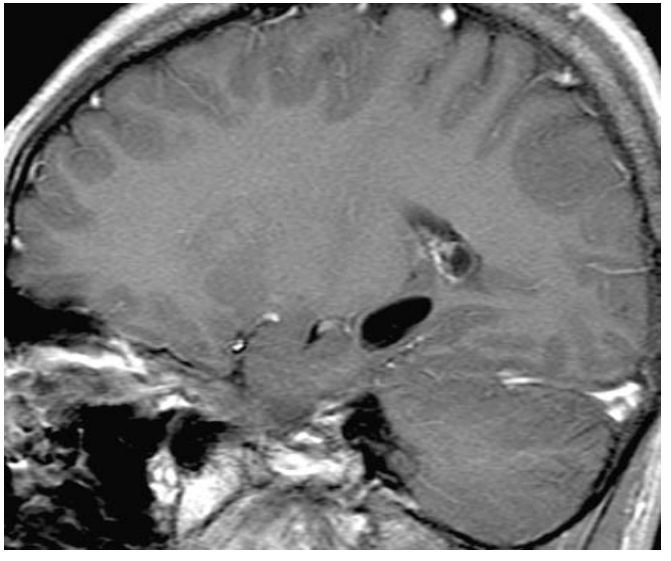
Low grade diffuse astrocytomas

Diffuse astrocytomas are poorly marginated neoplasms of varying potential which infiltrate the brain parenchyma. The appellation astrocytoma must be reserved to low-grade (WHO grade II) astrocytic tumors. These primary brain tumors account for 25–30% of all cerebral gliomas. The peak incidence occurs in young adults between ages 20 and 45 years in 60% of the cases (mean age of 34), after 45 years old it is about 30% and 10% before 20. They are unusual during the first decade and also in people older than 65. A slight male predilection is observed with a ratio M:F of 1.8:1. These are slowly-growing infiltrating tumors occurring anywere in the central nervous system but with a predilection to the cerebral hemispheres in adults following the path of white matter tracts without any associated significant damage, explaining the delayed symptomatology. These tumors are well-differentiated 'benign' but showing a great tendency for

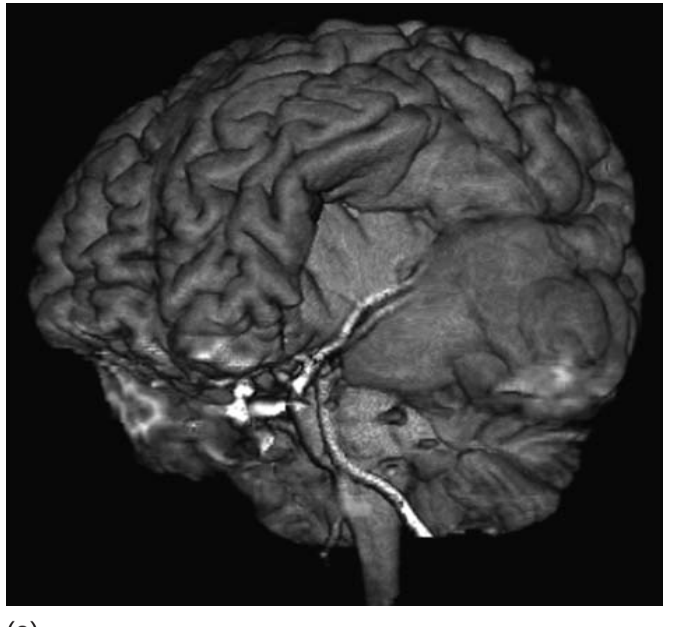


(a) (b)

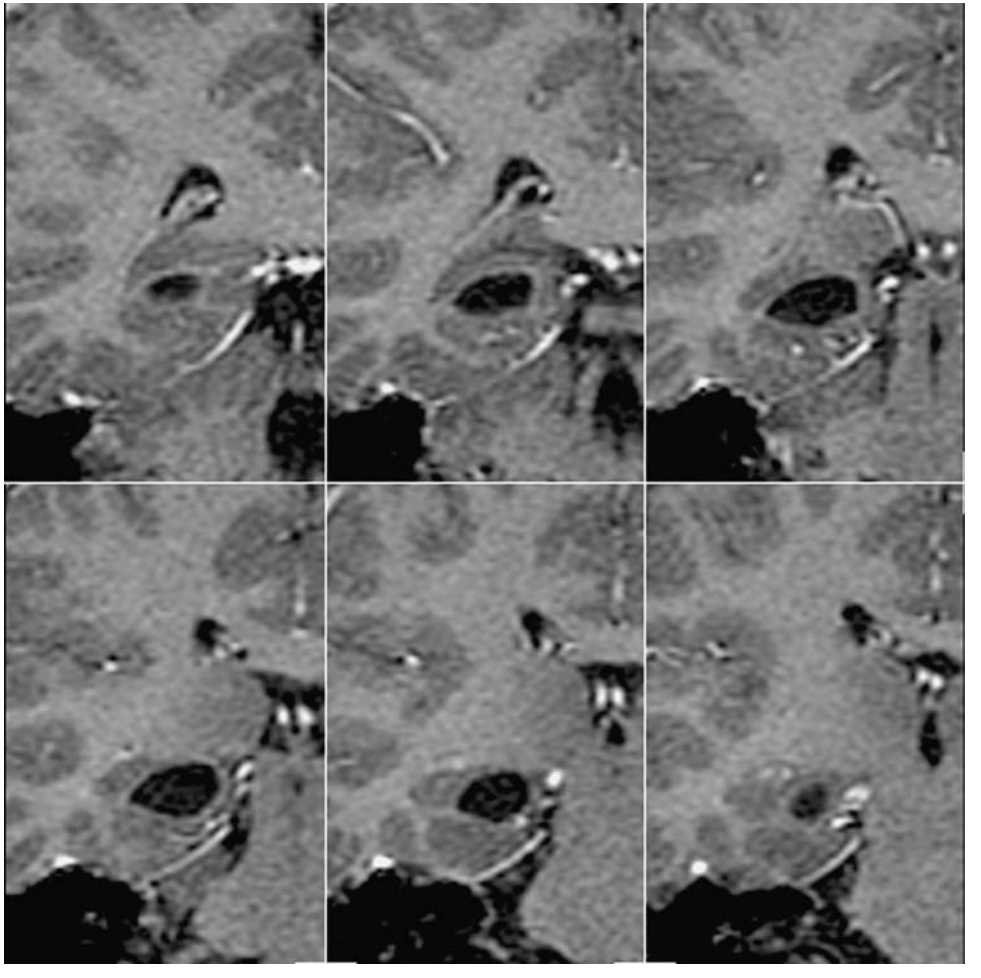
Figure 84.5 Developmental mesial temporal cyst of the choroidal fissure. Usually found incidentally and of small volume, arachnoidal cysts are found within the choroidal fissure. Commonly of small size, the cyst may be huge, as in this case, with significant mass effect on the hippocampal formation displaced superiorly and effacing the temporal lobe sulci. The cyst is smoothly marginated and appears isointense to CSF on all sequences. No contrast enhancement of the cyst wall and no mural nodule associated (b) as compared to T1-w precontrast parasagittal cut (a). Such cysts have to be differentiated from other cystic lesions that may develop in the mesial temporal lobe, such as glial parenchymal cysts, found in another patient with intractable epilepsy, arising in the white matter core of the parahippocampal gyrus expanded, with upward displacement of the body of the hippocampus.



(c)



(e)



(d)

malignant transformation or anaplasia. Many of these tumors show areas of different degrees of anaplasia.[100,102]

Histopathologically the tumors are formed of neoplastic astrocytes which are increased in number and size. Three major variants may be distinguished with respect to the related neoplastic cell type: (1) fibrillary astrocytomas, the most frequent variety formed of fibrillary astrocytes, elongated cells with little visible cytoplasm expressing GFAP; (2) gemistocytic astrocytomas, composed mainly of gemistocytic neoplastic astrocytes, plump cells with eosinophilic abundant cytoplasm expressing GFAP; (3) protoplasmic astrocytomas, a rare variant of stellate cells with small cell bodies and showing few or no stainable fibrils.

Morphology and imaging

Low-grade diffuse astrocytomas are commonly homogeneous infiltrating tumors, developed in the cerebral hemispheres in young adults or in children. They are found anywere in the cerebral hemisphere except in the occipital lobe. Ill-defined, they do not show clear-cut demarcation from the adjacent normal parenchyma as demonstrated on pathological specimen. It has been shown that the tumoral process due to its infiltrating nature may extend beyond the abnormality evidenced on imaging. The tumors tend to expand the anatomical structure involved which appear bulkier than normal or may infiltrate these structures without marked morphological changes or distortion of the normal anatomy. Occasionally invasion of the subarachnoid spaces may be shown but it is usually observed in case of malignant degeneration.

These low-grade tumors usually lack of peritumoral vasogenic edema due to a normal blood–brain barrier. Presence of cytotoxic edema is unlikely as well. There are no vascular flow voids within the tumoral process and no evidence of intratumoral hemorrhage or necrosis. Calcifications which occur in about 15–20% of cases are seldom evidenced on MR as compared to CT. On CT such tumors tend to be isodense to hypodense. Using MR, the tumor is homogeneously isointense to hypointense to white matter on T1-w images becoming typically hyperintense to cortex and brighter than CSF, almost homogeneously, on PD-w images and hyperintense to white matter on T2-w and FLAIR images (Figure 84.6). Proton spectroscopy demonstrates an increase in Cho levels, a decrease in NAA levels and a mild elevation of Cr, but with nearly absence of lipid resonance peaks.[101] Note that the spectrum of low-grade gliomas may be similar to normal brain. Low-grade diffuse fibrillary astrocytomas (WHO grade II) usually do not show contrast enhancement and this may constitute the so-called 'paradoxical' diagnostic imaging feature. Note that enhancement is common in the circumscribed partly cystic pilocytic astrocytomas (WHO grade I) involving the mural nodule as in pleiomorphic xanthoastrocytomas and as in higher grade anaplastic astrocytomas (WHO grade III) or glioblastomas (WHO grade IV). Enhancement may be demonstrated during the course of the disease, mainly with tumor transformation. Note that recurrent low-grade gliomas usually show a more malignant form. Approximately 50% of glioblastomas show evidence of a pre-existing lower-grade astrocytoma. Note that enhancements do not correlate adequately with the histological grade of the tumor because anaplastic astrocytomas show variable behavior, including patchy enhancement or faint enhancement, or even no enhancement. Only half of the low-grade astrocytomas with characteristic imaging features prove to be low-grade tumors.[102–104] The prognosis is variable as well because of frequent transformation into high-grade tumors either spontaneously or in recurrent tumors.

Pilocytic astrocytomas

Pilocytic astrocytomas, are circumscribed low-grade (WHO grade I) benign tumors, also called juvenile pilocytic astrocytomas or polar spongioblastomas.[72] They represent 2–6% of all primary brain tumors and are as frequent as low-grade diffuse astrocytomas in epilepsy surgery series. Most astrocytic tumors of childhood are pilocytic astrocytomas. These tumors are relatively slow-growing neoplasms with a relatively favorable outcome. They are found primarily in childhood with a peak age of presentation between 5 and 15 years old and an equal incidence in both sexes in most series. A slight female predominance has been reported in a ratio less than 4:3. Seizures are a common presenting sign.

Morphology and imaging

Pilocytic astrocytomas are well-circumscribed yet encapsulated tumors which usually do not invade nor infiltrate the adjacent normal brain tissue as do most astrocytomas, but tend to expand the brain parenchyma. Most of these tumors tend to develop a cystic component and may show calcifications in almost 25% of cases. The overall suggestive gross aspect of the tumor is described as a fluid-filled proteinaceous cyst with a mural nodule. The mural nodule may be round or plaque-like. The wall of the cystic component is surrounded by a non-neoplastic gliotic tissue. Tumors with a pure solid component are infrequent. Multilobulated cystic mass is a more common finding. The tumors are most commonly located in the cerebellum, hypothalamus, thalamus, brainstem, and cerebral hemispheres.

On CT, the mural nodule is usually isodense with eventually associated cytic component and calcifications. On MR, the tumor is isointense to white matter on T1-weighted sequences and hyperintense on T2-w. MR spectroscopy may show in addition a reduced NAA peak and an elevation of lactate and lipid levels.[105,106] An intense homogeneous or heterogeneous enhancement of the tumor or its mural nodule is a characteristic feature and is invariably present. Note that the walls of the cystic component usually do not enhance (Figure 84.7). Contrast enhancement helps to differentiate it from a diffuse low-grade astrocytoma. Conversely it may lead to an erroneous diagnosis of a high-grade astrocytoma, especially in the cerebral hemisphere due to the possibility of associated vasogenic edema.

Oligodendrogliomas and mixed gliomas

Oligodendrogliomas are glial tumors arising from oligodendrocytes, usually slow-growing and developing in the cerebral hemispheres with a duration between symptoms and surgery ranging from 2 to 7 years. The presenting sign is most frequently a focal or generalized seizure found in 50–70% of cases. Signs related to intracranial hypertension with headaches are found in about 1/5 of cases. About 30% reduction in seizure frequency is observed after surgery.[107,108]

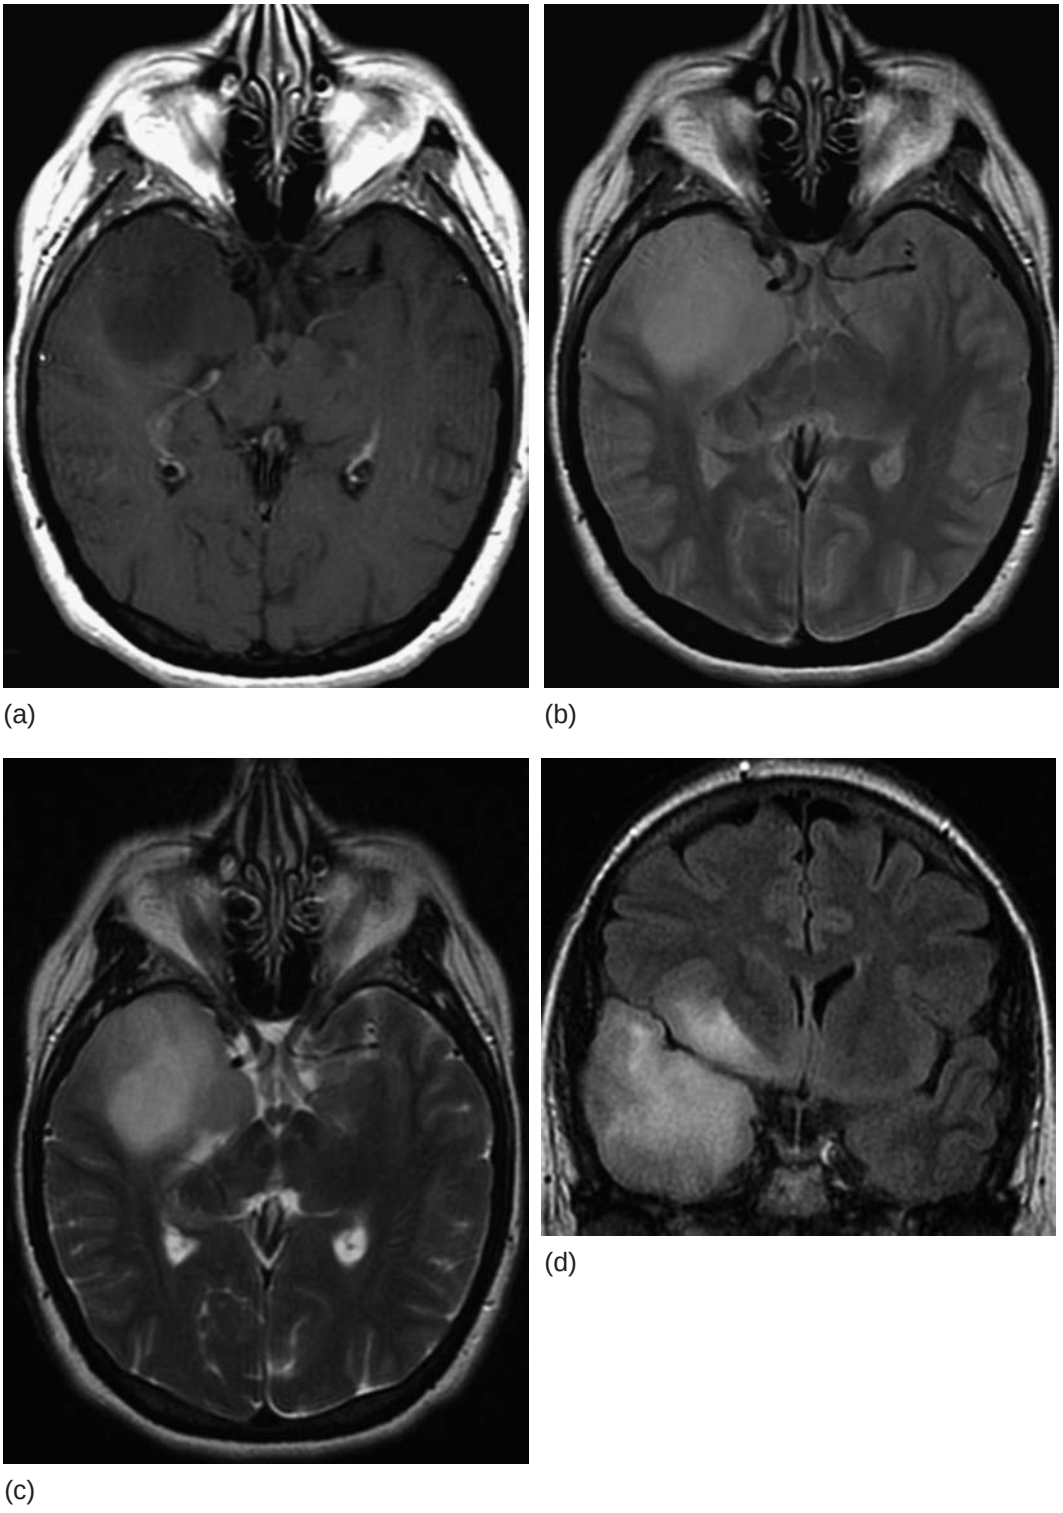

Figure 84.6 Low grade diffuse fibrillary astrocytoma (WHO grade II). MR shows a relatively well-demarcated temporal lobe mass expanding the pole with little associated edema and moderate mass effect on the mesial temporal region. The tumor is homogeneously hypointense to white matter on T1-w (a), hyperintense to gray matter on PD-w (b), T2-w (c), and FLAIR (d) sequences. The tumor infiltrates superiorly the sublenticular area and part of the insular lobe (d). No contrast uptake has been evidenced.

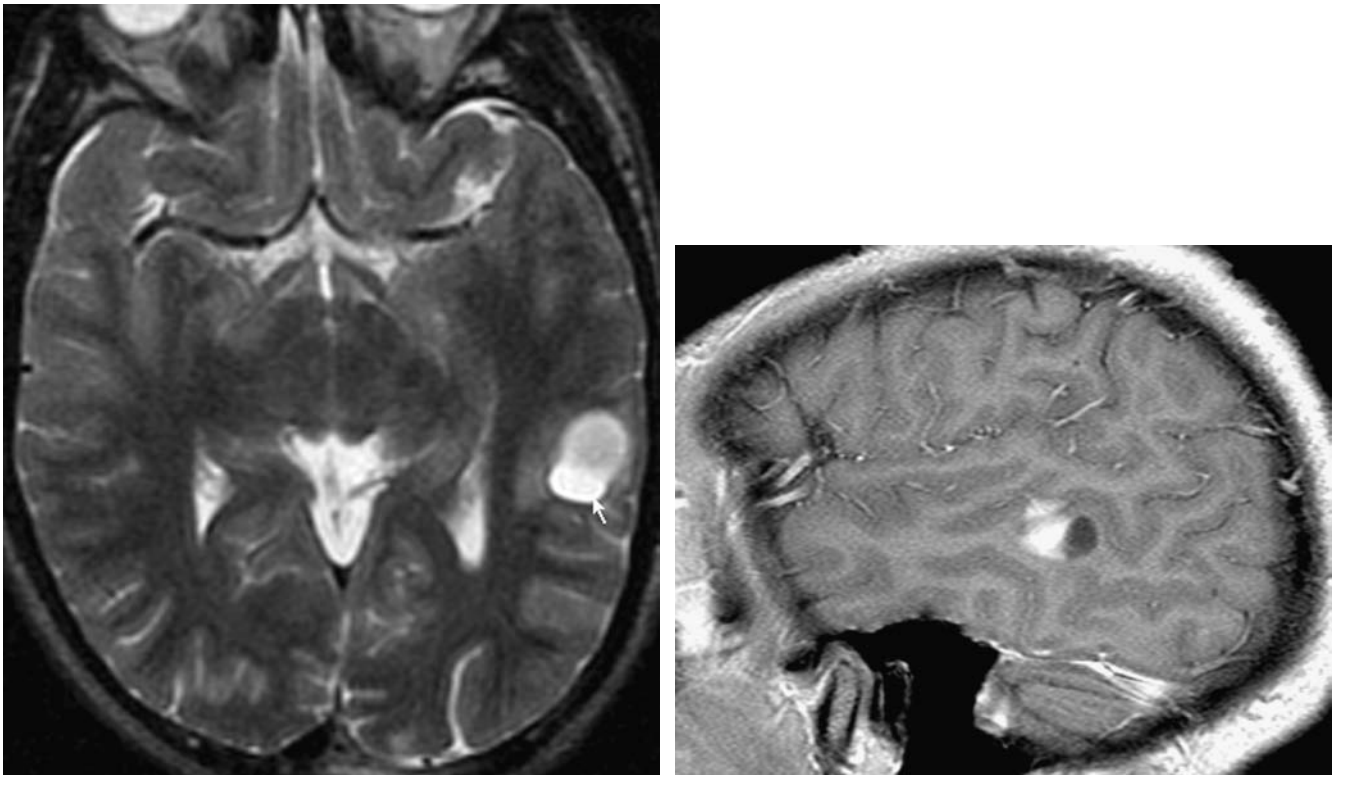
The overall 15-years, survival is about 25%[109] improving to reach almost 70% in the pediatric population.[108] Oligodendrogliomas are infiltrating usually well-defined tumors formed of cells resembling oligodendrocytes. Oligodendrogliomas account for 5–10% of all intracranial neoplasms and about 18% of all gliomas. They are found most commonly in adults in the fourth and fifth decades and are rare in infants or children found in about 6% of cases. A biphasic age distribution of 6–12 years and 26–46 years is found.[108,110] A slight male preponderance is observed with a 2:1 ratio.

Histopathologically, oligodendrogliomas correspond to WHO grade II in well-differentiated tumors and WHO grade III for anaplastic tumors. The Kernohan and Saint-Anne/Mayo classifications differentiate prognostically low-grade (1 and 2) from high-grade (grade 3 and 4) tumors. The classification is still debated. Oligodendrogliomas show a wide



(a) (b)

Figure 84.7 Pilocytic astrocytoma (WHO grade I). The tumor arising in the lateral temporal lobe demonstrates a characteristic cyst with mural nodule. The nodule is moderately hyperintense to the cortex on the T2-w axial image (a) and shows marked homogeneous enhancement on the T1-w lateral sagittal cut (b). Notice that the cystic component does not enhance with contrast.

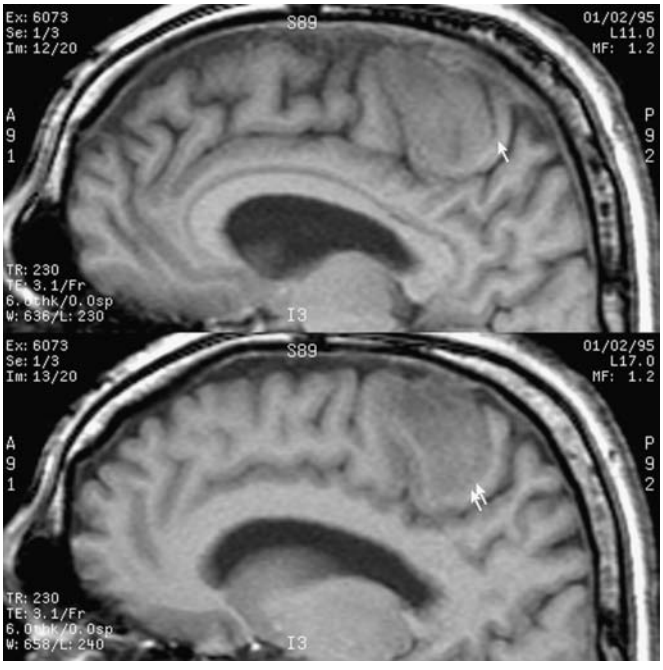
variation ranging from well–differentiated to highly malignant lesions.[111] Oligodendrogliomas are moderately cellular with a characteristic presence of intratumoral microcalcifications in 70% of cases which may also be found in the adjacent cortical area. Most neuropathologists require a preponderance of 75–90% of neoplastic oligodendrocytes within the tumor to be qualified as oligodendrogliomas, the remaining being considered as mixed gliomas.

Morphology and imaging

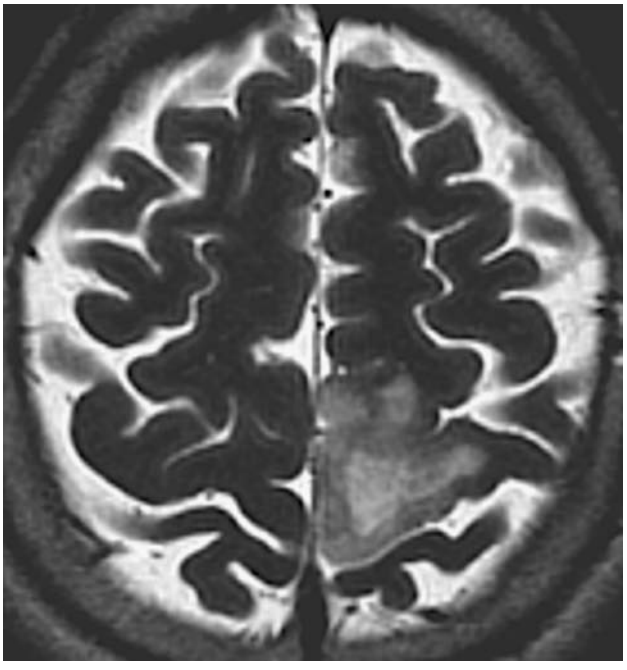
Oligodendrogliomas are supratentorial in location in 90–95% of the cases from which more than 50% up to 85% are located in the frontal lobe followed by the temporal, parietal and occipital lobes.[109,112,113] The tumors tend to progressively grow toward the cortex infiltrating and expanding the corresponding gyri in a nondestructive manner similar to low-grade astrocytomas rather than centrally infiltrating the corpus callosum. The tumors develop and spread similarly to astrocytomas through white matter which appears largely expanded before symptoms are produced. The importance of infiltration is usually more limited than in diffuse astrocytomas. Blurring of the gray-white matter interface is caused by the propensity to invade the cortex and even the leptomeninges with secondary desmoplastic reaction. This superficial extent and slow growth often causes a remodeling of the inner table of the skull observed in 17% of cases.[109] Meningeal gliomatosis and ventricular seeding are found in almost 10% of oligodendroglial tumors.[113] Oligodendrogliomas are commonly fairly well-circumscribed tumors with poorly defined boundaries, showing little peritumoral edema. Some may appear heterogeneous due to the intralesional presence of small cystic areas of degeneration (20%) and/or hemorrhages (20%) and / or calcifications (50–70%), the latter being best demonstrated on CT as dense or gyriform in shape commonly limited to the cortical areas and mimicking Sturge-Weber disease except that the brain is not atrophic. Calcifications may be to some extent depicted on MR using T2* gradient–echo sequences due to magnetic susceptibility, sensitive to the presence of iron frequently present within dystrophic calcifications. Most calcifications are isointense on T1-weighted and may become markedly hypointense on T2-weighted sequences.

Anaplastic oligodendrogliomas appear as diffusely infiltrating tumors much less demarcated than oligodendrogliomas, with increased associated edema and mass effect. Occuring in adults in their fifties, they are found in the frontal lobes in 60% of cases and in the temporal lobe in roughly 30%. Their estimated incidence is unsettled due to less defined criteria for grading ranging from 20–50%. A variable heterogeneous aspect is found owing to the presence of necrotic or cystic areas, hemorrhages and calcifications, similar to that observed in other anaplastic gliomas. This variety respond well to chemotherapy.

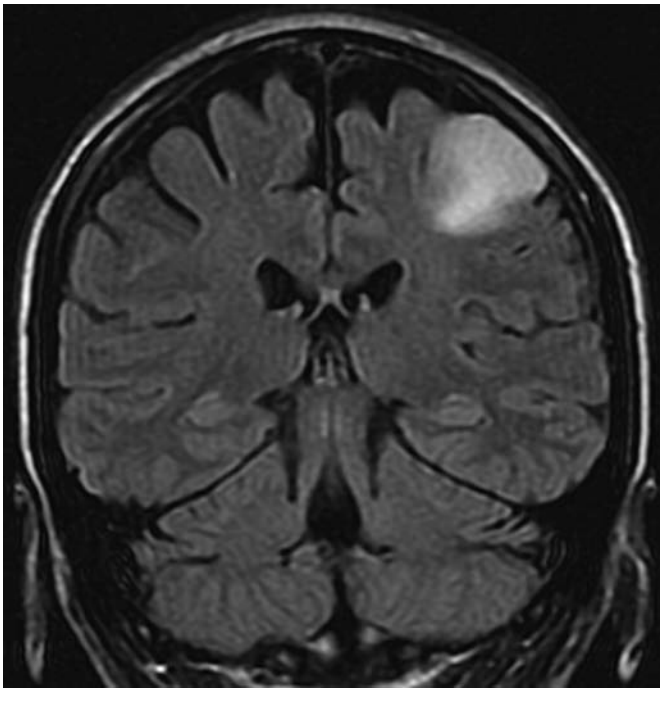
Mixed gliomas in which are demonstrated two neoplastic components are most frequently of the oligoastrocytic variety. These WHO grade II oligoastrocytomas are found in young adults with a mean age of 45 years, in the frontal and less frequently in the temporal lobes and show no significant imaging differences as compared to WHO grade II gliomas (Figure 84.8).



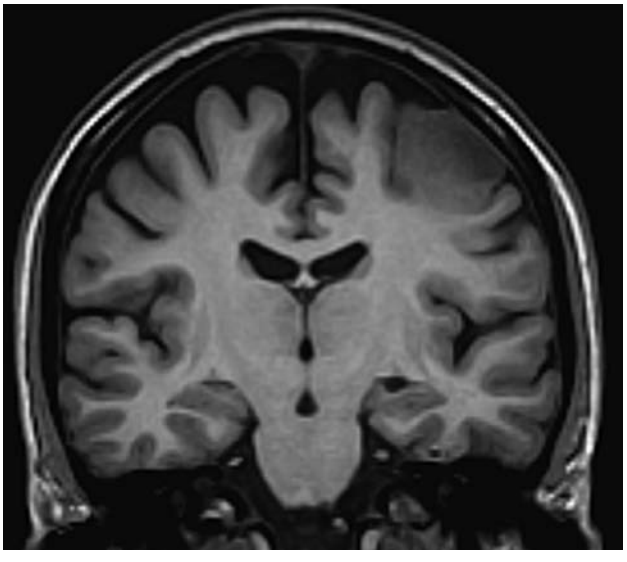
(a)



(b)



(c)



(d)

Figure 84.8 Mixed glioma (oligoastrocytoma, WHO grade II). Relatively well-delineated corticosubcortical tumor involving the superior part of the precentral gyrus extending medially into the paracentral lobule and anteriorly toward the superior frontal gyrus. The tumor is moderately hypointense to white matter on T1-w (a) images and appear roughly heterogeneous and moderately hyperintense on T2-w axial cuts (b). A slight sulcal effacement of the central sulcus is evidenced posteriorly. No associated edema not contrast enhancement were observed. The tumor is homogeneously hyperintense on FLAIR (c) sequence and best evaluated using 3D-T1w 2 mm contiguous slices acquisition (c) and volume renderings.

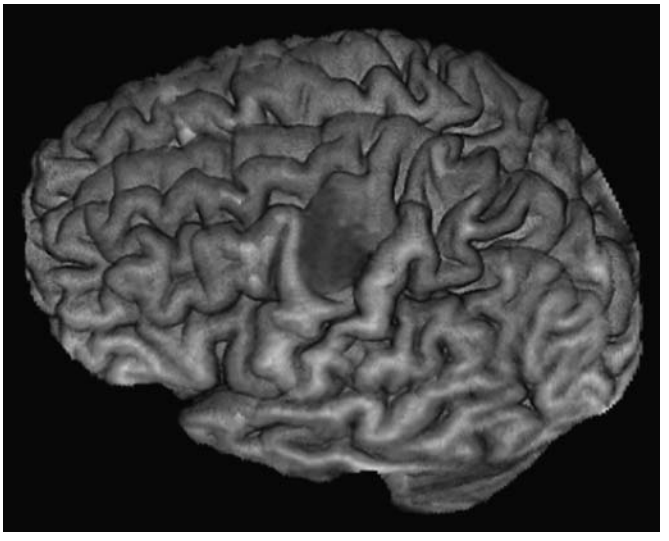


Figure 84.8 cont,d (e), Useful for presurgical planning, as shown in this other young patient with a mass expanding part of the hand unit of the precentral gyrus (c, d, e).

On CT oligodendrogliomas appear as well-circumscribed cortico-subcortical hypodense, partly calcified masses in about 40%, showing hemorrhagic areas in 20%, and presenting cystic formations in 20% of.[112,113] Sometimes a gyriform pattern of calcifications may mimic the changes observed in Sturge-Weber disease. On MR the tumor is remarkably hypointense to white matter or isointense to gray matter on T1-weighted images, hyperintense to cortex on PD-weighted images and hyperintense to white matter on T2-weighted or FLAIR images (Figure 84.9). In anaplastic oligodendrogliomas the aspect is more heterogeneous, showing small areas of necrosis. More infiltrating with a much less demarcated shape, they show a lower SI on T2-weighted sequences due to hypercellularity. Oligodendrogliomas may show contrast enhancement, usually mild and heterogeneous, reported in about 25% of cases on CT and almost 80% on MR.[111] Anaplastic oligodendrogliomas may show nonspecific irregular ring-enhancement patterns. Enhancement may have a negative correlation with patient survival.[114,115] In comparison with adults, oligodendrogliomas in children are less commonly calcified, enhance less frequently and show little peritumoral edema.[108]

Anaplastic astrocytomas and glioblastomas multiforme

Malignant astrocytic tumors are represented by the anaplastic astrocytomas (WHO grade III) nd the glioblastomas (WHO grade IV).

Anaplastic astrocytomas show a peak incidence in the fifth decade, with males more frequently affected than females with an almost 2:1 male-to-female ratio. They are slightly more frequent than low-grade fibrillary astrocytomas averaging 25% of gliomas. Almost 2/3 result from dedifferentiation of low-grade gliomas. The median survival averages 2.5 years. Histopathologicaly anaplastic astrocytomas are diffuse fibrillary astrocytomas of intermediate form showing on preparations focal areas of anaplasia involving roughly half the cells and focal or diffuse increased cellularity by 50% or more. They typically display mitotic activity. The microcystic changes found in low-grade tumors are lacking here. They may arise de novo or develop from low-grade tumors by malignant transformation.

Glioblastoma multiforme is the most frequent brain tumor in adults accounting for 50–60% of all astrocytic and 15–20% of all intracranial tumors. It is the most malignant of diffuse astrocytomas with a survival time of about 12 months. They usually arise as primary intracranial tumors but may develop as secondary tumors from low-grade diffuse or anaplastic astrocytomas. Glioblastomas are found at any age but most commonly in adults between ages 45 and 70 with/a mean of around 50 years old. They are rare in patients under age 30, with less than 3% reported.[117] The incidence in men is more frequent than in women, about 2:1. They are found most often in the cerebral hemispheres. Histopathologically the diagnosis of glioblastoma is based on the presence of anaplastic glial cells, frequent mitotic activity, endothelial proliferation and hypervascularity, found peripherally or around the necrotic zones. Frequent areas of necrosis are usually found in the center of the tumor. Apparent multicentric tumors are reported in as many as 5–15% of cases, presumably due to the presence of multifocal zones of anaplasia within a pre-existing low-grade diffuse astrocytoma.[116,118] Multiple glioblastomas are present as independent tumors in about 2.5–5% of cases.[118] Widening of the extracellular spaces through vasogenic edema facilitates spreading of the neoplastic cells.

Signs and symptoms: the clinical picture is similar in anaplastic astrocytomas to that presented in low-grade gliomas except for a shorter medical neurological history preceeding diagnosis and a higher mean age of 40 years old. The duration of the clinical history decreases dramatically in glioblastomas developed de novo, becoming as short as 3–6 months in almost half the cases as compared with those developing from pre-existing low-grade diffuse or anaplastic astrocytomas (4–5 years duration of the neurological history). In glioblastomas the symptomatology develops rapidly in a few weeks or months including generalized neurological symptoms and seizures followed by more definite lobar or callosal syndromes according to brain localization. The onset may even be sudden in 3–5%, pseudovascular in progression usually due to intratumoral hemorrhage or cystic formations within the tumor and leading to the development of focal cerebral signs. Glioblastomas show a very poor prognosis with less than 20% of patients surviving for 1 year and 10% beyond 2 years after the onset of clinical symptomatology. Younger patients, less than 45 years old, appear to have a better prognosis than the older presumably because of the higher frequency of secondary glioblastomas in such younger populations. Longer survival would be related to complete resection when possible.

Morphology and imaging

Anaplastic astrocytomas are morphologically often difficult to distinguish from low-grade astrocytomas but appear much more heterogeneous.[103,104] As in diffuse fibrillary astrocytoma the tumor shows tendancy to infiltrate the anatomical structures involved without obvious distortion except for a relative enlargement of the corresponding gyri or the basal ganglia. Vascular proliferation and necrosis are lacking. Occasionally proliferation of tumor vessels may be observed with flow void foci. Note that anaplastic astrocytomas are found in half the

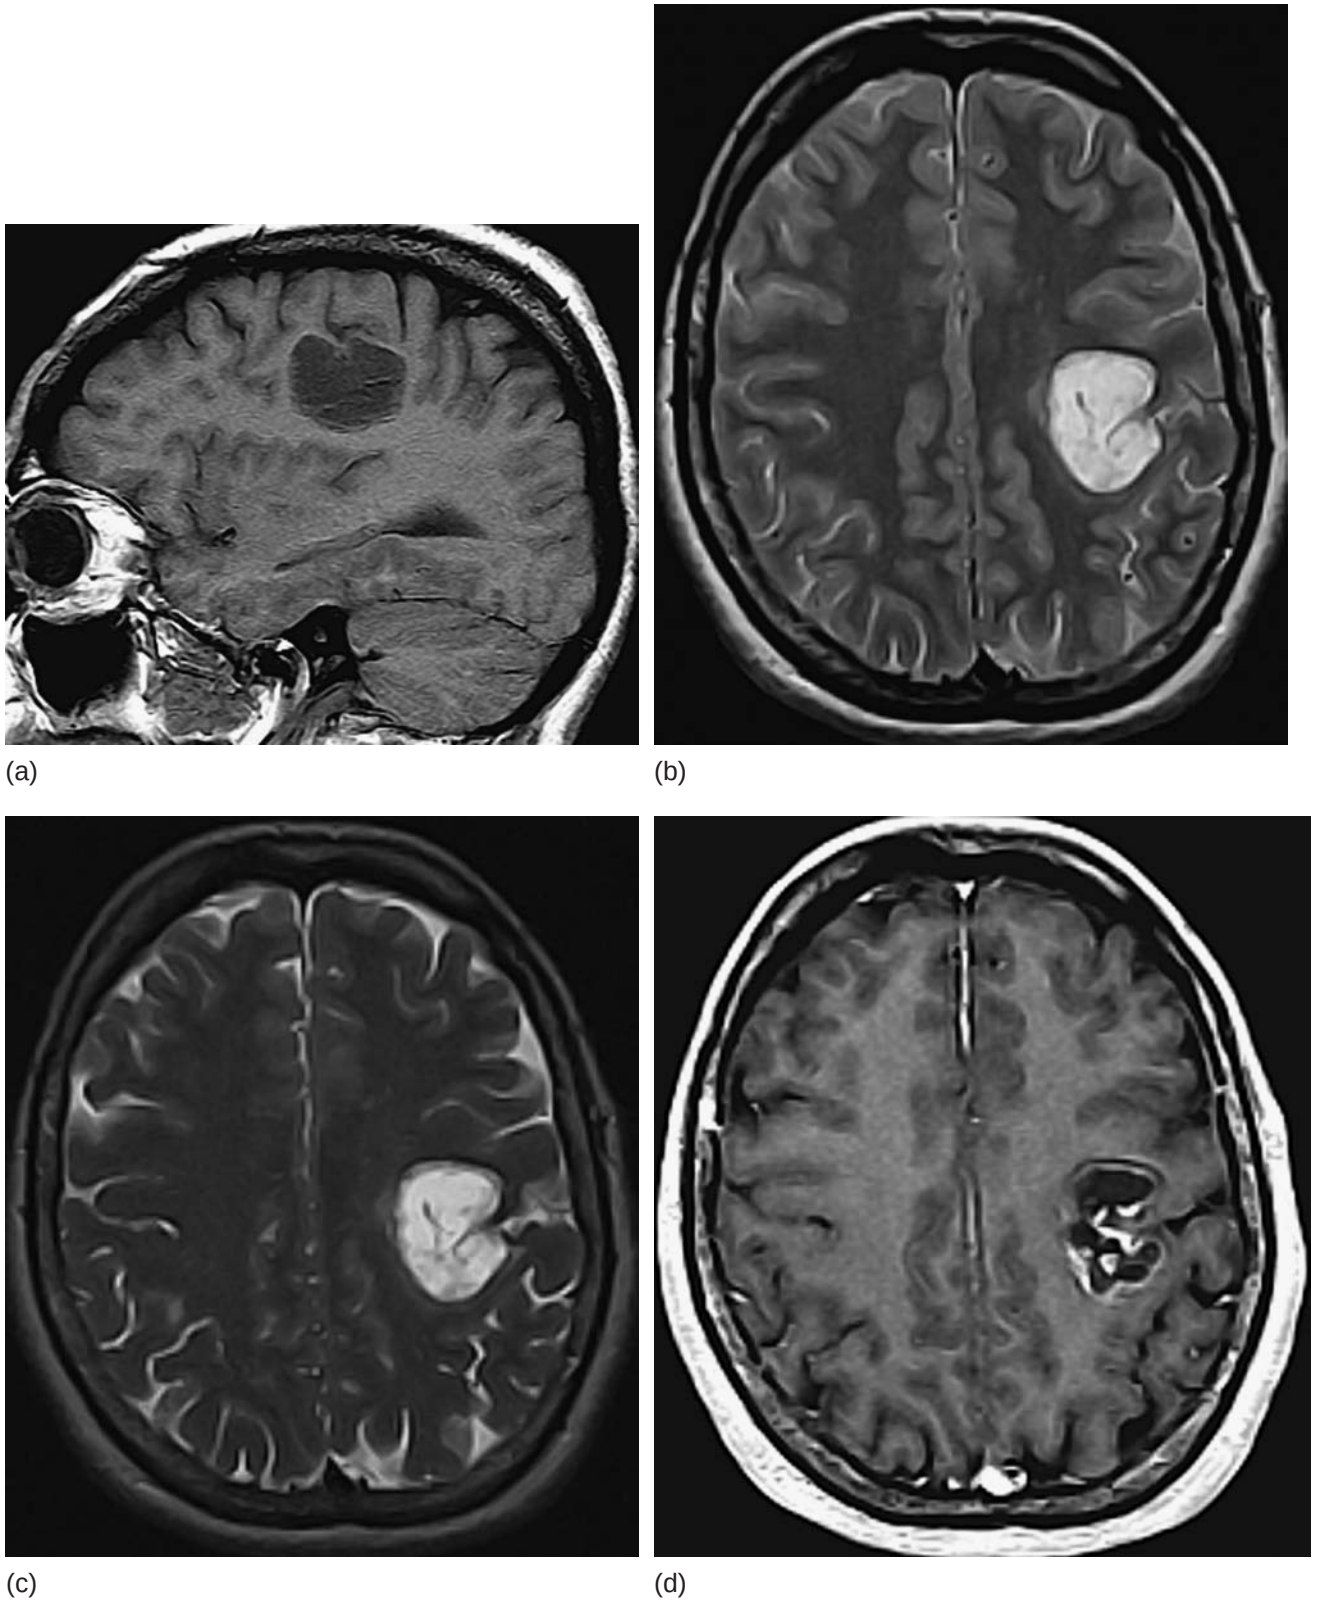

Figure 84.9 Oligodendroglioma (WHO grade II). Superficial fairly well-circumscribed mass developing in the central lobe within the subcortical white matter rand abuting the cortex. The tumor is hypointense to gray matter on T1-w sequence (a) and hyperintense on PD-w (b) and T2-w (c) sequences. Almost no mass effect, peripheral edema no intratumoral calcifications were evidenced. A peripheral contrast enhancement is noticed (d).

cases of recurrent tumors due to malignant transformation. Peritumoral edema and mass effect may be found but remain a feature of glioblastomas. Frank intratumoral necrosis is absent.

