this influence disappeared when multivariate analysis was performed adjusting for other more solid indicators of outcome.[14,44] Janszky found that epilepsy duration predicted long (at 5 yrs) but not short-term (at 2 yrs) outcome.[27]

Multiple theories attempted to explain those findings. One hypothesis relates epilepsy duration to secondary epileptogenesis as some data proposed a link of longer seizure history in patients with TL tumors to a higher incidence of bilateral independent EEG foci.[84,85] However, a similar incidence of secondary discharges have been described with illness of shorter length.[86] A second hypothesis may be that different epileptic foci mature at different rates, possibly in relation to original pathology or genetic predisposition.[47] In one study, the influence of epilepsy duration disappeared after adjusting for the occurrence of generalized seizures which remained as the only independent predictor of outcome. The authors hypothesize that a long history of seizures may then just correlate with the development of generalized seizures.[14] This may be possible since prior literature suggests that seizures may evolve and become more complex with time.[87,88]

Age at surgery

Most studies found no correlation between age at surgery and seizure outcome.[13,14,23,28,33,34,40,42,43,45,46,51,57,76,79,89] One longitudinal study in HS patients found that cases who were ≤24 years old at surgery were about four times more likely to be seizure free at 5 postoperative years when compared with the older surgical group (36 years or older).[44] Few other studies found similar results.[12,35,90]

One should note here that successful and safe ATLs have been performed in the elderly (>50 years old), although chances of achieving seizure freedom are not as high as in younger patients (3/6 SF in Cascino *et al.*,[91] 6/20 in Mclachlan *et al.*,[92] 16/30 in Sirven *et al.*[93]) versus 75% in younger individuals.[93] Older patients however were not more likely to have neuropsychological deficits from surgery and enjoyed the same benefits as young patients with regard to driving.[93] Therefore, older age by itself should not be a deterrent from surgery.

Absence of secondarily generalized tonic-clonic seizures (SGTCS)

Only 57% of MTLE-HS patients with SGTCS achieved a 1-year remission compared to 80% remission rate in those who had only partial seizures in one study.[28] Patients who had no GTCs were 2.2 times more likely to be seizure free 5 years after surgery in another study.[44] This effect may be most significant when GTCs are frequent (>2/year) and occurring within 3 years of surgery.[14] It correlates with early (by 2 years) but not later recurrences.[27,51] Although many studies of mixed TLE subgroups identified a prognostic role to GTCs,[33,51,58,82] one recent prospective multicenter trial found that their significance is restricted to outcome of MTLE patients.[52] No correlation to outcome was found in smaller or cross-sectional studies.[42,46,83,94]

SGTCS are not typical of MTLE-HS.[7,87] Their occurrence correlates with more extensive hippocampal sclerosis[95] and with multifocal irritative areas.[96] MTLE patients who had SGTCS prior to PET examination have an extended hypometabolism compared to those who have no SGTCS.[97] All those findings suggest that SGTCS may affect outcome through reflecting a diffuse epileptogenic zone or secondary epileptogenesis.

Preoperative seizure frequency

While multiple studies found no correlation between seizure frequency and outcome,[23,33,42,44,52,79,82,83,98] frequent seizures (>20/month) were associated with lower rates of seizure freedom: 50, 44, and 28%, and 17% vs 72, 67, 56%, and 50% SF estimates at 6 mo, 1 yr, 5 yr, and 10 yrs in one study[45] and 80, 74, 67% vs 89, 84, and 79% SF at 6 mo, 1 yr, and 2 yr in another study.[51]