Anaplastic astrocytomas are usually heterogeneous tumors but may mimic a low-grade astrocytoma showing a homogeneous SI with slightly heterogeneous areas.[102,104] Hypointense to white matter on T1-w images the tumor is hyperintense to cortex on PD-w images and appear hetereogeneously hyperintense to white matter on T2-w images and FLAIR. Proton spectroscopy has been reported in anaplastic astrocytomas to show an increase of Cho levels, a decrease of NAA levels and presence of lipid resonance peaks. Anaplastic astrocytomas show variable patterns of enhancement ranging from homogeneous to even nodular or patchy (Figure 84.10). Very occasionally a 'ringlike' pattern is found. The latter is more suggestive of a glioblastoma and should not be observed in anaplastic astrocytomas.[103]

Glioblastoma multiforme, the most aggressive and least differentiated variety of gliomas, occur most commonly in the

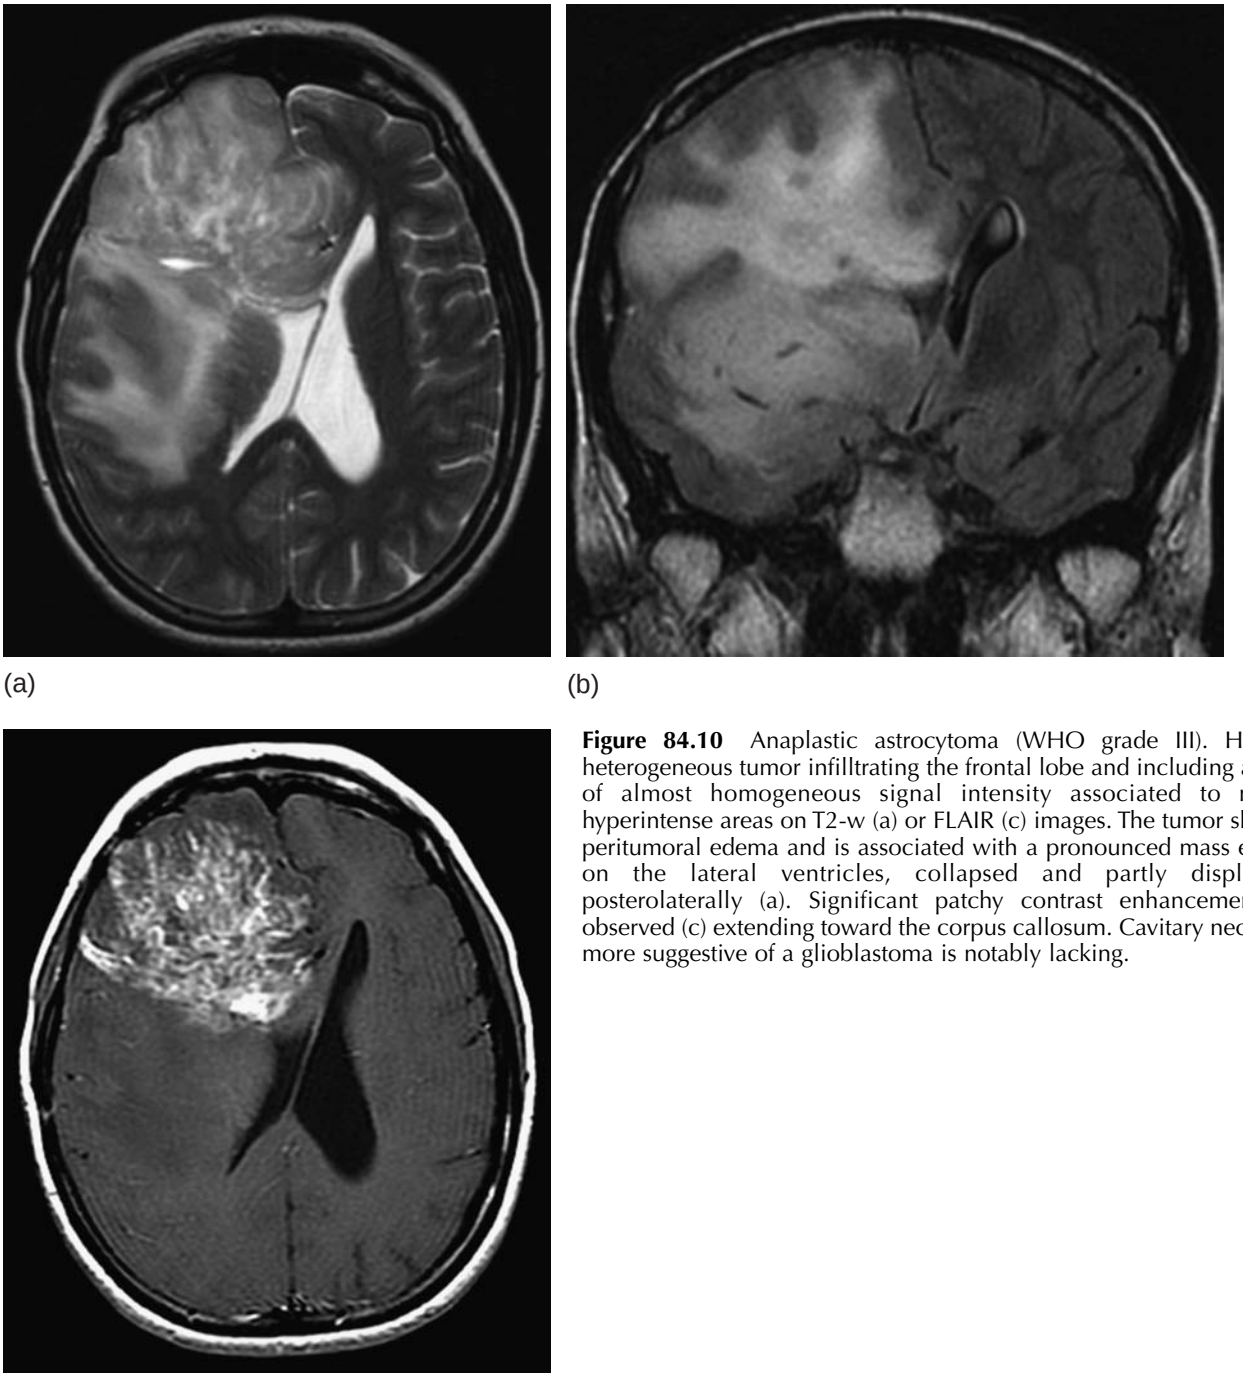

Figure 84.10 Anaplastic astrocytoma (WHO grade III). Highly heterogeneous tumor infilltrating the frontal lobe and including areas of almost homogeneous signal intensity associated to more hyperintense areas on T2-w (a) or FLAIR (c) images. The tumor shows peritumoral edema and is associated with a pronounced mass effect on the lateral ventricles, collapsed and partly displaced posterolaterally (a). Significant patchy contrast enhancement is observed (c) extending toward the corpus callosum. Cavitary necrosis more suggestive of a glioblastoma is notably lacking.

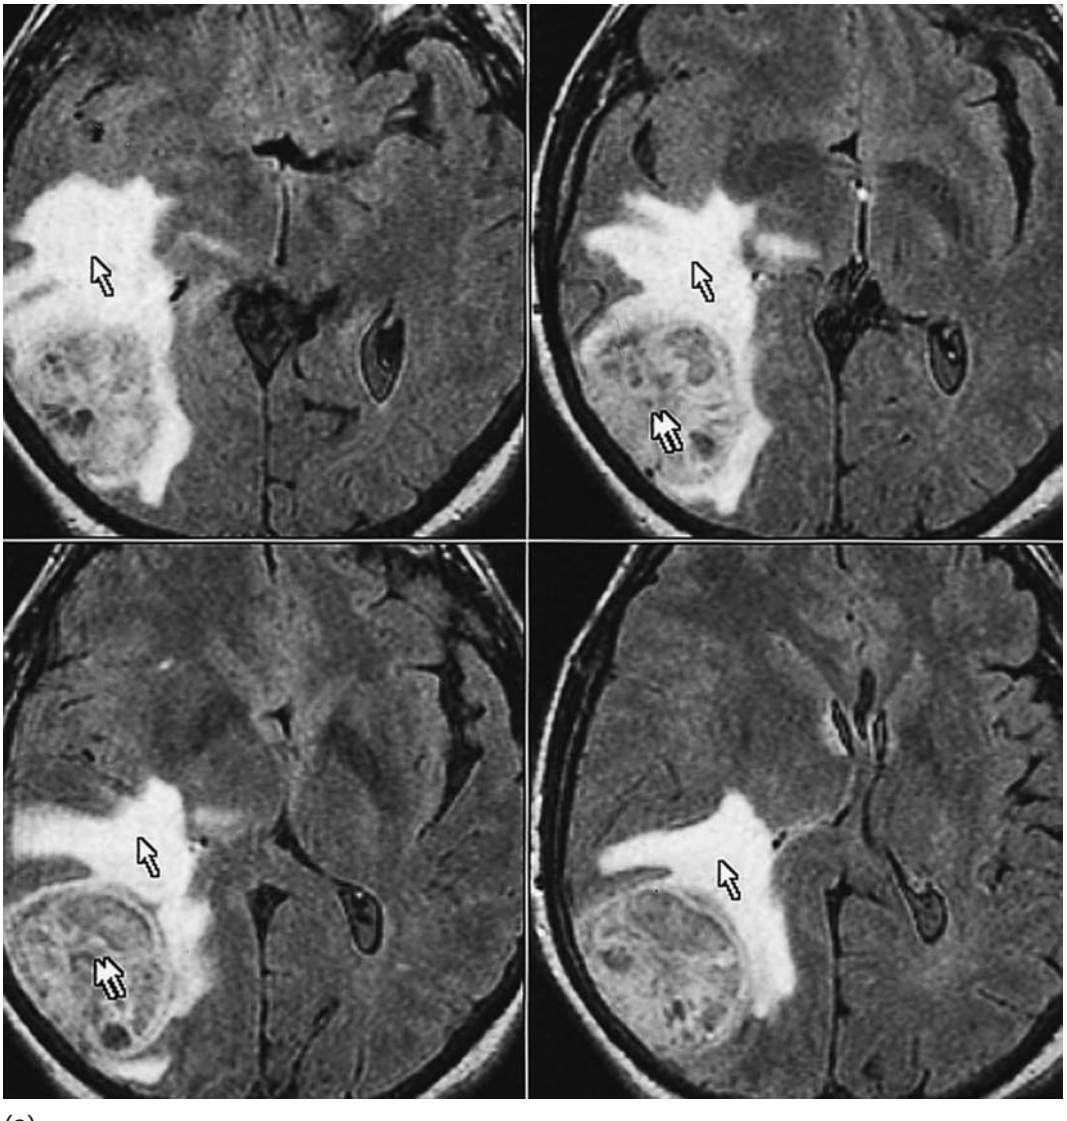
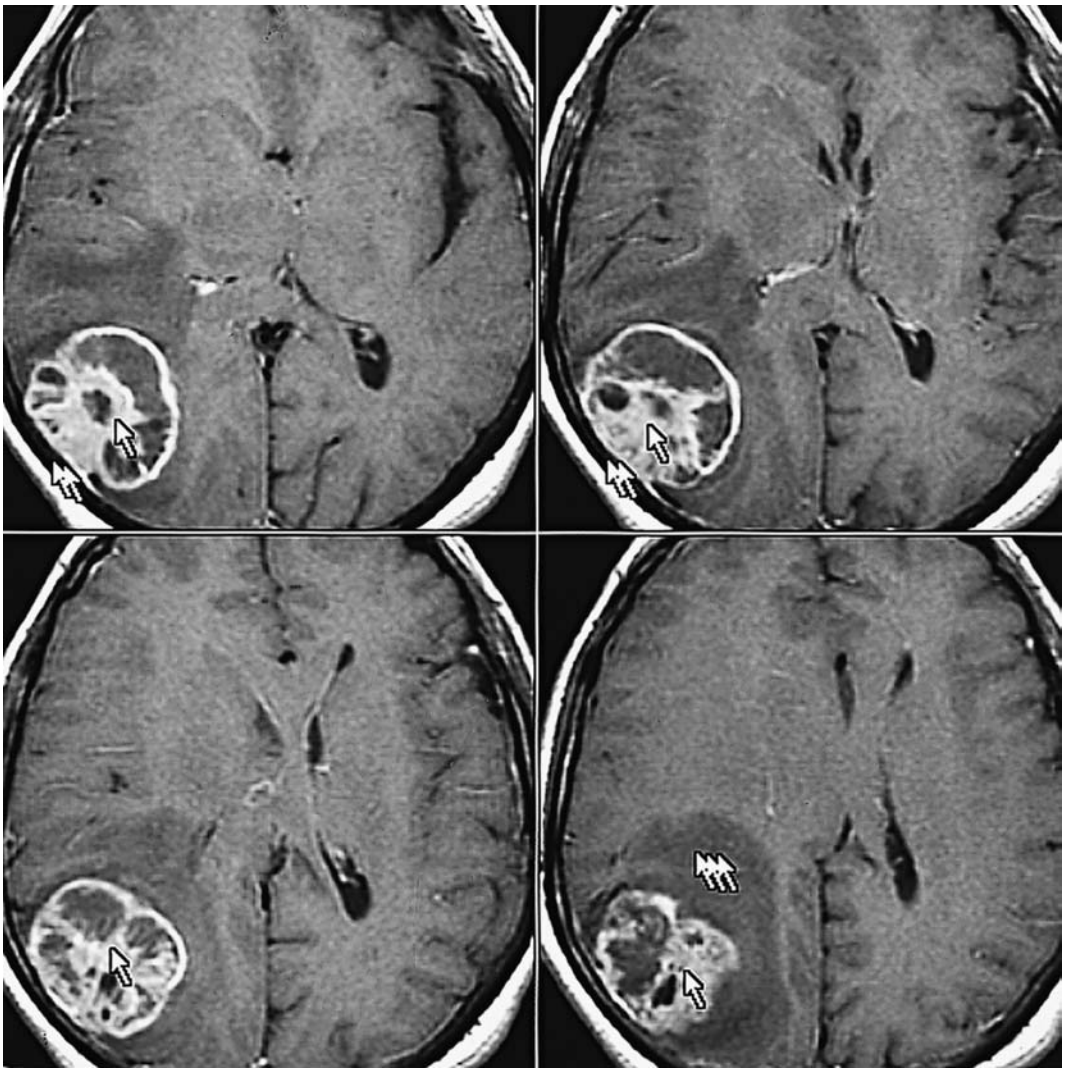
cerebral hemisphere located most frequently in the white matter, the epicenter of the tumor, of the frontal lobes, or temporal, and then parietal lobes. Some of these tumors are rather superficial in topography in contact with the leptomeninges and dura with possible subarachnoid seeding. Cortical infiltration may occur giving rise to a thickened appearance of gyri surrounding a necrotic area in the subjacent white matter. Glioblastoma commonly appear as an irregular almost well-circumscribed mass with highly suggestive central necrosis as compared to the anaplastic type, surrounded by relatively large areas of peripheral edema. The cellular peripheral zone is highly vascularized showing a microvascular proliferation corresponding to the zone of 'ring' enhancement. The large areas of intratumoral necrosis secondary to destruction of tumoral tissue may correspond to as much as 90% of total tumoral volume and appear as characteristic of primary glioblastomas, being absent in anaplastic astrocytomas. Hemorrhagic changes are common in the central portion of the tumor. Calcifications are very rare. Mass effect associated to peritumoral edema may be prominent with sulcal effacement or ventricular displacement or collapse. Sharply circumscribed tumors may be observed (Figure 84.11). Glioblastomas show a high propensity to rapidly expand along the white matter tracts to invade adjacent areas of the cerebral white matter or spread in the internal capsule or the fornix. This pattern of spread is facilitated by widening of the extracellular spaces through vasogenic edema. The tumor may also typically extend through the corpus callosum in almost 75% of cases and even cross the midline to reach the contralateral hemisphere with a 'butterfly' appearance. The latter aspect may also be encountered in lymphomas except that lymphomas exhibit a hypointense SI on T2 due to their hypercellularity. Glioblastomas may show subependymal or leptomeningeal spread in 5% of cases, best demonstrated after contrast enhancement.

Glioblastoma multiforme are markedly heterogeneous tumors showing on T1-w images a heterogeneously hypointense signal intensity to white matter with even more

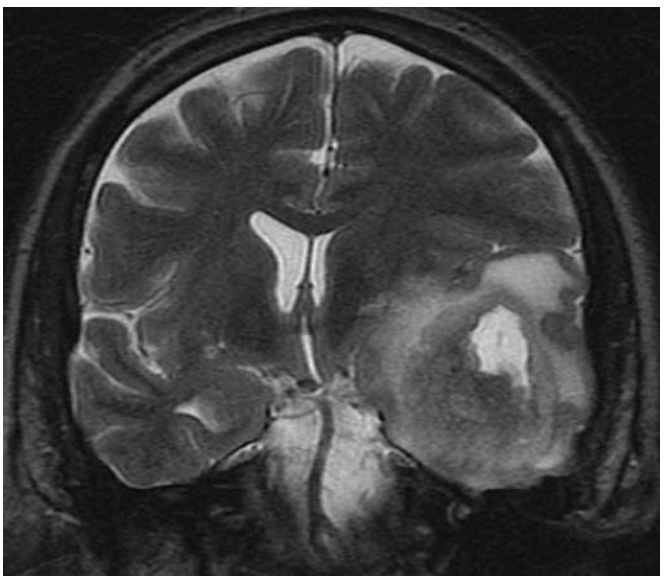


(a)

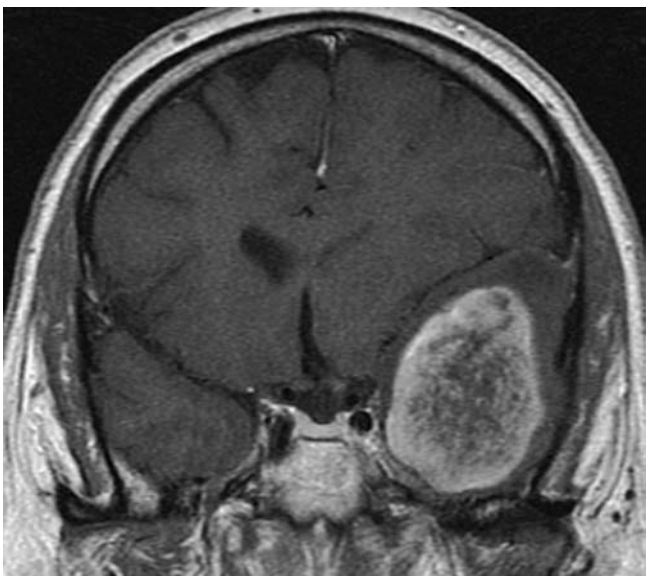
Figure 84.11 Glioblastoma multiforme (WHO grade IV). Highly heterogeneous aggressive tumors, appearing as almost-circumscribed, arising in the white matter of the temporal lobe, including areas of cavitary necrosis, which is the hallmark of glioblastomas as compared to anaplastic astrocytomas (a,b).



(b)



(c)



(d)

Figure 84.11 cont'd The tumor is heterogeneously hyperintense on FLAIR sequence (a, double arrows) showing a prominent enhancement (b, arrow) with an irregular ringlike pattern after Gd administration (b). Peritumoral vasogenic edema is pronounced (a, arrow and b, triple arrows) with important mass effect on the adjacent ventricular atrium almost collapsed and displaced anteriorly and medially. Extension to the leptomeninges (b, double arrows) and adjacent sulcal effacement may be observed as well. The tumor aspect may be misleading and appear as a well-circumscribed more homogeneous mass roughly well separated from the vasogenic edema as in an other patient (c,d).

hypointense intratumoral necrotic zones, unless including hemorrhagic areas which may be hyperintense due to the presence of paramagnetic methemoglobin. On PD-w images the tumor is hyperintense to white matter with areas of central necrosis that could show a more hyperintense SI than the solid part due to its high protein content and the presence of blood breakdown products such as extracellular methemoglobin, surrounded by extensive peritumoral vasogenic edema. T2-w images show a variably heterogeneous signal intensity of the solid portions of the tumor that may be mildly hyperintense to brain and/or may show iso- to hypointense areas due to tumoral hypercellularity. Serpentine fow void structures corresponding to vessels related to tumoral angiogenesis are also found. FLAIR sequence shows mild hyperintensity to normal brain tissue with variable intensity of the intratumoral necrotic areas associated to markedly hyperintense SI of the peritumoral vasogenic edema. Tumors may show a well-circumscribed appearance roughly well separated from the vasogenic edema (Figure 84.11). Proton spectroscopy has been reported in glioblastomas to show an increase in Cho levels, a decrease in NAA and the presence of peaks of lactate and lipids. A significant correlation has been observed between higher grade glial tumors and mobile lipid resonance peaks at 1.3 ppm. Glioblastoma multiforme always show a heterogeneous enhancement more sensitive with MR than with CT. Most commonly the enhancing pattern is irregular, ring-like, highly heterogeneous with variable thickness and a shaggy inner margin more conspicuously shown with delayed scans, surrounding the area of necrosis which do not enhance. Contrast enhancement correspond to the tumoral process but do not delimitate the outer tumoral boundary as shown on pathology. The nonenhancing surrounding edema has been demonstrated to include microscopic tumors. The extent of such microscopic adjacent peritumoral zone appear to be usually limited to 2 cm, an area which corresponds to the zone of tumor recurrence as observed in more than 85% of cases. It may extend to more than 2 cm and exceed 3 or 3.5 cm in 17–27% of cases according to imaging studies with pathological correlations to stereotactic biopsies.

The imaging aspect may mimic other malignant tumors such as anaplastic oligodendrogliomas, metastases, lymphomas, or other processes as radiation necrosis, cerebritis and abscesses. An abcess typically shows hypoperfusion as compared with high-grade gliomas which demonstrate a high perfusion. On diffusion-weighted images, abcesses show a bright signal intensity due to restricted diffusion, while necrotic areas of glioblastomas show a low or an isosignal on diffusion. On MRS the presence of a peak at 0.9 ppm corresponding to cytosolic amino acids is highly suggestive of an abcess. Note that Cho peak, the most specific marker of brain neoplasms may not be evidenced in tumors with significant necrosis. In lymphomas DWI shows similar high signal intensity. Hypoperfusion would be more suggestive of lymphoma probably due to elevated nucleus/cytoplasm ratios. MR spectroscopy will demonstrate the presence of suggestive significant high peaks in lipids associated to a decrease of NAA and Cr levels. Metastases may be differentiated and evidenced using MRS which demonstrates an almost absence of NAA and Cr peaks in the tumor and no elevation of Cho within the peritumoral area of vasogenic edema.[119] Conversely, high Cho levels peritumorally indicates infiltration of brain parenchyma by the tumoral process associated to edema. Radiation necrosis, eventually observed within 6 months, may demonstrate on multivoxel MRS similarly and with a greater sensitivity than PET, an increase in lipids and lactate peaks along with a decrease in Cho level or may show a normal spectrum.[47] Conversely in the case of elevation of Cho levels and Cho/NAA ratios in irradiated brain, tumor recurrence should be suspected.[46] Necrotic areas present in postradiation therapy or in postchemotherapy, show a drop in brain metabolites but an increase in lipids and lactate and disclose a large peak between 0 and 2 ppm related to cell necrosis. Note that administration of steroids may modify the absolute levels but do respect the ratio values of brain metabolites.

Pleiomorphic xanthoastrocytomas

Pleiomorphic xanthoastrocytomas, introduced in the 1993 WHO revision[53] are very rare circumscribed astrocytic tumors accounting for less than 1% of all gliomas and demonstrating marked cellular pleomorphism.[120] They are usually found in adolescents and young adults and children in the first or second decades with no sex predilection at a median age of 14 years old with a longstanding history of seizures, as in dysembryoplastic neuroepithelial tumors.[121–123] Pleiomorphic xanthoastrocytomas, classified as WHO grade II, are special variants of astrocytomas.[124] Considered as slow-growing low-grade tumors typically arising peripherally from the subpial astrocytes with predilection for a location within the temporal and parietal lobes, they may progress to a more aggressive behavior over time with transformation into a malignant glioma in more than 1/3 of cases.[125] Because of such potentiality the tumors are never better than grade II.

Morphology and imaging

Thought to arise from subpial astrocytes, the morphological aspect on imaging is suggestive. The tumor is characteristically a well-circumscribed peripheral mass showing cystic components with a solid mural nodule similar to the appearance of pilocytic astrocytomas and tends to develop at the surface of the cerebral hemisphere, often extending superficially to the pial surface of the brain which may show meningeal thickening and arachnoid spread in more than 2/3 of cases.[126] Cystic components, some of which very large, are found in 50% of the cases (Figure 84.12). Calcifications are infrequent. The neoplasm may be associated with a scalloping of the inner table of the cranial vault. Imaging features are suggestive, even if rarely diagnostic.[127–129] On CT, the mass is isodense to gray matter. On MR imaging, pleiomorphic xanthoastrocytomas show an isointense signal intensity or a mixed signal intensity to gray matter on T1-weighted and T2-weighted images and a hyperintense signal intensity on FLAIR. The solid portion of the tumor commonly enhances homogeneously or heterogeneously and may show a dural tail sign.[126] Cyst walls show variable contrast uptake.[130] Hemorrhagic foci and calcifications are rare and associated vasogenic edema minimal if not absent. These tumors may be differentiated from astrocytomas which are hypodense on CT and are more hypointense on T1-w and more hyperintense on T2-w images, due to their higher water content, but need to be differentiated from desmoplastic neuroepithelial tumors in infants and from gangliogliomas or oligodendrogliomas in children.

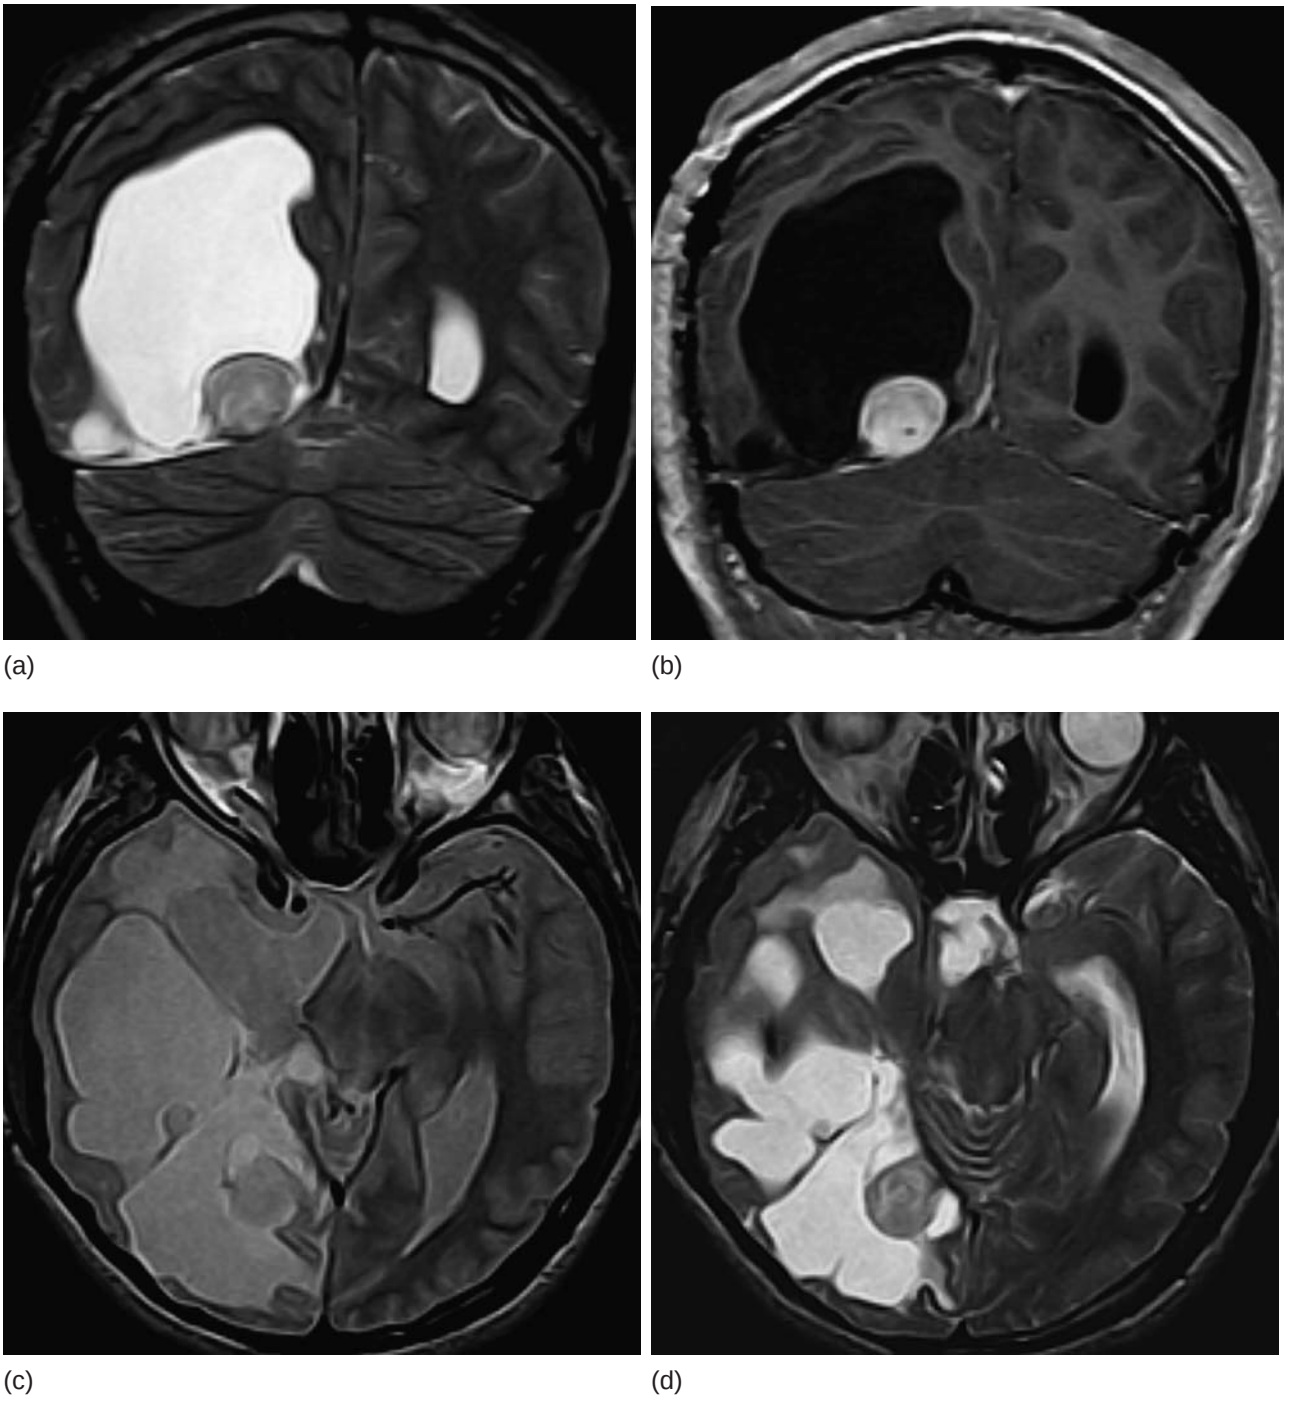


Figure 84.12 Pleiomorphic xanthoastrocytoma (WHO grade II). Huge multilobulated largely cystic fluid-filled mass with a relatively very small well-defined mural nodule superficially located adjacent to the cortical ribbon and showing a strong homogeneous enhancement (b) with a dural tail sign. Slight and limited contrast uptake involves the cyst walls. The morphological features are similar to pilocytic astrocytomas. The mass is isointense to gray matter on T1-w and PD w (c) or T2-w (a, d) sequences.

Gliomatosis cerebri

Recognized as a separate histopathological neoplasm by the WHO[53] most cases of gliomatosis cerebri are considered by most neuropathologists as representing an unusual extensive infiltration of the brain by a diffuse astrocytoma.[131,132] It is usually found in young adults with no sex predilection in their twenties to forties.

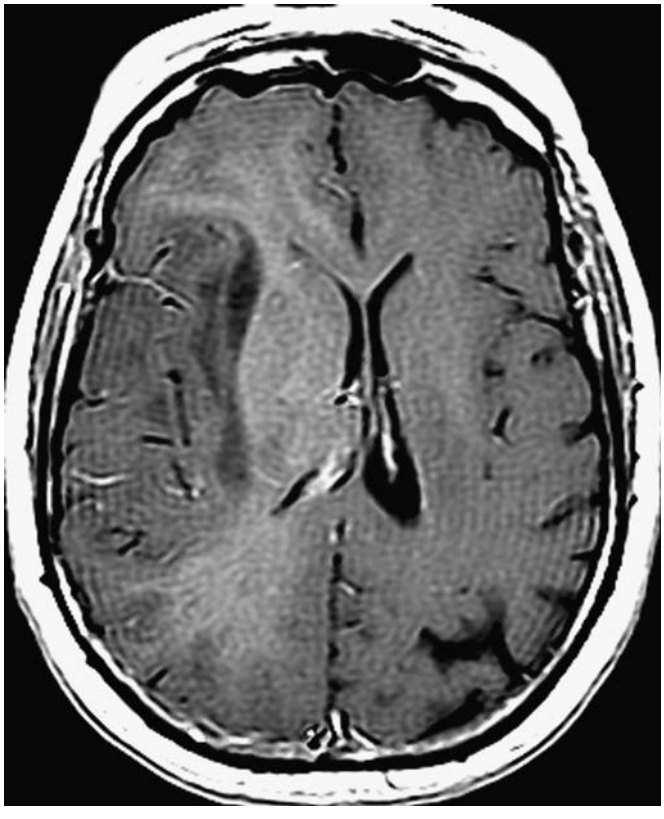
Morphology and imaging

Gliomatosis cerebri are very rare diffuse glial tumor (WHO grade III or IV) infiltrating the cerebral hemispheres in 2/3 of cases, uni- or bilaterally, and extending over more than one lobe which appear enlarged. The centrum semiovale is infiltrated in over 2/3 of cases and the cortex in less than 20%, followed by the brainstem in about half, the thalami in 40% and the basal ganglia in 30%. Leptomeningeal spread occurs in about 1/5 of the cases.[133] Age at diagnosis shows a peak incidence between 40–50 years old. Imaging features of gliomatosis cerebri include an isodense to hypodense appearance on CT but it is best imaged using MR, which is much more sensitive in depicting the neoplasm and evaluating its wide extension.[134] The neoplastic expansion along the anatomic

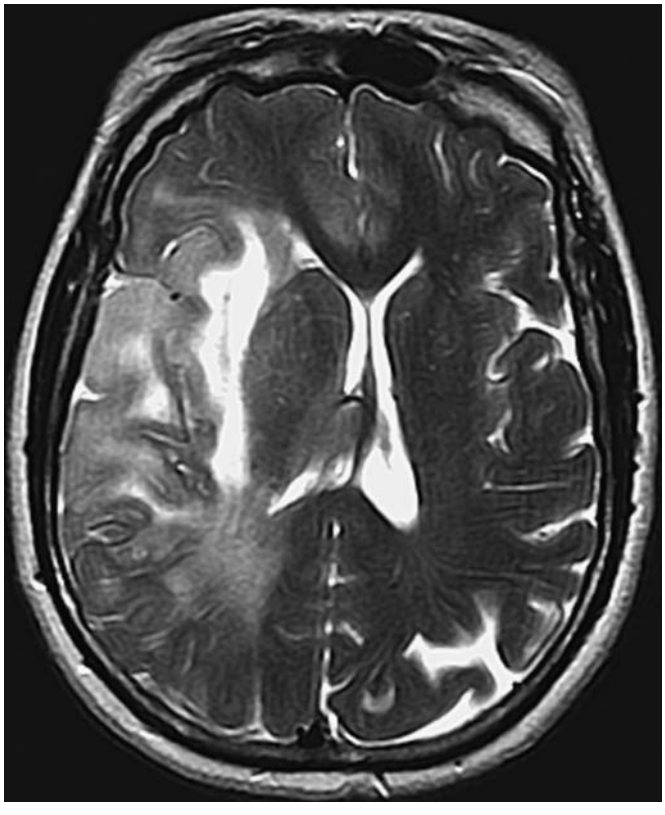
pathways is multilobar and often bihemispheric distorting rather than destroying the brain parenchyma in the manner of low-grade gliomas. Involvement of the white matter core is predominant with blurring of the gray-white matter junction (135). This ill-defined tumor is homogeneously isointense to hypointense on T1-weighted sequences and hyperintense on T2. Enhancement, usually faint, is observed in less than half of the cases and mass effect is usually moderate (Figure 84.13). Prognosis is poor.

Subependymal giant cell astrocytomas

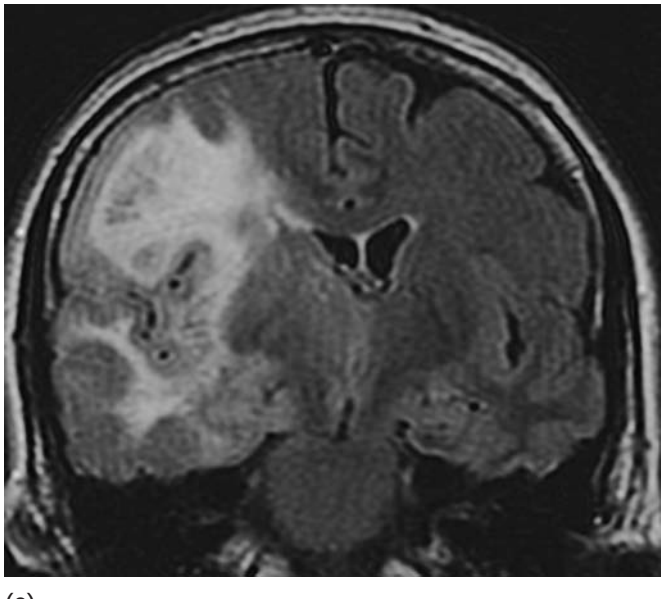
Subependymal giant cell astrocytomas are low-grade (WHO grade I) astrocytic tumors associated in more than 90% of



(a)



(b)



(c)

Figure 84.13 Gliomatosis cerebri (WHO grade III). Extensive tumoral process infiltrating the fronto-temporo-insular lobes in a young adult, associated with enlargement of the related gyri and moderate mass effect on the midline structures and the ventricular cavities displaced contralaterally. Note the predominant involvement of the white matter core with blurring of the gray-white matter interface (a,b) and the propensity to expand along the anatomical pathways such as the external and extreme capsules (b) or the temporal stem (c) in the manner of a low-grade glioma. This diffuse ill-defined glial tumor is hypointense on T1-w images (a), and hyperintense on T2-w (b) and FLAIR (c) images. Almost no contrast uptake is noticed (a).

cases with Bourneville's disease, a phakomatosis including cutaneous, visceral, and central nervous system manifestations. Almost 10–15% of these patients will develop, usually in their teens or twenties, the characteristic subependymal giant-cell astrocytoma.[136,137] The average age at diagnosis is 10 years old.[138] The clinical presentation is commonly hydrocephalus. Histologically, these tumors are similar to the subependymal hamartomas found in tuberous sclerosis[137] which is a genetically determined and familial disease transmitted in an autosomal dominant mode with low penetrance. Its incidence is evaluated as being 1:100–150 000 patients or may even be as high as 1:10–20 000. There is no sexual or racial preponderance. Clinically, patients with tuberous sclerosis present a classic triad of cutaneous angiofibroma (90%), appearing at 1–5 years old, in the nasolabial folds or extending to the cheeks and the malar region (butterfly appearance); myoclonic seizures and hypsarrhythmia (80%), and mental deficiency (about 60%) of variable severity. Tuberous sclerosis is characterized in the CNS by the presence of disseminated hamartomas or tubers consisting of nodules of disorganized cortical tissue containing atypical giant bizarre neurons and astrocytes. The subjacent white matter contains few myelinated fibers and fibrillary gliosis.

Morphology and imaging

The giant-cell astrocytoma is a slowly-growing well-demarcated tumor typically subependymal and almost always found in the lateral ventricle near the foramen of Monro, frequently causing an obstructive hydrocephalus with an ipsilateral or bilateral ventricular enlargement. This morphologic and topographic appearance is almost pathognomonic when associated with other features of tuberous sclerosis. The mass is fixed to the head of the caudate nucleus but does not infiltrate it or the adjacent parenchyma and does not show subarachnoid seeding (Figure 84.14). The tumor is covered by an intact layer of ependyma. Irregular calcifications may be commonly found. It may be rarely an isolated finding, a 'forme fruste' of Bourneville's disease.

The tumor is hypodense to isodense on CT showing calcifications. On MR the tumor is rounded or ovoid, presenting a heterogeneous signal intensity usually hypointense to isointense on T1-weighted images and hyperintense on T2-weighted images.[139,140] Associated subependymal nodules and tubers, best visualized on MR, are usually evidenced in Bourneville's patients. The tubers are centrally hypointense to white matter or isointense on T1-weighted images, but appear hyperintense in infants as compared with unmyelinated white matter. On SE-T2w or FLAIR images, the tumor is hyperintense to white matter. Note that in the case of associated calcified subependymal nodules or cortical tubers, GE-T2*w sequence is helpful for depicting the calcified portions due to the magnetic susceptibility differences with adjacent brain tissue. Calcifications may show a hypointense SI on SE-T2w and may even appear as bright areas on T1-w images. Subependymal nodules of more than 1 cm particularly if symptomatic should to be considered as subependymal giant cell astrocytomas.[140] Although cortical-subcortical tubers and subependymal hamartomatous and glial nodules within the white matter usually do not show contrast enhancement, subependymal giant-cell astrocytomas characteristically strongly enhance uniformly.[140] Note that enhancement of a subependymal nodule must be followed up with MR in order to rule out an eventual transformation into a giant cell astrocytoma. Regional parenchymal invasion or rapid growth is highly suspect of anaplastic transformation. Although benign, spontaneous intratumoral hemorrhage may occur leading to death.