History of febrile seizures

Data regarding the prognostic significance of febrile seizures are again contradictory. Multiple studies found no effect.[27,28,42,43,52,58,99] Some suggested that any proposed beneficial effects of febrile seizures found in many studies[34–38,52,100] simply reflects their association with HS.[43] The differing view argues that complex febrile convulsions, in contrast to simple febrile convulsions, correlate with a more restricted epileptogenic zone and constitute the main favorable prognostic indicator[15,27,52] and that failure to distinguish between the two types of febrile convulsions in analyzing outcome would miss this interaction. In fact, Janszky found in 2003 that complex febrile convulsions predicted a 91% SF rate at 2 years in MTLE (versus 64% if absent).[36] Re-evaluating the same cohort of patients 2 years later but without differentiating between simple and complex febrile convulsions, this effect could not be re-confirmed.[27]

Preoperative auras

No correlation between occurrence of auras and outcome was proven.[15,35,44,51,83]

Imaging variables

Magnetic resonance imaging

Multiple studies[24,43,48,52,83,101–105] and a recent meta-anlaysis[56] concur that a unilateral MRI abnormality is one of the strongest predictors of a good surgical outcome. Patients with MRI evidence of HS had a 54% chance of seizure freedom at 10 years after ATL compared to 18% if MRIs were normal in a recent longitudinal study.[14] However, the presence of ANY unilateral temporal MRI lesion also confers a good prognosis.[14,43,46,58,89,101,104,106,107] Recent data suggests similar outcomes regardless of the nature of the MRI lesion, although more research is needed to clarify this point.[14,54]

Concordance of imaging with ictal and interictal EEG improves outcome,[56] up to 94% at last follow-up in certain studies.[43] In fact, concordance of interictal EEG and MRI represented the test combination of closest association with outcome in MTLE.[108,109] The traditional view that a normal MRI is an automatic correlate to surgical failure[43,48,110] has recently been challenged by several studies showing seizure freedom rates of 41–48% as far as 8 years after ATL.[40,51,111–113] The pathologic substrate of this category of patients remains open to debate. Some findings suggest that successfully treated patients with normal MRIs actually represent undetected HS. This is supported by better seizure freedom rates of 78%[111]–100%[112] when presurgical evaluation is consistent with a mesial temporal focus: a history of febrile seizures,

anterior interictal discharges and a unilateral regular theta temporal ictal rhythm predicted better outcomes in 17 patients with normal MRI.[111] Those findings have all been correlated with HS on pathology.[114,115] In one study, all patients with a good outcome and normal MRI had pathologically confirmed HS.[105] Conversely, another study concluded that most cases of normal appearing hippocampi on high-resolution MRI have neocortical TLE since they had less febrile seizures, more delta rhythms at ictal onset and more extensive lateral neocortical changes on PET with surgical outcomes still comparable to those of MRI obvious HS[113] It should be emphasized that surgery was successful in nonlesional patients only when performed in context of concordant EEG and PET data.[51,113] 'Normal' MRIs correlating with bad outcomes in older studies using lower quality imaging may have included patients with extratemporal or contralateral pathology, findings that would currently exclude viable surgical options.[51,113] Focal epileptogenic zones may arise from tissue with microscopic or cellular dysfunction that is too subtle to be visible on MRI, but may still be amenable to surgical treatment.[51] A normal MRI should not therefore preclude a presurgical evaluation because an ATL performed with concordant presurgical data may still offer major benefits in refractory patients where with other treatment modalities such as AEDs and VNS, the chances of seizure freedom for more than 1 year are still less than 5%.[116,117]

Bilateral MRI lesions, including grossly bilateral HS, reflect multiple potentially epileptogenic foci and correlate with a worse surgical outcome: 58% seizure free at 2 years compared to 78% when compared to unilateral lesions or even normal MRI.[51,101,103,118] Subtle hippocampal asymmetries in studies using volumetrics were less predictive of outcome.[70,119]