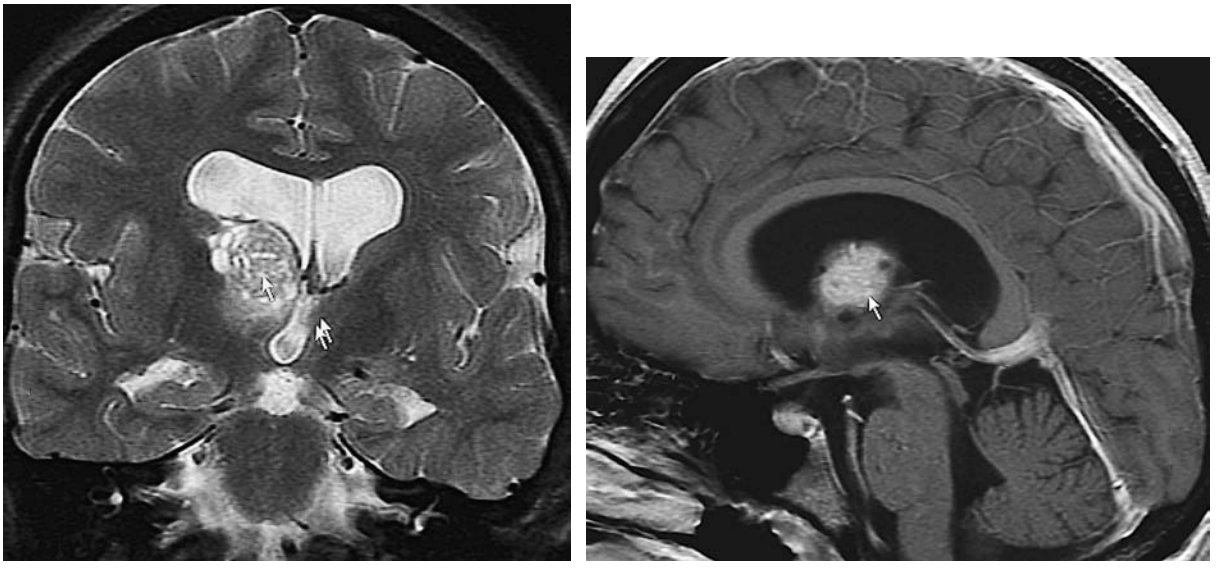


Figure 84.14 Subependymal giant-cell astrocytoma (WHO grade I). Intraventricular rounded mass found in association with tuberous sclerosis and developed in the lumen of the frontal horn of the lateral ventricle, at the foramen of Monro (arrow). It appears attached to the caudate nucleus which is not infiltrated. The mass is well demarcated including small cystic formations (a). It appears heterogeneously hyperintense to white matter on the T2-w coronal cut (a) and enhances intensely as shown on the parasagittal T1-w cut (b), overlying the interventricular foramen. Note the ipsilateral ventricular enlargement and the mass effect on the third ventricle (double arrows).

85 Magnetic resonance spectroscopy in patients with epilepsy

MA McLean, M Koepp, and FG Woermann

Introduction

Magnetic resonance spectroscopy (MRS) offers a unique opportunity to assay noninvasively the concentrations of metabolites in the brain in vivo. In epilepsy, this information can be used to aid diagnosis of the epileptogenic lesion, optimization of the extent of a surgical resection, or prediction of postoperative outcome. MRS may give important insights into the mechanisms of seizure generation and termination, and into the pharmacodynamics of antiepileptic drugs, and may thus help in deciding which patients may tolerate particular drugs.

Principles of MRS

The principles underlying the technique are the same as for MRI discussed in previous chapters. A magnetic nucleus in an applied magnetic field can be induced to emit signal at a specific frequency, which depends on its electronic environment (specifically, on the electronegativity of the chemical bonds in which it takes part). These frequencies can be analyzed as a spectral fingerprint, to tell us what chemicals are present.

MRS is an insensitive technique: typically only metabolites present at concentrations of about 1 mM or higher are detectable in vivo. Not all isotopes are magnetic, and not all magnetic isotopes produce signal which is equally easy to detect. The most commonly studied isotopes in epilepsy are ^{1}H and ^{31}P.

Proton MRS

The ^{1}H nucleus (a single proton), although both abundant and relatively sensitive in NMR terms, initially presented problems to study via MRS: techniques needed to be developed to exclude the strong signals arising from water and macromolecules (lipids and proteins) in order to study the more interesting small metabolites (amino acids, sugars, etc.). Such techniques are now available to suppress the water peak,[1] and to reduce and/or spatially exclude the macromolecule signal. Spatial exclusion (known as outer volume suppression, or OVS) is needed because of the very intense lipid signals arising from the scalp. Macromolecule signals can also be reduced by taking advantage of their short T_2 relaxation (by acquiring at echo times >100 ms) or their short T_1 (by preceding the acquisition with an inversion pulse). If the delay between inversion and acquisition is short, the lipid signal may be nulled;[2] if it is long, the metabolite signal may be nulled, and the resultant macromolecule signal may be subtracted from a spectrum without inversion to yield a clean metabolite signal.[3]

Following these technical advances, ^{1}H has become by far the most widely studied nucleus in clinical MRS. The metabolites studied are shown in Figure 85.1. At long echo times, signal is primarily present from N-acetyl aspartate (NAA), creatine plus phosphocreatine (Cr) and choline-containing compounds (Cho). As described previously, at this echo time of 144 ms the macromolecule signal (MM) has decayed completely, giving a flat baseline from which metabolite peak areas can be measured. Following hypoxic insults, some seizures, or more rarely in normal brain, an inverted doublet signal can be observed from lactate at 1.33 ppm.

At shorter echo times (e.g., 30 ms as shown), the MM peaks interfere with quantification not just at the frequencies below 2 ppm, but throughout the spectrum. Additional interesting peaks can be detected from myoinositol (Ins) and glutamate and glutamine (Glx), but sophisticated modelling is necessary to distinguish them from the overlapping peaks,[4] and baseline determination remains a major source of error.

Localization techniques

Localization is needed for ^{1}H-MRS, not merely to exclude scalp lipid signal, but to compare different tissues and locations in the brain (e.g., left vs. right hippocampus as shown in Figure 85.2). Localization makes use of frequency-selective excitation, where the rf pulses are accompanied by gradients. In imaging, this is used to excite a single slice for 2D images. In spectroscopy, we often choose to do slice-selective excitation in three orthogonal planes to excite a cuboid volume at their intersection. This is called single voxel (SV) MRS. The three rf pulses used are chosen to create either stimulated echoes (STEAM) or spin echoes (PRESS).

The other common localization tool is phase encoding, as used in imaging. This is known as spectroscopic imaging (MRSI), sometimes called chemical shift imaging (CSI). Sometimes we use both 3D localization (e.g., PRESS) and MRSI, to acquire a spectroscopic image of a cuboid volume, rather than over the whole slice (Figure 85.3). This aids in the exclusion of the intense scalp lipid signal.

Analysis methods

Since the areas of metabolite signals are directly proportional to their concentrations in the tissue, we can use MRS to estimate

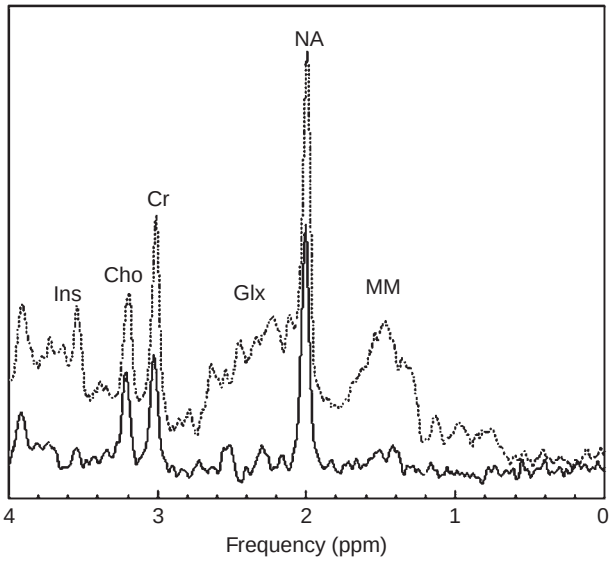

Figure 85.1 Sample proton spin-echo (PRESS) spectra from human frontal lobe in vivo, at long (144 ms, solid line) and short (30 ms, dotted line) echo times.

metabolite concentrations. However, since there are so many elements of the proportionality constant that are difficult or impossible to determine (e.g. characteristics of the coil hardware), we generally can only calculate a concentration relative to a known or assumed standard.

For example, we can scan a solution of 50 mM creatine and compare the area of the peak we measure to the area of the peak we measure in vivo. Then we can correct for differences in machine gains, the volume of tissue excited, relaxation properties, etc., to obtain an estimate for the concentration in vivo. Alternatively, sometimes only the ratio of one peak to another is reported, e.g., NAA/Cr, or NAA/(Cr+Cho). This has the advantage that any temporal, spatial, or inter-subject differences in machine performance cancel out. However, such ratios can vary in different tissues in the brain, or in disease, in ways that are not always easy to interpret.

Even the measurement of peak areas is not trivial, especially in short echo-time spectra, since many peaks of interest overlap with each other and with broad underlying macromolecule resonances. Therefore it is generally desirable to fit such spectra using automated routines which can take this broad baseline into account, and which incorporate information on the whole complicated spectral fingerprint of each metabolite of interest. The most commonly used spectral packages are LCModel[4] and MRUI (www.mrui.uab.es).

Finally, metabolite concentrations differ in gray matter, white matter, CSF and lesions, so it is desirable to estimate the proportion of each in the excited volume. Metabolite content of CSF can be assumed to be negligible,[5] and that of lesions would generally be expected to be lower than normal tissue for most metabolites. In gray matter, we and others have found significantly higher content of glutamate plus glutamine, creatine, and myoinositol than in white matter.[6]

Metabolite-specific spectroscopy

Only three to five metabolites are clearly visible in a conventional proton spectrum (perhaps up to seven can be estimated with spectral modelling at short echo times). If our metabolite of interest cannot be resolved from overlapping molecules, we must turn to more sophisticated methods.

One possibility is to perform 2D spectroscopic studies. If we collect data not merely at a single echo time, but at a series of incremented echo times, then we can perform a Fourier transform across this second time dimension to produce a second frequency dimension. Any coupled peaks in the spectrum are modulated at different echo times, so they appear spread out across the second frequency dimension. There are a number of slightly different techniques that use this approach: the most common are J-resolved PRESS[7] and localized correlation spectroscopy (L-COSY).[8] The main advantage of 2D techniques is that uncoupled signal is retained, so that, in theory, the entire metabolic content of the tissue can be determined from a single acquisition. The main disadvantage is that the spectral resolution in the second frequency dimension is often insufficient to fully resolve overlapping peaks.

Another approach with more potential specificity is spectral editing.[9] This is a difference technique: we collect one spectrum where we have manipulated a small range of frequencies, another spectrum where we have not, and we look at

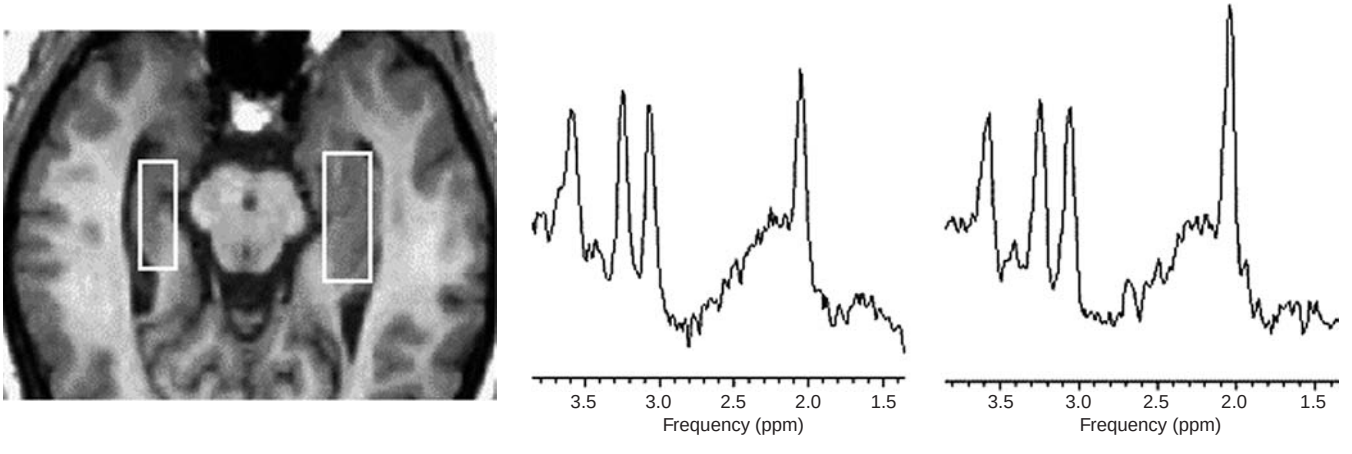

Figure 85.2 Proton spectra (using PRESS localization with an echo time of 30 ms and repetition time of 3 s) from the ipsi- and contralateral hippocampi of a patient with hippocampal sclerosis and epilepsy. Left: anatomic image showing the positions of the voxels studied. Middle: spectrum from ipsilateral hippocampus. Right: spectrum from contralateral hippocampus.

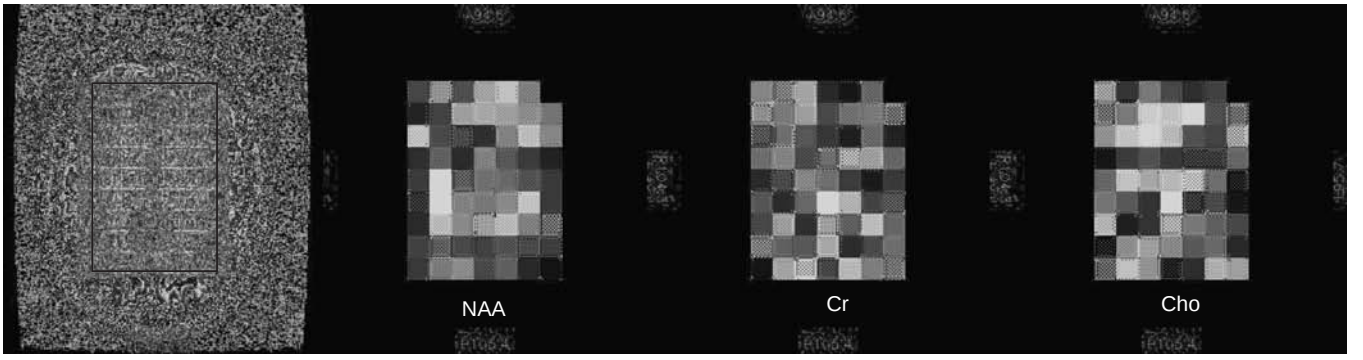

Figure 85.3 Long-echo-time (144 ms) MRSI in vivo at 3 Tesla: 20 × 20 phase encoding steps were acquired, but only those which fell inside the volume selected using PRESS are shown. The spectra from each voxel were fit using LCModel to obtain semiquantitative maps of N-acetyl aspartate, creatine, and choline.

the difference between them. There are still potential problems when multiple peaks in the same range pass through the spectral filter, or 'co-edit', but more complicated subtraction schemes can be developed to get around this limitation.[10] A more fundamental problem is motion: if it occurs, the subtraction will no longer cancel the unwanted resonances.

A final technique used to observe coupled peaks is multiple-quantum (MQ) filtration. If we create a MQ coherence, we can use gradients to filter out the uncoupled spins, which are not able to enter this state. The ratio between two gradients applied is chosen to select the desired coherence: the most common is a double quantum filter (DQF). This has been used to study GABA[11] and glutathione[12] in the brain.

Phosphorous MRS

^{31}P is the 100% abundant isotope of phosphorus, an important atom in biological systems. Its resonances can be detected by tuning the scanner into a frequency range roughly 60% lower than that of proton, although many clinical scanners are not equipped to transmit and receive signal over such a wide range ('broadband') of frequencies. The methods for studying ^{31}P are similar to those for proton, with two main exceptions.

The first is that the T_2 relaxation times are much shorter: about 10–30 ms. Therefore ^{31}P is unsuitable for spin-echo or stimulated-echo experiments, because the signal would have decayed away during the echo time. Instead, nonecho localization schemes such as ISIS[13] may be preferred.

The second major difference is that phosphorus signal is modulated by nearby protons. These heteronuclear splittings can complicate the spectral signal considerably, particularly the phosphomonoester (PME) and phosphodiester (PDE) peaks. Therefore, decoupling may be applied: this selectively saturates signal at the proton frequency, so that it no longer affects the ^{31}P signal.

Visible metabolites

The three resonances of adenosine triphosphate (ATP) are detectable in virtually every soft tissue in the body (Figure 85.4). They are not coupled with any protons, but they are coupled with each other: the gamma and alpha peaks are split into doublets by the beta peak, and the beta peak is split into a triplet with intensity ratios 1:2:1. The concentration of ATP tends to remain stable in living tissues, unless the bioenergetics are very severely compromised.

This stability is generally maintained by a store of phosphocreatine (PCr). This singlet (i.e., uncoupled) peak dominates spectra from skeletal muscle, and can be observed to radically reduce during exercise. In brain and other internal organs it is less prominent, but also less subject to reduction, except in hypoxic/ischaemic insults. It may reduce during seizures, as discussed below.

The singlet peak of inorganic phosphate (Pi) can also be detected. It has the interesting property that its chemical shift is dependent upon the local concentration of hydrogen ions, so that its distance from the PCr peak may be used as a noninvasive internal pH meter.[14] Similarly, the chemical shift of β-ATP can be used to monitor the concentration of free magnesium ions.

The other peaks visible in the phosphorus spectrum are broad signals assigned collectively as phosphomonoesters

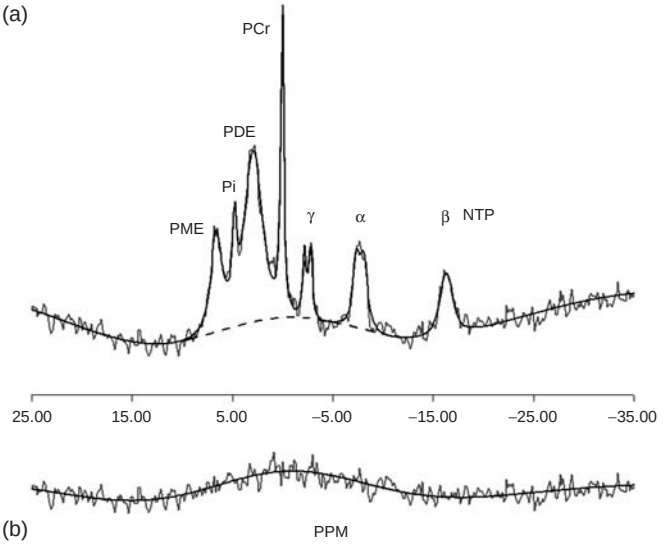

Figure 85.4 Seven peaks are characteristically identifiable in the ^{31}P-MR spectrum from a normal human brain. In order of decreasing chemical shift, these peaks are assigned to phosphomonoesters (PME), inorganic phosphate (Pi), phosphodiesters (PDE), phosphocreatine (PCr) and γ, α, and β nucleotide triphosphate (γ, α, and βNTP). These signals were quantified in the time domain using the AMARES algorithm included in the MRUI software program (a), with the residual shown (b) (courtesy of Prof B. Puri).

(PME) and phosphodiesters (PDE). These are thought to be associated primarily with membranes.

Clinical applications of MRS

MRS in temporal lobe epilepsy

In the presurgical evaluation of patients with TLE, the potential value of ^{1}H-MRS (or -MRSI) depends on the method's ability to detect lateralized metabolic changes not only in clear-cut cases of hippocampal sclerosis, but also in patients with normal MRI ('MRI-negative'); it depends on the method's ability to lateralize abnormality in the presence of bilateral EEG or MRI changes and to contribute to the detection of dual pathology; ultimately, the clinical value of ^{1}H MRS in this patient group is based on studies correlating presurgical measurements with post-surgical seizure and neuropsychological outcome.

Proton MRS in hippocampal sclerosis

In patients with hippocampal sclerosis, the typical finding in the epileptogenic hippocampus is a reduction of NAA and an elevation of Cr and Cho (or corresponding changes of ratios like NAA/Cr, NAA/Cr+Cho or Cr/NAA) relative to normal control subjects; the contralateral hippocampus may be normal or show a lesser degree of abnormality.

In a series of 100 consecutive TLE patients, the NAA/Cr values were abnormally low in at least one temporal lobe in all but one patient and were abnormally low bilaterally in 54%.[15] The asymmetry between right and left NAA/Cr ratios lateralized 92% of patients in concordance with lateralized ictal EEG findings. More abnormalities were detected using MRS than with MR volumetry, but only a few patients with postoperative outcome were reported in this study.

Prediction of postoperative outcome

The literature is discordant on the issue of predicting outcome with MRS. There is a restricted number of MR spectroscopic studies describing more than 20 operated adult TLE patients and providing individual MRS and outcome data.[16–22] A recent meta-analysis[23] aiming to assess the additional preoperative value of ^{1}H-MRS further included smaller studies (with 7–17 operated patients). Combining those studies on patients with TLE which allowed correlation of individual MRS data and seizure outcome according to the Engel Classification, unilateral MRS changes were reported to have a predictive value of 82% for good postsurgical outcome (Engel I+II). TLE patients with unilateral MRS abnormality had a markedly better chance of becoming seizure free compared to patients with bilateral abnormalities (odds ratio 4.891, CI = 1.965–12.172).[23] One study of 24 TLE patients included in this meta-analysis showed that unilateral abnormality in hippocampal ^{1}H MRS (in 61%) did not predict, and bilateral abnormalities (in about 30%) did not preclude, good surgical outcome.[16]

The predictive value of bilateral MRS abnormalities (for unfavorable outcome) is even less clear. Bilateral temporal MRS abnormalities have been observed to a varying degree in different studies in 0–70% of patients.[24] In 21 patients with bilateral hippocampal atrophy, discriminant ^{1}H-MRSI features associated with favorable post-surgical seizure outcome were: concordant ^{1}H-MRSI lateralization, a greater side-to-side asymmetry of NAA/Cr, and an absence of contralateral posterior NAA/Cr reduction.[18] However, in patients with preoperatively low NAA ratios contralateral to the seizure onset, a postoperative metabolic normalization on the non-operated side was observed.[25–27] It led to the view that a decrease of NAA does not necessarily represent neuronal loss, but that NAA might be a putative reversible, thus functional, marker.[28]

Bilateral MRS abnormalities might also affect neuropsychological prognosis. Patients with right sided TLE and with additional MRS abnormalities in the left temporal lobe performed worse on neuropsychological tests of episodic verbal memory compared to patients with right sided TLE and ipsi- and unilateral MRS changes.[29] Whether this particular combination of two independent markers for bilaterality has clinical significance remains questionable.

Proton MRS in temporal lobe epilepsy without MR abnormalities ('MR-negative')

Some TLE patients with apparently normal MRI ('MRI-negative') were the subject of feasibility studies[30] or part of studies correlating typical MRS changes (low NAA ratios ipsilateral to the seizure onset with a relatively low degree of contralateral abnormality) with good post-surgical outcome.[15,21,31–33] In 15 MRI-negative, but operated, TLE patients a single ^{1}H-MRSI study came to conflicting results.[34] This study curiously showed a greater degree of ipsilateral NAA/Cr changes in patients that were *not* seizure free after surgery. Extending this finding to the contralateral side, these results still confirmed the generally acceptable view that subjects with bilateral metabolic abnormalities might have seizure foci that extended beyond the ipsilateral hippocampus. Against all expectations, MRI-negative patients who were 'well lateralized' by NAA (i.e., ipsilateral NAA ratios lower than contralateral ratios) had worse surgical outcomes than patients who were 'poorly lateralized'.[35] A possible explanation for this solitary finding of a poor correlation between lateralization with NAA and surgical outcome, is that TLE patients with normal MRI may represent a different syndrome than TLE with hippocampal atrophy. In other studies, ^{1}H MRS described a metabolite profile in the hippocampi of MRI-negative TLE patients that was in fact different from patients with hippocampal sclerosis, with an increase in glutamate and glutamine and a less marked decrease in NAA than was seen in hippocampal sclerosis.[34,36]

Another explanation for a poor correlation between lateralization with NAA and surgical outcome in MRI-negative patients with TLE was put forward in a study correlating presurgical ^{1}H MRS, post-surgical histopathology and outcome.[19] In 13 patients with TLE, subtle histopathological signs of cortical malformations in the resected temporal lobes were found: six of them with concomitant hippocampal sclerosis (dual pathology) and seven without. The MRI-negative subgroup had a worse surgical outcome and showed more marked bilateral and/or contralateral MRS abnormalities possibly representing more widespread subtle developmental changes.

Proton MRS in dual pathology

These and other extrahippocampal or extratemporal abnormalities in patients with mesiotemporal/hippocampal sclerosis are called 'dual pathology'. Dual pathology is rarely

identified in a hypothesis-driven way allowing the targeted placement of regions of interest. ^{1}H-MRS/MRSI could only contribute to the detection of these changes when single voxels or single MRSI slices were placed outside the hippocampus and/or outside the temporal lobe or by the use of multislice ^{1}H-MRSI.[37] Making a virtue of technical necessity, some MRS studies placed their voxels outside the mesial temporal lobe due to the difficulty in sampling such small structures and the difficulty in achieving an adequately homogeneous magnetic field owing to the magnetic susceptibility effects at the tissue-air interface near the petrous bone. MRS measurements in the superior temporal lobes and inferior insular cortex lateralized 45% of TLE patients with a low extrahippocampal temporal lobe NAA/Cr.[21] Using multislice ^{1}H-MRSI in combination with tissue segmentation, significantly lower NAA in ipsi- and contralateral frontal gray and nonfrontal white matter compared with controls was found, although not correlated to outcome.[37] Further studies by the same group found that TLE was associated with extrahippocampal reductions of NAA/(Cr+Cho) in several lobes consistent with those brain areas involved in seizure spread and that temporal and extratemporal NAA/(Cr+Cho) reductions might be helpful for focus lateralization.[38]

Widespread abnormalities of ratios were found not only in TLE, but also in extratemporal lobe epilepsy.[39] Even in normal controls, large differences in metabolite concentrations were seen between posterior lateral temporal lobe (predominantly subcortical white matter) and the posterior mesial temporal lobe, most notably lower creatine, Glx, and myoinositol, and higher NAA/(Cr + Cho) in the lateral than mesial temporal lobe; this pattern was similar to that previously seen for gray/white matter differences in the frontal, parietal, and occipital regions.[40] It remains to be seen whether widespread MRS changes in TLE are specific and have prognostic value.

Brain GABA and glutamate-glutamine (Glx) in temporal lobe epilepsy

In adult patients with complex partial seizures, poor seizure control was found to be associated with low brain GABA levels measured with ^{1}H-MRS within a 14-cm^{3} volume in the occipital lobe, i.e., outside of the epileptic focus,[41] although other studies did not find a correlation between GABA and seizure control or recent epileptic seizures.[42] In one study, low GABA/Cr seemed even to lateralize the hemisphere with the seizure onset zone and predicted increases of the GABA/Cr signals after successful antiepileptic treatment with vigabatrin.[43] Acute and/or longstanding GABA increases were shown with different antiepileptic drugs, like gabapentin, lamotrigine, topiramate, and vigabatrine,[44–46] but not with carbamazepine, phenytoin, or valproate.[47]

Increased intracellular glutamate content in epileptic human hippocampus may also contribute to the epileptogenic nature of hippocampal sclerosis.[48] Short-TE MRS studies in patients with TLE showed an increase in the overlapping peaks of glutamate and glutamine in MRI-negative patients with TLE.[35,36]

Phosphorous MRS in temporal lobe epilepsy

Results from the few studies using ^{31}P-MRS in TLE are controversial. ^{31}P-MRS studies of the anterotemporal lobes of patients with medically refractory TLE showed that the pH was significantly more alkaline and the inorganic phosphorous concentration was greater on the side of the epileptogenic focus.[49–51]

Differences in intracellular pH between controls and patients were not observed in other studies, although some bilateral, but lateralizing, phosphorus metabolite abnormalities were found (e.g., the phosphocreatine/inorganic phosphate ratio was reduced in the epileptogenic temporal lobe).[52,53] The decline in energetics (reduced ATP/Pi, both ipsilateral and contralateral)[53] has been discussed as a seizure-mediated imbalance, because successful treatment of the seizures might reverse the contralateral impairment.[54] Further study is needed correlating presurgical ^{31}P-MRS with postsurgical ^{31}P-MRS and seizure outcome.

Summary: MRS in temporal lobe epilepsy

Although ^{1}H-MRS/-MRSI has been advocated as part of a cluster or a sequence of clinical tests prior to epilepsy surgery in TLE, its contribution to the overall validity of the cluster or sequence remains to be determined. Influential epilepsy surgery programs with early enthusiasm for ^{1}H-MRS/-MRSI ('NAA/Cho is an excellent marker for localizing the epileptogenic zone in TLE', Ng *et al.*, 1994) abandoned this noninvasive but tedious method as part of their presurgical evaluation of patients with TLE (H. Luders, personal communication). Is it time to reconsider?

MRS in extratemporal neocortical epilepsy

Studies correlating presurgical ^{1}H-MRS/-MRSI data with post-surgical seizure outcome in patients with extratemporal neocortical epilepsy seem not to be available in this increasingly important patient population. It remains to be seen whether ^{1}H-MRS/-MRSI can help to select those candidates whose extratemporal neocortical epilepsy can be treated successfully by epilepsy surgery.

Proton MRS in frontal lobe epilepsy

In the relatively large frontal lobes, the use of a restricted region-of-interest approach (single voxel or single slice) might reduce the sensitivity of ^{1}H-MRS/-MRSI for the localization or the lateralization of the epileptogenic region.

Mean NAA/Cr in the epileptogenic frontal lobe was found to be decreased compared to the contralateral homologous region;[55,56] however, widespread, even bilateral frontal lobe NAA/Cr changes have also been described.[57] 50% of patients with extra-TLE had NAA/Cr reduction outside the clinical and EEG-defined primary epileptogenic area.[18]

In individual patients, correct lateralization varied between 50 and 100%. Using reduced frontal lobe NAA/Cr, four out of seven patients were correctly lateralized.[58] Comparing MRSI in patients with MCD and in 'MRI-negative' patients with neocortical epilepsy, localization of the focus was correct in 70% of the patients with an MRI-visible malformation and in 60% of the patients with normal MRI.[59]

Phosphorous MRS in frontal lobe epilepsy

There are preliminary findings in patients with frontal lobe epilepsy awaiting replication in larger patient populations. Studying eight patients with frontal lobe epilepsy, interictal alkalosis and decreased phosphomonoester levels in the epileptogenic region compared to the contralateral frontal lobe were found.[60]

MRS in neocortical epilepsies due to malformations of cortical development

Some proton magnetic resonance spectroscopy studies have been performed in patients with malformations of cortical development (MCD), although without correlation to post-surgical outcome. A decrease in NAA (concentrations or ratios) was the most frequent finding in individual MCD and in group comparisons.[61–66]

Using quantitative short echo time ^{1}H-MRSI, abnormal metabolite concentrations in MCD, perilesional tissue and brain tissue remote from MCD were demonstrated in patients with localization-related epilepsy.[64] These findings support the concept of widespread abnormalities in patients with apparently focal MCD. Spectroscopic abnormalities do not necessarily represent widespread structural changes as described earlier in MCD,[67,68] but might demonstrate dysfunction.

Measurements of individual metabolites were abnormal in some malformations and normal in others, suggesting metabolic heterogeneity.[64] Even within a single MCD, metabolically normal regions were interspersed with metabolically abnormal regions.[66] Categorizing MCD based upon the step at which fetal cortical development was likely first disturbed (as proposed by Barkovich)[69] might reduce the variability of MRS results in MCD. NAA/Cr was shown to be most markedly reduced in MCD secondary to very early disturbances during stem cell formation.[62] This ratio was variably reduced in heterotopic gray matter (MCD due to a later developmental step, abnormal migration) and normal in polymicrogyria.[62,71]

Whether MR spectroscopy can contribute to the distinction between low-grade gliomas and focal MCD (especially FCD), remains unclear. Promising results from group comparisons (less NAA in tumours compared to MCD) await replication and prospective translation to clinical practice in individual patients.[71]

Prototypically in epilepsy patients with tuberous sclerosis, the presence of multiple bilateral lesions can make it difficult to identify a single lesion responsible for intractable epileptic seizures. Using MRS, a lactate peak was detected in the regions corresponding to an epileptic focus in some patients[72], but this was not a universal finding (Figure 85.5).

MRS in neocortical epilepsies without MR abnormalities ('MR-negative')

The usefulness of multislice ^{1}H-MRSI in combination with tissue segmentation for the identification of the epileptogenic focus, was extended from patients with MCD to MRI-negative patients with neocortical epilepsy.[38] MRSI correctly identified the lobe containing the epileptogenic focus as defined by EEG in 65% of the patients with neocortical epilepsy. MRSI localization of the focus was correct in 70% of the patients with an MRI-visible malformation and in 60% of the patients with normal MRI. Of the patients, 15% had metabolically abnormal brain regions outside the epileptogenic lobe, and 35% of the patients had evidence for secondary hippocampal damage.[38] It remains to be seen whether these changes have prognostic value and whether these widespread abnormalities are specific, as they are also found in temporal lobe epilepsy.[39]

Summary: MRS in extratemporal neocortical epilepsy

In contrast to the numerous ^{1}H-MRS of TLE, there are only a few reports in other types of localisation-related epilepsies. These studies suggest that the potential of correct seizure focus lateralisation is less than in TLE.

MRS in children with epilepsy

Metabolite concentrations change with early brain maturation, and this differs between different brain regions,[69] which complicates investigations of infants and young children. In older children and adolescents with TLE, ^{1}H-MRS of mesial temporal lobe regions showed similar results compared to adults. Abnormally low NAA/Cho+Cr was seen in 75%; 55% were correctly lateralized; bilateral abnormalities were seen in 45%.[73] These results were extended to young TLE patients who showed no abnormality on specialised structural MRI investigation.[30]

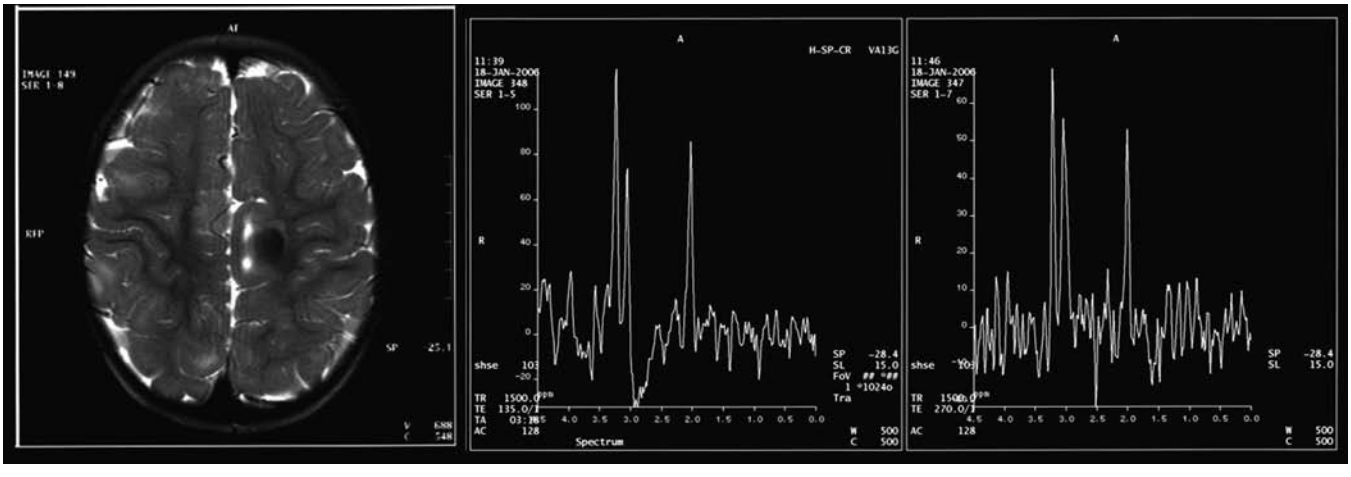

Figure 85.5 Left panel: MRI of a young patient with tuberous sclerosis with a large calcified tuber in the left pericentral region. Right panel: MR spectra (TR 1.5 s, TE 135 and 270 ms) showing low NAA and relatively high Cho as described recently in a larger series of patients with TS.[72] Note the presence of spectral distortion around 2.9 ppm, and that the SNR is lower than would be expected for a voxel of this size: both effects are presumed to be due to the presence of calcification, which degrades spectral quality.

Comparing children with TLE and a history of complex febrile convulsions and children without any history of complex febrile convulsions, changes in the metabolite ratios were detected to a similar degree (60%).[74] MRS-detectable neuronal dysfunction throughout the temporal lobes of children with TLE was already as severe at the time of diagnosis as it was in patients with long-standing intractable TLE.[75] Whether longitudinal MRS studies might help to clarify the role of febrile convulsions in the pathogenesis of TLE remains unclear.

The most frequent pathology in children undergoing epilepsy surgery is malformation of cortical development (MCD). Heterogeneous MRS findings in MCD have been reviewed in an earlier paragraph of this chapter. In pediatric epilepsy surgery, extensive resections (multilobar resections, hemispherotomies) are more frequent than in adults. Whether MRS can help to characterize the contralateral hemisphere and to define it as normal, remains unclear. In single cases of MRS investigations in hemimegalencephaly, the normal-appearing hemisphere was mildly affected (decreased NAA in white matter).[76]

There are case reports describing MRS results in catastrophic epilepsy, i.e., childhood epilepsy with very frequent seizures and the loss of neurological or neuropsychological function ('epileptic encephalopathy'). In these patients, MRS measurements at a single time point should be treated with caution considering the possibility of fluctuating metabolite profiles related to seizure activity. In an 8-year-old boy with Rasmussen's encephalitis, five MRS examinations were performed over 9 months.[77] Following complex partial status, MRS showed a reduction in N-acetyl aspartate, total creatine and choline. Subsequent scans showed complete resolution of these metabolite abnormalities, followed later by development of further abnormal metabolite values. In this case, lactate and Glx were elevated after status. In hemimegalencephaly, another cause of catastrophic epilepsy, a single case study reports signs of progression of MRS measures of glial proliferation after one year (reduced NAA and elevated myoinositol).[78] In Sturge-Weber syndrome, a vascular malformation underlying catastrophic epilepsy, NAA was reduced in the ipsilateral gadolinium-enhanced volume of interest compared to a similarly placed contralateral volume.[79] A focal area of elevated choline without significant alteration of NAA might characterize the early pathophysiological manifestation of Sturge-Weber syndrome.[80]

In pediatric neuroimaging, MRS has some role in diagnosis and follow-up of encephalopathies due to metabolic diseases,[69] which might be the cause of epileptic seizures. In the neuronal ceroid lipofuscinoses (NCL), probably the most common progressive metabolic encephalopathies of childhood associated with seizures, MRS might help to distinguish different subtypes. Infantile NCL was characterized by a complete loss of NAA, a marked reduction of Cr and Cho, and an elevation of myoinositol and lactate in both gray and white matter; reduced NAA and elevated Lac were also detected in gray and white matter of late infantile NCL; in contrast to the infantile forms, juvenile NCL exhibited normal metabolic profiles.[81,82] In late infantile NCL, proton MR spectra revealed progressive changes, with a reduction of NAA and an increase of myoinositol and Glx; myoinositol became the most prominent resonance.[83]

Decreased NAA, sometimes increased Cho and myoinositol, but mainly the presence of lactate can also be found in peroxisomal or mitochondrial disease. For example in Zellweger syndrome, a peroxisomal disease, widespread bilateral MCD might be associated with decreased NAA and an abnormal signal consisting of lactate and lipids.[84] Lactate has been detected in young patients with mitochondrial encephalopathies, but as with all other means used to diagnose rare disorders, MR spectroscopy does not depict elevated lactate in all cases.[85] Lactate is usually not seen in spectra of normal adult brain. Lactate was detected, however, in all 35 normal control infants at 31–42 wk of gestational plus postnatal age studied at 2.4 T, making the use of MRS to diagnose abnormal lactate in this very young age range difficult.[86]

Future research

MRS will benefit substantially from the increased availability of higher magnetic field strength scanners. The gain in SNR will allow shorter acquisition times, better spatial resolution, or a combination of both. The dispersion of individual peaks contributing to a spectrum will also increase, allowing separation of metabolite peaks that would otherwise not be distinguishable. These improvements should allow both more precise quantification of common metabolites, and assessment of a broader range of metabolites.

Future developments in MRS may enable the technique to benefit the investigation of seizure generation by correlating metabolite changes with interictal discharges or monitoring progression of neuronal damage due to ongoing seizure activity. In induced seizures in animals NAA ratios were reduced,[87] but have been observed to increase initially during the ictal phase.[88] Lactate/Cr ratios were observed to increase ictally, being elevated up to 24 hours after a seizure and returning to the baseline levels within 7 days in induced status in animals.[88] Increase in lactate ratios in kainic-acid treated rats was prevented by cycloheximide pretreatment, suggesting that in situ lactate increase is a marker of seizure-induced neuronal damage.

In human studies NAA levels were not changed after complex partial seizures and absences.[15] Significant increases in lactate/Cr during and soon after complex partial seizures were reported, but this was not seen during absence seizures. Castillo *et al.*[89] demonstrated increased lipids/lactate in the hippocampus of patients within 24 hours of their last seizure. The increase in lactate in these studies was maximal over the area of the seizure focus and this might explain the absence of change of lactate distant to the seizure focus. The rise in lactate seen following secondarily generalized tonic clonic seizures in two patients implies a spread of seizure activity into the frontal lobe.

In the first study using magnetization transfer (MT) MRS in patients with epilepsy, we recently observed that the MT effect on choline was reduced after seizures, while choline concentrations remained unaltered.[90] We hypothesise this is due to membrane perturbation as a consequence of seizure activity, possibly due to NMDA receptor activation, which has been shown to induce choline release from membranes by inhibition of phosphatidylcholine synthesis.

The future lies in the development of new MRS acquisition techniques and the refinement of existing ones. Increasing the

speed of MRS protocols would facilitate their validation in larger numbers of patients, which is an essential step in the more widespread application of the technique in clinical evaluation.

Conclusion

There is no doubt that MRS detects relevant metabolite changes in patients with TLE. There are indications that these changes are reversible with treatment. However, in children as in adults with epilepsy, 'the cornerstone of neuroimaging remains anatomic; the physiologic data (from spectroscopy, diffusion, or perfusion) should always be interpreted in association with anatomic neuroimaging, as well as knowledge of the patient's history, clinical exam, and laboratory data' (from the preface of Barkovich, 2005).[69]

86a Post-processing of the magnetic resonance imaging to better define structural abnormalities

S Knake, F Rosenow, and PE Grant

Introduction

Magnetic resonance imaging (MRI) has become one of the most important tools in the pre-surgical evaluation of patients with medically resistant focal epilepsies. The importance of detecting a concordant lesion on MRI is reinforced by the impact it has on predicting surgical outcomes.[1,2] In many patients with medically intractable focal epilepsies that are MRI negative a focal cortical dysplasia (FCD) is later detected histopathologically. On MRI FCD are often characterized by a combination of increased cortical thickness, increased T2 signal within the dysplastic cortex and blurring of the gray and white matter junction. However, the visual identification of these abnormal characteristics may be difficult and time consuming, even for the experienced reader, because the changes on MR are subtle and the lesions may be only a few millimeters in size. Additional challenges include determining the full extent of the FCD and the secondary changes in brain structure and organization that may occur. New imaging techniques and post-processing methods have the potential to detect subtle lesions undetected in previously MRI-negative patients[3–5] and the ability to better define full impact on brain structure and organization. This chapter presents a brief overview of post-processing techniques currently in use, both clinically and experimentally, to diagnose, plan treatment, and increase our understanding of the neuropathology of focal epilepsies:

Advanced brain imaging technologies now provide a means to investigate disease specific morphological changes in their full spatial and temporal complexity. New imaging techniques have the potential to uncover patterns of altered structure and function that cannot be detected by visual inspection alone.

Analyzing the cortex

2D and 3D reformatting

Planar brain surface reformations

Curvilinear reformatting of the 2D images is used to reconstruct the images into thin, curved slices where the distance from the surface of the hemispheric convexities is kept constant.[6] These reformations ('pancake views') aid in the visual detection of subtle cortical lesions (Figure 86a.1). To create these images, isotropic 1 mm, three-dimensional (3D) MRI data sets are post-processed using a curved multiplanar reformatting technique.[3] These images preserve the spatial relation of adjacent cortex areas and surface structures in one view.[8] This technique can increase the reader's ability to detect cortical abnormalities compared to standard imaging planes.[9]

Surface rendering

Gyral folding patterns, although quite variable normally, can be significantly altered in a variety of diseases. Sulcal pattern anomalies have been identified in schizophrenia and epilepsy[10–12] and visually obvious gyral folding anomalies have been reported in patients with cortical dysplasias.[8] Subtle gyral folding abnormalities may not be identified on two-dimensional images. A 3D reconstruction of the cortical surface can aid in the identification of gyral folding abnormalities associated with cortical dysgenesis.[14]

Volumetric Analysis

Voxel-based morphometry

Voxel-based morphometry (VBM) can be performed as a semiautomated or automated procedure carried out on MRI data acquired at high resolution in a three-dimensional (whole-brain) format, typically a T1-weighted MRI volume data set (MPRAGE, 3DFLASH, 3DSPGR) that is normalized and segmented using algorithms from SPM99 (Statistical Parametric Mapping Software, Wellcome Department of Imaging Neuroscience, London). The distribution of gray and white matter is analyzed on a voxelwise basis and compared with a normal database of healthy subjects. The volumetric T1-weighted scans are used and a stereotactic normalization, segmentation, smoothing is performed before an automated statictic voxel-based comparison of T1-differences is performed.[15]

VBM has been used in previous studies in a variety of populations including healthy adults, patients with various forms of dementia, and schizophrenic patients to identify regions of cerebral abnormality as well as to determine how these regions correlate with neuropsychological function.[16] Some groups have used this methods to better define the epileptogenic lesion.[17–19] One of the advantages of this method is the automated, user-independent determination of gray-scale differences in each voxel that allows large amounts of data to be processed in a reasonable time frame. VBM analyses the whole brain voxel by voxel without the selection of predefined regions of interest that are based on a priori hypothesis.

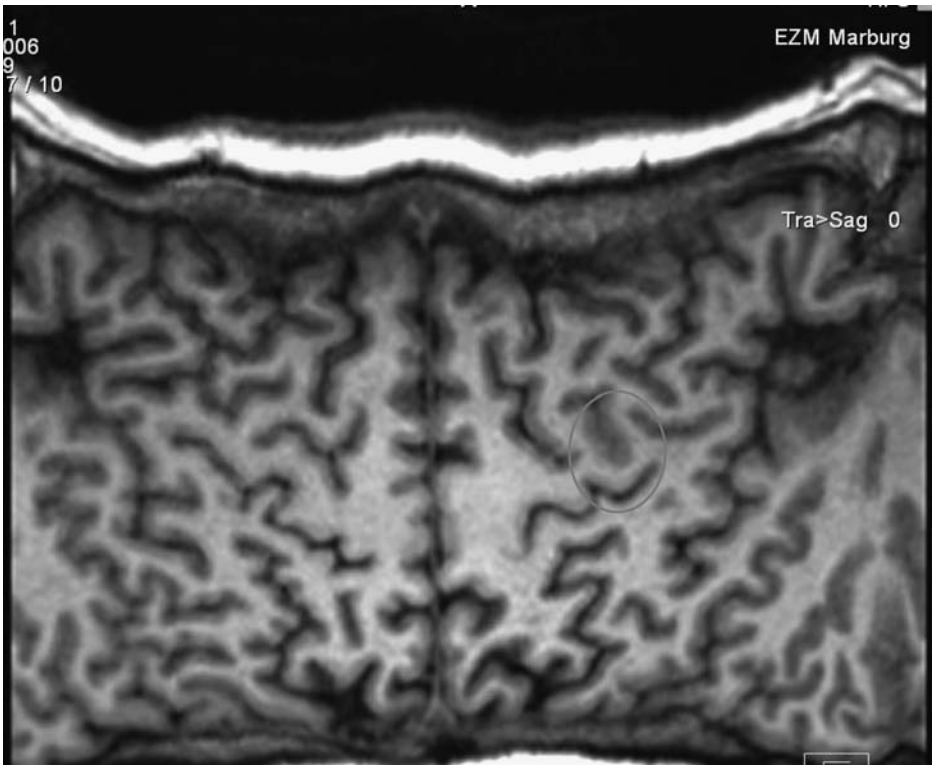

Figure 86a.1 Cortical flat map of a T1-weighted MR datatset of a 34-year-old right-handed woman with left frontal lobe epilepsy due to focal cortical dysplasia (FCD) (Taylor type 2). The area of FCD is represented by a difference in cortical folding and a subtle blurring of the sulci (see circle). We have used the technique in a 34-year-old patient with left central cortical dysplasia. Planar reconstruction images show the blurring in the depth of the cortical sulcus as demonstrated in Figure 86a.7.

The disadvantage of this method is that the accuracy is based on the voxel size and subtle differences, smaller than the voxel size cannot be detected. The performed stereotactic normalization is only a rough correction of global differences, subtle differences of individual brains might not be registered correctly and might have an influence on the result.

Atlas based segmentation

Fischl and Dale[22] have developed an automated technique for assigning neuroanatomical labels to each voxel in an MRI volume. The technique is based on probabilistic information that is estimated automatically for each voxel based on a manually labeled training set and is embedded in the Freesurfer program (CorTechs Labs, La Jolla, CA, USA). In contrast to several existing segmentation procedures the program assigns one of 37 labels to each voxel, including left and right caudate, putamen, pallidum, thalamus, lateral ventricles, hippocampus, and amygdala. The classification technique employs a surface-based registration procedure that seems robust to anatomical variability, including the ventricular enlargement typically associated with neurological diseases and aging.[23] The technique has to be comparable in accuracy to manual labeling, and of sufficient sensitivity to robustly detect changes in the volume and tissue of noncortical structures in epilepsy patients.[23,24] We have used the program to automatically label brains of patients with cortical dysplasia and periventricular heterotopia. The program labeled dysplastic cortex as 'cortex of unknown origin'. The technique therefore seems to be a useful approach to direct the eye of the radiologist reading the film (Figure 86a.2).

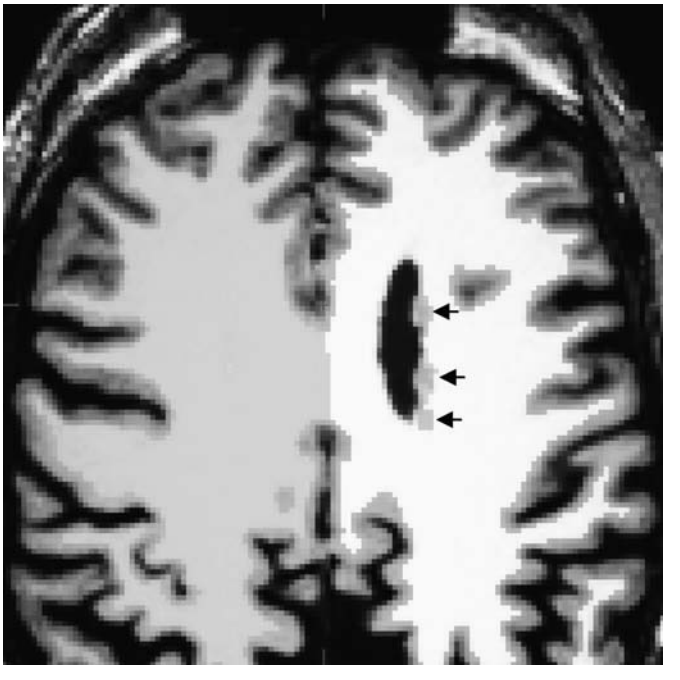

Figure 86a.2 Automated segmentation of a T1-weighted 3D MRI (mprage) of a 42-year-old right-handed patient with left periventricular heterotopia. The program detected the heterotopiua that were labeled as gray matter of unknown origin (see arrowheads).

Quantitative tissue characterization

Huppertz *et al.*[25] have used three novel VBM techniques in SPM for texture analysis of 3D MRI which may improve lesion detection by enhancing image properties not readily accessible by visual analysis. To better identify focal cortical dysplasia, they created 3D maps called 'thickness image', 'extension image', and 'junction image', which characterize three different features of FCD, i.e., abnormal thickness of the cortical ribbon, abnormal extension of gray matter into the white matter, and blurring of the gray-white matter junction (see Figure 86a.3). These methods were applied to the MRI data of 25 epilepsy patients with histologically proven FCD. In each of the new feature maps the locations of the five highest maxima (corresponding to the maximum deviations from the mean of the normal database) were automatically determined and compared with the sites of the lesions in the conventional MR images or – in case of cryptogenic epilepsy – with the resection areas in the post-operative MRI. This approach was able to identify 15/25 lesions in the thickness image and 18/25 lesions in the junction and extension image, respectively. With all feature maps combined, 23 out of 25 dysplastic lesions were identified. Among these cases there were also four patients in whom the dysplastic lesion itself or at least an essential part of it had not been recognized on conventional MR images despite acquisition and assessment in a tertiary epilepsy center.[25,26] These novel VBM techniques may facilitate the detection and localization of FCD and increase the diagnostic yield of MR imaging.

Another method of tissue characterization is to perform multiflip, multiecho FLASH sequences to quantitate T1, T2, and PD at each voxel in the brain. Combined with an atlas, this allows tissue classification and detection of differences that occur with disease.

Cortical thickness analysis

The human cortical surface is extensively folded so that two-thirds is in the sulci. Accurate manual determination of the

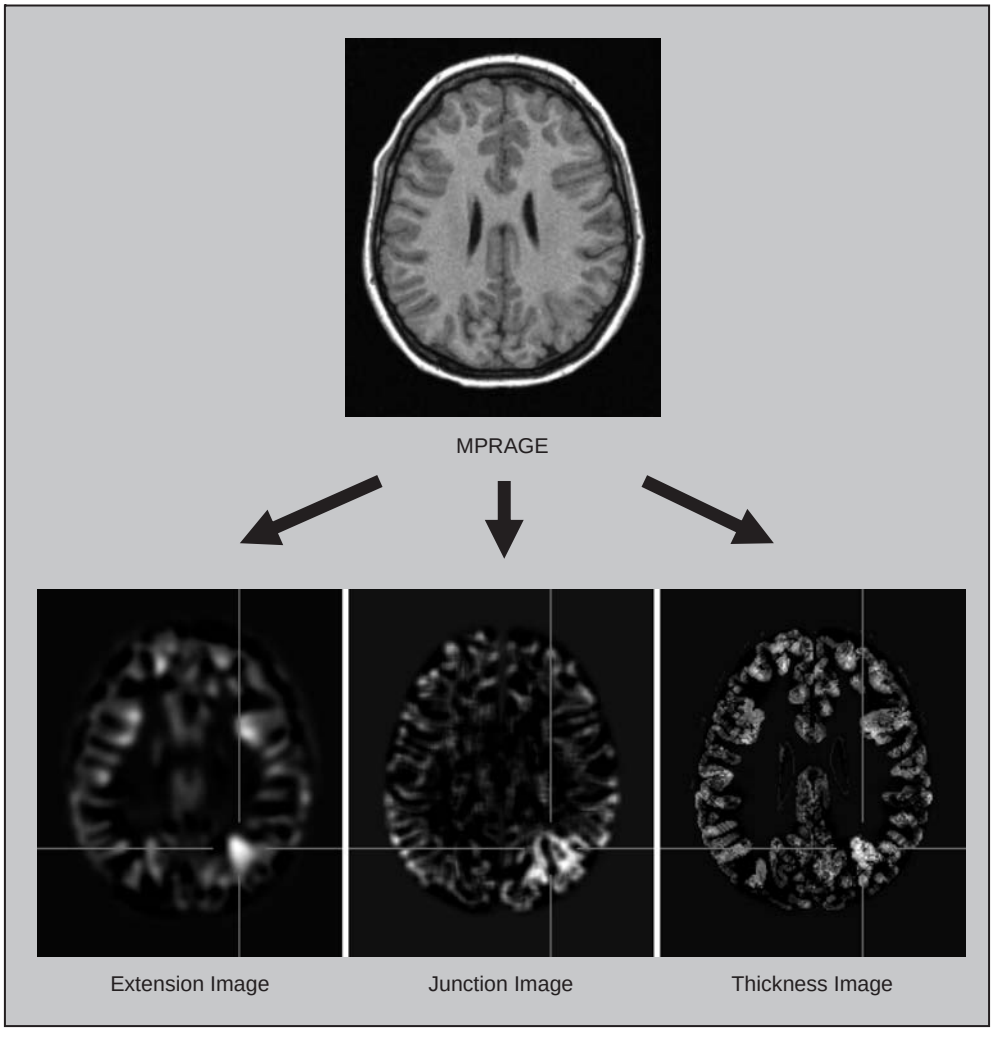

Figure 86a.3 Voxel-based 3D MRI analysis in an 18-year-old female patient with FCD Palmini 2b and SPS, CPS and SGTCS since the age of 2 years: Following the principles of voxel-based morphometry a T1-weighted MRI volume data set (MPRAGE) is normalized and segmented using algorithms of SPM2 (Statistical Parametric Mapping Software, Wellcome Department of Imaging Neuroscience, London). Then, the distribution of gray and white matter is analyzed on a voxelwise basis and compared with a normal database consisting of the MR images of over 50 healthy subjects. Based on this analysis, 3-dimensional maps called 'extension image', 'junction image', and 'thickness image', are created which characterize three different features of FCD, i.e., the abnormal extension of gray matter into the white matter (1), blurring of the gray-white matter junction (2), and slightly abnormal thickness of the cortical ribbon (3). (Courtesy of HJ Huppertz, Swiss Epi Center, Zurich.)

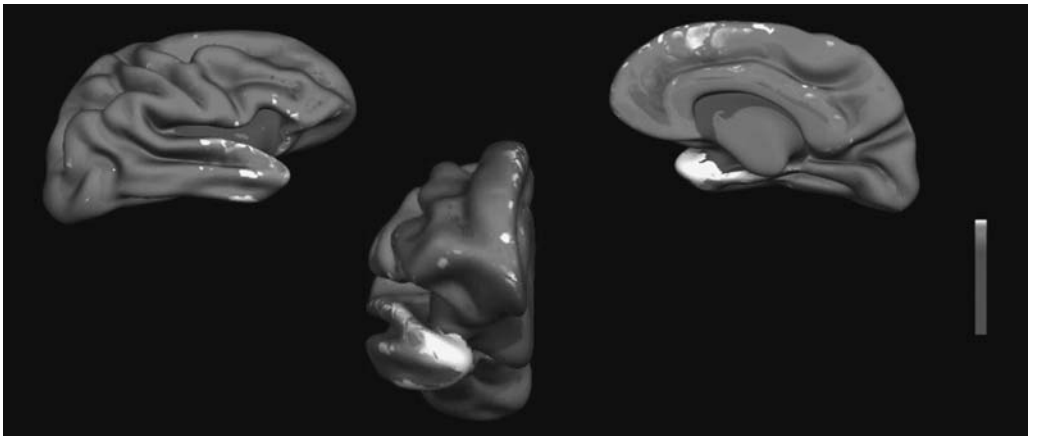

Figure 86a.4 Cortical thickness analysis of the cortex of a 38-year-old right-handed patient with right pericentricular heterotopia.

cortical thickness is labor intensive, time consuming and usually focuses on a priori selected regions of interest. In recent years, semiautomated techniques for analyzing cortical thickness have been developed.[23,27] Using this technique, disease-specific differences in cortical thickness have been detected in patients with Huntington's disease and in aging.[28,29] These intravoxel interpolation methods detect differences in cortical thickness that cannot be appreciated visually and are below the resolution of the image voxel. Cortical thickness measures have the potential to increase the diagnostic yield of MRI and to increase our understanding of the extent and location of cortical involvement associated with different epilepsy syndromes.[3] For example, in four patients with periventricular heterotopia we detected cortical thinning in the ipsilateral temporal lobe, concordant with the seizure semiology (see Figure 86a.4). Tools analyzing the cortical thickness may also help delineate the anatomical extent of epileptogenic cortical lesions. If validation is possible, this technique could provide a more accurate and regionally specific description of normal and abnormal cortex. Kotini *et al.* report the findings of increased cortical thickness in the affected cortex in a patient with unilateral perisylvian syndrom.[30] This technique may be especially beneficial for detecting unexpected widespread cortical pathology or in focusing the visual inspection for lesions in MRI-negative patients with focal epilepsies.[3] By using semi-automated tools, user-dependent inaccuracies are avoided. Currently, these cortical thickness measures rely on the ability to automatically detect a normal gray-white junction in a fully myelinated brain. Therefore, these measures are limited to subjects over approximately 2 years of age. Lesions with blurred gray-white junction are typically detected but the measured thickness of the cortex may be inaccurate due to the poorly defined gray-white junction.

Gyral folding

Quantitative analysis of 2D surfaces in 3D

Techniques like planar or 3D reformation of the brain focus on the visual detection of gyral and sulcal differences. However, the identifiation of subtle changes may require quantitative analysis of the brain curvature and comparison to previously established populations of normals. To perform quantitative analysis of surface properties a topologically correct 2D surface in 3D must be created. As it turns out, the cortical surface is folded in on itself in a way that makes it almost impossible to create a topologically correct surface from the existing volumetric MR data. This occurs because gyral surfaces touch, making it hard to resolve boundaries in an automated fashion. The gray-white surface in comparison does not have this property and therefore it is much easier to construct topologically correct 2D surfaces from this interface. The gray-white boundary is the surface area through which connections exit or enter from gray matter and therefore the characteristics of this interface have implications for cortical and white-matter organization. Only a few centers have begun to quantify properties of these surfaces. Quantities that are calculated include surface areas, local curvature and its components, local Gaussian curvature, local fractal dimension, and wavelet decompositions. Our preliminary data of normal neonatal brain development suggest that the gyri develop in a very regular manner, resulting in conserved curvature properties. We believe that these techniques hold great potential for defining normal growth trajectories and differentiating normal from abnormal brain development. It addition, these methods may improve our ability to detect global changes that occur with congenitial malformations or persistent seizures.

Different techniques have been used describe differences in cortical gyrification in patients with shizophrenia[31] and in Williams syndrome,[32] Ronan *et al.*[33] have used stereology. Quantitative examination of human cerebral gyrification has been applied to detect abnormal gyrification in schizophrenia on healthy brains using the isoperimetric ratio (IPR) as an index of cerebral gyrification. The IPR is a dimensionless ratio defined as surface area corrected for volume allowing for a robust and reliable quantification cerebral gyrification.[33]

Analyzing subcortical structures and white matter

Automated subcortical labelling and volumetry

Accurate manual segmentation techniques are labour intensive, time consuming and tedious. Automated techniques have the potential to make cerebral volumetrics part of a routine clinical assessment, but they currently require validation and standardization before this potential can be realized. The identification of anatomical substructures is based on tissue classification by classifying different gray-level intensities in different voxels. Fully automated analysis tools have been

developed to label different MRI substructures in an unbiased, user-independent fashion.[22,23,34]

Previous studies have shown that volumetry might help identifying the epileptogenic lesion. Especially in patients with temporal lobe epilepsy, volumetry seems superior to pure visual MRI inspection in correctly lateralizing the hippocampal pathology.[11]

We have used the technique developed by Dale and Fischl[23,34,35] to automatically segment the brain in patients with medically refractory epilepsies due to cortical dysplasia. Areas of cortical dysplasia were identified correctly and tissue was classified as 'grey matter of unknown origin' in the respective ares (Figure 86a.2).

Magnetic resonance diffusion imaging

Diffusion-weighted imaging and ADC maps

Diffusion imaging is based on changes in the diffusion properties of water molecues in diseased brain tissue: 'Diffusion' describes the random microscopic translational motion (Brownian motion) of water molecules.[36] Unrestricted diffusion of freely diffusing molecules is spherical, with the radius of the sphere increasing as the square root of the time of diffusion. Diffusion behavior in a highly organized system like the human brain is more complex and restricted and is determined by multiple variables such as fiber crossings, myelinization, ischemia, and neuronal cell density. Diseases of the central nervous system are often accompanied by changes in diffusion. The application of diffusion imaging on patients with epilepsies has been used to postictally identify areas of transient postictal changes.[35,37,38] Acute postictal changes have also been reported in areas distant from the EEG focus, often near the corpus callosum or the splenium.[39,40] Diffusion imaging has been used interictally to study patients with focal epilepsies: Wieshmann *et al.* showed significantly reduced diffusion in sclerotic hippocampi as compared to the nonsclerotic side.[36,41]

Diffusion tensor imaging

The phenomenon of a restricted diffusion is of particular interest to studies that evaluate the integrity of white matter and of fiber tracts. Like DWI, DTI uses the diffusion properties of water in the brain. With standard DTI, in addition to an ADC map from DWI, one also acquires a map that is a measure of the directional bias of diffusion. DTI therefore provides information about the rate, magnitude, and directionality of water diffusion in the brain. DTI contrast is associated with water diffusion and is influenced by microstructural factors such as myelin and other fiber components. A normalized metric of white matter integrity, termed 'fractional anisotropy' (FA) is computed from the diffusion properties within a voxel. Similar metrics have been used to detect white-matter pathology in epilepsy and neurodegenerative diseases.[42–46] Specifically, the more tightly packed and coherent the white matter tract, the more likely the diffusion is dominated by fewer versus many directions, the greater will be the FA value, resulting in a brighter signal intensity on an FA map. The signal abnormality in the DTI scan is presumed to reflect alterations in tissue properties, including decreased myelination or changes in the number of myelinated nerve fibers.[45] DTI is presently being explored as a research tool.

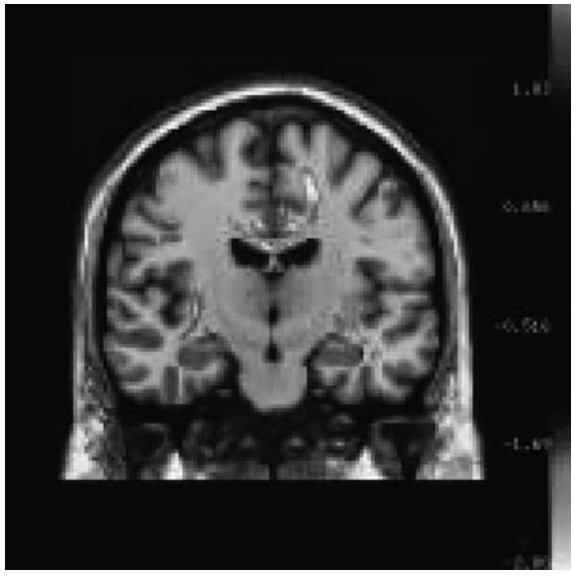

Figure 86a.5 Comparison of fractional anisotropy (FA) maps of 14 patients with left temporal lobe epilepsy due to hippocampal sclerosis and healthy normal controls. Statistically significalnt differences in white-matter organization, measured in FA, are presented co-registered on the anatomical T1-weighted image. Diffences mainly occur in the ipsi- and contralalteral temporal stem and the ipsilateral frontal lobe.

Information of WM integrity provided by DTI could be very useful in the characterization and quantification of epilepsy-associated brain damage and might be used as a marker of disease severity and progress. Our preliminary studies show decreased FA values in the ipsilateral and contralateral temporal stem as well as in the frontal lobe of patients with mesial temporal lobe epilepsy (TLE) (Knake *et al.*, unpublished data) (Figure 86a.5).

In addition to determining the coherence of white matter tracts, DTI can be used to estimate fiber orientation in the brain. To visualize fiber direction, images are color coded according to the direction of the diffusion and then superimposed on an image aquired without diffusion weighting (B0-image) (Figure 86a.6). The green codes for anterior to posterior vectors, blue for superior to inferior, and red for left to right.[48] Although it seems that DTI can identify networks and anatomical tracts, it is uncertain at present, if DTI is able to delineate relevant tracts with sufficient reliability. Voxel-size, artefacts and a variety of technical issues make it difficult to extract fiber directionality from water diffusion.[36]

Conclusions

Improved imaging technique and sequences as well as improved accuracy in data registration and the use of fully automated techniques will have a huge impact on standard MR imaging in the pre-surgical evaluation in future. However, most techniques are new and have to be validated in large, prospective studies.

It would be desirable to combine functional imaging techniques like EEG, fMRI and MEG with new structural imaging techniques to better define the epileptiogenic lesion, the irritative zone and the seizure onset zone, in respect to the eloquent cortex.

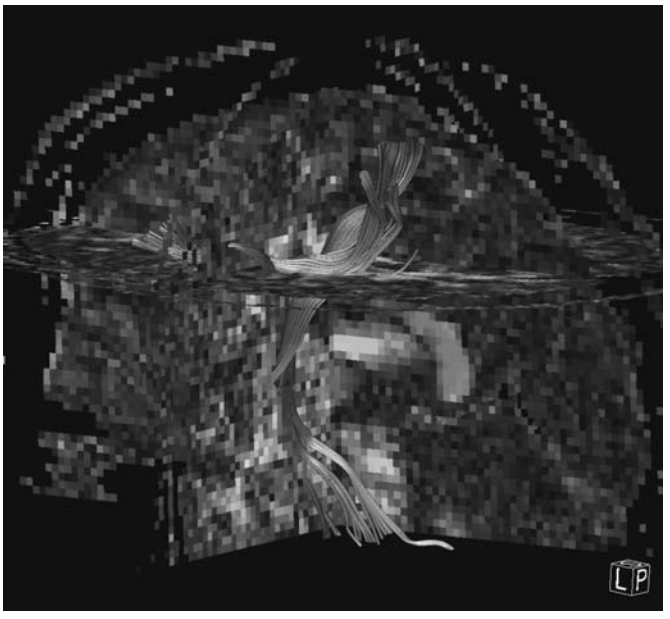

Figure 86a.6 Diffusion tractology image. Left corticospinal tracts (blue), interhemispheric connections (green), calculated from high-resolution diffusion tensor sequence at 3 T using custom built software by Drs Ruopeng Wang, Greg Sorensen, and colleagues at the HST A.A. Martinos Center for Biomedical Imaging. The directional bias of the diffusion can provide information about the structure of underlying white-matter tracts. Analysis techniques under development may enable statistical measures of connectivity which, in turn, may further our understanding of cerebral malformations and seizure propagation.

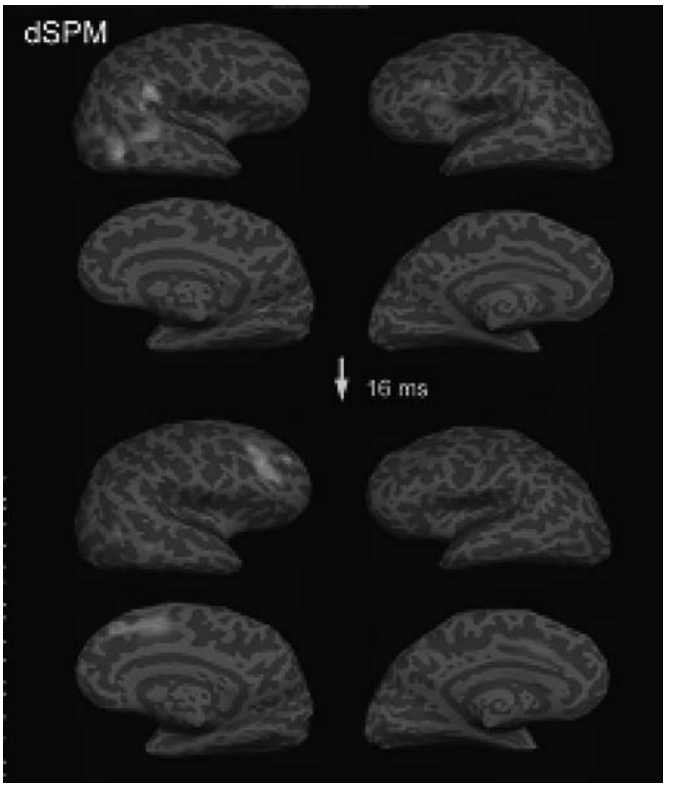

Figure 86a.7 MEG data of a 17-year-old right-handed boy suffering from right hemispheric epilepsy (referred by Dr G. Holmes, Children's Hospital, Boston). During the investigation several MEG-only spikes but no spikes were recorded on EEG. Magnetic source imaging of all recorded MEG spikes (right side) mapped the IED to the right posterior temporal lobe. Dynamic SPM of one IED shows that the spike is spreading from right posterior temporal to the right frontal region within 16 msec. 86b Multimodal image processing in pre-surgical planning

C Vollmar, S Noachtar, and PA Winkler

Introduction to the multimodal image processing approach

As described in Chapter 47, the definition of the epileptogenic zone is the key challenge in pre-surgical evaluation of epilepsy. The epileptogenic lesion and the seizure onset zone will typically be included in the epileptogenic zone. However, it is known that they may reflect only the core of the epileptogenic zone and that the irritative zone, the symptomatogenic zone or even the functional deficit zone can further contribute to epileptogenicity and can also define an additional part of the epileptogenic zone. In most chronic focal epilepsies, all these zones are partially overlapping, with different spatial extent and a complex mutual relationship between them. Additionally, most of these zones are not visualized directly by any imaging modality, but images reflect various physiological tissue characteristics and different aspects of epileptogenicity. Interpreting diagnostic images in the pre-surgical evaluation of epilepsy includes the task of assigning individual imaging findings to the theoretical zones described above: a regional hyperperfusion shown in an ictal SPECT study may reflect the seizure onset zone only, or spread to the symptomatogenic zone can already be involved. This judgment will be based on the exact time of injection in relation to seizure onset, EEG findings, seizure semiology and other information on the clinical context.

The presence of any structural lesion can further influence the regional perfusion. Facing the complexity of this mutual relationship between different imaging modalities, a precise topographic correlation of all available diagnostic modalities is helpful. Image coregistration and the combination with a three-dimensional reconstruction of the patient's individual cortical anatomy can assist the interpretation of each single modality and finally support a conclusive interpretation with the aim to individually define the epileptogenic zone for resection.

To transfer imaging findings from original or post-processed images into the operating theatre, it is necessary to provide some guidance, which allows a reliable correlation of images with the real brain.

The use of navigation systems is possible[1], however epilepsy surgery often includes large craniotomies, causing a significant brainshift, due to loss of CSF or distortions during the course of an extensive resection.[2,3] A significant brain shift also occurs after removal of a subdurally implanted grid, which is typically the occasion to proceed with the resection of the epileptogenic zone. To overcome this issue, we focussed on the topography of the cerebral venous system to provide anatomical landmarks for planning and tailoring cortical resections. The specific shape of the superficial venous anatomy is fixed to cortical anatomy via the arachnoid trabecular system.[4,5] This makes superficial cortical veins a reliable anatomical landmark, overcoming the trouble of brainshift. Finally this allows for a precise intraoperative localization of previously identified structures like subcortical lesions or the seizure onset zone or eloquent cortex, even in extensive craniotomies.

The aim of this chapter is to provide the reader with a short overview of techniques for multimodal image correlation, applicable in the pre-surgical evaluation of epilepsy. The specific contribution of multimodal image processing to the definition of the epileptogenic zone and for planning individually tailored cortical resections will be illustrated in several clinical examples.

Requirements

Increasing computing performance makes the technical basis for multimodal image processing available to a wide community. All the images in this chapter were created on a standard Personal Computer (Intel Pentium IV, 1.8 GHz CPU, 512 MB RAM), equipped only with an additional consumer class ('gamer') graphic acceleration card. Improvements in diagnostic imaging, like the invention of 3 T MRI scanners or multislice CT scanners, allows the acquisition of datasets with a higher spatial resolution, resulting in bigger image datasets being processed. However, this development coincides with a continuous increase in computing power and storage capacity of personal computers. In practical terms this means, a standard personal computer in the $ 1000 category has always been sufficient for multimodal medical image processing for the last few years, and most likely there will be no need for a higher investment during the next few years.

Searching the internet for 'medical image processing' will provide a broad bandwidth of possible software packages, including free and commercial products. The decision on which software to use should be based on previous experience in your department, since all available software packages require some period of time for training. It is important to mention, that most of the software is marketed for research

purpose only, and not for clinical patient care. This reminds us that every single step of image processing is a possible source of errors, and that clinical decisions should never be based on image processing results, without confirmation by the clinical context. The decision, how much image processing is allowed to contribute to clinical decision underlies the physician's responsibility. Typically, the involvement will increase over time, with more experience and confidence in the image processing procedures.

Another issue for image processing is the comfortable accessibility of digital image data. In a fully digitized hospital, employing modern network infrastructure and a PACS system, it will be easy to collect and process image data from several departments. However, with a less advanced infrastructure it is just a bigger effort, to export, convert, and transfer image data from different modalities and departments, yet image processing can still be performed.

Image acquisition

The basis for multimodal imaging is typically a T1-weighted, high-resolution volume acquisition MRI dataset. It serves as the primary dataset for all further image registration procedures, and also provides the anatomical basis for all further localizations, including the three-dimensional reconstruction of the patient's cortical surface. At the University of Munich Epilepsy Centre we use a sagittally acquired fast gradient echo T1 sequence, providing isotropic 1 mm^3 pixels ('mprage' on Siemens MRI-scanners or 'FSPGR' on General Electric scanners). An image matrix of 256 × 256 pixels and a slice thickness of 1 mm are entirely sufficient to depict the patient's individual cortical anatomy; however, the higher resolution that is becoming available with higher field strengths can further improve the image quality. Besides this anatomic basis dataset, a number of additional sequences will be acquired, following established protocols for epilepsy, or driven by specific questions from the clinical context. There are no specific requirements to allow further processing of additional MRI sequences. Limiting the slice thickness to not more than 4 mm warrants a minimum image quality after reformatting of images and will improve the reliability of image registration.

For visualization of the superficial cortical veins, we currently use a contrast enhanced 2D-Time-of-Flight-Angiography-sequence with a 512 × 256 matrix and 2 mm slice thickness. However, comparable results have also been achieved with different angiography sequences.

In nuclear medicine, SPECT and PET images can usually be acquired by routine protocols; most departments will create transverse datasets with isotropic pixels of about $3 \times 3 \times 3$ mm^3 which can perfectly be used for further image processing.

Image coregistration

The first step in multimodal image processing is image coregistration. This term describes the procedure of spatially aligning two different image datasets in a way that both studies show the same anatomic structure in every pixel. One dataset is defined as 'primary' or 'reference' and is left unchanged. The 'secondary' dataset is then transformed, to match the reference. Since the transformation and resampling of the secondary dataset requires interpolation, a modest loss of image quality is possible. For this reason, typically the higher resolution data like MRI is defined as 'reference', and the lower resolution data like PET is transformed to match the MRI.

The minimal necessary transformation to align two three-dimensional datasets from one patient is a 'rigid body' transformation, and uses six degrees of freedom: translation and rotation along the three perpendicular axes of a coordinate system. The scaling and internal configuration of both datasets remains unchanged. For image registration from different individuals or for the registration of an individual dataset to a normative template, a 'nonrigid transformation' might be necessary, which includes additional scaling or stretching of the datasets. These nonrigid transformations are based on complex algorithms and contain several sources of artificial influence on the image data. Currently this limits their use in clinical routine; nonrigid transformations are primarily applied for group comparisons in research settings.

In the pre-surgical evaluation of an epilepsy patient, the rigid body transformation of several imaging modalities will be sufficient to achieve the image registration, necessary for multimodal correlation of different imaging findings. However, even a rigid body transformation has to be verified to estimate the accuracy of the procedure, before its results are allowed to influence clinical decisions.[6] A rigid body image registration can be performed either automatically or manually.

Automatic image registration

All automatic methods are based on comparable principles, which will be illustrated briefly using the example of the 'pixel uniformity registration', also known as Woods' algorithm[7] as a representative method. The first step in this method is a classification of the primary modality, e.g. an MRI, into several groups of pixel values. The idea is that each of these pixel groups should represent an 'organ' or an anatomically defined structure. When matching this group of pixels with a second modality, e.g. a PET, it is obvious that the PET pixel values will be different in these defined 'organs'. Also there will not be a linear relationship between an 'organs' pixel values in each modality. However, at least the 'organ' is supposed to show homogenous pixel values, also in the second modality. With this assumption, the uniformity of pixel values in the second modality, within each pixel class of the first modality is analysed. An improvement of this uniformity is assumed to represent a better registration. Therefore, this uniformity is defined as a measure for the quality of a registration. The last step is now to optimize this measure of quality. The aim is to find the transformation of the secondary dataset that leads to the best possible pixel uniformity, according to the above definition. This is usually achieved with an iterative optimization process, which is a trial-and-error approach initially, changing the transformation parameters arbitrarily and recalculating the measure of quality. Parameter changes that improve the quality of the registration are recognized by the optimization algorithm and the next changes will be guided by previous achievements. This iterative procedure is repeated, until a predefined threshold is reached, or until a maximum number of iterations have been performed.

Most automated methods for image registration can be broken down into these three steps: First, some kind of classification or segmentation of the primary datasets is performed.

Secondly a measure of the quality of the registration is defined, typically including some correlation of pixel values between the two datasets. It is assumed, that an optimization of this error measure reflects an improved registration. Thirdly, this error measure has to be optimized, typically by an iterative approach. Each of these three steps can be modified and optimized independently, in order to improve automatic image registration.

However, despite all the major improvements in the field of automated image registration, all automatic algorithms are inevitably still prone to errors when used in the clinical setting of epilepsy surgery.

From a clinical point of view, divergences between different imaging modalities are exactly what we expect from a multimodal pre-surgical evaluation. In a patient with normal MRI, we perform a PET scan, because we expect the patient's pathology to be apparent by a change in glucose metabolism or receptor density, in spite of a normal MRI. This is the clinical reason why we perform the PET scan. For an automated algorithm this discrepancy will be regarded an error, worsening the measure of registration quality and the algorithm will try to correct this 'mismatch'. The possible work to identify those regions manually from an image dataset and exclude them from the automated registration algorithm is significant.

Manual image registration

On the other hand, there is the possibility to perform image registration manually. This typically means that a user interface is provided to the operator to perform the registration by hand. Usually the primary dataset is displayed as grayscale image in the background and is superimposed by the second dataset, using a transparent colour encoding, isolines or alternating display patterns. The user then has to shift and rotate the secondary dataset manually in all three orientations, until the best fit has been achieved visually. This is an interactive process, including a final visual control by scrolling through the whole dataset, to ensure an adequate registration quality.

This manual approach has several advantages, which is the reason why we only perform manual image registration in clinical routine at the University of Munich Epilepsy Centre.

Many 'automated' methods for image registration require a significant amount of user interaction to prepare the automatic procedure. The removal of the skull from images, or the manual identification of 'regions of interest', are often necessary tasks. The time spent in such preparations of the data quickly amounts to several minutes. Furthermore, one can hardly trust an algorithm blindly, and every automated image registration has to undergo some plausibility check by the physician. The minimum check a physician has to perform, is scrolling through the whole registered dataset to check the registration accuracy. This check will typically take a few minutes. Both of these steps are not necessary if the registration has been performed manually under permanent visual control of the user.

In the case of suboptimal image quality in either modality, the physician can identify the more reliable areas, or the areas of more clinical interest, and then focus on these areas during the manual image registration procedure. Not only technical artifacts, but also discrepancies in the imaging findings, can easily be detected and interpreted by the physician, who knows the clinical context. An automatic algorithm usually does not know how to handle such difficulties, and is likely to fail.

Finally, it could be shown, that the achieved accuracy of manual registration is superior to that of automated algorithms, when analyzing the registration of MRI and ECD-SPECT.[6] An accuracy of 1.5 mm could be achieved manually, and the effect of user- dependency could be shown to be negligible. Similar results have been achieved for registration of other modalities to an MRI dataset, namely PET, CT and MR-angiography, with errors between 0.9 and 1.5. Even the total processing time is lower for manual image registration, taking into account the above-described preprocessing and quality checks for automated algorithms. A manual registration can usually be performed in less than five minutes.

Image segmentation and 3D reconstruction

Image registration alone already allows a correlation of imaging findings from two different modalities. However, datasets are still only analyzed in 2D slices, not in the context of the patient's individual cortical anatomy.

Visualization of the cortical surface requires a three-dimensional rendering of an anatomical MRI dataset. Usually some manual image preprocessing is required before 3D rendering can be performed, namely the segmentation of the brain to separate it from skull and skin. This processing step can be performed automatically or manually. Our preliminary experience with automated segmentation algorithms showed that they work fine at the lateral convexity of the brain and can provide sufficient segmentation within minutes. However, in clinical routine, these algorithms are often limited by artifacts, e.g. skull base susceptibility artifacts or artefacts from eye movement, which typically appear at the level of the temporal lobes. Separating the dura from the cortical surface is also a challenge for automated algorithms, especially in images from patients with a history of previous neurosurgery or meningitis. Fully manual image segmentation, on the other hand, is the most time consuming step in 3D image processing. To manually segment a high resolution MRI of the brain, a trained user will need 15–30 minutes, depending on the characteristics of the dataset, software and user skills. Even the use of supportive tools, like interpolation of the segmentation or automated edge detection, barely reduces the total processing time. As with image registration, we also perform image segmentation manually at the University of Munich Epilepsy Centre. A time-saving compromise can be, to segment only the hemisphere of interest and leave the other side unsegmented. Other than segmenting the whole brain to display the patient's cortical anatomy, in some cases it is reasonable to also segment pathological findings from other MRI sequences or from other modalities. For example, FLAIR images can show focal signal increase in cortical dysplasia or may help to delineate the extent of structural lesions such as posttraumatic gliosis, and can reasonably be segmented for further visualization. In complex cases, the segmentation and colouring of anatomical landmarks such as the precentral gyrus can be helpful.

After the segmentation of the brain surface, we perform 3D volume rendering in order to display the cortical surface three dimensionally. Volume rendering applies for each pixel transparency settings, defined by a colour table, which is specifically adjusted to the underlying MRI sequence. Pixel values for gray and white matter will typically be displayed almost opaque, while lower values for CSF or higher values for fat will be displayed more transparent or completely invisible. This allows for some tolerance with the brain surface segmentation, because thin layers of dura will only slightly change the appearance of the underlying gyri. In case other image modalities show subcortical findings, then the overall transparency of the 3D rendering can be increased, to improve the view to the depth of the dataset. On the other hand, this procedure will reduce the quality of the superficial cortical anatomy.