Nuclear imaging

Unilateral temporal hypometabolism on FDG-PET predicts a good surgical outcome in patients with MTLE.[107,120–123] This effect is independent of pathological findings and is observed regardless of whether MRI is normal or not. In a recent review of the literature,[120] Casse found that 86% of patients with unilateral temporal hypometabolism ipsilateral to the side of surgery had a good outcome as defined by more than 90% reduction in seizure frequency or Engel Class I or II. This number was slightly reduced to 82% if the MRI was normal. Chances of successful outcome, similarly defined, dropped to 62% when PET was normal and to 50% when it showed bitemporal hypometabolism.[120] With extratemporal hypopmetabolism, chances of seizure freedom are even worse: complete seizure freedom at last follow-up (mean 6.1 years) was seen in 45% of patients with extratemporal cortical hypometabolism confined to the ipsilateral cerebral hemisphere, and only 22% with contralateral cortical hypometabolism.[124]

Abundant data supports the usefulness of ictal SPECT in localizing the epileptogenic zone in TLE[125–130] with 70–100% of ictal being correctly localising and only 0–7% incorrectly localizing.[130] Clear correlations with postoperative outcome, however, need further clarification. Atypical perfusion patterns on ictal SPECT correlated with lack of pathology in the surgical specimen and with a poorer surgical outcome (33% SF after 2 years of follow-up) when compared to typical (60% SF after 2 years), typical with posterior extension (69%) and even bilateral temporal hyperperfusion pattern (67%).[131] Multiple other studies have also suggested that a correct localization of the epileptogenic focus by ictal SPECT correlates with a favorable seizure outcome.[132–136] This conclusion was not confirmed though when a multivariate analysis was performed evaluating the predictive value of multiple noninvasive modalities: Son *et al*. found that while MRI, EEG, and PET had comparable predictive values for Engel Class I, SPECT had less predictive value.[137] Results for interictal SPECT suggest that it is relatively poor at localising the seizure focus.[130] Further research is needed to clarify the role of SPECT in TLE.

Electrophysiological variables

Noninvasive EEG

Focal interictal EEG predicts a favorable outcome when lateralized to the side of surgery,[35,43,57,138,139] or when highly localized to the resected temporal lobe.[28,30,35,57,66,94] Patients whose interictal EEGs showed ≥90% predominance on the operated-on side had an 80% chance of complete seizure freedom after a mean 5.5 years of follow-up versus 54% in those with lesser degrees of lateralization in a recent prospective study.[57] In general, interictal evidence of a diffuse irritative zone predict a worse outcome: postoperative seizure freedom is worse when interictal spiking was posterior temporal,[35,114] extratemporal,[28,43] or bitemporal[35,43,66,94] in multiple studies. Posterior temporal and extratemporal spiking in patients with pathologically confirmed HS may reflect diffuse epileptogenicity, or 'dual pathology' with associated neocortical epileptogenic zones thereby explaining the associated worse prognosis.[28,35,43] However, prognostic implications of bilateral interictal spiking on surface EEG deserve more careful consideration, as they do not automatically preclude postoperative seizure freedom. One study found that if ≥90% of surface interictal bitemporal spikes arise from one temporal lobe, excellent outcome is possible (92% seizure-free in the second postoperative year vs 50% if <90% lateralization), and further evaluation with depth EEG electrodes may not even be indicated.[139] In the presence of a unilateral temporal structural MRI abnormality (HS or other lesion),[94,140,141] and with lateralizing WADA or neuropsychiatric testing,[141] up to 64% of patients with bilateral interictal spikes achieved complete seizure freedom at ≥1 year postoperatively[141] when seizure onset was strictly unilateral on invasive evaluation. A history of febrile seizures or early onset of epilepsy (prior to age 3–6 years)[94,100] also correlated with favorable outcome in patients with bitemporal interictal spikes. Such a constellation of findings (clear unilateral HA on MRI, unilateral predominance of spikes, lateralized Wada, history of febrile seizures) are consistent with unilateral HS: contralateral spiking may be spread from a surgically treatable hippocampus. If, however, MRI is normal or shows widespread abnormalities, then seizure recurrence is the rule[140–142] as an extratemporal focus spreading to both temporal lobes or bitemporal epilepsy become likely.