For visualization of subdural or depth electrodes from a CT scan, no segmentation is necessary. Since the metal electrodes have a higher X-ray density than any tissue, a simple threshold technique with a cutoff at 2300 Hounsfield units can usually isolate the electrodes for further visualization.[8] Some subdural electrodes can be more difficult to display, if by chance the thin platinum contacts are positioned almost parallel to the CT slice orientations. This can happen to temporo-basal or fronto-orbital electrodes, typically resulting in lower pixel values in the CT scan which requires an adjustment of the threshold value. Once the invasive electrodes are visualized, all results from EEG recording and cortical stimulation can also be localized in the image data.

Image arithmetic

For some images, further processing has to be performed, before the final results can be defined and included in the multimodal visualization. The most common application of arithmetic calculations performed on image datasets is the subtraction of ictal and interictal perfusion SPECT, as described in the chapters on SPECT scans.[9] It is important to keep in mind, that such a subtraction is prone to different influences. The amount of injected activity may vary between both SPECT studies, requiring a normalization of the datasets' count rate before subtraction. After subtracting the interictal 'baseline' image from the ictal image, a 'difference' image is created, showing the specific change in perfusion at the time of injection. This image can now be displayed with different thresholds, modifying the extent of change that is visualized. Typically, the most prominent change in perfusion can be found in the seizure onset zone; however, areas of seizure spread, like the symptomatogenic zone or parts of the irritative zone may also be involved. A later time of 'ictal' injection might result in an actual postictal scan, showing a reduced blood flow. In this case, the postictal image would then be subtracted from the interictal scan. The knowledge of the clinical context of the tracer injection, is vital to handle the images adequately, and this requires a close interaction between different involved departments.

In some cases, the regional hyperperfusion can be prominent enough to be displayed without subtracting the interictal scan; in others, it might be beneficial to combine both and add the subtraction result to the whole ictal scan. Whichever way is chosen to calculate and visualize the relevant findings, it is important to always check the original data, to confirm the plausibility of any postprocessing result.

Illustrative case reports

After this technical introduction, illustrative case reports should demonstrate the relative contribution of each imaging modality, and of image processing, in the pre-surgical evaluation of epilepsy patients.

Patient 1

M.R. is a 32-year-old male patient, suffering from frontal lobe epilepsy since the age of 15. He suffers from tonic seizures of the face, evolving to left sided tonic and clonic seizures, eventually further evolving to hypermotor or automotor seizures and GTCS. At the time of pre-surgical evaluation, the seizure frequency on medication was 18 per month.

Initial MRI studies were normal, an FDG-PET scan revealed extensive right temporal and right frontal hypometabolism. Video-EEG monitoring with surface electrodes was performed, and showed interictal spikes and polyspikes, in the right frontal region, and continuous right frontal slowing. Ictal EEG showed consistent right frontal seizure patterns. Therefore, the patient was considered for epilepsy surgery and scheduled for implantation of subdural electrodes to prepare a right frontal resection.

Additionally, a Flumazenil-PET scan was acquired in order to localize the seizure onset zone. The scan showed a circumscribed reduction in GABA-A receptor density (white arrow) in the right frontoorbital cortex (coronal slices through the frontal lobes, Figure 86b.1a). The right frontal lobe was extensively covered with subdural electrodes, as shown in the right lateral view in Figure 86b.1b. Visualization of the electrodes was carried out by image registration of an anatomic T1-weighted MRI scan and a postimplantation CT scan and then combined 3D volume rendering. Figure 86b.1c is a combined image registration of the same MRI, the electrodes and the colour encoded Flumazenil-PET scan (inferior view to temporal lobes and orbitofrontal cortex). It shows the right fronto-orbital reduction in GABA-A receptor density (dark blue area) and its good correlation with the seizure onset zone as recorded from invasive EEG (black electrodes).

An ECD-SPECT scan was performed to visualize the regional hyperperfusion during a seizure, and it revealed a prominent hyperperfusion in the lateral right frontal lobe (Figure 86b.1d). Image fusion with MRI (Figure 86b.1e) allowed anatomic localization of the hyperperfusion (red spot). Figure 86b.1f shows the corresponding 3D rendering, localizing the hyperperfusion to the most posterior portion of the middle frontal gyrus. Since early spread of seizure activity and the maximal frequency of interictal spikes were also recorded from this area, it was decided to include this region in the resection. The detailed 3D view and corresponding equivalent intraoperative photograph (Figure 86b.1g and 1h) show a perfectly matching cortical anatomy. The posterior border of the frontal lobe resection was marked by a black cord intraoperatively and it includes the inferior portion of the central region(Figure 86b.1h). The photograph also shows a prominent artery and vein, crossing the border of the resection. Vascular anatomy was not included in the pre-operative imaging procedure at the time, but this example shows how helpful it would have been for the resection planning.

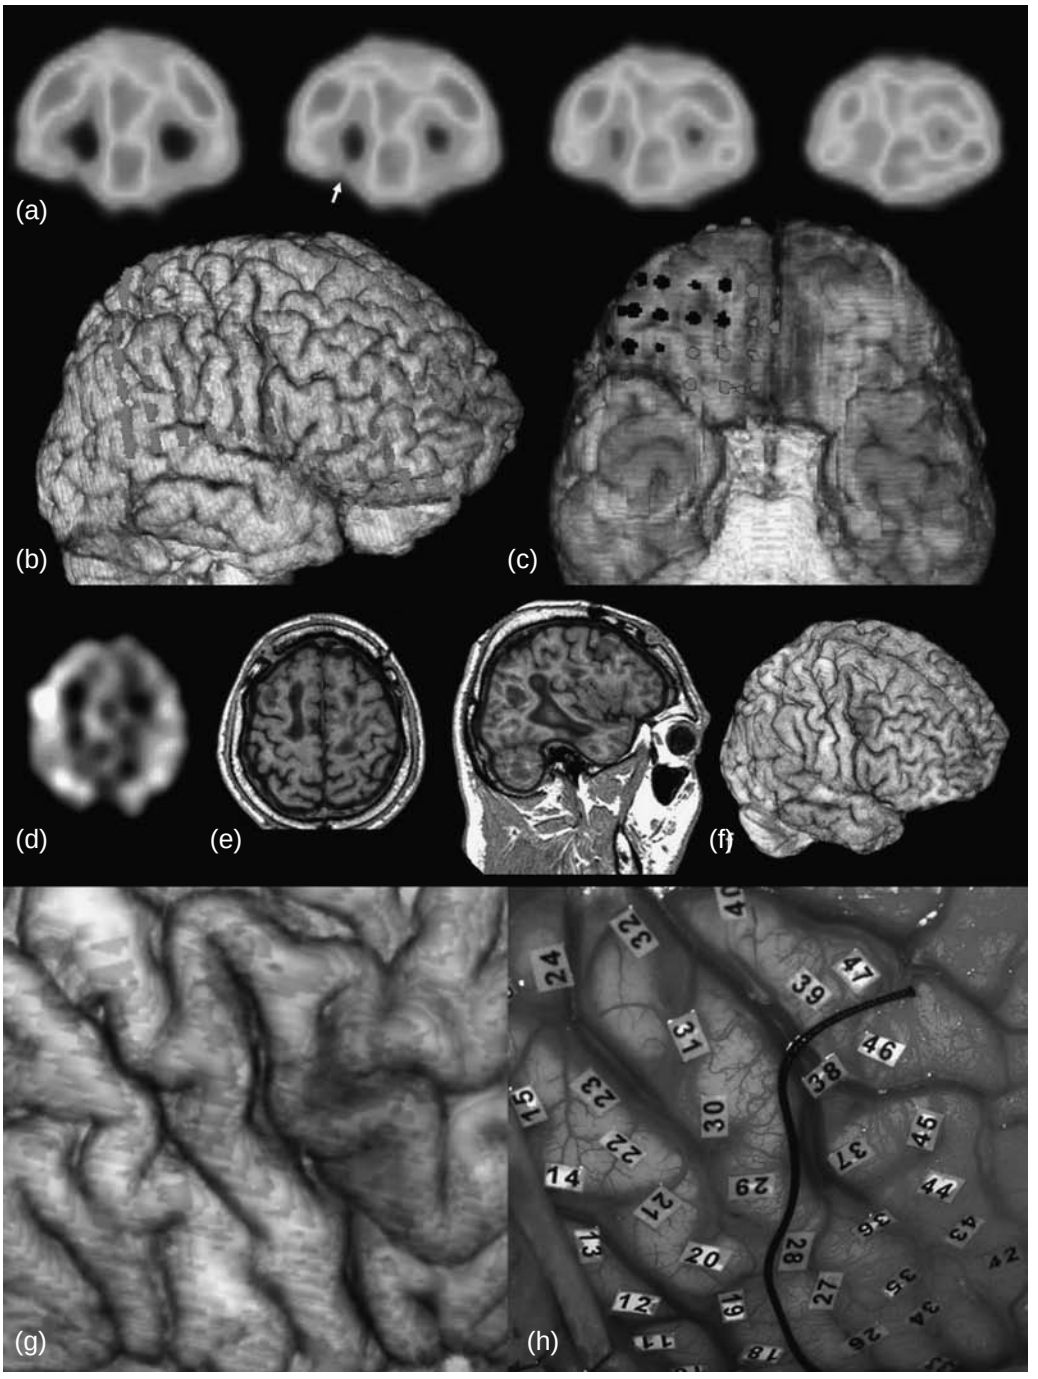

Figure 86b.1 Patient 1. Flumazenil-PET (coronal slices) showing reduced GABA-A receptor density in the right frontoorbital region (a). Subdural electrodes were implanted (b), confirming right frontoorbital EEG seizure onset (black electrodes), overlapping with the PET hypointense area (blue) (c). Ictal SPECT showed marked hyperperfusion (d) in the right middle frontal gyrus (e,f,g). This area was included in the resection (h). (See Color plates.)

Patient 2

A.F. is a 45-year-old female patient, who developed posttraumatic left temporal lobe epilepsy as a consequence of head trauma at the age of 17. Ten years after a car accident, she suffered from epigastric auras, dialeptic seizures, and automotor seizures with an increasing frequency (ten per month at time of admission). T1-weighted MRI showed a posttraumatic defect in the left temporal neocortex (white arrow, Figure 86b.2a, sagittal, transverse and coronal view). Video-EEG monitoring with surface electrodes confirmed left temporal origin of the seizures. Recurring postictal aphasia was indicative of a close topographic relation between the seizure onset zone and language relevant areas. Consequently, subdural electrodes were implanted, to localize the seizure onset precisely and to perform cortical stimulation for the identification of eloquent areas. Figure 86b.2b shows the implanted electrodes and their relation to the posttraumatic defect, which was labeled in orange (derived from FLAIR images). Figure 86b. 2c shows the results of the invasive evaluation, with a seizure onset zone (black electrodes) on the posterior border of the lesion, and an overlap with speech relevant areas (yellow electrodes). Because speech representation was very extensive in this case, and since we know, that inferior temporal language areas are usually accessory areas, it was decided to include this electrode in the resection. Motor responses were elicited from the red electrodes. The gray electrodes indicate

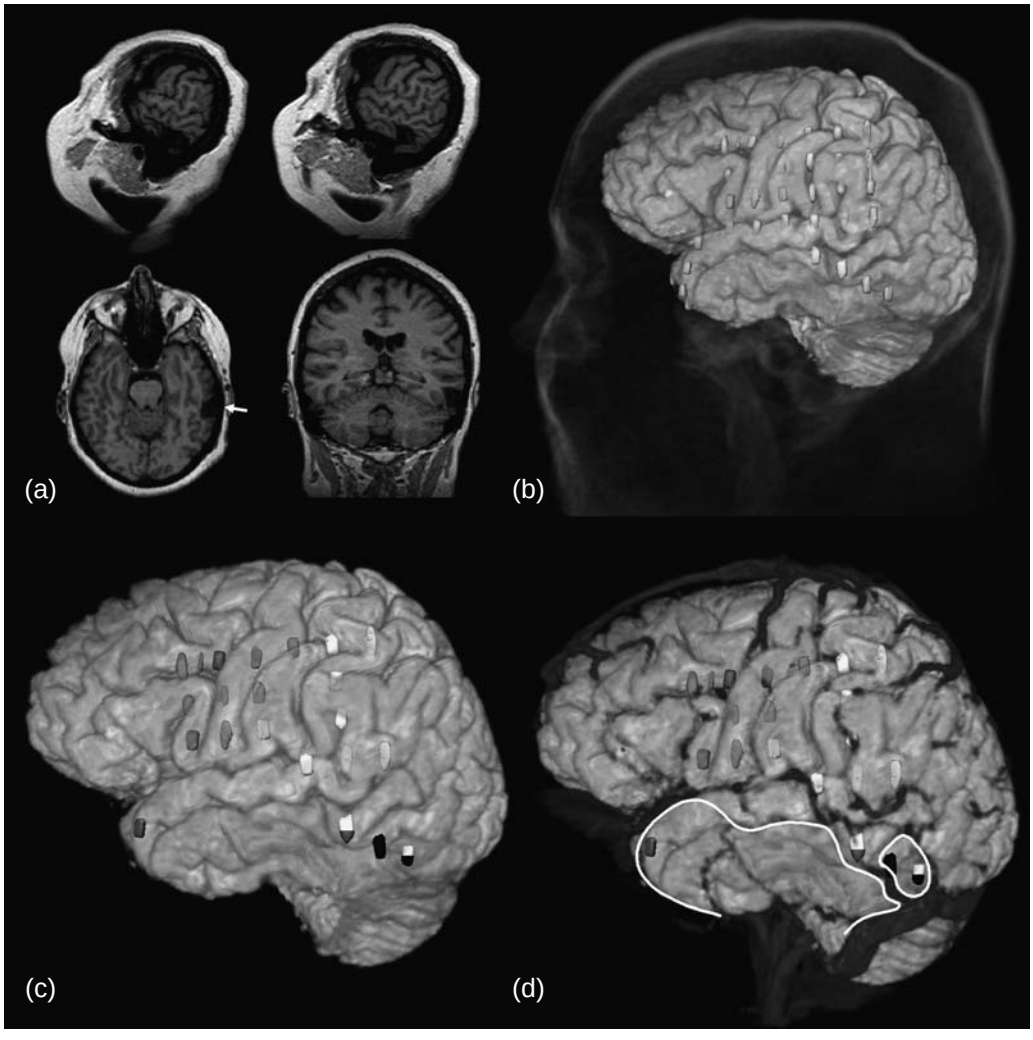

Figure 86b.2 Patient 2. T1-weighted MRI showed a posttraumatic defect in the left inferior temporal gyrus (a), with adjacent gliosis, apparent as FLAIR hyperintensity (orange in b,c,d). Subdural electrodes were implanted (b), localising the seizure onset (black electrodes) and language relevant areas (yellow electrodes, c). Venous MR-angiography revealed a prominent anastomotic vein of Labbé that had to be preserved during the resection (d). (See Color plates.)

interictal spiking. However, the maximum of interictal spikes was recorded from the mesio-temporal stripe electrodes (not visible in this lateral view), and justified a complete resection of the anteromesial temporal lobe. The newly developed technique to visualize the superficial cortical veins, showed a prominent anastomotic vein of Labbé, which had to be preserved, crossing the planned area of resection (Figure 86b. 1d). Additionally, an accessory duplicate vein of Labbé was present in this case, a common variation already described by Labbé in 1868.[10] Therefore, resection was limited to the part of the temporal lobe anterior to the vein. An additional topectomy of the seizure onset zone between both, the first order and the accessory veins of Labbé was also carried out (white resection line).

Patient 3

M.V. is a 44-year-old secretary, who suffered from short bilateral tonic seizures at night since childhood. Occasionally, she would also experience astatic seizures and GTCS. Initial MRI studies were normal, EEG showed rare interictal polyspikes in the right frontal region. At time of admission for epilepsy surgery, a new MRI was performed and 3 mm T1-weighted inversion recovery images (Figure 86b.3a) showed a circumscribed blurring of the cortical band with a corresponding slight increase in FLAIR signal (Figure 86b.3b) in the medial aspect of the dorsal superior frontal gyrus, close to the margin, on the left side. These findings confirmed the clinical hypothesis of a focal cortical dysplasia (FCD).

However, the reconstruction of the superficial veins (Figure 86b.3) showed a complex formation of draining veins over the FCD, making the implantation of subdural electrodes more difficult. From the venous topography, it was obvious that the craniotomy had to be extended towards the frontal pole, to allow for an implantation of electrodes in the medial surface of the frontal lobe, circumventing by the bridging veins Figure 86b.3d shows the localization of the medial electrodes, covering the FCD in a view to the medial surface of the left hemisphere. EEG Seizure onset in the region of the FCD could be confirmed (black electrodes). Cortical stimulation identified

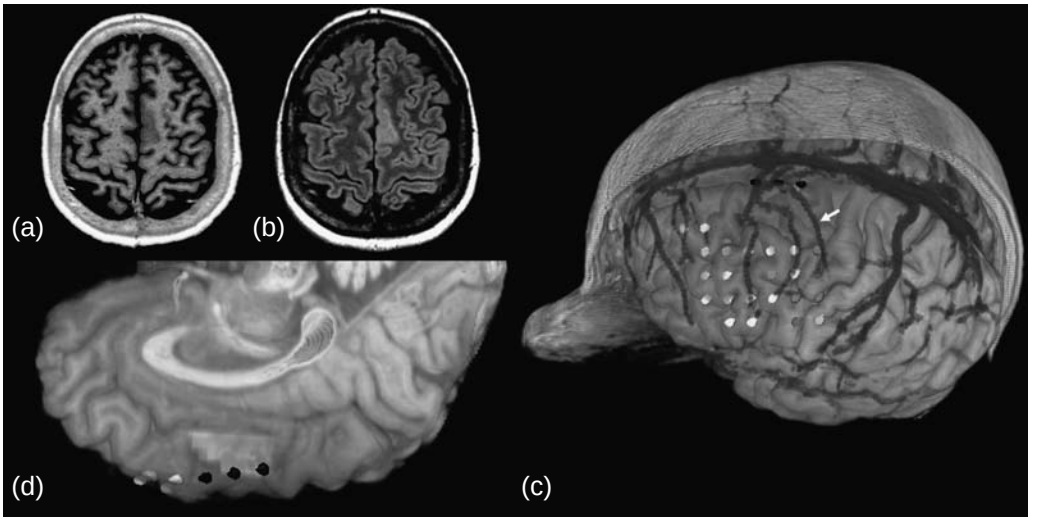

Figure 86b.3 Patient 3. Repeat MRI identified a focal cortical dysplasia in T1 (a) and FLAIR (b) images. Surgical access to the lesion (orange) was complicated by an intricate formation of cortical veins (blue), one of them also draining parts of the primary motor cortex (arrow). Preservation of this vein was crucial in order to avoid venous infarction. (See Color plates.)

motor (red), sensory (green) and speech (yellow) relevant eloquent areas.

A critical aspect of the venous anatomy is the drainage of the central region. A prominent vein (white arrow in Figure 86b.3c), draining the central region, which includes the right hand primary motor area was draining anteriorly and passing through the caput- medusa- like configuration of veins over the FCD. This vein had to be preserved, to avoid venous infarction of the central region. Part of the implanted grid electrode had already been cut off to avoid compression of this fragile venous configuration. The resection was a tricky surgical procedure, since it had to remove the complete FCD, reaching down to the cingulate gyrus, without sacrificing the adjacent lateral eloquent cortex, and without damaging the critical vein draining a part of the central region. This case shows how the reconstruction of superficial cortical veins helped in planning the implantation of invasive electrodes, as well as the resection itself. Also, the risk of a planned resection and the chances for complete removal of the target can be estimated more reliably. This combination of lesion localization and venous reconstruction allowed the veins to serve as robust anatomic landmarks, guiding the surgeon to the target region on the medial surface.

Summary

Defining the epileptogenic zone and defining the borders of a neocortical resection are the key challenges in epilepsy surgery. A wide range of different imaging modalities is included in the pre-surgical evaluation of epilepsy patients. It is beneficial to use all the available information from MRI, PET, SPECT, and CT scans. However, 2D images are usually not sufficient to precisely evaluate the topographic relationship between different imaging modalities. Multimodal image processing, including 3D reconstructions of the patients, individual cortical anatomy, allows a true anatomical correlation of all integrated relevant imaging findings. This approach is helpful for the interpretation of single imaging findings and in the individual planning of cortical resections.

The visualization of the superficial cortical veins can serve as brainshift-resistant anatomic landmark and therefore allows the transfer of diagnostic information into the operating theatre. Furthermore, the information about the venous anatomy can help to avoid complications such as venous infarction and improves the estimation of the individual risk benefit ratio of epilepsy surgery.

SECTION 9

The functional deficit zone

87 The functional deficit zone: general principles

C Baumgartner and E Lehner-Baumgartner

Definition

The functional deficit zone is defined as the brain area that shows abnormal functioning in the interictal period. This abnormal functioning can be due to the effects of a structural lesion and/or due to the functional consequences of the persisting epileptic condition. The location and extent of the functional deficit zone can be assessed directly with the neurological examination and neuropsychological assessment (including the Wada test) and indirectly using surrogate markers of abnormal functioning including electroencephalography (EEG), magnetoencephalography (MEG) as well as functional neuroimaging tools like single-photon-emission-tomography (SPECT), positron-emission-tomography (PET), magnetic resonance spectroscopy (MRS) and functional magnetic resonance imaging (fMRI).

Neurological examination and neuropsychological assessment

In the early days of epilepsy surgery careful neurological examination was the only way to localize the epileptogenic lesion and the epileptogenic zone. However, even in the age of modern neurophysiology and neuroimaging, the clinical examination should precede the use of these techniques in order to exploit their full diagnostic potential. Careful neurological examination can reveal abnormal function, be it behavioral, motor, or sensory. Characteristics of the dysfunction often pave the way for a topographical diagnosis.[1] Nevertheless, neurological deficits are only present in a minority of surgical candidates because many cortical regions may be dysfunctional without causing abnormalities in the neurological examination, i.e. clinically silent.[2]

Several different causes can be responsible for neuropsychological dysfunctions in patients with focal epilepsy:

- A circumscribed structural lesion responsible for the patient's epilepsy, i.e., the epileptogenic lesion. Here, location and type of the lesion are decisive for the profile of neuropsychological impairment.
- Structural lesions remote from the seizure-onset zone, for instance in a patient with multiple lesions due to cerebral trauma. Approximately 10% of patients who survive severe traumatic brain injury will develop epilepsy. While memory and attention/information processing speed and efficiency are typically the cognitive domains most severely affected by head injury, intellectual, language, and perceptual skills tend to be relatively preserved.[3]
- Diffuse brain damage causing both the patient's epilepsy and neuropsychological impairment.
- Neuropsychological deficits can also occur in patients suffering from focal epilepsy with normal MRI scans. This patient-group constitutes about 20–30% of surgical candidates.
- Functional disturbances can arise remote from the epileptogenic lesion, i.e., lateral temporal or extratemporal dysfunctions in patients with mesial temporal lobe epilepsy.
- Functional disturbances can be caused by interictal epileptiform discharges, also referred to as 'transient cognitive impairments (TCI) caused by interictal epileptiform EEG discharges'.[4] While interictal epileptiform EEG discharges may cause additional and independent transient cognitive impairments, their incidence is as low as 2.2%[5] and their effect is usually small to moderate and limited to transient mechanistic cognitive processes (alterness and mental speed).[4]
- Functional disturbances can be the consequences of seizures, i.e., circumscribed postictal neuropsychological deficits.[6,7]
- Antiepileptic drugs can cause generalized, but also specific neuropsychological dysfunctions. Thus, topiramate can cause verbal dysfunctions which can be difficult to distinguish from dysfunctions as a consequence of the functional deficit zone in patients with seizures arsing adjacent to speech cortex.[8]

The concept of the functional deficit zone should be restricted to neuropsychological impairments caused either directly or indirectly by the epileptogenic zone. However, the segregation of the various causes of neuropsychological deficits can be difficult and requires an astute and experienced neuropsychologist.

Depending on the location of the epileptogenic zone several distinct neuropsychological profiles can be distinguished.[9–11] In patients with temporal lobe epilepsy, the most important neuropsychological symptoms consist of material-specific or even non-specific deficits in episodic memory due to hippocampal dysfunction.[9] While impairment of episodic verbal memory can be consistently found in left temporal lobe epilepsy, the relationship between figural or visuospatial memory deficits and right temporal lobe epilepsy is far less consistent. This could be explained by confounding of figural memory with

verbalization, sex differences, as well as by atypical language representation and suppression of right hemispheric functions due to crowding phenomena.[10] Within the temporal lobe a differentiation between mesial and lateral temporal lobe dysfunction is frequently possible by the assessment of verbal learning versus verbal memory. While lateral temporal dysfunction affects primarily verbal learning, mesial temporal structures are critical for verbal memory.[12] In addition, naming difficulties can be frequently found in patients with temporal lobe epilepsy. While deficits in visual confrontation naming indicate inferotemporal dysfunction, auditory confrontation naming requires inferotemporal and lateral temporal structures.[13] Finally, patients with temporal lobe epilepsy and more specifically patients with mesial temporal lobe epilepsy frequently suffer from considerable generalized cognitive impairments (intelligence, academic achievement, language, and visuospatial functions) indicating an extension of the functional deficit zone beyond the temporal lobes to frontal lobe structures.[14] Thus, frontotemporal dysfunctions frequently can be found in patients with temporal lobe epilepsy.[12] While prefrontal lobe functions such as attention and executive functions are frequently spared in patients with temporal lobe epilepsy, the occurrence of frequent secondarily generalized tonic-clonic seizures poses the patients at risk for global intellectual as well as specific impairment of prefrontal lobe functions. These neuropsychological deficits were associated with a prefrontal hypometabolism on [^{18}F]FDG-PET which therefore can be considered as a surrogate marker of the functional deficit zone.[15] Seizure-freedom after successful epilepsy surgery may lead to a normalization of this prefrontal hypometabolism and the corresponding neuropsychological impairments indicating the dynamic nature of the functional deficit zone.[16]

The complexity and diversity of frontal lobe functions and the intense connections between the frontal and the temporal lobes explain the variability of neuropsychological dysfunctions in patients with frontal lobe epilepsy. While frontal lobe epilepsy patients show little if any impairments of general intelligence and memory, some but not all patients show deficits in executive functions, psychomotor speed and attention.[17–19]

The neuropsychological characteristics of parietal and occipital lobe epilepsies have not been well characterized in larger groups of patients. Lesions of the parietal lobe may cause visual associative agnosia, hemineglect, visuospatial and constructive disorders, apraxia as well as linguistic deficits.[9] However, these symptoms are rarely found in patients with chronic epilepsies most probably due to compensatory mechanisms especially in patients with seizure-onsets early in life. More often impairments are diffuse and often mimic frontal or temporal dysfunction.[20] The neuropsychological profile of patients with idiopathic occipital lobe epilepsies does not systematically differ from that of normal controls.[21]

The intra-carotid-amobarbital procedure or Wada test

The goals of the intracarotid-amobarbital procedure or Wada test include language and memory lateralization.[22] In epilepsy patients, atypical language lateralization, i.e., right hemispheric or bilateral representation, is more likely than in normal controls.[23,24] The determinants for atypical language dominance include early injuries, lesions adjacent to speech cortex and finally the epileptic process *per se*. Thus, early left hemispheric injuries occurring before the age of 5 years result in an interhemispheric reconstitution of language functions to the right hemisphere,[25] while later injuries – when language becomes gradually lateralized – cause contralateral language reorganization more seldom.[24] In mesial temporal lobe epilepsy, left-sided speech occurred in 76% of left-sided and in 100% of right-sided patients. Atypical language representation was also associated with a higher spiking frequency and sensory auras representing an ictal involvement of lateral temporal structures indicating the influence of interictal and ictal epileptic activity on language lateralization.[26]

The rationale of the Wada memory test consists of anesthetizing mesial temporal structures which should simulate the potential mnestic effects of the proposed surgery in a crude way.[22] Injection of the hemisphere contralateral to the epileptogenic zone usually results in impaired memory performance due to the functional deficit of the affected temporal lobe. The functional status of the diseased temporal is also referred to as 'functional adequacy' and can be considered as a marker of the functional deficit zone of the ipsilateral temporal lobe. If the temporal lobe, which is planned to be resected, supports significant memory function (i.e., high functional adequacy), a greater memory decline should be anticipated because functionally intact tissue is removed. Anesthetization of the hemisphere ipsilateral to the epileptogenic zone, on the contrary, tests the functional integrity of the contralateral 'healthy' temporal lobe also referred to as 'functional memory reserve'. A poor performance after ipsilateral injection thus would indicate an extension of the functional deficit zone to the contralateral temporal lobe and also would suggest poor memory performance after surgery. Both functional adequacy and functional reserve are therefore important predictors for post-operative memory performance.[27] Patients with a strong asymmetry of memory performance, i.e., impaired memory ipsilateral to the epileptogenic focus and intact memory contralaterally, are those at the lowest risk for post-operative memory decline. In the case of symmetric Wada scores, functional adequacy will determine memory decline in patients with bilaterally good performance, whereas functional reserve will be decisive in patients with bilaterally poor performance. Especially in left temporal lobe epilepsy, high functional adequacy poses a major risk on post-operative memory decline. The highest risk for post-operative memory decrease is present in patients with unexpected asymmetry in Wada test performance, i.e., better performance after contralateral injection.[27] Some patients may fail the Wada memory component without developing a significant memory decline after surgery,[28] whereas others pass the Wada test and still experience a significant post-operative memory loss.[29,30] Nevetheless, failures of the Wada memory component can be considered as a risk factor for post-operative memory decline and always have to be viewed in the context of the results of other investigations.[27]

The Wada test was found to be a clearly superior predictor of seizure laterality in comparison to neuropsychological

testing.[31] Functional asymmetries as assessed by Wada memory scores were significantly correlated with structural asymmetries as measured by hippocampal volumetry on MRI.[32-34] Wada memory scores showed a significant negative correlation with the degree of hippocampal cell loss indicating that a severely damaged hippocampus could not support memory after contralateral amobarbital injection.[35–37] Furthermore, the Wada test has been used to predict post-operative seizure control.

Interictal EEG and MEG

Slow wave activity can be classified according to its distribution as focal or generalized, according to its persistence as intermittent or continuous and according to its morphology as rhythmic or polymorphic.[38] While continuous slowing (CS) on interictal EEG is usually caused by a structural lesion, intermittent rhythmic slowing (IRS) can be considered as the EEG/MEG marker of the functional deficit zone and often can be seen in the absence of structural lesions.

Temporal interictal rhythmic delta activity (TIRDA) – characterized by trains of 50–100 μV sinusoidal or saw-toothed 1–4 Hz activity localized predominantly over anterior temporal regions – was found in 45 of 127 recordings of patients with epilepsy with complex partial seizures. Because TIRDA often occurred in association with anterior temporal spikes or sharp waves particularly during sleep, TIRDA was considered as an accurate interictal indicator of epilepsy with complex partial seizures.[39] In a study reviewing 12 198 EEG recordings, TIRDA was present in 33 records of 27 patients and was associated with sharp waves either in the same record (23 patients) or on previous occasions (3 patients). All patients suffered from seizures and 23 patients from well-documented epilepsy with complex partial seizures.[40] Concerning its localizing significance, TIRDA was strongly associated with temporal lobe epilepsy, although it was infrequently seen also in extratemporal epilepsy. Temporal intermittent polymorphic delta activity (TIPDA), on the contrary, occurred at an equal rate in both temporal lobe and extratemporal epilepsy.[41] In a series on patients with medically refractory focal epilepsy undergoing prolonged video-EEG monitoring, TIRDA was present in 52 out of 129 patients (40.3%) and showed a significant correlation with mesial and mesio-lateral TLE, mesial temporal sclerosis, interictal epileptiform discharges localized over the anterior temporal regions and 5–9 Hz temporal ictal discharges. Therefore it was concluded that TIRDA can be considered as an EEG marker of an epileptogenic zone involving mesial temporal structures.[42]

The lateralizing significance of slow wave activity in temporal lobe epilepsy was investigated in several studies. In patients with unilateral seizure-onsets, exclusively or predominately unilateral delta waves occurred ipsilateral to the seizure-onset zone in 46 out of 56 patients (82%) and never were seen contralaterally.[43] Conversely, in patients with lateralized arrhythmic delta waves the concurrence with the side of seizure onset was 90% with delta waves in one EEG and 100% with delta waves in ≥ 4 EEGs.[43] In mesial temporal epilepsy, the lateralizing accuracy of delta waves was studied in relation to spikes and hippocampal atrophy as assessed by volumetric measurements in 56 patients – 35 patients had unilateral (group I) and 21 had bilateral hippocampal atrophy with lateralized predominance (group II). Unitemporal trains of delta waves lateralized the side of hippocampal atrophy with equal accuracy as interictal spikes (delta: 29 of 32 patients (92%) in group I and 12 of 19 of patients (63%) in group II; spikes: 85% or 28 of 33 patients (85%) in group I and 13 of 20 patients (65%) in group II). Delta waves and spikes occurred together in >85% of cases. Delta activity almost always occurred ipsilateral with unilateral spiking (19 of 21 of patients (90%) in group I and seven of eight of patients (88%) in group II) and bilaterally independently with bilateral spiking (six of nine of patients (67%) in group I and ten of ten patients (100%) in group II). Furthermore, spiking and delta activity were never in disagreement with respect to lateralization. It was concluded that intermittent delta waves are a reliable indicator of the epileptogenic focus and presumably reflect the epileptogenic process rather than the underlying structural pathology.[44]

The correlation of intermittent slow wave activity with other markers of the functional deficit zone, namely with hypometabolism on interictal [^{18}F]FDG-PET and functionality on fMRI was investigated in several studies. In the first study, 16 of 28 patients (57%) had lateralised IRS with a maximum over the temporal regions which was always ipsilateral to the resection and significantly correlated with hypometabolism in the lateral temporal neocortex on [^{18}F]FDG-PET, but not to mesial temporal sclerosis or any other pathology.[45] The authors suggested that IRS should be conceptualised as a distinct electrographic phenomenon directly related to the epileptogenic abnormality and that the lateral temporal hypometabolism may delineate a field of reduced neuronal inhibition which can receive interictal and ictal propagation.[45] In the second study on 40 patients with intractable temporal lobe epilepsy, the severity of temporal lobe hypometabolism on [^{18}F]FDG-PET was significantly correlated with the amount of delta activity in the interictal EEG, independently of MRI findings.[46] Therefore, common pathophysiologic mechanisms for metabolic and electrical dysfunction in temporal lobe epilepsy were suggested.[46] Finally, activation of malformations of cortical development (MCDs) by simple (sensomotor, visual) or complex (language, memory) functional magnetic resonance imaging (fMRI) paradigms was assessed in 28 patients with focal epilepsy and MCDs. Besides an influence of the type of MCD, both focal neurological signs and focal EEG slowing independently were correlated with MCD inactivity.[47]

Magnetoencephalography (MEG) which measures the weak magnetic field induced by neuronal currents has the advantage of a better spatial resolution as compared with scalp-EEG.[48] In one study, one or more sites of focal low-frequency magnetic activity (LFMA) were detected in 29 of 33 patients and showed a 48.5% specificity with respect to the presumed epileptogenic region. LFMA was in agreement with the final consensus as often as was ictal scalp-EEG, and was exceeded in specificity overall only by invasive ictal EEG.[49] In 29 patients with mesial temporal lobe epilepsy, LFMA with maximum amplitude over the temporal area was found in 17 patients (58.6%); it always occurred ipsilateral to the side of resection and the side of MEG interictal spike sources. Dipolar sources of LFMA were found in the posterior superior temporal region in the majority of cases and, occasionally, in mesial temporal structures.[50]

Functional neuroimaging with SPECT and PET

Functional neuroimaging techniques like SPECT and PET provide additional and independent information to structural neuroimaging during persurgical evaluation. While the recent developments of PET tracers aim to measure abnormalities of neurotransmission underlying neuronal hyperexcitability and thus could possible directly visualize the epileptogenic zone,[51] the classical SPECT and PET tracers measure regional cerebral blood flow, oxygen consumption and glucose metabolism associated with epileptic dysfunction and therefore can be considered as surrogate markers of the functional deficit zone.

SPECT ligands most commonly used in epilepsy, i.e., ^{99m}Tc-Hexamethyl-propyleneamine (^{99m}Tc-HMPAO) and ^{99m}Tc-ethyl cysteinate dimer (^{99m}Tc-ECD), are markers of regional blood flow. Both tracers are lipophilic, generally pass the blood–brain barrier on their first pass through brain tissue, become trapped and exhibit little subsequent redistribution. In temporal lobe epilepsy, interictal SPECT shows a regional temporal hypoperfusion ipsilateral to the epileptogenic zone in 40–50%, while 5–10% of studies are falsely lateralizing.[52] These results concur with PET studies demonstrating an uncoupling of glucose metabolism and blood flow resulting in significantly higher sensitivity and specificity of glucose metabolism for the lateralization of the epileptogenic zone in temporal lobe epilepsy.[53] Thus, interictal SPECT is of limited value and inferior to interictal [^{18}F]FDG-PET for the localization of the functional deficit zone.

[^{18}F]FDG has been the most widely used PET tracer used during pre-surgical evaluation. While [^{18}F]FDG crosses the blood brain barrier before phosphorylation in the cell compartment, unlike glucose-6-phosphate it does not enter into further steps of the Krebs glycolysis cycle, but accumulates in the intracellular compartment and thus directly reflects the energy demand of the brain cells.[51] The mechanisms underlying interictal glucose hypometabolism are not fully understood. While glucose consumption occurs primarily at the synapse, reduced regional metabolism appears to reflect a decrease in glucose influx from reduced glucose transport across the blood brain barrier which correlates with subsequent reduced phosporlyation.[54] Possible mechanisms of reduced interictal glucose metabolism include (1) atrophy and partial volume effects; (2) neuronal loss; (3) hypometabolic macro- or microscopic lesions; (4) decreased synaptic activity (diaschisis), (5) deafferentation due to reduced numbers of synapses, (6) postictal metabolic depression, (7) inhibitory mechanisms of seizures.[51]

Converging evidence has been accumulated that interictal hypometabolism represents a reversible functional state for several reasons. First, an increase of glucose metabolism can be observed during ictal PET scans in the interictal hypometabolic zone. Second, interictal hypermetabolism can be reverted by the application of a specific $GABA_A$ receptor agonist (4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol), THIP. After THIP injection, the increase of glucose metabolism in the hypometabolic focus was larger than the mean increase in the whole brain. Within the hypometabolic focus, this increase was significantly higher in regions with the lowest basal metabolic levels. This metabolic response in the hypometabolic focus suggests that $GABA_A$ receptors are up-regulated or at least preserved in temporal lobe epilepsy. Furthermore, $GABA_A$ receptor mediated inhibition apparently increases the metabolic demand and therefore the hypothesis that hypometabolism is caused by increased inhibition becomes questionable.[55,56] Third, hypometabolic zones surrounding the epileptogenic zone pre-operatively showed a normalization of glucose metabolism after successful surgery.[16, 57, 58] This normalization of glucose metabolism was paralleled by an improvement in neuropsychological functioning.[16]

The sensitivity of [^{18}F]FDG-PET varies according to etiology and location of the epileptogenic zone.[51] In temporal lobe epilepsy, the sensitivity ranged between 65–90% in early studies encompassing patients with varying etiologies. This figure is closer to 60% in patients with normal MRI scans and closer to 90% in studies with newer scanners.[52] In a prospective study in patients with hippocampal atrophy on MRI, sensitivity approached 100%.[59] In frontal lobe epilepsy with normal MRI scans, abnormalities on [^{18}F]FDG-PET are found in only 50% of patients.[51]

The differing sensitivities of [^{18}F]FDG-PET according to the location of the seizure onset zone, the finding that hypometabolism on [^{18}F]FDG-PET was not related to the epileptogenicity of cavernous angiomas[60] and the low indicence of hypometabolism in new onset temporal lobe epilepsies,[61,62] indicate that hypometabolism is not directly related to the epileptogenic process itself, but rather may reflect the functional and maybe structural consequences of repeated seizures. This is in line with some studies which found a correlation between hypometabolism and epilepsy duration as well as age at epilepsy onset, although these results could not be replicated by other authors.[51]

Although the lateralizing value of [^{18}F]FDG-PET approaches 100% in temporal lobe epilepsy, bitemporal hypometabolism – which is usually less pronounced on the side contralateral to the epileptogenic zone – can be found in up to 32% of patients with unilateral temporal lobe epilepsy using statistical parameter mapping.[63] Conversely, bitemporal hypometabolism was indicative of bilateral independent seizure onsets in approximately 50% of patients, especially when involving the inferior temporal gyrus. Moreover, bitemporal hypometabolism was associated with a more rapid contralateral seizure spread, a longer disease duration and worse memory performance during the Wada test and therefore could reflect an advanced stage of the disease process, characterized by a breakdown of the inhibitory mechanisms in the contralateral hemisphere.[64]

The localizing significance of PET within the hemisphere or lobe of seizure onset is far less well-defined than its lateralizing value. In temporal lobe epilepsy, this is already intuitively clear from the usually widespread hypometabolism involving – besides the temporal lobe – also the ipsilateral frontal and parietal neocortex, ipsilateral subcortical structures such as the thalamus and the striatum as well as the contralateral cerebellum.[52] Recent studies suggested that lateral temporal hypometabolism is correlated with extrahippocampal structural changes including white matter changes in the anterior temporal lobe,[65] temporal neocortical microscopic cortical dysplasia[66] or temporal polar signal changes on MRI scans.[67] Furthermore, some specific patterns of hypometabolism may help to differentiate mesial from lateral temporal lobe

epilepsy. Whereas hypometabolism is more prominent in lateral than in medial structures both in medial and lateral temporal lobe epilepsy, a hypometabolism in the medial temporal structures is found less frequently in lateral temporal lobe epilepsy than in medial temporal lobe epilepsy. Furthermore, the extent of hypometabolism is significantly larger in medial temporal lobe epilepsy.[63]

Several studies correlated the functional deficit zone defined by interictal [^{18}F]FDG-PET with the irritative zone and the seizure-onset zone defined by EEG. A consistent unilateral spike focus concurs with a lateralized hypometabolism on PET in over 90% of the cases. However, bilateral independent spikes can occur in the presence of unilateral hypometabolism.[51] Several studies compared the location and extent of hypometabolism on [^{18}F]FDG-PET with the location of the irritative zone defined by EEG and MEG dipole modeling of interictal spikes.[68–70] While dipole sources usually were contained within the extended hypometabolic zone on [^{18}F]FDG-PET, dipole localizations did not concur with the degree of hypometabolism within this hypometabolic zone.[68,70] This is accordance with a study which found a poor agreement between stereo-EEG localizations of the irritative zone and [^{18}F]FDG-PET quantitative measures of regional metabolism.[71]

In temporal lobe epilepsy and lesional epilepsy, the seizure-onset zone defined by intracranial EEG usually is contained within the functional deficit or hypometabolic zone on [^{18}F]FDG-PET. On the contrary, in nonlesional neocortical and especially in nonlesional extratemporal epilepsy, the localizing value of [^{18}F]FDG-PET in comparison to intracranial EEG seems to be limited. In a series of 41 patients with nonlesional temporal epilepsy including 16 with frontal lobe epilepsy, 11 with neocortical temporal lobe epilepsy, seven with occipital lobe epilepsy, four with parietal lobe epilepsy, and three with multifocal onsets, [^{18}F]FDG-PET correctly predicted the lobe of seizure-onset zone on intracranial EEG in only 42.9% of the cases.[72] [^{18}F]FDG-PET analyzed by statistical parametric mapping correctly localized the epileptogenic lobe in 15 of 22 patients (68.2%) with nonlesional neocortical temporal lobe epilepsy, but only in three of 11 patients (27.3%) with nonlesional extratemporal epilepsy.[73] Furthermore the degree of hypometabolism does not correlate with the location of seizure-onset on stereo-EEG.[71]

The question whether the presence of hypometabolism on [^{18}F]FDG-PET and its restriction to the epileptic temporal lobe are necessary and sufficient prerequisites for a good surgical outcome after temporal lobectomy remains controversial. Whereas several studies identified a temporal hypometabolism as good prognostic sign independently of hippocampal atrophy on MRI,[74] other studies failed to verify such an association.[75]

Hypometabolism on [^{18}F]FDG-PET also has been correlated with other measures of the functional deficit zone, namely EEG and neuropsychological parameters. The correlation between slowing or background depression on stereo-EEG and quantitative measures of regional metabolism on [^{18}F]FDG-PET was poor.[71] Regional hypometabolism on [^{18}F]FDG-PET was associated with corresponding circumscribed neuropsychological deficits. Relative reductions in glucose metabolism of the left lateral temporal lobe and the left thalamus independently predicted verbal memory impairments in temporal lobe epilepsy patients.[76] Prefrontal hypometabolism which was more frequent in patients with left temporal lobe epilepsy and a history of secondarily generalized seizures correlated with impairments of neuropsychological 'frontal lobe measures', including verbal and performance intelligence measures.[15] The results of [^{18}F]FDG-PET – especially medial temporal metabolism – significantly correlated with Wada memory scores.[77,78] Finally, pre-operative [^{18}F]FDG-PET was predictive for post-operative memory performance in patients with left-sided temporal lobe epilepsy. Patients with no/mild asymmetry in temporal lobe metabolism exhibited significantly greater verbal memory decline compared with patients with moderate/severe hypometabolism.[79]

Proton magnetic resonance spectroscopy

Magnetic resonance spectroscopy (MRS) allows noninvasive in vivo detection and quantification of various brain metabolites.[80,81] ^{1}H or proton spectroscopy which measures N-acetyl aspartate (NAA), choline (Cho) and creatine (Cr) can be regarded as a surrogate marker of the functional deficit zone. NAA – a mitochondrial neuronal compound – is generally considered as a marker of neuronal density and viability. Cho which is bound to cell membranes, myelin and complex brain lipids indicates membrane damage and gliosis. Cr, finally, is used as an internal reference for other metabolites, because it is a relative stable compound and a marker for cell density of glial and neuronal cells.[82] In epilepsy, abnormalities of proton spectroscopy typically consist of (1) a reduced NAA/Cr or NAA/(Cho+Cr) ratio or (2) a reduced NAA signal without significant changes in Cho and Cr signals.[82,83] These MRS abnormalities reflect neuronal and glial dysfunction rather than neuronal cell loss as has been shown in a study comparing metabolic dysfunction measured by MRS and hippocampal volume loss detected by MR volumetry.[84] This concept is further supported by a recovery of the NAA signal remote from the epileptogenic zone after successful epilepsy surgery.[85–88]

Proton spectroscopy correctly lateralized the epileptogenic zone in 86% of patients with various forms of temporal lobe epilepsy[89], in 61% of patients with nonlesional temporal lobe epilepsy[90] and in 97% of patients with mesial temporal lobe epilepsy.[91] Proton spectroscopy can be used to differentiate patients with temporal and extratemporal epilepsies[92] as well as patients with mesial and neocortical temporal lobe epilepsy[93] although these discriminations were less accurate than lateralization. In neocortical epilepsy, multislice MRS imaging in combination with tissue segmentation correctly localized the epileptogenic zone in 70% of patients with an MRI-visible malformation and in 60% of patients with normal MRI.[94]

Proton spectroscopy is extremely sensitive for the detection of metabolic dysfunction. In one study on 100 patients with temporal lobe epilepsy, MRS was abnormal in 99 of 100 patients, while volumetric amygdala-hippocampal measurements were abnormal in only 86 of 98 patients.[89] These results were essentially confirmed in a subsequent study were no correlation was found between the degree of hippocampal volume loss and the NAA/Cr ratio indicating that the two techniques examine distinct pathophysiologic processes.[91]

Moreover, metabolic dysfunctions are usually found in widespread regions extending beyond the epileptogenic zone. In one study, 38% of patients with temporal lobe epilepsy and 50% of patients with extratemporal lobe epilepsy had NAA/Cr reductions outside the clinical and EEG-defined epileptogenic area.[95] In mesial temporal lobe epilepsy, comparisons between individual brain regions revealed trends toward lower NAA/(Cr + Cho) ratios in many areas of the ipsilateral and, to a lesser extent, the contralateral hemisphere outside the hippocampus and the temporal lobe, suggesting a diffuse impairment.[96] In patients with mesial and nonlesional temporal lobe epilepsy, reduced NAA/(Cr + Cho) ratios were found in the ipsilateral temporal and parietal lobes and bilaterally in the insula and the frontal lobes consistent with those brain areas involved in seizure spread.[97,98] Metabolic abnormalities of the contralateral temporal lobe were observed in 33% of patients with nonlesional temporal lobe epilepsy[90] and in 54% of patients with various forms of temporal lobe epilepsy.[89] MRS was more sensitive for the detection of bilateral involvement than MR volumetry in both studies.[89,90] Nevertheless, the reduction of the NAA ratios seems to be greater in the epileptogenic region as compared with nonepileptogenic regions.[99]

The MRS defined functional deficit zone was correlated with the irritative and the seizure-onset zone in several studies. One study found a moderate level of concordance between the distribution of proton spectroscopy and interictal EEG abnormalities, while proton spectroscopy identified abnormalities contralateral to the predominant seizure focus more often than EEG.[100] In nonlesional temporal lobe epilepsy, NAA/Cho was significantly decreased in the MEG spike zone indicating that functional abnormalities can be detected in vivo in radiographically normal-appearing cortex exhibiting abnormal excitability.[101] In patients with mesial temporal lobe epilepsy, there was a significant correlation between the asymmetry indexes of interictal epileptiform discharges recorded on foramen ovale electrodes with the asymmetry index of NAA/Cr ratios within medial temporal structures.[102] Finally, regional metabolic alterations on proton spectroscopy were correlated with electrophysiological abnormalities recorded by depth electrodes and with structural lesions in patients with temporal lobe epilepsy[103] and frontal lobe epilepsy.[104] NAA/(cho+cr) ratios were significantly lower in regions involved in SEEG electrophysiological epileptic abnormalities, while regions without electrophysiological abnormalities showed normal ratios. No differences between the metabolic profiles of the irritative and the seizure-onset zone were found. The metabolic alterations included, but also extended beyond, the structural lesions indicating that metabolic abnormalities are linked to interictal and ictal epileptiform activities rather than to structural alterations.[103,104] Proton spectroscopy was useful to predict seizure control after epilepsy surgery in temporal lobe epilepsy,[105] mesial temporal lobe epilepsy[106–108] and MRI-negative temporal lobe epilepsy.[109] Furthermore, proton spectroscopy may provide information on the individual best type of surgery.[108]

The relationship between metabolic dysfunction on proton spectroscopy and other methods assessing the functional deficit zone was addressed in several studies. There was no correlation between interictal background delta activity as assessed by quantitative EEG and abnormalities seen on proton spectroscopy.[110] Controversial results were found for the comparison of proton spectroscopy with [^{18}F]FDG-PET. While in one study [^{18}F]FDG-PET was more sensitive than proton spectroscopy for the lateralization of the seizure-onset zone in temporal lobe epilepsy ([^{18}F]FDG-PET: 87% vs. proton spectroscopy: 61%),[90] in two other studies [^{18}F]FDG-PET and proton spectroscopy showed an identical lateralization accuracy of 76%[111] resp. 85%,[112] although in general proton spectroscopy was more sensitive than [^{18}F]FDG-PET in depicting metabolic abnormalities.[111] In a recent study on patients with mesial temporal lobe epilepsy, hippocampal metabolic disturbances as measured by [^{18}F]FDG-PET and by proton spectroscopy did not correlate which was explained by differential effects of disturbed cellular energy metabolism on mechanisms of glucose use and biosynthesis of NAA.[113]

Several studies related proton spectroscopy to neuropsychological testing. In mesial temporal lobe epilepsy, material-specific memory deficits and memory performance during the WADA test were correlated significantly with hippocampal metabolic dysfunction, visual confrontation naming was selectively associated with left hippocampal metabolic function, whereas performance on a facial recognition task was correlated with right hippocampal metabolic function.[114–117] In patients with unilateral mesial temporal lobe epilepsy, reduced left hippocampal NAA/Cr ratios were more sensitive to predict verbal memory impairments than hippocampal volumetric measurements.[118] Furthermore, some studies indicate that pre-operative MRS findings may be useful to predict memory decline after epilepsy surgery.[115, 117, 119]

Functional magnetic resonance imaging (fMRI)

fMRI offers a unique technique for the assessment of the functional deficit zone because it not only allows to visualize areas of functional deficits, but also provides information where in the brain the remaining functions are actually represented. Thus, fMRI gives insights in mechanisms of compensation, shift and plasticity.

The primary contrast mechanisms used for fMRI are blood oxygenation level-dependent (BOLD) contrast and perfusion contrast obtained by using aterial spin labeling (ASL) which uses magnetically labelled arterial blood flow water as a flow tracer. Because BOLD contrast is easier to obtain and generally provides a higher signal-to-noise ratio for task-specific activation, it has been widely adopted as the method of choice for imaging regional brain activation.[120] BOLD contrast is based on the fact that brain areas actively engaged during functional activation experience a local increase in cerebral blood flow. The amount of blood flow increase exceeds the associated increase in local cerebral oxygen consumption resulting in a localized increase in the ratio of oxyhemoglobin (which is diamagnetic, i.e. its effect on T_2-relaxation is negligible) to deoxyhemogelobin (which is paramagnetic, i.e., it accelerates the rate of T_2-relaxation) which can be visualized using a variety of pulse sequences, including routine gradient-echo sequences and gradient-echo echoplanar sequences, which particularly emphasize T_2*-effects.[120, 121] For the assessment of

the functional deficit zone, fMRI language and memory lateralization and localization can be used.

Focal epilepsy can be associated with a disruption in normal language organization resulting in a high incidence of atypical language dominance (bilateral or right hemisphere) in epilepsy patients as compared to normal controls (epilepsy group: 78% left hemisphere dominance, 16% bilateral symmetric language representation, 6% right hemisphere dominance; normal subjects: 94% left hemisphere dominance, 6% bilateral symmetric language representation, none right hemisphere dominance) which was especially evident with early brain insults and weak right hand dominance.[24] In another study, 33% of patients with left-sided temporal lobe epilepsy showed bilateral or right hemispheric language lateralization which was significantly higher as compared to patients with right-sided temporal lobe epilepsy suggesting considerable plasticity of language representation in the brains of patients with intractable epilepsy.[122] However, it is difficult to infer intra- versus inter-hemispheric language reorganization on the basis of the vicinity of early pathology to classical language areas, because in a recent study lesions in or near Broca's area were not associated with inter-hemispheric language reorganization in four out of five cases, but with perilesional activation within the damaged left hemisphere. Paradoxically, lesions remote from the classical language areas were associated with nonleft language lateralization in four out of five cases.[123]

fMRI showed excellent agreement with the Wada test for language lateralization in several studies.[122,124–128] Concordance was usually best in left hemisphere dominant patients ranging from 91 to 100%, lower in patients with right hemisphere dominance (range: 67–100%) and worst in patients with bilateral hemisphere dominance ranging from 50 to 75% although the numbers in these latter groups were small.[122,125,126] Furthermore, agreement was better in left-sided temporal with 97% than in left-sided extratemporal epilepsy with only 75%.[127] fMRI was predictive for post-operative confrontation naming deficits after left anterior lobectomy showing 100% sensitivity and 73% specificity.[129]

fMRI also has been evaluated as an alternative to intraoperative cortical stimulation mapping for the localization of critical language areas in the temporoparietal region.[130] Correspondence between functional magnetic resonance imaging and intraoperative cortical stimulation mapping depended heavily on statistical threshold and varied between patients and tasks (i.e., verb generation, picture naming, verbal fluency, and sentence comprehension). Whereas fMRI correctly detected all critical language areas with high spatial accuracy (sensitivity of 100%), fMRI activity was found also at noncritical language sites with an overall specificity was 61%. Although fMRI cannot replace intraoperative cortical stimulation mapping at the present time, it can be used to optimally plan this procedure and increase its safety.

fMRI can be used to visualize asymmetries in the lateralization of memory activation in patients with temporal lobe epilepsy and therefore can serve as a marker of the functional deficit zone. While mesial temporal lobe structures are activated symmetrically in normal controls during various memory encoding tasks, a decreased activation was seen ipsilateral to the seizure focus in patients with unilateral temporal lobe epilepsy.[131–134] Verbal encoding engaged the right mesial temporal lobe in left mesial temporal lobe epilepsy, whereas nonverbal encoding engaged the left mesial temporal lobe in right mesial temporal lobe epilepsy.[134] In patients with left mesial temporal lobe epilepsy, an extensive left prefrontal activation was seen during memory encoding and retrieval which was not evident in normal controls.[135] In nonamnesic patients with left hippocampal sclerosis, verbal memory encoding was associated with reorganisation to the right hippocampus and parahippocampal gyrus, while it involved activation of the left hippocampus in normals. The additional presence of left amygdala sclerosis resulted in reorganisation for encoding of emotional verbal material to the right amygdala.[136] These findings indicate both a functional deficit of the diseased temporal lobe and a functional shift to the nonaffected temporal lobe or to extratemporal structures indicating a high degree of plasticity of medial temporal lobe functions.

fMRI memory lateralization concurred with the results of neuropsychological testing[133] and of intracarotid amobarbital testing.[132,134,137] The degree of verbal memory encoding activity in the left mesial temporal lobe was inversely related to the extent of verbal memory loss after left anterior temporal lobectomy and provided the strongest independent predictor of memory outcome after surgery in a multiple regression analysis.[138] In right mesial temporal lobe epilepsy, the pre-operative asymmetry index of memory-fMRI, consisting of retrieval from long-term memory induced by self-paced performance of an imaginative walk, significantly correlated with post-operative changes in memory retention: Reduced activation of the mesiotemporal region ipsilateral to the epileptogenic region correlated with a favorable memory outcome after right-sided anterior temporal lobectomy.[139] Finally, in patients with both left and right temporal lobe epilepsy, a greater post-operative memory decline was observed with increased pre-operative activation ipsilateral to the seizure focus using a complex visual scene-encoding task.[137]

MEG language lateralization and localization

MEG language lateralization obtained by various language paradigms including a word recognition task,[140] a silent reading task[141] as well as a verb generation and picture naming task[142] showed a high degree of concordance with the Wada-test ranging between 89 and 95%. MEG may also be used for intrahemispheric language localization where excellent agreement with direct cortical stimulations could be achieved in selected cases.[143,144] Finally, MEG was useful to study inter- and intrahemispheric language reorganization in patients with temporal lobe epilepsy.[145–147]

Conclusions

The functional deficit zone provides information on the functional deficits associated with focal epilepsies. These functional deficits manifest themselves as neurological and neuropsychological abnormalities. Surrogate markers of the functional deficit zone include interictal EEG and MEG as well as functional neuroimaging tools like SPECT, PET, MRS and

fMRI. When assessing the functional deficit zone mechanisms of neuronal compensation, shift and plasticity have to be taken into account, which in turn are influenced by epilepsy variables including age at insult and epilepsy onset, as well as duration, activity and severity of disease. Fixed and reversible functional deficits can be distinguished. The former are caused by structural lesions, most often the epileptogenic lesion; the latter represent consequences of the epileptogenic process per se, vary according to epileptic activity and can be reverted by successful surgical treatment. Thus, the functional deficit zone has to be considered as a dynamic concept. The various surrogate markers of the functional deficit zone measure different parameters of functional deficit and differ concerning their sensitivity. Therefore, the extension of the functional deficit zone varies according to the investigational technique applied. The functional deficit zone usually is spatially more extended than the epileptogenic zone. With the currently available techniques there is only a poor correlation between the local degree of functional abnormality and of epileptogenicity. Therefore, the functional deficit zone can only lateralize and localize the epileptogenic zone on a lobar, but not on a sublobar level. This could be improved by measuring dysfunctions more closely related to epileptogenicity. Nevertheless, the functional deficit zone provides important information during pre-surgical evaluation complementary to the five other zones (irritative zone, seizure-onset zone, ictal symptomatogenic zone, epileptogenic lesion, epileptogenic zone), can be used to derive prognostic information on post-operative seizure control and most importantly is critical to predict the post-operative functional status.

88 Mesial temporal lobe epilepsy and positron emission tomography

A Mohamed and MJ Fulham

Introduction

Positron emission

Positron emission tomography (PET) is a molecular imaging technique that uses radiolabeled compounds to image molecular interactions *in vivo*. PET relies on the nature of positron decay. The positron was first conceived by Dirac in the late 1920s and discovered experimentally in 1932. The positron is the antimatter counterpart to the electron and has the same mass as an electron but a positive charge. PET scanners detect photons, which are released when a positron emitting radionuclide, such as fluorine-18, carbon-11, and oxygen-15 emit positrons, which then undergo annihilation after a collision with electrons. The commonly used positron emitting isotopes and their half-lives are shown in Table 88.1.

A key benefit of PET is the ability to quantify molecular events *in vivo*. This depends in part on the ability of PET to measure the tracer concentration in the region of interest, to account for photon attenuation by the body and to apply a mathematical model, which describes the kinetic behavior of the process of interest.

PET instrumentation

Positron annihilation is a unique form of radioactive decay where two photons (gamma rays with an energy of 511 keV) are emitted at 180 degrees to one another. Scintillation crystals (or detectors) detect these gamma rays and they are regarded as true events when they are detected simultaneously or 'coincidentally'. These detectors produce light output, which is detected and magnified by photomultiplier tubes. Logic circuits localize precisely where the annihilation event occurred. High-speed timing circuits provide temporal localization. This time window for coincidence detection is typically 6–12 nsec. Photons outside this time window are considered as single events and discarded by the coincidence circuit. Compared with most radioisotopes used in nuclear medicine, PET ligands emit photons with much higher energies. Hence, PET detectors require greater stopping power. The scintillation crystals may be made of sodium iodide (NaI), bismuth germinate (BGO) and more recently lutetium oxyorthosilicate (LSO) and gadolinium orthosilicate (GSO). The absorption efficiency of BGO is greater than LSO but the latter has five times more light output. Additionally, the decay time for LSO compared with BGO is lower at 40 nsec as opposed to 300 nsec. Consequently, it takes less a shorter period of time to obtain the necessary scintillation events (counts) for image generation with LSO.

The first human PET study was carried out in 1977 using 18-F-fluorodeoxyglucose (FDG) and was 'primitive' by today's standards.[1] These tomographs were generally restricted to large universities and devoted mainly to neuroscience research. They were slow and had poor spatial resolution but nevertheless they were regarded as a great advance because for the first time 'function' rather than just anatomy of the brain could be depicted. Instrumentation advances coupled with faster techniques to acquire data, corrected for attenuation and reconstructed the massive amounts of data that came with the addition of more than one image plane. This allowed the introduction of this technology into clinical practice rather than just basic research. The next major advance and arguably the most important advance in medical imaging over the past decade, was the development of the PET/CT scanner. Townsend[2] developed the combined PET/CT scanner in the late 1990s and the first commercial PET/CT devices were installed in 2001. The PET/CT combines a helical CT, which provides anatomical data and as well allows for correction of varying degrees of photon attenuation by different tissues. The PET device is attached to the 'back end' of the CT scanner. CT and PET studies are carried out sequentially and this allows for good registration between the anatomical (CT) and the functional (PET) data, such that the two images that are produced can be overlain to provide a 'fused' image (Figure 88.1). The introduction of the faster PET detectors (LSO, GSO) into these devices, volume acquisitions (3D) and CT attenuation has resulted in a dramatic shortening of scan time. At our institution prior to PET/CT a brain acquisition using FDG on a PET-only device took approximately 60 mins. The same study with our current PET/CT scanner (LSO Biograph Duo, Siemens, Hoffman Estates, IL, USA) takes only 10 minutes.

FDG

PET ligands are produced when ions are accelerated in a cyclotron to high speeds and directed to bombard a 'target'. The ensuing nuclear reaction in the target produces the positron emitter, which can then incorporated into a specific compound. In the case of FDG, fluorine-18 is incorporated into an analogue of glucose, deoxyglucose that can describe glucose metabolism in the body *in vivo*. FDG is the most commonly used PET isotope in the assessment of refractory epilepsy. In the early years

Table 88.1 Positron emitting isotopes

Radionuclide	Half life
^{11}Carbon	20.3 minutes
^{13}Nitrogen	9.97 minutes
^{15}Oxygen	124 seconds
^{18}Fluorine	110 minutes

of neuroscience research with PET, ^{15}O was also used; this ligand when attached to water (^{15}O-H_2O) labels blood flow but the signal to noise ratio with this ligand is far inferior to FDG and it is not routinely used in PET centers.

Patient preparation for FDG-PET

Patients are asked to fast for approximately 6 hours prior to the scan. They are instructed to avoid caffeine and caloric beverages but may drink water in this period. A clinical history is obtained before the PET procedures commence. It is important to determine the seizure frequency, in particular, the timing and type of the last. This is because seizures can induce postictal glucose hypometabolism, which can persist for many hours after a seizure. This hypometabolism can be focal or generalized and present outside the epileptogenic zone. In addition, it is important to determine the patient's medication history as sedatives, major tranquillisers and steroids can reduce cerebral glucose metabolism. Before injection of FDG, a blood sugar level is measured; a level of less than 150 mg/dL is desirable. An elevated BSL results in a technically poor PET scan because FDG uptake competes with glucose for the surface membrane protein (glucose transporter – [GLUT]), which facilitates glucose and deoxyglucose transport into cells.[3] An intravenous cannula is placed, usually in an arm vein prior to isotope injection. Typically, 10 mCi of FDG is injected intravenously. Patients then rest quietly and remain awake during the 'uptake period' as FDG equilibrates in the brain. This 'uptake period' is typically 45 minutes. Activity and speech are limited during this time to minimize physiologic uptake into 'active' areas of the brain. FDG is safe and there are no known contraindications or side effects. Imaging is initiated approximately 40 minutes following isotope injection. EEG monitoring prior to and after isotope injection is recommended to detect seizures, which at times may confound the interpretation of the scan.

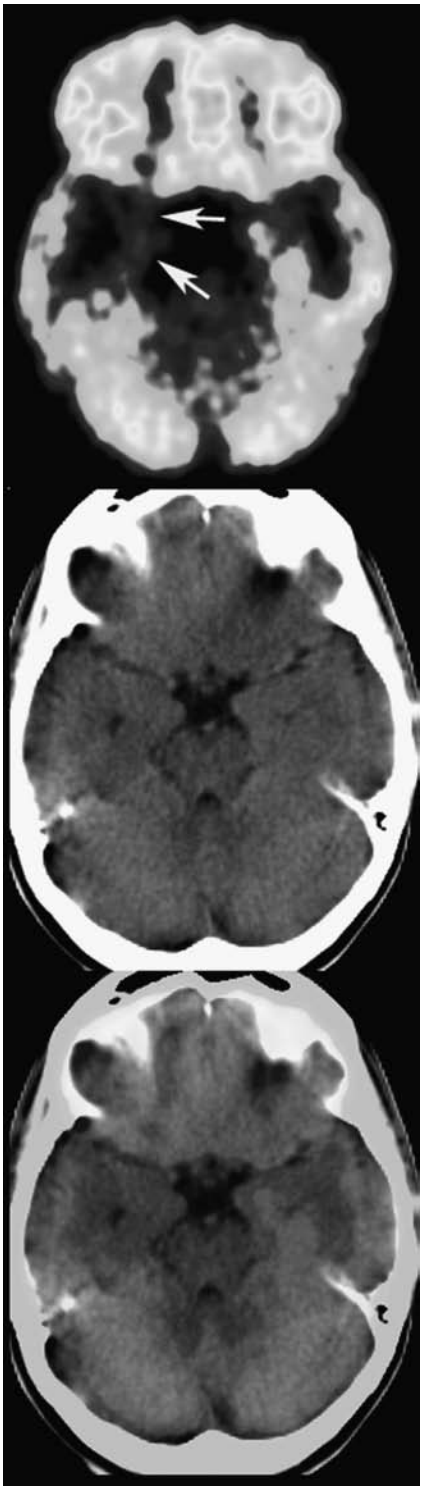

Figure 88.1 FDG-PET/CT of patient LS, a 23-year-old female with MTS. Top image, FDG-PET, middle image, co-registered CT, bottom image, PET/CT-fused images. Images show reduced glucose metabolism in the right anteromesial temporal structures including the amygdala, hippocampus and temporal pole (arrows).

Interpretation of FDG-PET studies

Interictal FDG-PET in mesial temporal sclerosis (mTLE)

The overall aim of functional imaging in mTLE is to map the site of seizure generation – the so-called 'epileptogenic zone'. FDG uptake in the brain represents synaptic activity [4] together with glutamate-mediated uptake of the ligand into astrocytes.[5] The first FDG-PET studies in epilepsy were done in the early 1980s and the typical findings that were reported by the early investigators were extensive and marked glucose hypometabolism of the involved temporal lobe[6–9] where severe mesial temporal sclerosis (MTS) was usually found (Figure 88.2). However, over the past decade the pattern of glucose hypometabolism in MTS appears to have changed.[10] The extensive glucose hypometabolism of the entire temporal lobe is now more commonly replaced by a more restricted region of glocose hypometabolism in to the anteromesial temporal structures, including the hippocampus, amygdala, temporal pole, entorhinal and anterior fusiform cortices (Figure 88.1).

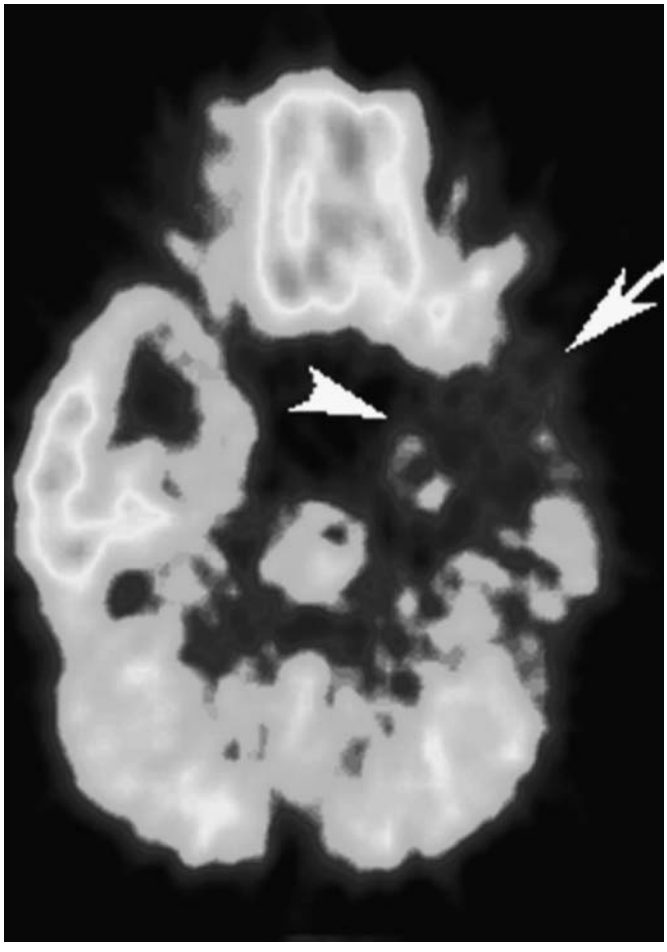

Figure 88.2 FDG-PET in a 35-year-old man with severe hipppocampal atrophy on MR and left temporal lobe seizures showing severe glucose hypometabolism in the entire left temporal lobe.

Subtle or marked glucose hypometabolism can also be seen in ipsilateral extra temporal structures including the thalamus, basal ganglia, frontal, parietal and occipital cortices and sometimes the contralateral cerebellar hemisphere.[11,12] These patterns of associated hypometabolism reflect the extra temporal connections of the seizure focus involved in the epileptogenic circuit. In the temporal lobe, the hypometabolic region involves the grey matter, which is involved in the initial ictal electrophysiologic discharges seen with intracranial monitoring.[13,16] Occasionally, glucose metabolism may be normal in the involved temporal lobe.[10] The reason for this is unclear but it may relate to differences in instrumentation and periscan ictal events that can increase glucose metabolism. In addition, the mesial temporal structures can be hypometabolic secondary to extra temporal neocortical epilepsy, in particular, due to seizure spread from the ipsilateral occipital lobe.[17,18] This change in pattern of involvement may reflect the earlier identification of patients with mTLE through the more widespread availability of surgical epilepsy programs and the advances in MR imaging.

Ictal FDG-PET

Ictal FDG-PET scans are difficult to obtain, in part, because of the half-life of FDG and the difficulty in predicting a seizure. Furthermore, they are problematic as there is always some degree of movement associated with all but simple partial seizures. Such head motion has its own problems for image interpretation but generally complex partial seizures (CPS) and generalized motor seizures will mean that the scan has to be aborted. Nevertheless, if the ictal event can be captured with imaging, the PET findings can be extremely valuable in seizure localization. The typical findings are focal, markedly increased glucose metabolism at the site of seizure onset [19,20] (Figure 88.3) and there may be ipsilateral increased metabolism in the basal ganglia and crossed cerebellar hypermetabolism due to increased efferent input to the contralateral cerebellar hemispheres via the cortico-ponto-cerebellar (CPC) pathway. The more problematic issue is when the patient has a seizure in the uptake period whilst awaiting the scan. If EEG monitoring is done prior to the scan acquisition it may provide valuable localising data but the practical issue is to whether to continue with the scan acquisition. Given that the static FDG-PET scan represents glucose metabolism over the entire uptake period and the study acquisition, a seizure produces a mixed interictal-ictal-post ictal scan where there may be regions of increased and decreased metabolism. However, the patient has already been injected with isotope and so our practice is to continue with the scan. If the scan results are problematic then we suggest that the study is repeated at a later date.

Visual versus quantitative analysis

Experience plays a large part in interpretation of PET scans and an extensive review of normal subjects is necessary to appreciate normal variation prior to the attempted interpretation of clinical cases. Co-registration programs that relate structural information to PET images allow a more precise anatomical localization of the lesion but this problem has been partially addressed with PET-CT. The limitations of qualitative visual analysis of PET images also apply to its quantitative analysis. With these limitations in mind, a few studies suggest that quantification enhances the clinical utility of FDG-PET[21,22] and may prevent misinterpretation of normal right and left variation.[23] However, in our experience quantification of studies, although a useful research tool, adds little to the clinical interpretation of PET studies. The routine quantification of clinical PET studies in every case of epilepsy is also tedious and is not practical in most centers.

Effect of blood glucose and anticonvulsants on FDG-PET

Endogenous molecules that compete with the ligand in the biological process can increase noise or reduce ligand tissue uptake. High blood glucose levels interfere with FDG uptake and lead to studies with poor signal-to-noise ratio. Antiepileptic medications produce a global reduction in cerebral metabolism in particular the deep nuclei and cerebellum[24–27] but this is not as marked as major tranquilisers and corticosteroids.[28] Chronically administered barbiturates, phenytoin, carbamazepine and valproate have all been shown to globally reduce absolute values of cerebral glucose metabolism but not to alter interregional ratios of metabolism.[29,30] Valproic acid reduces glucose metabolism by up to 10% and cerebral blood flow by up to 15%. The degree of glucose hypometabolism is not related to the serum valproate level and is similar to that of carbamazepine (10%) and phenytoin (11.5%). The reductions in cerebral glucose metabolism

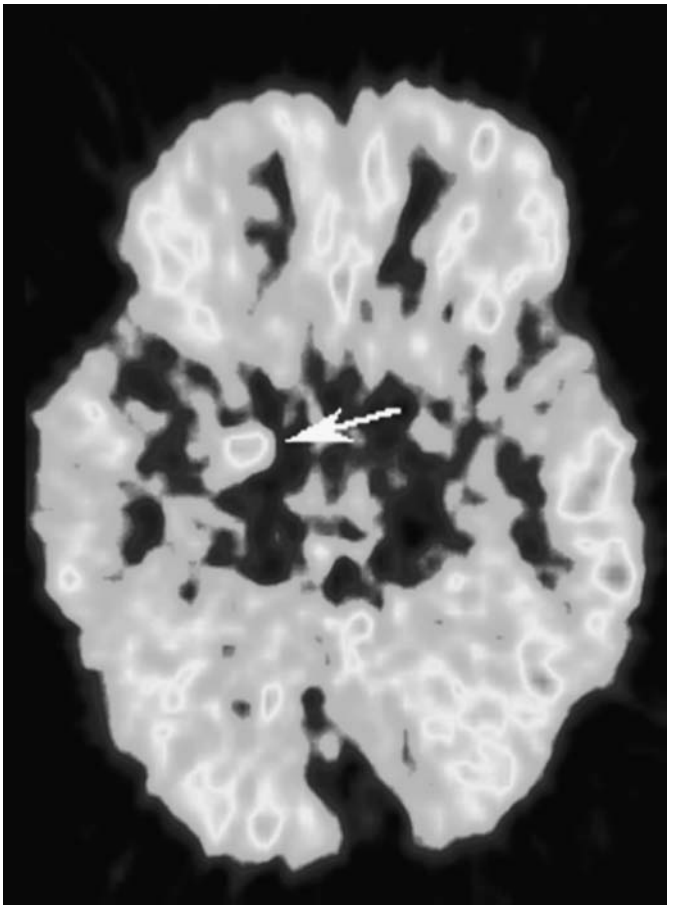

Figure 88.3 Ictal FDG-PET in a patient with right mesial temporal epilepsy who had a prolonged seizure in the uptake period showing markedly increased glucose hypometabolism in the right hippocampus (arrows).

is more pronounced with barbiturates (27%), diazepam (20%) or the combination of valproate and carbamazepine.[26,27,31,32]

Artifacts

Common artefacts that the reader should be familiar with may arise from partial volume effects, incorrect attenuation-correction, motion and seizures in the periscan period.

Partial volume is an artefact common to all tomographic imaging. If a structure is smaller than the detection threshold permitted by a scanner's spatial and contrast resolution, its functional activity will be averaged together with that of the activities of adjacent structures. Small structures may lose border detail if their contours are complex. Computer simulations show partial volume errors can cause up to a 15% change in the apparent size of an object in the PET image.[33] Incorrect attenuation correction can lead to false increases or decreases in the perceived tracer uptake. The most common mechanism for this in current PET-CT devices is head movement. The relationship of the scan to seizure activity is extremely important as discussed previously. Continuous EEG monitoring should be performed prior to the scan, during the uptake phase and when practical during scan acquisition to exclude unintentional ictal scanning which could lead to misinterpretation of FDG images.[34] However, it is important to note that surface EEG monitoring does not provide a complete solution to this problem, as subclinical electrographic seizures in small cerebral volumes or deep structures may not be detected with surface EEG.[35]

Current role of FDG-PET in assessment of mTLE

Interpretation of the literature on the role of FDG-PET in mTLE presents a formidable challenge to even experienced users of functional imaging. This in part relates to the different hardware/software methodologies, interpretation skills and variable emphasis on different investigation algorithms in the various centers. Further, local expertise across all facets (EEG, MR imaging, PET, SPECT) is usually not readily available in all centers. Although the studies in mTLE, which have compared FDG-PET to other imaging modalities, were done using older generation scanners, a number of reports have identified that interictal FDG-PET is more sensitive than volumetric MR imaging in identifying the temporal lobe of seizure origin.[36,37] FDG-PET also provides valuable information in patients with nonlocalizing surface ictal EEG, which can then reduce the need for intracranial EEG studies.[23] However, FDG-PET does not provide additional information when hippocampal atrophy is present on MR imaging.[38] The concordance between MR and FDG-PET is also associated with a better post-surgical seizure outcome.[39] However, false lateralization on FDG-PET, confirmed by depth EEG, can occur in a small percentage of patients.[6,22,40,41] Ictal HMPAO SPECT and interictal PET are probably equivalent for the lateralization of mTLE, although ictal SPECT generally requires hospital admission, cessation of medications and is more labor intensive and expensive when compared to an outpatient procedure.[42,43] In the comparison of FDG-PET to proton MR spectroscopy (MRS) there is little difference in lateralizing seizure onset according to the available data, although falsely lateralization is more common with MRS (6 vs. 3%) and expertise in MRS is restricted to only a few centers.[44,45]

Della Badia *et al.* has suggested that the combination of sleep EEG and MR imaging may be more cost-effective as outpatient screening tools.[46] It is our experience that the widespread availability of MR imaging at 1.5 T has meant that the need for routine FDG-PET scanning in mTLE has diminished. FDG-PET is now more directed to cases where there are discordant data and in this situation FDG-PET may be lateralizing and in this setting patients have a good post-surgical outcome.[47,48] FDG-PET may also be used to prognosticate on postoperative memory deficits (see below).

Pathophysiology of glucose hypometabolism with FDG-PET

Although it is over 25 years since the first interictal FDG-PET studies were done in the study of epilepsy the pathophysiology of the glucose hypometabolism in mTLE remains unknown. Various mechanisms have been suggested including neuronal loss, diaschisis, postictal depression and other epilepsy-related phenomena. There is no correlation between cortical metabolism on preoperative FDG-PET and neuronal density of resected hippocampi in mTLE.[49] There is also a lack of correlation between hippocampal volume loss and the degree of temporal glucose hypometabolism.[50] Diaschisis was described by Von Monakow over a century ago to explain a disconnection between functionally related parts of the nervous system.[51] In the 1980s the most common example of this was the reduction in blood flow and

metabolism in the contralateral cerebellar hemisphere ('crossed cerebellar diaschisis' – CCD), which was noted in patients with hemispheric or deep white matter strokes due to interruption of the cortico-ponto-cerebellar (CPC) pathway when PET scanning was used as a research tool.[52] However, despite the reduced metabolism and blood flow in the contralateral cerebellar hemisphere there were no obvious associated neurological signs. The most common example of CCD today is that seen with FDG-PET scans done in patients with brain tumors. Whilst this effect may in part explain the remote hypometabolism in extra temporal sites where there are known connections from the mesial temporal structures, it cannot be the sole mechanism and there is difficulty with this mechanism in explaining the marked neocortical temporal hypometabolism that is sometimes seen.

Dlugos *et al.* reported a correlation between hilar cell densities and the degree of glucose hypometabolism in the deep nuclei, which suggests that there may be functional changes in neurons and their associated circuits in relation to seizure spread.[53] Still other investigators have hypothesized that interictal spikes at sites inaccessible to surface EEG may explain the reduction regional glucose metabolism[54] and this is partly supported by depth EEG recordings.[55] These remote sites of regional glucose hypometabolism return towards normal after successful surgery for MTS.[56] But rather than an effect of diaschisis, Bartenstein *et al.* linked these findings to down-regulation of opiate receptors.[57]

The exact cause of glucose hypometabolism in mTLE remains unknown. The evidence so far suggests that it is due to a combination of factors and that neuronal loss does not adequately explain the reversible and functional changes seen with FDG-PET.

Interictal FDG-PET in early temporal lobe disease

Investigators have studied FDG-PET in early mTLE to understand the underlying cause for the glucose hypometabolism seen in focal epilepsy. There are conflicting data in the literature. There is evidence that temporal hypometabolism may already be present at the onset of mTLE. In a cross sectional study of pediatric patients with refractory mTLE, the incidence of FDG-PET hypometabolism was similar to that of the adult population.[58] These findings would also be in agreement with studies in adult patients that have failed to detect an association between the lifetime frequency of seizures and the severity of temporal lobe glucose hypometabolism on PET[59] or hippocampal atrophy on MR imaging.[60] There have been examples of patients with severe temporal glucose hypometabolism where hippocampal volumetric measurements were normal.[60] These data support the postulate that glucose hypometabolism represents the severity of the underlying epilepsy syndrome, rather than simply an effect of repeated seizures.

Other authors have argued that the degree of glucose hypometabolism may worsen with continuing seizure activity.[61] They cite prospective imaging studies[62] and studies done in children with new onset temporal epilepsy.[63] However, none of these studies have been longitudinal and the results may reflect a mixed cohort, some of whom may have a more benign epilepsy syndrome.

The evidence with FDG-PET in early TLE parallels that of clinical experience. That is, the natural history of refractory mTLE is different from mTLE which is easily controlled by anticonvulsants. It is not surprising that abnormal glucose metabolism may be present early in patients with refractory disease.

Clinical aspects of mTLE and FDG-PET

FDG-PET and seizure semiology

There is a weak association between seizure semiology and the pattern of interictal glucose hypometabolism. Early animal and clinical FDG-PET studies described temporal hypometabolism together with limbic auras, automatisms and posturing that are typical findings with mTLE.[8,64,65] A quantitative study by Savic *et al.*[18] confirmed that the topographical pattern of interictal glucose hypometabolism in mTLE was not only a reflection of regions involved in seizure generation but also included regions of the cerebrum involved in seizure expression. Limbic auras or staring spells without other motor manifestations were limited to the ictal onset zone. However, these authors found more widespread areas of glucose hypometabolism in patients with more complex motor behaviors during the seizure. Patients with motor automatisms, thrusting movements, head turning or swinging of the extremities had more widespread hypometabolism in the limbic structures, often involving the contralateral side. Posturing during the seizure was associated with hypometabolism in the dorsolateral frontal and/or motor cortex. In subjects with secondary generalized seizures there was cerebellar and parietal lobe hypometabolism in addition to the abnormalities described above.

The pattern of glucose hypometabolism in the temporal lobe may be also used to distinguish patient with mTLE from patients with neocortical temporal lobe epilepsy. Ipsilateral insular and temporal neocortical hypometabolism is more pronounced in patients with neocortical temporal lobe epilepsy when compared to mTLE.[66,67] Also patients with neocortical temporal lobe epilepsy who describe an acoustic aura can be differentiated from mTLE by reductions in glucose metabolism primarily involving temporo-perisylvian locations.[67]

FDG-PET and interictal epileptic abnormalities

There are conflicting reports on the relationship between the frequency of interictal temporal EEG spikes and severity of glucose hypometabolism on PET. This may be due to the different patient groups studied; evolution of PET technology; relative sophistication of MR imaging and PET equipment and the scanning protocols. Early studies did not find a relationship between interictal scalp and depth EEG spikes and the severity of temporal lobe hypometabolism[9] but this group may have been studied much later in the natural history of mTLE. In addition, continuous focal slowing or focal suppression of barbiturate-induced beta activity during the PET study did not correlate with the severity of temporal lobe hypometabolism.

More recent studies suggest that FDG-PET hypometabolism may reflect not only a permanent functional deficit but also a transient regional cerebral dysfunction related to the occurrence of interictal spikes.[68,69] Some researchers have found a relationship between interictal EEG abnormalities and the severity of glucose hypometabolism. In another study

there was a significant negative correlation between asymmetry in glucose hypometabolism in temporal lobes and total number of interictal spikes recorded.[55] Investigators have also shown a concordance between temporal lobe glucose hypometabolism and regional slow activity recorded over temporal electrodes [70] and the amount of delta activity in the interictal EEG that is independent of MR findings.[71] However, none of these studies accounted for the seizure frequency around the time of the PET study. This is an important issue because patients with more frequent interictal epileptic discharges often have more frequent seizures. Without controlling for seizure frequency around the time of the PET study, it is difficult to conclude that a reversible diaschisis from interictal epileptic activity results in neuronal dysfunction that in turn leads to abnormal glucose metabolism. At present there is no evidence that there is a strong relationship between interictal discharges and the severity of glucose hypometabolism on PET.