Many recent studies failed to show a correlation of lateralization or localization of interictal EEG with outcome.[24,27,40,52,83,99] This is felt to reflect a selection bias as one study found that unilateral interictal epileptiform discharges occurred more frequently in patients who underwent TLE compared to those who had a presurgical evaluation but ultimately did not undergo surgery, suggesting that patients with unilateral discharges are more likely to be chosen for surgery.[27]

Similar concepts apply to the prognostic value of ictal EEG. Again, focal[58] or anterior[114] ictal EEG correlates with a more favorable outcome, and patients who had bitemporal ictal onsets on surface EEG still achieved seizure freedom rates of up to 64%[141] at one postoperative year if seizures were exclusively unilateral with depth recordings and imaging or neuropsychological testing were also consistent with unilateral temporal dysfunction.

Absence of epileptiform activity on postoperative EEG at 3 months,[43] 6 months,[51] or 1 year[143,144] all correlate with seizure freedom.

Invasive EEG

Depth electrode evaluations have traditionally been used to clarify lateralization of the epileptogenic zone, whereas subdural recordings may help define its extent. Those modalities are therefore reserved for patients with a poorly defined epileptogenic zone, which may explain poorer outcomes seen in patients who required invasive recordings preoperatively compared to those who did not.[13,16,30,51,145] Specific findings obtained with those evaluations also help to predict postoperative seizure frequency. During depth recordings, exclusively unilateral seizure onset,[94,141,146,147] and ictal spiking as opposed to low-voltage fast activity, electrodecrement, or any other rhythmic sustained activity at seizure onset,[148] represent well-documented predictors of surgical success, whereas evolution into distinct contralateral electrographic seizures lowered seizure freedom from 84% to 47% at one postoperative year.[149–151] Short interhemispheric propagation times, ranging from <1 sec[152] to <8 sec[147] correlate with seizure freedom. Favorable prognostic variables with subdural evaluation include a short duration between EEG and clinical seizure onset,[153] and anterior and/or middle basal temporal ictal onset group[154] as opposed to diffuse or posterior temporal onset.

Surgical technique and outcome

The side of surgery does not correlate with outcome.[13,35,36,42,46,51,57,89] Similar seizure freedom rates have been observed with SAH and ATL.[22,51,53,57,105] Many studies failed to correlate the extent of temporal resection,[40,58,89] the extent of hippocampal resection,[13,33,155,156] nor having a mesial versus neocortical resection[51,52] to outcome. Those studies, however, did not evaluate patients with MTLE separately. In the presence of unilateral MTLE with HS, the extent of mesial resection becomes a very important predictor of postoperative seizure freedom.[7,46,56,99,157,158] In a prospective, randomized, blinded clinical trial, Wyler *et al.* found that only 38% of patients where the hippocampal resection was limited posteriorly by the anterior edge of the cerebral peduncle (partial hippocampectomy) were seizure free at 1 year, compared with 69% of those where the hippocampus was removed further, to the level of the superior colliculus (complete resection).[10] Using intraoperative electrocorticography may limit the extent of hippocampal resection without compromising outcome for both MTS and non-MTS patients.[155] The amount of amygdala that must be resected to achieve seizure freedom is unclear, although one study found no correlation between residual amygdalar tissue and outcome.[99] The ideal extent of lateral temporal resection also remains to be defined. Evidence from several retrospective,[25,46] and one prospective[159] study suggest it has no relation to outcome, while older studies reported better outcomes with more extensive lateral resections.[29,160]

In the presence of a well-circumscribed lesion, such as a tumor or a vascular malformation, a lesionectomy might suffice unless there is associated hippocampal atrophy.[7,161–163] In such cases of dual pathology, complete seizure freedom at last follow-up was lowered from 73% with lesionectomy plus mesial temporal resection to 20% with mesial temporal resection alone, and 12.5% with lesionectomy alone.[164]

Etiology, pathology, and outcome

When pathological findings in the resected temporal lobe were restricted to gliosis, worse short and longterm outcomes have consistently been observed.[47,48,51,81] In a recent longitudinal study of 371 patients, 44% of cases who only had gliosis were completely seizure free at 8 years, compared to 64% if a specific pathological diagnosis was identified.[51]

Furthermore, many,[14,33,43,52] but not all[30,47,51,61,66,83,123] studies described more favorable outcomes if either HS or any other clear lesion was identified in MTLE. It is not clear, however, whether the specific type of pathological abnormality affects outcome. Seizure-freedom rates were similar between HS and other types of lesions in many recent,[14,51] or prospective[52,54] studies, although the older literature[48,59] had suggested higher rates of late recurrence for MTLE-HS. This was thought to reflect a progressive quality of MTLE-HS. It is also possible that outcome depends not only on the presence of HS, but also on its severity: worse disease may predict better outcome. One group found that 84% of patients with classical HS, as defined by neuronal loss and sclerosis in CA1, CA4, and the granule cells of the dentate gyrus, achieved at least 95% seizure reduction at last follow-up, compared to only 29% of those where cell loss was restricted to the dentate gyrus and/or CA4.[165] Another group also found that rates of Engel Class I outcomes at last follow-up increased from 60 to 76 to 89% as the pathological severity of HS ranged from mild to moderate to severe.[22]

Conclusion

Epilepsy surgery is an essential treatment modality for patients with pharmacoresistent MTLE. Our knowledge about the predictors of postoperative seizure freedom and the mechanisms of recurrence is still evolving. Multiple factors seem to influence outcome. The ideal surgical candidates are those with concordant presurgical evidence suggestive of focal, and well-localized epileptogenic foci. Clinical, electrophysiological, or imaging findings suggestive of bilateral or diffuse pathologies tend to predict worse outcomes. Further research is needed to evaluate the implications of our current knowledge on the mechanisms of seizure recurrence.

131 Resective surgery in children

T Loddenkemper and E Wyllie

Introduction

Surgery has become an established therapy for selected patients with pharmacologically intractable epilepsy.[1] Since the report of the first cases early in the 20th century,[2] advances in neuroimaging and surgical techniques have made this treatment option also available to children and infants. Seizure outcomes have been favorable in adolescents and children,[3–5] and even in infants.[5–11]

The first randomized prospective study comparing medical treatment with epilepsy surgery in adult epilepsy patients demonstrated a higher percentage of seizure-free patients in the surgical group and a higher quality of life following surgery. Additionally, one patient in the medical group died of sudden unexplained death.[12]

Advances in the areas of medical refractoriness, localization of the epileptogenic zone, functional cortical representation and mapping, and plasticity and adaptability of the developing brain as well as postoperative seizure outcome allow us now to use epilepsy surgery in more and more carefully selected children and even infants. Candidate selection has to be guided by seizure semiology and frequency, age-related variation in etiology, localization of the epileptogenic zone in relationship to functional cortical areas and has to consider possible risks and benefits of surgical intervention.

Candidate identification and selection

Medically intractable seizures

In theory medical intractability means resistance of seizures to any antiepileptic medication without major side-effects from medications. Practically, and in order to determine intractability of seizures, ineffectiveness of antiepileptic drug treatment needs to be demonstrated. Trials of combinations of all drugs and drug combinations may take several years. Adequate pharmacological treatment needs to be monitored by serum drug levels. Despite of the development of many new antiepileptic drugs, the percentage of patients with pharmacologically intractable epilepsy has remained stable. Children that do not respond to older antiepileptic drugs are therefore also less likely to respond to newer medications.