FDG-PET and ictal epileptic discharges

Early studies showed a good relationship between the site of focal hypometabolism and the epileptic focus determined by the combined results of all electrophysiological studies.[7] These findings then led to performing anterior temporal lobectomies without chronic intracranial recordings as a routine part of clinical practice provided there were no discordant data.[13] In mTLE, the zone of intracranially recorded electrographic ictal onset is almost always located in the region of glucose hypometabolism on FDG-PET.[72] This regionalization of the ictal onset zone has been borne out in more recent studies. The area of glucose hypometabolism is usually larger than the pathological abnormality and may even be present in the absence of any MR scan abnormality.[38]

There are also subtle differences between epilepsies of mesial temporal origin versus those from the lateral neocortex on FDG-PET.[72] Patients with mTLE as a group have the lowest FDG uptake in the entire temporal lobe when compared to patients with lateral or mesio-basal temporal seizure origin but there is no discernible correlation between the degree of hypometabolism and the location of EEG-defined epileptogenic zone.[21]

FDG-PET has superior sensitivity and specificity when compared to scalp EEG in mTLE.[13] These data are old and more recent studies have not been done but one would expect an improved performance with the new generation of scanners. FDG-PET is as accurate as MR imaging in identifying the temporal lobe of onset in patients with bitemporal epilepsy[73] and can provide lateralizing data in patients with a nonlocalized surface ictal EEG[23] or nonlateralized MR findings.[48] However, occasionally both metabolic and electrophysiological techniques can produce false positive as well as false negative results.[7]

FDG-PET and neuropsychological outcome and intracarotid amobarbital memory testing (ICAMT)

There are limited studies that have investigated the distribution of FDG-PET abnormalities, the temporal structures involved and neuropsychological measures. A number of general rules have emerged from these studies: patients with mTLE and left temporal hypometabolism perform poorly on verbal memory tasks and those with right temporal hypometabolism perform less well in visual memory tasks;[74,75] left thalamic and left lateral temporal hypometabolism are independently associated with impairment of delayed verbal recall[76] and more severe left hemispheric hypometabolism on FDG-PET is associated with poorer overall cognitive performance in patients with left hemisphere language dominance.[76]

FDG-PET has shown the mesial temporal region to be a dominant and leading area for lateralizing Wada memory dominance.[77] In one study 65% of patients with TLE and glucose hypometabolism on FDG-PET had impaired memory on the ICAMT and memory impairment contralateral to the temporal glucose hypometabolism was never found.[78,79] FDG-PET is also useful to help predict postoperative memory loss. Patients with mild to no glucose hypometabolism on the left side have a significantly greater verbal memory decline following a left temporal lobectomy when compared with those with findings of moderate to severe hypometabolism (89 versus 33%). However, there does not appear to be a significant relationship between the extent of PET hypometabolism and memory outcome for right anterior temporal lobectomy patients.[80]

FDG-PET and seizure outcome following surgery

FDG-PET can be predictive of postoperative seizure outcome and neuropsychological deficits following temporal lobectomy for mTLE but may be less useful in patients with bitemporal epilepsy. Studies that have examined the relationship of FDG-PET to outcome of temporal lobectomy independent of EEG findings have found that asymmetries in glucose metabolism in the temporal lobes of at least 15% can be predictive of good post surgical outcome.[22,81] The prognostic value of the exact location of glucose hypometabolism within the temporal lobe is more controversial. Some data suggests that patients with mesial temporal glucose hypometabolism on PET have a high probability of becoming seizure free postoperatively.[82,83] However, other studies have indicated that lateral[22,81] or polar temporal hypometabolism[84] are better predictors of a seizure-free postoperative course. Despite these conflicting results these studies provide us with a number of other important findings: (i) the high correlation between temporal hypometabolism and seizure outcome is independent of the pathologic diagnosis[83] (ii) a 100% lateralization by depth EEG, nonlateralized PET scan and MR imaging do not indicate poor surgical outcome;[6,73] (iii) unilateral temporal lobe hypometabolism is 'falsely lateralized' in approximately 1–2% of patients (iv) prior intracranial surgery, including depth electrode placement, can produce temporal hypometabolism that is falsely lateralized.[13]

Although bilateral temporal hypometabolism is a relative contraindication to surgery,[12] FDG-PET is as sensitive and specific as volumetric MR in patients with bitemporal epilepsy. However, in these patients, a lateralizing PET that is convergent with depth EEG recordings and MR imaging[73] does not increase the probability of successful postoperative seizure outcome.

FDG-PET and pathology

As described earlier cell loss in the mesial structures is only one component in the pathophysiology of glucose hypometabolism.

It is not surprising that reduced glucose metabolism on FDG-PET corresponds closely with the presence of a histologic lesion in the mesial temporal lobe that, rarely, may not be detected on MR imaging.[48] However, as already discussed, glucose hypometabolism on PET does not correlate with the degree of neuronal loss in surgical specimens[13,49,85–87] or hippocampal atrophy on MR imaging.[50]

FDG-PET is also very sensitive in patients with mTLE and a concomitant pathology located outside the hippocampus, i.e., 'dual pathology'. Alien-tissue lesions, including ganglioglial, oligodendroglial, and astroglial tumors, occur in 10–20% of patients who undergo surgery for temporal lobe epilepsy. Up to 91% of patients with dual pathology have abnormal PET scans[88] where they may also have a different distribution of glucose hypometabolism. For example in the subgroup of patients with dual pathology who have microscopic temporal cortical dysplasia and concurrent MTS there is more prominent lateral temporal metabolic dysfunction compared with isolated MTS.[89]

Other PET ligands

Several other PET ligands have been developed over the last two decades that have provided insights into the pathophysiology of epilepsy. These include ^{15}O-water, ligands that bind to benzodiazepine, cholinergic, opiate, serotonin, and monoamine oxidase receptors together with agents to identify protein synthesis and positron-labeled anticonvulsants.

[11C] Flumazenil (FMZ)

FMZ is a competitive central benzodiazepine receptor antagonist. Histopathologic and autoradiographic studies of surgically removed sclerotic hippocampi have shown reduced neuronal counts, central benzodiazepine receptor (cBZR) densities and a reduction of cBZR density per remaining neuron.[90] There is a reduction of available cBZR on remaining neurons in MTS detected *in vivo* by using FMZ-PET. After correction for grey matter atrophy there is reduced FMZ binding, which suggests that a reduction in cBZR binding is not solely due to hippocampal atrophy or neuronal loss.[91] These changes are not permanent and may be in part due to the effects of seizures on projection areas from the mesial temporal lobe.[92]

Comparison FMZ-PET with FDG-PET in defining the ictal onset zone

FMZ-PET studies when compared with FDG-PET have shown a less extensive reduction in cortical binding (Figure 88.4) but are as sensitive in localizing the temporal lobe of seizures onset.[93–95] It has been postulated that unlike more widespread glucose hypometabolism seen with FDG-PET, the FMZ-PET changes may be more specific to the epileptogenic zone (Figure 88.4). Ryvlin *et al.*[10] studied a series of patients with partial epilepsy the majority whom had temporal lobe epilepsy. An abnormal FMZ-PET was found in 94% of patients with temporal epilepsy in which 81% also had concordant MR abnormalities. There were a small number of patients who had a positive FMZ-PET with a normal FDG-PET and vice versa. False lateralization occurred rarely with FMZ-PET. However, as with FDG-PET where there are clear-cut MR findings of MTS, the more sensitive FMZ-PET does not provide any additional clinical information. By the same token, where hippocampal volumetry fails to show hippocampal atrophy, reduced binding on FMZ-PET as with FDG-PET, may provide evidence for functional impairment.[10,96] However it is important to note that transient and falsely lateralized abnormalities with FMZ-PET can occur in patients with normal MR imaging.[97]

Both visual and quantitative assessments of FMZ-PET are very sensitive where there is a coexistent cortical lesion in addition to MTS.[98,99] In patients with microdysgenesis where the MR images are normal, some authors have also found increased binding on FMZ-PET in the white matter and periventricular region and have postulated that it may represent benzodiazepine receptors on heterotopic neurons.[100–102] These authors did not confirm their postulate by a pathological study.

Opiate receptors

^{11}C-carfentanil PET binds to the mu opiod receptors, which are increased in the temporal neocortex, but decreased in the amygdala on the side of the epileptic focus.[103] On the other hand, ^{11}C-diprenorphine binding – that reflects mu as well as nonmu opiate subtypes – is not different among regions of affected and nonaffected temporal lobes in patients with unilateral TLE. One possible explanation of this increase in mu opioid receptors in the lateral neocortex without an overall increase of opioid receptor binding includes an up-regulation of mu receptors in response to epileptic activity and down-regulation or occupation of kappa opioid receptors.[104] This reduced binding of opioid receptors appears to persist after surgical removal of the epileptic focus.[57] The studies done so far in mTLE suggest that this ligand is of limited clinical value.

Cholinergic receptors

Cholinergic receptors have been imaged using [^{76}Br] 4-bromodexetimide (BDEX) or [^{11}C] *N*-methyl-4-piperidyl benzylate (NMPB). With mTLE BDEX there is a reduction in binding in the temporal lobe ipsilateral to the seizure focus.[105] Highly restricted zones of reduced activity in the anteromesial temporal regions are seen with NMPB[106] – similar to the distribution seen with FMZ-PET. These findings have also been reproduced using SPECT ligands.[107]

Monoamine oxidase type B (MAO-B) receptors

Deprenyl is an irreversible inhibitor of MAO-B with a very high affinity for the enzyme. In the brain, MAO-B is preferentially located in astrocytes and there is histological evidence for increased binding of MAO-B enzyme in sclerotic hippocampi. PET with ^{11}C-deuterium-deprenyl in patients with temporal epilepsy showed increased binding in its ipsilateral mesial temporal lobe.[108] However, ^{11}C-deuterium-deprenyl PET adds little to FDG-PET in patients with TLE.[109]

N-Methyl-d-Aspartate (NMDA) receptors

^{11}C-(*S*)-*N*-methyl ketamine that binds NMDA receptors in the brain may have a 9–34% reduction of tracer radioactivity in

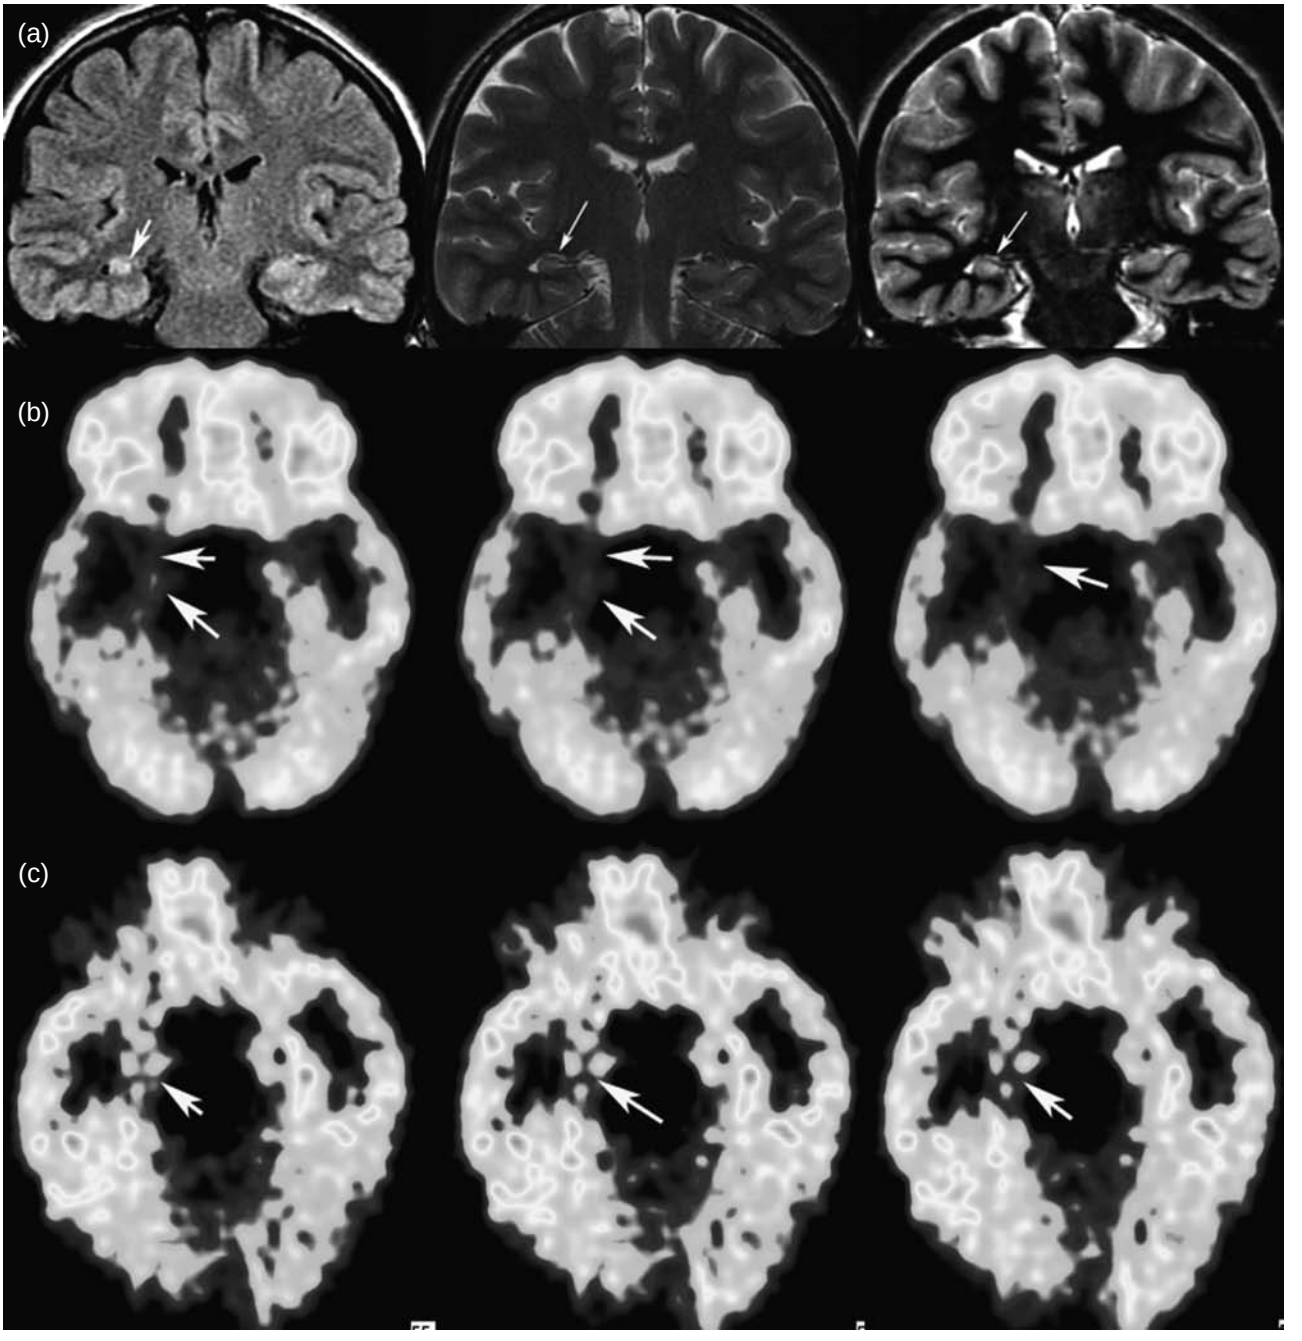

Figure 88.4 Patient LS from Figure 88.1. with left mesial temporal sclerosis and temporal lobe seizures. Row A,MR images. Arrows showing increased signal and atrophy in the right hippocampus on T2-weighted images. Row B,FDG-PET. Arrows showing marked anteromesial glucose hypometabolism. Row C,FMZ-PET. Arrows showing a more restricted area of reduced ligand binding in the right hippocampus when compared to the FDG-PET images.

the temporal lobes of ictal onset; very similar to the metabolic pattern seen on PET scans with FDG-PET.[110] However, only a few patients have been studied with this technique and its role in clinical assessment is at present uncertain.

Serotonin receptors and metabolism

Studies exploring the serotonergic mechanisms in animal models of epilepsy and human surgical specimens have shown increases in serotonin and its metabolites in epileptic tissue.[111,112] Patients with severe mTLE have reduced 5-HT1A serotonin receptor binding in the mesial temporal lobe and its limbic connections. There is decreased binding of the PET ligand [18F] FCWAY to the 5HT1A receptor in both mesial and lateral temporal regions ipsilateral to the epileptic focus[113] together with the ipsilateral anterior cingulate, insula and lateral temporal cortex, contralateral hippocampus and the raphe nuclei.[114] These findings have been echoed by another ligand that is an antagonist of the 5-HT1A receptor – 4-(2Vmethoxyphenyl)-1-[2V-(N-2-pirydynyl)-p-fluorobenzamido]-ethylpiperazine (MPPF).[115] Assuming that these findings are not due to the effect of anticonvulsant medications, they can be explained by increased endogenous serotonin release that results in agonist-mediated down-regulation of 5HT1A receptors in the hippocampus.

PET with alpha [11C] methyl-l-tryptophan (AMT) has been used to examine serotonin synthesis and has revealed an

increase in AMT uptake in the hippocampus.[116] The increased AMT uptake in the hippocampus has been speculated to be the result of serotonergic fiber sprouting.[117]

Although there have been limited studies of many ligands in temporal lobe epilepsy research in this area continues. None of the above ligands apart from perhaps FMZ have found a clinical place in the assessment of patients with mesial temporal epilepsy. However, even FMZ has not gained widespread clinical use due to its limited availability and little additional benefit when compared to FDG. This may reflect the fact that in temporal lobe epilepsy there is not only a change in the distribution of receptors but also altered function of the remaining receptors that will require new methodologies to investigate.

Conclusion

The current clinical role of FDG-PET/CT appears to be in the nonlesional cases of mTLE or where there is discordance between the MR and EEG data. Although instrumentation has improved markedly over the past decade and scan times are shorter, it should be emphasized that patients with mTLE are subject to dynamic changes in the periscan period. Accurate accounts of seizure frequency and EEG recordings around the time of the scan are essential to correct interpretation. Although many ligands have been used over the past decade, FMZ shows the most promise but in the extra temporal seizure disorders. A ligand that is able to map the seizure onset remains elusive.

89 PET in neocortical epilepsies

HT Chugani, C Juhász, E Asano, and S Sood

Summary

- PET techniques have contributed to the clinical management of epilepsy.
- In extratemporal lobe epilepsy, glucose metabolism PET guides placement of intracranial electrodes. Dynamic metabolic changes occur with persistent epilepsy.
- Flumazenil PET is useful in detection of 'dual' pathology, more precise localization of the epileptogenic zone, defining perilesional epileptogenic cortex, and possibly identifying 'secondary epileptic foci'.
- α-[^{11}C]methyl-L-tryptophan (AMT) PET can differentiate between epileptogenic and nonepileptogenic tubers in tuberous sclerosis complex.
- AMT-PET can localize the epileptic focus in lesional and occasionally in nonlesional epilepsy.
- In cases of failed epilepsy surgery, AMT-PET may identify residual epileptogenic cortex for a second surgery.

Introduction

Positron emission tomography (PET) is a noninvasive functional imaging tool which can be used to measure regional uptake and affinity of ligands or metabolic substrates in brain and other organs. In epileptic disorders, PET scanning has been applied both in the clinical setting and also to investigate basic mechanisms associated with epileptogenicity and seizure propagation. The commonest clinical application of PET is in the evaluation of patients with intractable epilepsy for surgical treatment. In such instances, PET scanning can assist in the selection of appropriate surgical candidates, localize epileptogenic brain regions, evaluate the integrity of brain areas outside the epileptic focus, and even predict postoperative cognitive dysfunction in some patients. In this review, we summarize the findings of previous PET studies which have investigated clinical applications in patients with *neocortical* epilepsies with the aim of defining epileptogenic cortex for surgical resection. The application of PET in mesial temporal lobe epilepsy has been discussed in the previous chapter.

PET tracers used in neocortical epilepsy

The most widely available PET tracer for presurgical evaluation of both adults and children with intractable focal epilepsy is 2-deoxy-2-[^{18}F]fluoro-D-glucose (FDG), which is used to measure glucose utilization in various brain regions and, in the interictal state, shows decreased metabolism (hypometabolism) in the vicinity of the epileptic focus. It is important to monitor the EEG during the PET tracer uptake period, since an active focal epileptiform discharge present on the EEG may be associated with local *hypermetabolism,* even on the interictal PET scan. In such instances, the relative hypometabolism on the contralateral (normal) side may be mistakenly interpreted as an interictal epileptic focus, an interpretation that would lead to false lateralization of the focus.[1]

Of the receptor ligand PET tracers, the most commonly used in epilepsy is [^{11}C]flumazenil (FMZ) which binds to $GABA_A$ receptors.[2–8] It should be pointed out that in clinical studies with FMZ-PET, patients taking benzodiazepine drugs have generally been excluded, but the effects of drugs that result in allosteric interactions with $GABA_A$ receptors have not been well studied. Although quantification of FMZ-PET images can be performed using a three-compartmental model[9] or a simpler two-compartmental model,[10] a disadvantage is the requirement of arterial blood sampling to define the input function. However, experience has shown that visual as well as objective detection of focal cortical and subcortical abnormalities for clinical purposes can be reliably achieved using FMZ activity images that do not require arterial blood sampling. Comparison of focal FMZ abnormalities in patients with neocortical epileptic foci showed that summed FMZ activity images obtained between 10 and 20 min after tracer injection represented excellent agreement between FMZ activity and the quantitative 'volume of distribution' images.[11]

In our center, we also use alpha-[^{11}C]methyl-L-tryptophan (AMT) which measures tryptophan metabolism[12–14] for epilepsy surgery evaluation. AMT is an analog of tryptophan (the precursor of serotonin), and is converted in the brain to α[^{11}C]methyl-serotonin, which is not a substrate for the degradative enzyme monoamine oxidase, and therefore accumulates in serotonergic terminals. Obviously, patients taking medications that affect tryptophan or serotonin metabolism should not undergo AMT-PET scan.

Other PET tracers with the potential for detecting epileptic brain regions include radiolabeled ligands which bind to opioid receptors,[15] histamine H_1 receptors,[16] monoamine oxidase type B enzyme,[17] N-methyl-D-aspartate receptors,[18] peripheral-type benzodiazepine receptors,[19] and serotonin 1_A receptors.[20] Among these, only the few that have been applied in the study of intractable neocortical epilepsy will be described in further detail below.

Extratemporal lobe epilepsy

Unlike temporal lobe epilepsy, in which there is a 'standard' lobectomy procedure, extratemporal lobe resections are quite variable and range from small topectomies to unilobar or multilobar cortical resections. Defining the location and extent of *even the primary epileptic focus (let alone secondary foci)* can be quite challenging, particularly in frontal lobe epilepsy, which constitutes 20–30% of all partial epilepsies and the majority of extratemporal lobe epilepsy.[21–25] In a review of surgical outcome from 10 epilepsy surgery centers worldwide,[26] only 45% of 805 patients undergoing extratemporal cortical resections became seizure free. The success rate is even worse when no structural lesion can be identified on MRI.[27–29] For example, Schiller *et al.*[30] reported that of the nonlesional patients subjected to chronic intracranial EEG monitoring, only 22% became seizure free after surgery. Even with the many advances in neuroimaging techniques (reviewed in Kuzniecky & Knowlton, 2002,[31]) current success rates for extratemporal lobe epilepsy surgery remain modest at the 50–60% range.[32–34]

Nonlesional extratemporal lobe epilepsy

When the MRI scan fails to show a focal structural abnormality in extratemporal lobe epilepsy, the epileptologist is guided only by seizure semiology and scalp-EEG findings for the placement of intracranial electrodes, an approach that is fraught with sampling errors and may lead to surgical failure. In such instances, PET often provides important localizing data that can be compared to EEG localization and guide intracranial electrodes placement, thus increasing the confidence of the epilepsy surgery team (Figure 89.1). Using a high resolution PET scanner in a predominantly pediatric population, a sensitivity of 92% in the detection of frontal lobe epileptic foci with FDG-PET, and a specificity of 62.5% were demonstrated.[35] In an adult population with nonlesional neocortical epilepsy, however, the sensitivity was 42.9%.[36] Unfortunately, the consistent observation of large areas of glucose hypometabolism on PET extending beyond the primary epileptogenic region has precluded the use of FDG PET to define *precisely* the boundary of the epileptogenic zone for surgical resection, although it remains a very valuable tool for lateralization and *general* localization of epileptogenic brain regions.[37–39] This is supported by a recent study, which found that localization data obtained by FDG PET and interictal EEG tended to predict a seizure-free outcome.[34]

The large areas of glucose hypometabolism seen in patients with partial epilepsy are more often seen in cases of chronic epilepsy than in patients with recent onset epilepsy.[40,41] Indeed, in a PET study of 40 children with newly diagnosed partial epilepsy with normal MRI, only eight (20%) showed focal cortical hypometabolism on FDG-PET.[41] More recently, we measured changes in the extent of cortical hypometabolism defined by an asymmetry-based method and projected on the 3D-reconstructed cortical surface in 15 children who underwent two consecutive FDG-PET scans 7–44 months apart.[42] Change in seizure frequency between the two PET scans correlated positively with the change in the extent of cortical glucose hypometabolism ($r = 0.81$, $p < 0.001$; corrected for interval time between the two scans). Patients with persistent or increasing seizure frequency (≥1 seizure per day) showed extension of hypometabolic cortex over time (Figure 89.2). In contrast, patients whose seizures were characterized as <1 seizures per day during time interval between the first and second PET scan showed a decrease in the size of the hypometabolic cortex. These findings are consistent with our earlier studies, which found that in patients with an epileptogenic lesion, the extent of perilesional glucose hypometabolism increases with the number of seizures.[6] Together, these observations suggest that intractable epilepsy in children is a progressive disorder and that expansion of cortical hypometabolism may reflect a growing seizure network, i.e., an expansion of dysfunctional circuitry

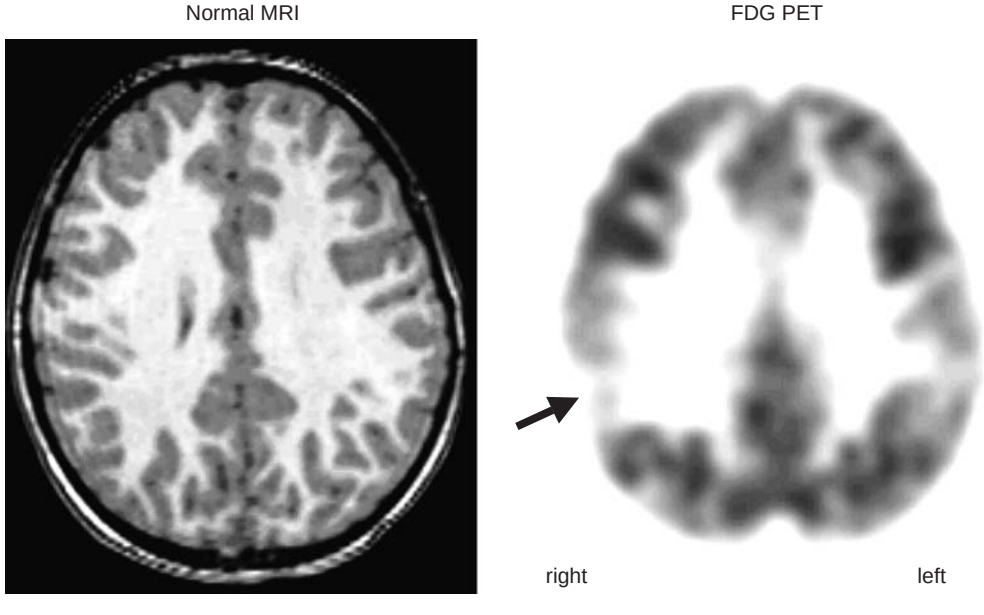

Figure 89.1 Focal cortical parietal glucose hypometabolism (arrow) on FDG-PET in a child with normal MRI and uncontrolled seizures. Video-EEG monitoring suggested ictal onset from the right centro-parietal cortex, consistent with the PET abnormality. High-resolution MRI was normal.

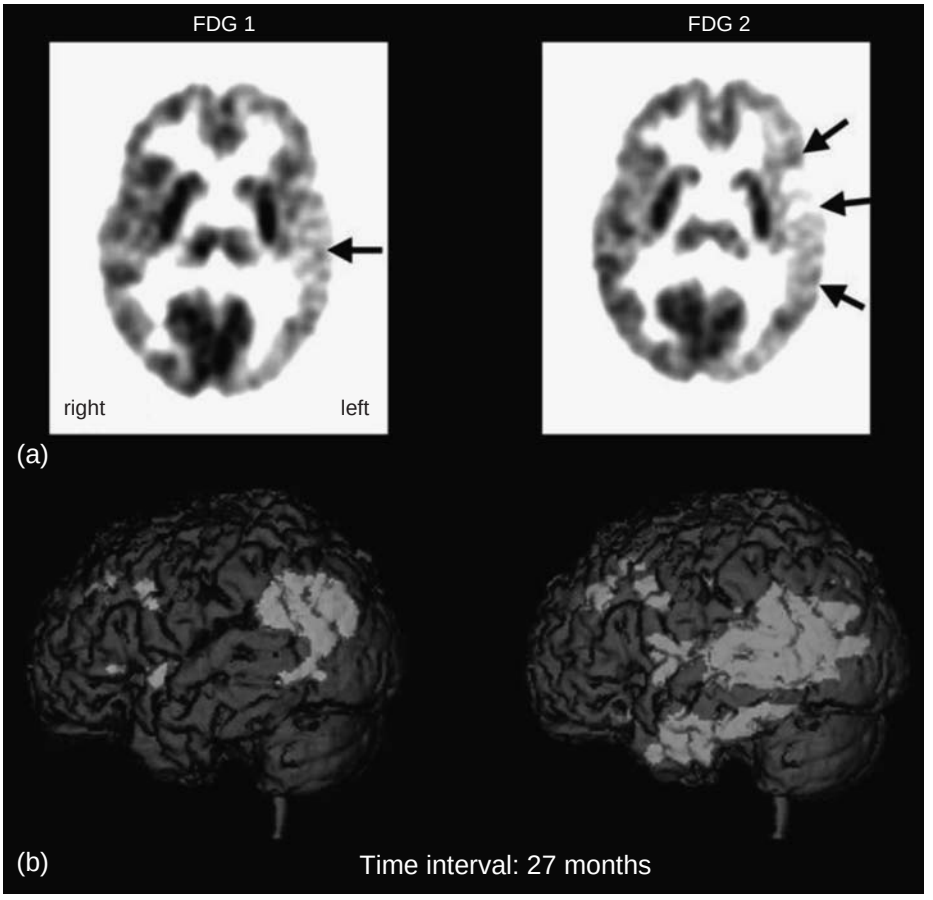

Figure 89.2 Expansion of cortical glucose hypometabolism in chronic epilepsy in a child with frequent seizures originating from the left hemisphere. The first PET scan (FDG1, at 15 years of age) showed left temporal hypometabolism which extended to the frontal cortex on the second PET scan (FDG2) performed 27 months later (see arrows on panel a). Panel b demonstrates the extent of cortical hypometabolism as projected to the 3D brain surface. Seizure frequency had increased between the two scans from 1 per day to more than ten seizures per day.

involving cortical (and subcortical) areas. It is tempting to speculate that the mechanisms associated with these dynamic changes may also play a role in the development of epileptic encephalopathy in children who experience repeated seizures during an early sensitive period when there is exuberant synaptic connectivity in the brain, but further studies are required to test this hypothesis.

Infantile spasms

Glucose metabolism PET studies in children with intractable cryptogenic infantile spasms have shown unifocal (Figure 89.3a) and, more commonly, multifocal (Figure 89.3b) cortical areas of hypometabolism interictally. Less commonly, increased focal glucose utilization may be seen if the study is performed ictally or in the presence of an actively discharging focus on the EEG. The EEG localization of focal ictal or interictal abnormalities corresponds well to the PET focus in most cases.[43,44] However, when hypsarrhythmia is present on the EEG, focal electrographic abnormalities either preceding or following the presence of hypsarrhythmia correlate best with the location of FDG-PET cortical abnormalities. When available, therefore, EEGs performed before the onset of spasms must be reexamined in conjunction with the PET study.

The discovery of these focal cortical metabolic abnormalities on FDG-PET has allowed some infants with refractory spasms to be treated with cortical resection. Thus, when a single region of abnormal glucose metabolism is present, and there is good correlation between the region localized with PET and the focus identified on the EEG, surgical removal of the epileptogenic region results not only in seizure control but also in complete or partial reversal of the associated developmental delay. Neuropathological examination of the resected tissue typically reveals cortical dysplasia.[43–45]

Unfortunately, about 65% of infants with cryptogenic spasms show more than one area of cortical hypometabolism on the FDG-PET scan[46] and are therefore not ideal candidates for cortical resection (Figure 89.3b). Within this group, there is a subgroup of infants with bilateral temporal hypometabolism (Figure 89.3c) and a typical clinical phenotype, comprising about 10% of all infants with cryptogenic spasms. The clinical features include severe developmental delay (particularly in the language domain) and autism.[47]

It is now recommended that all infants with intractable cryptogenic spasms undergo an evaluation with FDG-PET. In some cases, PET reveals bilateral symmetric or generalized cortical hypometabolism, with or without associated cerebellar involvement (Figure 89.3d). This pattern suggests an underlying genetic/metabolic condition, rather than cortical dysplasia, and strongly discourages pursuing of presurgical evaluation but may prompt more detailed metabolic and genetic studies.

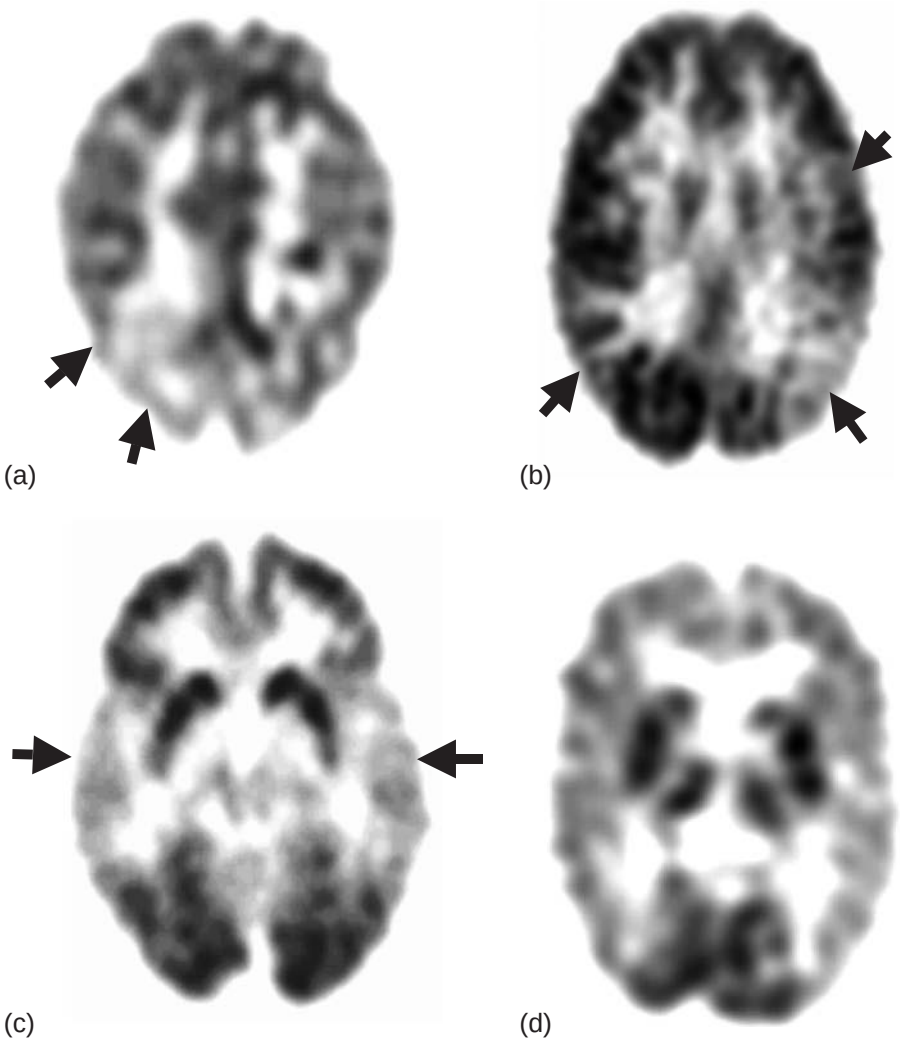

Figure 89.3 Various patterns of cortical glucose hypometabolism in infantile spasms. (a) Unifocal hypometabolism; (b) multifocal hypometabolism; both of these focal patterns are likely to be associated with focal cortical dysplasia. (c) Bitemporal hypometabolism, which is often associated with autistic features; (d) diffuse cortical hypometabolism, presumably indicating an underlying genetic and/or metabolic condition.

Other epilepsy syndromes

PET scanning has been used in the study of various other epilepsy syndromes occurring in infants and children. Studies with FDG-PET have provided a different classification of *Lennox-Gastaut* syndrome based on metabolic anatomy. Four metabolic subtypes have been identified: (1) unilateral focal, (2) unilateral diffuse, (3) bilateral diffuse hypometabolism, and (4) normal patterns.[48–50] These glucose metabolic patterns may be useful in determining the type of surgical intervention indicated for those patients with uncontrolled seizures. In children with *Sturge-Weber syndrome*, FDG-PET typically reveals hypometabolism ipsilateral to the facial nevus and thus allows the degree and extent of hemispheric involvement to be determined.[51,52] In addition, the rate of hemispheric deterioration can be determined by quantifying the degree of hypometabolism in sequential PET studies. PET has been useful both in guiding the extent of focal cortical resection (i.e., correlating better with intracranial EEG recordings than CT or MRI) and in assessing candidacy for early hemispherectomy in patients with Sturge-Weber syndrome. Paradoxically, children with mild but extensive glucose hypometabolism (confined to one hemisphere) often have worse cognitive outcome than children with early and severe unilateral hypometabolism;[53] this finding suggests that early and rapid demise of the affected hemisphere may be beneficial in allowing unaffected areas to take over lost functions (Figure 89.4a). In contrast, when the affected areas show slow deterioration, seizures tend to persist and plasticity may not be optimal; such patients may be good candidates for resective surgery in our efforts to prevent cognitive decline (Figure 89.4b). FDG PET scanning of glucose metabolism in infants and children with *hemimegalencephaly* reveals the expected, severe interictal hypometabolism of the affected hemisphere and, more importantly, allows the functional integrity of the better hemisphere to be evaluated (Figure 89.5). In a study of eight children with hemimegalencephaly, seven of whom underwent hemispherectomy, a general correlation was found between the degree of metabolic involvement of the less-affected hemisphere and overall prognosis.[54]

Flumazenil PET

In PET studies, flumazenil (FMZ) is usually labeled with the positron emitting isotope ^{11}C, which has a half-life of

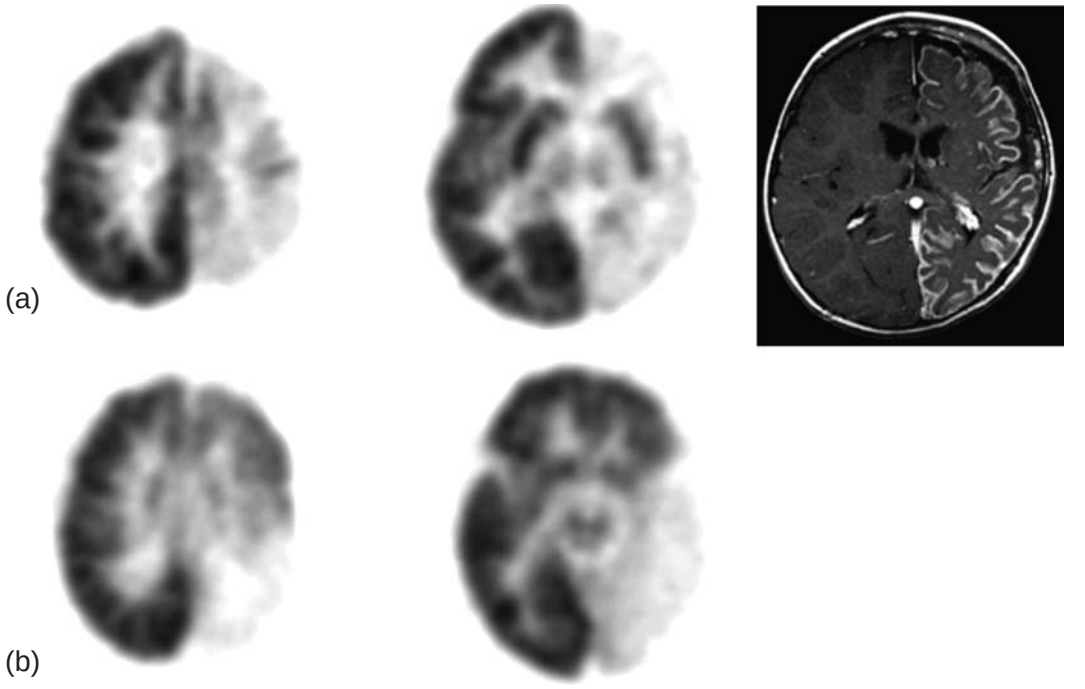

Figure 89.4 (a) Early, severe left hemispheric hypometabolism in a 2-year-old boy with Sturge-Weber syndrome (SWS). MRI with gadolinium showed extensive left hemispheric leptomeningeal angiomatosis, while the right hemiphere is not involved. Such patients typically show relatively preserved cognitive functions due to early reorganization and do not require resective surgery. (b) Lobar hypometabolism in a 1y 2m-old-boy with SWS and a left posterior angiomatosis. Note the severe hypometabolism in the left posterior quadrant (consistent with atrophy and calcification) and further, mild decrease of glucose uptake in the left frontal lobe. Seizures typically originate from the mildly hypometabolic cortex which needs to be resected to achieve seizure freedom.

20 minutes. Therefore, unlike FDG, which can be transported from another facility housing a cyclotron or purchased daily, the FMZ has to be synthesized on site using a cyclotron. FMZ binds to central benzodiazepine receptors and is useful in showing decreased receptor binding in medial temporal sclerosis, including that seen in association with an ipsilateral temporal or extratemporal lesion, so-called 'dual' pathology.[55] In neocortical epilepsy, FMZ-PET provides a better indication of seizure onset zones when compared to FDG-PET, an estimation of perilesional epileptogenic zones, and may also detect secondary epileptic foci in patients with chronic intractable epilepsy.

Seizure onset zone

Despite the very high sensitivity of FDG-PET in localizing the general area of seizure onset in patients with partial epilepsy, it is known that this hypometabolic area exceeds the epileptogenic zone and overestimates the extent of surgical resection in order to achieve seizure freedom. Glucose hypometabolism is relatively nonspecific and can be seen in patients even without seizures. For example, children born prematurely who have periventricular leukomalacia often show areas of cortical hypometabolism even when the MRI shows no overt abnormalities in cortex.[56] The situation becomes very complex when such children exhibit partial epilepsy because areas of glucose

Figure 89.5 FDG-PET in hemimegalencephaly shows gross structural and metabolic abnormalities in the affected hemisphere. Normal metabolism in the opposite hemisphere suggests relatively good cognitive outcome after hemispherectomy.

hypometabolism will encompass not only the epileptogenic zone, but also areas of hypometabolism related strictly to the periventricular leukomalacia. The extensive hypometabolism seen with FDG-PET may also include areas related to the primary epileptic focus, such as areas of seizure propagation, secondary epileptic foci, or areas of diaschisis, all of which are difficult to distinguish from the primary seizure focus.