Kwan and Brodie studied 525 patients (including adolescents and children, median age 29 years) that were not being treated for epilepsy at the time of referral.[13] Among 470 patients that had never received and antiepileptic drug before 47% became seizure free after treatment with the first antiepileptic drug, 13% responded to the second drug and additional 4% responded to a third or multiple antiepileptic medications. Despite inclusion of newer antiepileptic drugs, 36% of patients remained unresponsive to AED treatment, and predictors for persistent treatment were symptomatic or cryptogenic epilepsy and patients with more than 20 seizures prior to initiation of treatment.[13] Patients who did not respond to the first drug were also less likely to respond to a second drug, if treatment was discontinued due to ongoing seizures. Multiple clinical medication trials will only indicate medical intractability asymptotically, but never with absolute certainty.

Reasons for apparent intractability may include treatment of non-epileptic seizures with AEDs[14] or noncompliance in adolescents. A review of 21 pediatric cases referred for epilepsy surgery revealed drug treatment omissions, and two children with structural lesions improved significantly with carbamazepine treatment.[15] Confirmation of medical intractability is therefore always important. However, this should take place in a timely fashion as ongoing recurrent seizures pose a threat to the child's overall wellbeing and to the developing brain, including cognitive decline[16] and neuronal structural changes and injury.[17,18]

Referral for epilepsy surgery is warranted in patients with focal epilepsy. The decision may therefore also be influenced by the probability of seizure control in case of a surgical intervention. In excellent surgical candidates, e.g., in patients with a circumscribed benign tumor on imaging and congruent seizure semiology and EEG findings, the decision for surgery may be made earlier than in less surgically remediable cases. Definition of medical intractability and the decision for epilepsy surgery is therefore also a balance between probability of seizure freedom after medical and after surgical treatment. Nevertheless, even seizure semiology and EEG findings may be misleading in predicting the outcome after surgical intervention in children. There is evidence that patients with generalized seizure semiology have become seizure free after epilepsy surgery.[8] Based on our own experience, selected patients with presumably generalized epileptiform discharges may also be candidates for resective epilepsy surgery.

Identification of the epileptogenic zone

Resective epilepsy surgery aims towards complete removal or disconnection of the epileptogenic zone without removing eloquent cortical areas. The epileptogenic zone is "defined as

the area of cortex indispensable for the generation of clinical seizures."[19] At this point the gold standard and proof of identification of the epileptogenic zone is therefore resection of this cortical area followed by seizure freedom. Prior to surgery, several techniques can be used in conjunction in order to estimate the epileptogenic zone prior to surgical intervention, such as history and physical examination, seizure semiology as documented by history taking and video recordings, (Video-) EEG, neuroimaging and functional tests.

History and physical examination

History and physical examination in the presurgical evaluation of children with epilepsy includes the time of onset of seizures and identification of different seizure types, detailed description of seizures according to the patient and according to observers with respect to clinical semiology[20] and lateralizing features,[21] seizure duration, frequency and longest seizure-free interval, occurrence of last seizure, generalized seizures and history of status epilepticus, possible injuries due to seizures, and postictal presentation. Risk factors for epilepsy, such as head trauma, CNS infections, tumors or vascular disease, family history of seizures, developmental history and possible delay or retardation, febrile seizures, and other important medical conditions need to be documented. Additionally, a detailed history of previous work-up and all previous and current antiepileptic medications including maximum doses, duration, possible drug levels and side effects is important to determine pharmacological intractability of seizures. Although more difficult to elicit in children, complete examination will highlight clinical deficits indicating a focal structural lesion such as impaired visual fields, hemiparesis, or language deficits.

Video-EEG and seizure semiology

Video-EEG monitoring is an important tool in the determination of the epileptogenic zone. The goal is the exclusion of generalized epilepsy and non-epileptic paroxysmal events. Additionally, video-EEG provides information on seizure semiology including a vast amount of localizing and lateralizing clinical features.[21] Furthermore, a large sample of interictal abnormalities such as background changes and generalized slowing indicating encephalopathy, focal slowing and asymmetry indicating a structural lesion, and interictal epileptiform activity as localizing evidence for epilepsy are also helpful information. Finally, the correlation of ictal onset patterns with clinical seizure semiology is important and can supply localizing information. However, some of this data may not be as reliable as in adult epilepsy patients. Especially in younger children and infants inability to communicate specific features of auras and limitations to clinical testing during seizures require attention. Recent nonpublished data from the Cleveland Clinic also suggests that diffuse or generalized EEG may be neglected in the setting of a focal lesion on neuroimaging in infants and young children. Electrophysiological findings may therefore be less important than the actual imaging findings in children.

Structural neuroimaging and functional tests

Identification of a structural lesion on neuroimaging is one of the most important prognostic factors in epilepsy surgery, in particular in extratemporal lobe epilepsy. The most important neuroimaging technique is MRI and this has been indirectly demonstrated by improvement of surgical outcomes before and after the introduction of MRI.[22] Results in patients with a focal lesion such as focal malformation of cortical development, low grade neoplasm, or mesial temporal sclerosis indicate more commonly seizure freedom after epilepsy surgery in lesional as compared to nonlesional cases.[23–25]

2-[^{18}F]fluoro-2-deoxyglucose positron emission tomography (FDG-PET) can be helpful in the identification of lesional epilepsy cases. Prior to the advent of high-resolution MRI, Chugani *et al.* reported five children with infantile spasms and decreased cerebral glucose metabolism as demonstrated by PET.[7] Results were concordant with EEG findings. Four out of five patients underwent epilepsy surgery and became seizure free. Pathology demonstrated cortical dysplasia.[7] These results have later been confirmed in a larger series.[8] Although MRI imaging and resolution improved over the last decade, FDG-PET remains a helpful localization tool in the diagnosis of MRI negative cases providing additional information on placement of intracranial electrodes.[26]

Single-photon emission computerized tomography (SPECT) can also assist in the localization of the seizure focus in children.[27–30] Rapid injection of a radioactive tracer during seizures allows subtraction of ictal and interictal blood flow images. Simultaneous electrophysiological confirmation of habitual seizures is necessary to ensure that the actual seizure in question has been imaged.

Using a modified protocol, intracarotid amobarbital testing can also be successfully applied in children over the age of 5 to 6 years old in order to lateralize language function and memory.[31] In selected cases, intracarotid amobarbital testing may also assist in unmasking bilateral hypersynchrony on EEG.

Neuropsychological evaluation

Neuropsychological evaluation of younger children and infants is more difficult and less objective than in adults. Most reliable features in infants include the evaluation of developmental milestones. Neuropsychological test results in older children and adolescents may reflect those in adults including differentiated IQ assessment, memory evaluation and lateralization of other cortical functions. Plasticity and ability to transfer or relocate cortical functions within the first decade and even beyond this age represents an unique opportunity and window for surgery in childhood epilepsy.[32,33] Nevertheless, these patients remain at risk for a general reduction of cognitive development due to a 'crowding effect'.[34]

Patient management conference

Results of the presurgical evaluation are discussed in a multidisciplinary meeting including specialists from epileptology and neurophysiology, neurosurgery, neuroradiology and nuclear medicine, neuropsychology and psychiatry, and if warranted from the ethics committee. Information will be presented by specialists in the team and then weighed towards localization of the epileptogenic zone and anticipated chances of seizure freedom. This will be compared to risks of loss of eloquent cortex and function, and possible complications. Finally, timing and type of surgery or additional workup and investigations will be recommended.

Types of surgeries in pediatric patients

More than 90% of epilepsy surgeries in infants are extratemporal resections, hemispherectomies, or resections of multiple lobes.[5,8,9] This changes in older children and adolescents,[5,35] in whom temporal resections become more frequent. Temporal resections are with 70% the most frequent epilepsy surgery in adults.[1]

Extratemporal focal resection

Extratemporal resections are more frequent in children than in adults. Indications for extratemporal resections include either a cortical extratemporal epilepsy focus or a lesion. Electrocorticography or subdural electrode recordings can assist in the determination of the extent of the resection. Damage to nonepileptic cortical regions should be limited and spare function if possible. Based on the underlying etiology, either lesionectomies, lobectomies or multiple lobar resections can be performed. Results from extratemporal resections have not been as good as temporal lobectomies.