Because the cortical regions showing hypometabolism on FDG-PET do not necessarily correspond exactly to the site of seizure onset, there has been an effort to develop PET tracers which are more specific for delineating the epileptic focus. Early studies using FMZ-PET in patients with intractable partial epilepsy showed very clearly that FMZ-PET was able to detect epileptogenic cortical regions and that the areas of decreased FMZ binding were smaller than the areas of decreased glucose metabolism.[2,4] Moreover, in patients with frontal lobe epilepsy, cortical areas of decreased FMZ binding showed good correspondence with the locations of seizure onset as determined with subdural electrodes (Figure 89.6).[3,57] Another study reported that 13 of 18 patients with normal MRI had regions of abnormal cortical FMZ binding, consisting of increases, decreases or a combination of both, and these tended to be concordant with at least the hemisphere of presumed seizure onset.[60]

In a study comparing the sensitivity and specificity of FDG and FMZ-PET to intracranial EEG data, we found that FMZ-PET detected at least part of the seizure onset zone in all patients studied, whereas FDG-PET failed to detect cortex showing seizure onset in 20% of subjects.[5] FMZ-PET was also more sensitive than FDG-PET in identifying cortical regions showing frequent independent spiking which are likely to be resected (Figure 89.7). Neither FDG nor FMZ-PET was sensitive in identifying cortical areas of rapid seizure spread.[5] In a subsequent study, in which we tested these findings against outcome in a cohort of subjects undergoing surgical resection for intractable neocortical epilepsy, we found that patients with large cortical regions showing decreased FMZ binding preoperatively had poor surgical outcome. Furthermore, there was a significant correlation between leaving behind (i.e., not resecting) cortical regions in the lobe of seizure onset showing decreased FMZ binding in the preoperative PET scan and a poor surgical outcome.[7] Stated differently, it appears that the entire area showing decreased FMZ binding in the lobe of seizure onset as revealed by intracranial electrodes should be resected in order to achieve a good surgical outcome and that leaving behind such areas is associated with a high risk of failed epilepsy surgery.

Perilesional epileptogenic zone

When medically-refractory partial epilepsy is associated with a cortical lesion visible on the MRI, and there is general concordance between scalp EEG localization and the lesion, surgical resection of the lesion is indicated. However, the extent of the epileptogenic zone is often underestimated by the MRI evidence of structural abnormality. In some cases, the lesion itself may be epileptogenic (e.g., cortical dysplasias), but additional epileptic tissue may lie in a concentric or, more commonly, eccentric location to the lesion. In other cases, the lesion may show little epileptogenicity (e.g., some cystic or glial abnormalities), and the seizures are arising from some adjacent site. A one-stage lesionectomy with intraoperative corticography or a two-stage surgery with invasive EEG monitoring are both reasonable approaches in surgical planning.

In such cases, FMZ-PET provides an alternative preoperative localization of epileptogenic tissue in and adjacent to the lesion. Richardson *et al.*[61] studied 12 patients with cortical dysgenesis identified on MRI, and found that regions showing abnormal FMZ binding frequently extended beyond the MRI-identified lesion, i.e., cortex that appeared normal on MRI often had abnormal FMZ binding. This has been confirmed in an FMZ-PET study of ten patients with malformations of cortical development following corrections for partial volume effects.[8] Interestingly, in this latter study, increased FMZ binding was found in several regions adjacent to some of the MRI detected malformations in apparently normal cortex. Similar findings were also reported in a study of 11 patients with various types of cortical lesions.[62] However, neither of these studies included correlations with intracranial EEG data. In a study of 17 patients with a lesion and intractable epilepsy undergoing resection, we found that the FMZ-PET abnormality (decreased binding) was significantly larger than the structural lesion, but smaller than the FDG PET hypometabolic area, which tended to be very large surrounding the lesion particularly in patients with a long history of epilepsy.[6] The extent of the perilesional FMZ PET abnormality showed an excellent correspondence with spiking cortex determined with intracranial electrodes (Figure 89.8). Resection of this zone of decreased FMZ binding in addition to the lesion itself resulted in a seizure-free outcome in 16 of the 17 patients. Thus, FMZ-PET may be a useful guide to the neurosurgeon during the surgical planning of lesional epilepsy surgery.

Secondary epileptic foci

One of the most challenging aspects in surgery for neocortical epilepsy is that the 'epileptogenic region' may include not only a focus of seizure onset, but also altered cortical regions, which are potentially epileptogenic, along the path or network of seizure propagation. These 'secondary' foci may be 'dependent' upon the primary focus, in which case they tend to disappear after removal of the primary focus, or they may be 'independent', in which case they may emerge as a new epileptic focus and, therefore, it is important to identify these 'epileptic networks'.[63,64] Patients with a prolonged history of seizures prior to epilepsy surgery have a poorer seizure outcome following resection of the primary focus when compared to individuals with a shorter history of seizures, suggesting that secondary epileptogenesis at sites located elsewhere in the brain may develop with persistence of uncontrolled seizures (e.g., Eliashiv *et al.*).[65] Secondary epileptic foci are defined as a 'trans-synaptic and long-lasting alterations in nerve cell behavior characterized by paroxysmal electrographic manifestations and clinical seizures' induced by seizures from a primary epileptic focus.[66,67]

Morrell[67] has described three stages in the formation of secondary epileptic foci. In the first stage, epileptiform activity in the new region is dependent on a trigger from the primary focus. In the next stage, epileptiform activity occurs spontaneously in the new focus, but removal of the primary focus results in a cessation of activity from the secondary focus with time. In the third stage, the epileptiform activity in the secondary focus is irreversible ('independent' secondary focus). This model is

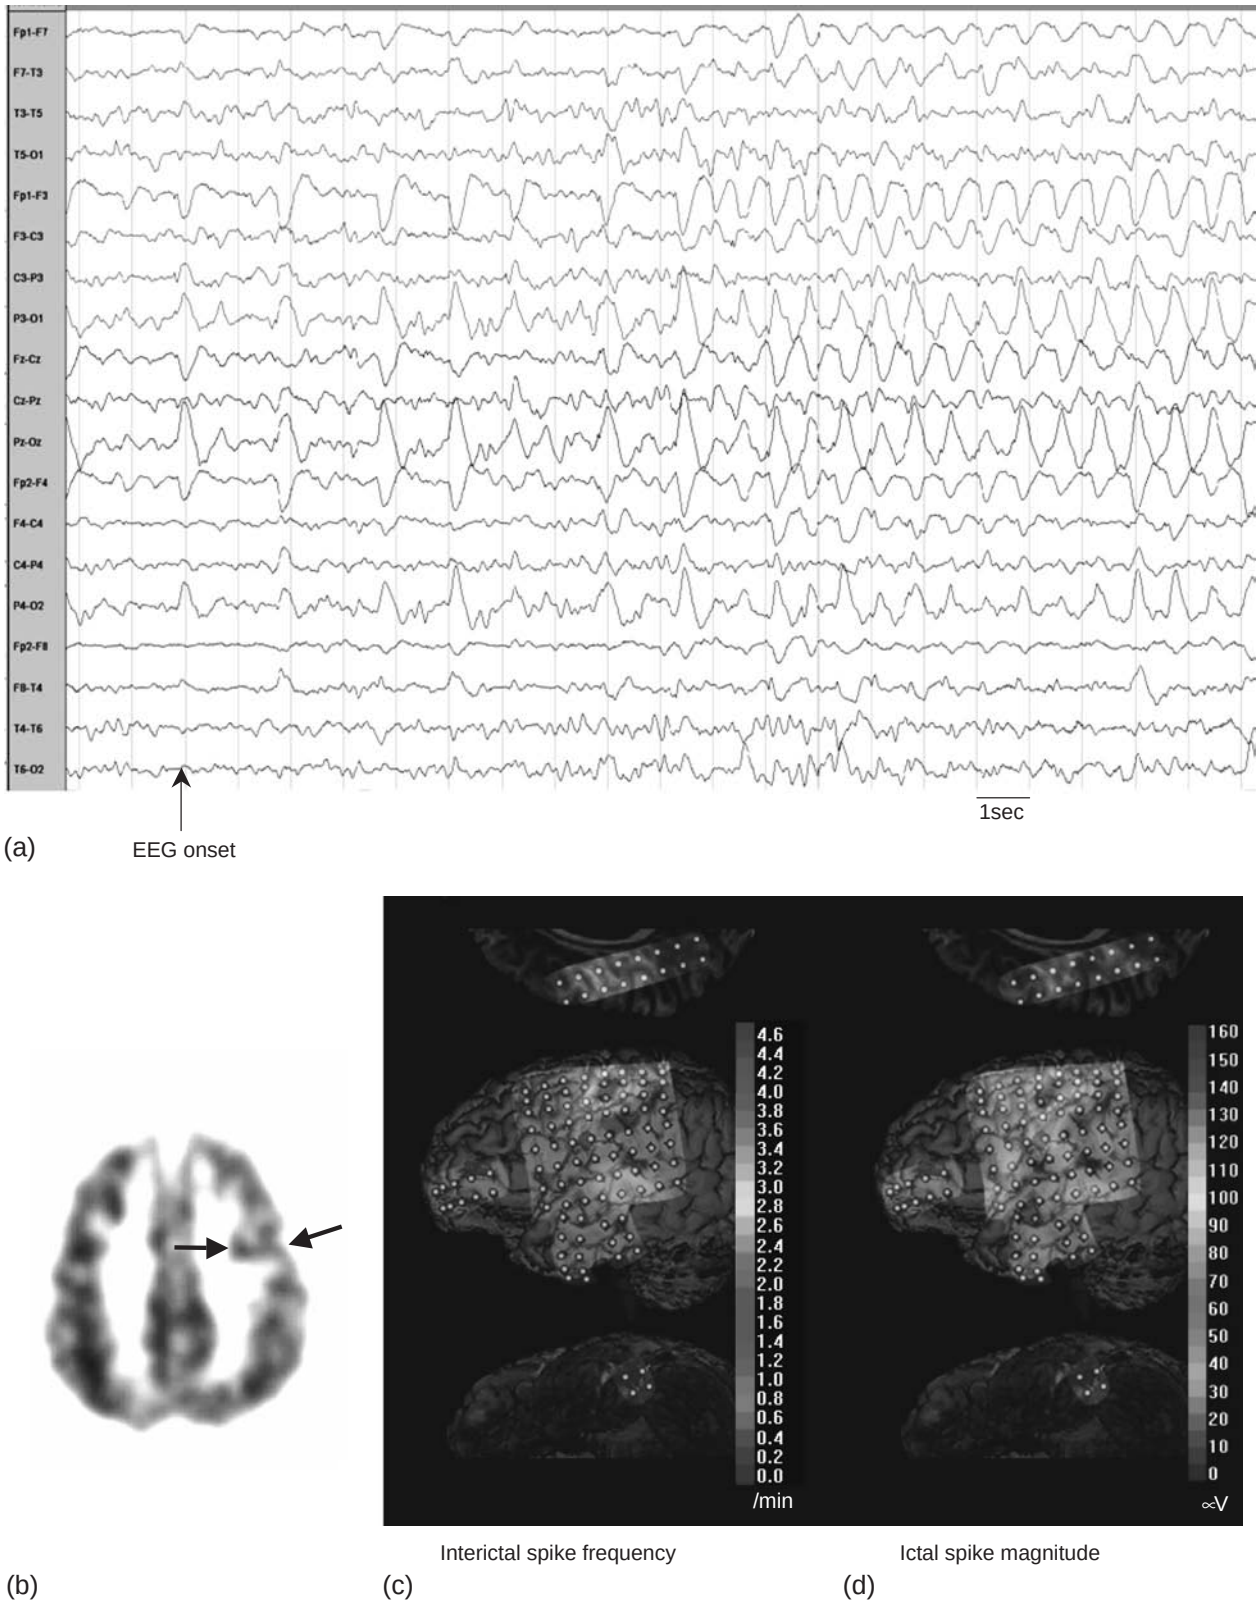

Figure 89.6 A 3-year-old girl with nonlesional neocortical epilepsy. (a) Ictal scalp-EEG on a bipolar montage showed a widespread periodic slow wave activity with frontal-central dominance, which was followed by a widespread continuous rhythmic slow-wave activity with higher amplitude in the left frontal-central region. Ictal EEG was diagnostic of focal seizures, but the exact location of epileptogenic zone was difficult to estimate solely based on scalp-EEG. (b) Decreased FMZ binding was seen in the left frontal region just anterior to the left precentral gyrus. (c) Quantitative interictal subdural EEG analysis[58] revealed that the frequency of interictal spike activity was highest in the left frontal region showing decreased FMZ binding. (d) Quantitative ictal subdural EEG analysis[59] revealed that the magnitude of ictal repetitive spike activity was highest again in the left frontal region showing decreased FMZ binding. The patient has been seizure free for 20 months since neocortical resection involving this region. (See Color plates.)

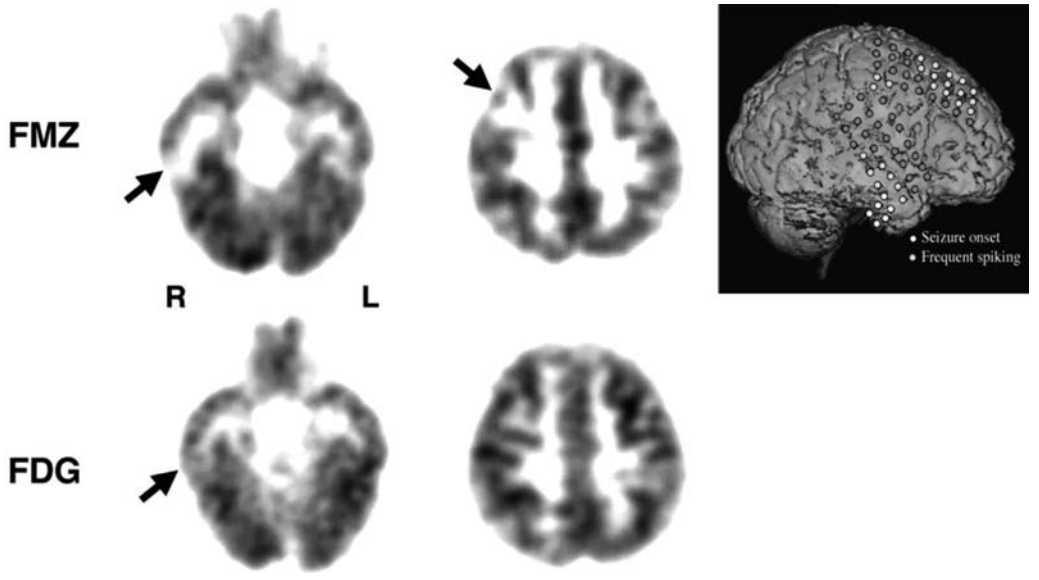

Figure 89.7 Flumazenil (FMZ) PET scan in a 7-year-old girl with neocortical epilepsy. MRI was normal. Decreased FMZ binding was seen in the right inferior temporal cortex, which showed seizure onset on subdural EEG; see electrode locations vs. PET abnormalities in red on 3D brain surface. An additional area of decreased FMZ binding was seen in the right frontal cortex, which showed independent interictal spiking on EEG (see again 3D surface). This latter area was not clearly abnormal on FDG-PET. (See Color plates.)

consistent with FMZ-PET data from Savic *et al.*[68] that some of the FMZ abnormalities outside the primary focus are *reversible* following surgical removal of the primary focus.

We have previously reported that FMZ-PET may detect cortical areas of decreased binding 'remote' from the presumed primary epileptogenic region as indicated by scalp EEG and seizure semiology; we believe that these 'remote' cortical areas represent secondary epileptic foci.[6] Unfortunately, it is not uncommon for secondary epileptic foci to remain quiescent on scalp and intracranial EEG during preoperative evaluation and to become manifest only after surgery to remove the primary focus has been performed. We made the observation that FMZ-PET identifies both primary and additional remote epileptic foci (i.e., secondary epileptic foci) in children with nonlesional epilepsy (Figure 89.9). Although we had reported similar results in patients with MRI lesions, our most recent analysis[57] considered only patients with nonlesional epilepsy in order to avoid the confounding effects of lesions on data interpretation. Of the 25 children (mean age 7.5 years) with normal MRI scans included in this study, cortical regions showing decreased FMZ binding were observed in the seizure onset area (determined by scalp EEG ictal localization and seizure semiology) in 18 children (72%). Of these 18 children, 13 showed *additional* cortical areas of decreased FMZ binding in remote

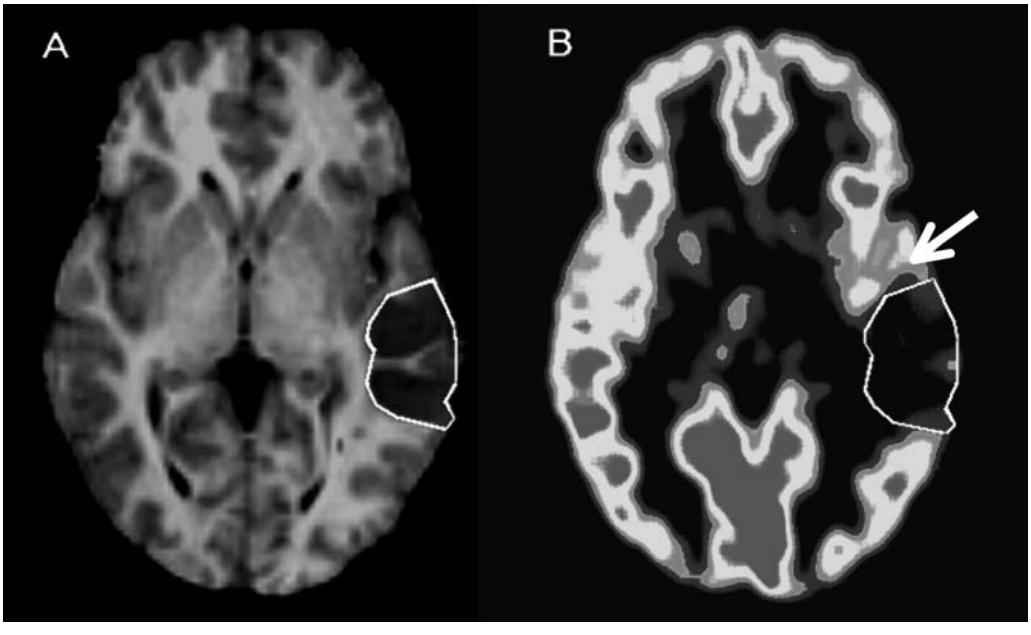

Figure 89.8 Flumazenil (FMZ) PET detects perilesional epileptic cortex. This patient had left temporal lobe seizures and a low-grade tumor (dysembryoplastic neuroepithelial tumor). The tumor mass itself did not show any FMZ binding, but decreased binding was seen in the peritumoral cortex (arrow), which showed frequent interictal spiking on intracranial EEG (reproduced from Juhasz *et al.*, 2000). (See Color plates.)

Figure 89.9 Multifocal decreases of cortical flumazenil (FMZ) binding (arrows) in the epileptic right hemisphere of a 14-year-old boy with daily complex partial seizures. Decreased FMZ binding in the right parietal cortex indicated the area of seizure onset (as shown by intracranial EEG), while rapid seizure spread occurred in the posterior temporal as well as central regions.

locations from the primary seizure onset region, and most of these remote areas (89%) were involved in rapid seizure propagation or showed frequent independent interictal spiking on subdural EEG recordings. Patients with complete removal of both perifocal and remote cortex showing decreased FMZ binding became seizure-free, and pathological examination of the resected tissue from remote sites typically showed gliosis. The concept that PET imaging with FMZ might identify secondary epileptic foci is novel and may play an important role in the future of epilepsy surgery evaluation.

α-[^{11}C]Methyl-L-tryptophan PET

The PET tracer α-[^{11}C]methyl-L-tryptophan (AMT) was originally developed for the *in vivo* measurement of the rate of serotonin synthesis,[69,70] but it now appears that what is actually measured is an 'index' of serotonin synthesis rather than the absolute rate; we have referred to this index as the 'serotonin synthesis capacity,[71,72] for an editorial discussion see Chugani and Muzik.[73] Our choice of the tracer AMT in studying epilepsy in children was based on several lines of evidence which implicated serotonergic mechanisms as playing a role in epileptogenesis.[74–80]

AMT PET in tuberous sclerosis complex (TSC)

Because AMT accumulates in the vicinity of the seizure focus, PET scanning of this radiotracer reveals an increased signal in the interictal state, as compared to FDG and FMZ which both reveal decreased uptake. This feature of AMT makes it an ideal PET tracer in patients with multiple lesions, not all of which are epileptogenic. Indeed, AMT-PET is able to differentiate between epileptogenic and nonepileptogenic tubers in patients with tuberous sclerosis complex (TSC): epileptogenic tubers show increased AMT uptake interictally whereas nonepileptogenic tubers show decreased uptake[12] (Figure 89.10).

The AMT PET method was used in the preoperative evaluation of 17 children (mean age: 4.7 years) with TSC and intractable epilepsy.[82] Fourteen of the 17 children had long-term intracranial EEG monitoring. Increased AMT uptake was found in 30 tubers of 16 patients and 23 of these tubers (77%) were located in epileptic foci as defined by intracranial EEG. In three of the 17 children, a 'palliative' surgery was performed because an optimal resection would have resulted in unacceptable consequences such as hemiplegia. Of the remaining 14 patients, 12 became seizure free. There was an excellent correlation between resection of tubers showing increased AMT uptake and good outcome;[82] see also editorial by Roach.[83] AMT-PET is particularly useful in localizing epileptogenic tubers that are close to the midline and EEG lateralization is difficult. Although clearly an advance in seizure focus localization in patients with TSC, cortical areas of increased AMT uptake are seen in only about 2/3 of subjects. The remaining patients, while their seizures are poorly controlled with medications, fail to show any areas of increased AMT uptake. It is not clear why this is the case and whether there are differences between TSC1 and TSC2 patients in this regard.

AMT PET in non-TSC subjects

Increased AMT uptake in epileptic tissue is not limited to patients with TSC, but may also be seen in other patients with epilepsy. Indeed, we recently reported increased uptake of AMT near the epileptic focus in approximately half of non-TSC patients with neocortical epilepsy[14] (Figure 89.11). Similar results had been reported in a study of 18 patients with cortical dysplasia ($n = 7$) or normal MRI and FDG PET ($n = 11$).[84] In that study, increased AMT uptake was found in seven patients (4/7 (57%) with cortical dysplasia and 3/11 (27%) of patients with normal MRI).

Kynurenine pathway of tryptophan metabolism

Analysis of resected brain tissue showing increased AMT uptake revealed *normal* serotonin levels but evidence of increased tryptophan metabolism along the kynurenine pathway. It appears that in addition to being converted into serotonin or incorporated into protein, tryptophan may, under some circumstances (e.g., ischemia, immune activation, epilepsy), be metabolized by tryptophan 2,3-dioxygenase[85] and indoleamine 2,3-dioxygenase[86] via the kynurenine pathway in the brain. Several metabolites of the kynurenine pathway, quinolinic acid, kynurenine and 3-hydroxykynurenine are convulsants through their action as agonists at N-methyl-D-aspartate (NMDA) receptors.[87–91] While quinolinic acid concentrations were not increased in the seizure focus as

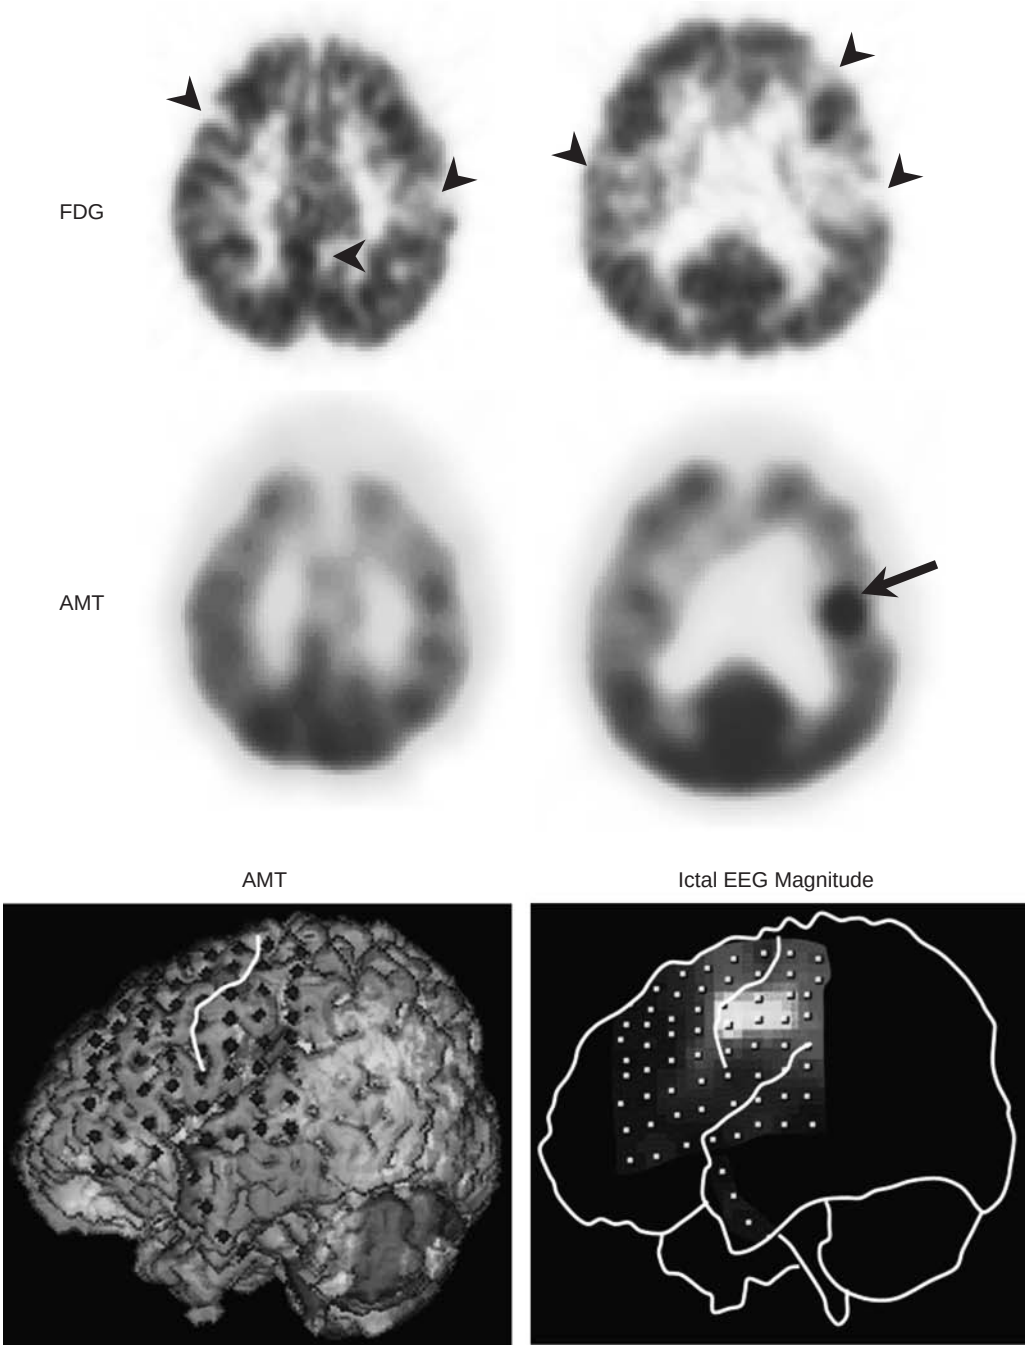

Figure 89.10 A 1-year-old boy with uncontrolled neocortical epilepsy associated with tuberous sclerosis complex. (A) FDG and alpha-[^{11}C]methyl-L-tryptophan (AMT) PET images are shown. Multiple tubers in both hemispheres were associated with decreased glucose metabolism (arrowheads) on FDG-PET, without indicating the epileptogenic tuber. In contrast, AMT-PET showed increased uptake in a single tuber (arrow) located in the left central region. (B) Increased AMT uptake (coded with red) was localized in the left inferior parietal region on a 3D-reconstructed MRI. (C) Quantitative ictal subdural EEG analysis[81] revealed that the magnitude of ictal rhythmic activity was highest in the superior margin of the cortical tuber showed increased AMT uptake. Neocortical resection involving this epileptogenic tuber resulted in a seizure-free outcome (follow-up period: 5 months).[82] (See Color plates.)

compared to nonfocus brain regions from adults undergoing surgery for temporal lobe epilepsy,[91] brain tissue showing increased AMT uptake on PET did indeed show much higher levels of quinolinic acid compared to adjacent brain tissue and tubers which do not show increased AMT uptake.[92] These findings suggest that, in at least some cases of epilepsy, including the epilepsy seen in TSC, the mechanism of epileptogenesis may involve activation of the kynurenine pathway leading to the production of endogenous convulsants.

Reoperation for failed epilepsy surgery

As alluded to above, the success rates (seizure freedom) in neocortical epilepsy surgery have not changed appreciably in the past several decades and remain in the 50–60%.[32,33] Some of these patients will be candidates for a second epilepsy surgery evaluation, since it is well documented that reoperation can achieve seizure control in a significant

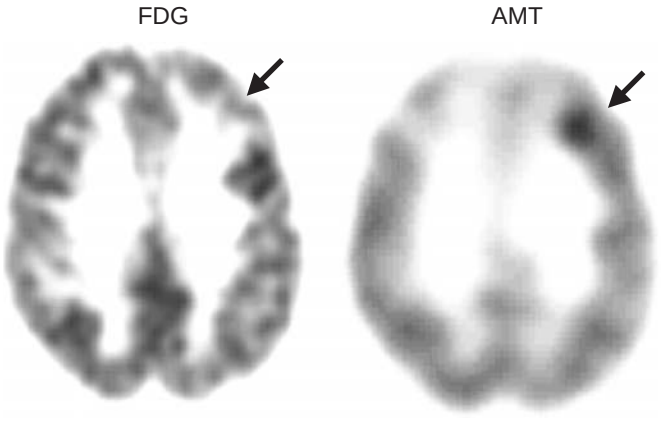

Figure 89.11 Increased uptake of alpha-[^{11}C]methyl-L-tryptophan (AMT) in an epileptogenic region of frontal cortex (as verified by subsequent intracranial EEG) in a patient with normal MRI. FDG-PET showed only a mild decrease of glucose metabolism in this region.

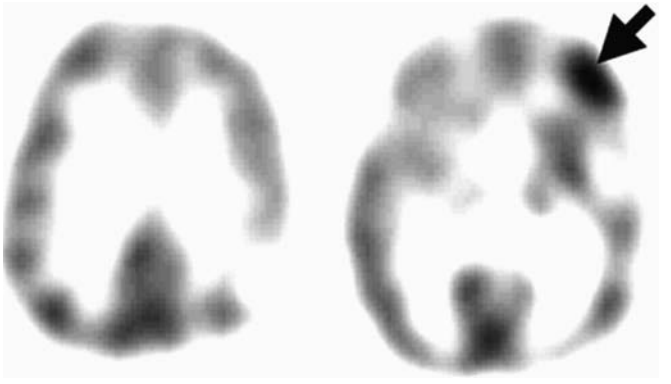

Figure 89.12 Detection of nonresected epileptic cortex by alpha-[^{11}C]methyl-L-tryptophan (AMT) PET. Increased AMT uptake was seen in the left frontal cortex (arrow) of a 10-year-old boy with a previous left parietal cortical resection. MRI was normal before surgery. Postoperative EEG monitoring suggested left inferior frontal seizure onset, consistent with the AMT-PET finding.

number of cases.[93,94] Yet, there have been remarkably few neuroimaging studies aimed at the localization of residual epileptogenic cortex. With the more widely used PET tracers FDG and FMZ, one typically looks for decreased glucose metabolism or $GABA_A$ receptor binding (i.e., a 'negative' signal) in epilepsy surgery evaluation, but both of these PET tracers are of little use in the setting of reoperation evaluation because the initial resection results in diaschisis or tissue damage which also appear as areas of decreased uptake. Ideally, a PET tracer which gives a 'positive' signal interictally (i.e., increased uptake) in epileptogenic cortex would be preferable in order to avoid the confounding effects of prior resection.

Juhasz *et al.*[95] used AMT-PET in 33 patients (mean age: 10.8 years; age range 3–26 years) who continued to have seizures following a neocortical resection. They reported that 10 (43%) of 23 patients scanned greater than 2 months, but less than 2.3 years of the failed resection manifested increased AMT uptake (Figure 89.12). These areas of increased uptake showed excellent concordance with the area of seizure onset on ictal EEG. Seven patients with localizing AMT-PET scans underwent a second resection and five became seizure free, while the remaining two showed considerable decrease in seizure frequency. Interestingly, if the AMT-PET scan was performed within 2 months of resection, a diffusely increased hemispheric uptake was found, presumably resulting from inflammatory changes.[95] While the sensitivity of AMT-PET in detecting residual epileptogenic cortex may not be great, the technique is useful in a considerable number of subjects undergoing reoperation and sets the stage for further research in this group of patients.

Other PET tracers for neocortical epilepsy

While FDG, FMZ and AMT have been the most widely used tracers for PET scanning in epilepsy surgery evaluation, a number of other tracers have also been studied and may have potential use for localization of neocortical epileptic foci.

[^{11}C]carfentanil

One of the first receptor ligands used in epilepsy was [^{11}C]carfentanil, which labels mu-opiate receptors.[15,96] The rationale for studying opiate receptors with PET is based on observations that recurrent seizures induce changes in the expression of opioid peptides and receptors[97] and that endogeneous opioid release play a role in termination of seizures in animal models of epilepsy.[98] Initial studies using [^{11}C]carfentanil PET reported *increased* interictal binding in temporal neocortex ipsilateral to the seizure focus in patients with temporal lobe epilepsy.[15,96] Interestingly, PET studies using the delta-receptor-selective antagonist [^{11}C]methylnaltrindole showed a different regional pattern of increased binding as compared to [^{11}C]carfentanil.[99] In contrast, there was a lack of overall asymmetry in studies using the ligand [^{18}F]cyclofoxy, which binds to both mu and kappa opioid receptors.[100] Together, these studies suggest a differential regulation of opiate subtypes in epilepsy, with greater involvement of mu and delta receptors. Although of potential clinical value, these PET tracers have not been validated for localization of epileptogenic zones in neocortical epilepsy.

[^{11}C]doxepin

Doxepin is an antidepressant medication with a high affinity for histamine H_1 receptors. Since histamine mechanisms in the brain are involved in termination of seizures, [^{11}C]doxepin PET was performed in order to study seizure mechanisms and provide localization data of epileptic foci. Indeed, patients with neocortical epilepsy showed areas of *increased* cortical binding where FDG PET showed decreased glucose metabolism.[16] Again, this PET ligand has not been adequately studied in relation to intracranial EEG data to determine its role in the evaluation for epilepsy surgery.

Conclusion

We have seen, in this chapter, how functional neuroimaging with PET continues to evolve as an important tool in the

diagnosis, monitoring, and eventual treatment of patients with neocortical epilepsy. In some cases, such as infantile spasms, PET findings have led directly to new treatment options previously not considered. In most cases, anatomic and functional neuroimaging, together with interictal and ictal EEG, provide complementary data and should be carefully used together for optimum management. Studies over the past few years have provided several examples of how application of new PET tracers (e.g., those for imaging benzodiazepine receptors or tryptophan meabolism) have led to more specific localization of epileptogenic brain regions. The synthesis of even newer PET tracers designed to evaluate various biochemical processes in the brain is proceeding at a rapid pace. These tracers will be applied in neocortical epilepsy to yield a wealth of new and specific information related to pathophysiology and therapeutic guidance.

90 Pre-surgical neuropsychological workup: risk factors for post-surgical deficits

RM Busch and RI Naugle

Introduction

A comprehensive pre-surgical evaluation is essential to lateralize and localize the seizure onset zone and to determine whether the epileptogenic region can be safely resected without significant neurological or neuropsychological deficits.[1] Neuropsychological examinations have long been an integral part of pre-surgical epilepsy evaluations. The assessment of pre-surgical cognitive functioning can provide supplemental information about seizure lateralization and localization and help to identify patients who are at risk of cognitive decline following surgical treatment for intractable focal epilepsy. The purpose of this chapter is to discuss the factors that are related to cognitive outcome in adults following epilepsy surgery and to summarize existing literature on multivariate prediction of post-operative cognitive risk.

Pre-surgical neuropsychological patterns in epilepsy

Frontal lobe epilepsy

Frontal lobe epilepsy is the second most prevalent type of seizure disorder in adults. Studies have demonstrated that, when compared with patients with temporal lobe epilepsy, patients with frontal lobe epilepsy tend to perform more poorly on measures of attention, visuomotor and visuoperceptual speed, motor coordination, fluency, concept formation, planning, response inhibition, and language. However, these cognitive tasks have generally been unsuccessful in assisting with lateralization or localization of seizures within the frontal lobe. Motor impairment appears to be the most reliable method for assisting with lateralization and localization in patients with frontal lobe epilepsy.[2–5]

Although there has not been a great deal of research examining post-operative risk in this population, Helmstaedter and colleagues[3] found that frontal lobectomy patients demonstrated improvements in short-term memory when their seizures were successfully controlled. Examination of site of surgery revealed that patients with resections in the premotor/SMA or precentral/central area were at highest risk for cognitive declines following surgery, often demonstrating significant psychomotor slowing, initiation problems, and language difficulties (i.e., speech arrest or transcortical aphasia following dominant SMA resection). It has also been reported that, similar to findings in patients with temporal lobe epilepsy, cognitive outcome following frontal lobectomy is inversely related to pre-operative cognitive ability.[3]

Parietal and occipital lobe epilepsies

Because these types of focal epilepsies are relatively rare, descriptions of the neuropsychological characteristics of seizures originating from the parietal and occipital lobes have been based on rather small numbers of patients. Although the neuropsychological profiles of patients with parietal lobe epilepsy are variable depending upon seizure lateralization and localization, age of seizure onset, and age at first risk, parietal lesions have been associated with visual agnosia, hemineglect, apraxia, and visoperceptual/constructional difficulties.[6] Research on patients with occipital lobe epilepsy has failed to find any unique neuropsychological profile in comparison to other focal epilepsies.[7]

Temporal lobe epilepsy

Temporal lobe epilepsy is the most prevalent type of seizure disorder in adults, comprising approximately two-thirds of all surgical epilepsy procedures.[8] Patients with temporal lobe epilepsy often show deficits on neuropsychological measures of memory, particularly if the seizures are arising from the dominant temporal lobe. In individuals with typical language dominance, lesion studies have demonstrated the importance of right and left temporomesial structures for visuospatial and verbal memory, respectively.[9] Over the years, a large number of studies have investigated material-specific memory performance in patients with temporal lobe epilepsy. Patients with dominant temporal lobe epilepsy typically display deficits in verbal memory, whereas those with epilepsy arising from the nondominant temporal lobe show deficits in visuospatial memory, albeit less frequently.[9–13] In addition to memory dysfunction, patients with mesial temporal lobe epilepsy in the language dominant hemisphere often demonstrate confrontation naming problems, marked by word-finding difficulties.[6,14,15]

Risk factors for post-surgical decline

Given the high prevalence of temporal lobe epilepsy and the relative paucity of information pertaining to post-operative outcome following other focal surgeries, the remainder of this chapter will focus almost exclusively on findings pertaining to adults after temporal lobe resections. In light of the functional role of the temporal lobes in memory and language, most studies have focused on post-operative risk for decline in these two cognitive functions. Because memory decline is the most frequently observed deficit following temporal lobe surgery, the vast majority of these studies have sought to identify factors related to decline in memory.

Memory

Case studies published in the 1950s underscored the essential role of the mesial temporal lobe memory system, which consists of the hippocampal formation and adjacent parahippocampal region, in memory for new information.[16] Since that time, epilepsy researchers have sought to determine which patients are at greatest risk for memory decline following temporal lobectomy. Over the years, a number of predictors of post-operative memory decline have been identified.

Side of surgery

The dominant hemisphere of the brain has been associated with verbal cognitive functions while the nondominant hemisphere has been associated with nonverbal cognitive functions, although the former relationship is observed more consistently.[9,17,18] It is unclear why the relationship between nonverbal cognitive functions and the nondominant hemisphere is not always observed. Researchers have speculated that visuospatial memory functions may be less well localized/lateralized than verbal memory functions allowing the brain to more easily compensate following right temporal damage.[19–24] It may also be the case that the measures used to assess nonverbal memory functions are not as sensitive as those used to measure verbal memory. Nevertheless, neuropsychological tests are best at determining seizure laterality when dissociations are observed between performance on verbal and visuospatial measures.[25]

Material-specific memory deficits are readily observed in patients who have undergone temporal resections. The relationship between left temporal lobectomy and verbal memory deficits is a rather reliable finding across studies[26–30] whereas the relationship between right temporal lobectomy and nonverbal memory deficits has been less robust.[11,26,29–38]

Pre-surgical memory performance

Several studies have reported improvements in memory functioning following temporal lobe surgery, particularly with dominant temporal resections that resulted in seizure freedom.[36,39] Findings such as these led to the development of the *functional reserve* model, which posits that post-operative memory decline is largely a function of the capacity of the contralateral mesial temporal structures to support memory following resection of the ipsilateral structures.[21–24] However, more recent studies have demonstrated that persons with higher pre-operative performance on memory measures (average or above) are generally at greater risk for post-operative memory decline following temporal lobectomy than those with lower pre-operative memory scores.[8,40–44] This finding is most frequently observed following dominant temporal lobectomies, with observable declines in verbal memory among an estimated 10–60% of patients undergoing dominant temporal resections.[30,41,45] These studies support a *functional adequacy* model, suggesting that post-operative memory decline is inversely related to the functional adequacy of the resected tissue.[42] The majority of functional and structural studies to date provide support for the *functional adequacy* model.[41,42,45–47]

Language

In addition to memory dysfunction, patients with mesial temporal lobe epilepsy in the language dominant hemisphere often demonstrate confrontation naming problems, marked by word-finding difficulties.[6,14,15] Patients who undergo dominant temporal resections often show acute post-operative naming difficulties,[48,49] although this finding has not been universal.[50,51] An estimated 30–38% of patients who undergo dominant temporal resections show declines on confrontation naming measures, such as the Boston Naming Test or the Visual Naming Test from the Multilingual Aphasia Examination.[51,52] Similar to the findings with memory, patients with higher pre-operative scores on language measures appear to be at greater risk for post-operative decline in language functioning.[41]

Other important predictors to consider

Pre-operative evaluation findings

In addition to pre-operative neuropsychological test results, other data obtained during pre-operative investigations have been associated with cognitive outcome following temporal lobectomy including MRI and functional MRI (fMRI) findings, EEG results, intracarotid amobarbital procedure performance, event related potentials, and intraoperative mapping results. The extent of surgical resection has also been demonstrated to be related to post-operative cognitive outcome. These topics are addressed here only briefly. Interested readers are encouraged to review other chapters of this volume that address these topics in greater detail (MRI – Chapter 82; fMRI – Chapter 75; IAP – Chapter 93; event related potentials – Chapter 94; intraoperative mapping – Chapter 115; and surgical resection – Chapter 116).

MRI/pathology findings

Mesial temporal sclerosis (MTS), characterized by neuronal loss and gliosis in mesial temporal structures, is found in approximately 80% of patients with temporal lobe epilepsy.[47,53] MTS is often visualized as volume loss and signal change on MRI. The degree of MTS visualized on pre-operative MRI and the severity of MTS apparent on pathological investigation of the resected tissue have been shown to be inversely related to post-surgical memory decline. In other words, temporal lobe epilepsy patients without MTS are at greater risk for memory decline following surgery than those with MTS.[47,54–58]