Temporal lobectomy

The first adult cases of temporal lobectomy in epilepsy patients were reported by Bailey and Gibbs in 1951,[36] and the first series on surgical outcome after temporal lobectomy in 40 children under 15 years of age was published by Davidson and Falconer in 1975.[37] Types of procedures include resection of the mesial temporal structures, lesionectomy in the mesial or lateral temporal lobe, or lateral neocortical resections.[38] The pathology in children with temporal lobe epilepsy varies from adults. Whereas mesial temporal sclerosis is the predominant cause in adults, children frequently present with temporal neocortical lesions, including malformations of cortical development and neoplasms.[39]

Hemispherectomy

The first cases of improvement of seizures after hemispherectomy have been reported by Krynauw in 1950,[40] and additional cases followed in 1951 by Cairns and Davidson,[41] and 1952 by Penfield.[42] Several types of hemispheric removal techniques exist, with anatomic and functional hemispherectomy being the most frequent ones. Although hemispherectomy leads to contralateral hemiplegia and hemianopia, the increased plasticity of the maturing brain allows many patients to ambulate after several months. The *anatomic hemispherectomy* involves a complete resection of the whole hemisphere excluding the basal ganglia.[43] Anatomic hemispherectomy can lead to superficial hemosiderosis seen in up to 25% of patients and to hydrocephalus occurring in up to 30% of patients.[43] A *functional hemispherectomy*[44] is a physiologically complete hemispherectomy, but anatomically incomplete. After a temporal lobectomy, the central fronto-parietal cortex is resected, the insula is removed, and the remaining frontal and parieto-occipital lobes are disconnected. A modification of this procedure includes a suprasylvian window, which reduces postoperative hydrocephalus rates down to 18% as compared with 30% in patients with anatomic hemispherectomy.[43] Other complications such as infection, and hemorrhage may also occur less frequently after functional hemispherectomy. Additional options include hemispherotomy,[45] hemidecortication,[46] and the Oxford modification of anatomic hemispherectomy.[47]

Multiple subpial transections

Frank Morrell introduced the technique of multiple subpial transections based on the observations that epileptogenicity is potentiated by horizontal connections between cortical neurons and functional elements are depend on vertical connections and columnar structure of the cortex. The technique of multiple subpial transections is the selective interruption of horizontal intracortical fibers within the suspected epileptogenic zone. Interruption of the horizontal connections impairs the cortical ability to generate synchronous discharges while maintaining physiological activity that is mainly mediated via the vertical cortical columns. This technique is predominantly used if the epileptogenic zone lies within eloquent cortex, i.e., resection of this cortical area would lead to an unacceptable clinical deficit in language, motor or sensory function. It differs from other disconnection procedures such as corpus callosotomy by disconnection within the epileptogenic zone. Other disconnection procedures attempt to disconnect the epileptogenic zone from the symptomatogenic zone.[48] In the first clinical patient series of multiple subpial transections, complete seizure control has been observed in 11 out of 20 cases and recurrence of epilepsy in different cortical areas was only seen in patients with underlying progressive diseases, such as Rasmussen's encephalitis, tumors and subacute sclerosing panencephalitis.[48]

Multiple subpial transsection in conjunction with resective surgery lead to seizure freedom in up to 46% of children.[49] Although the exact extent of the effect is unknown, Spencer *et al.* demonstrated in a metaanalysis of 211 adult and pediatric patients efficacy of the procedure itself.[50]

Corpus callosotomy

Corpus callosotomy was first described by Van Wagenen and Herren in 1940.[51] Currently, it is used as a palliative procedure in patients with predominantly atonic seizures. Anterior callosotomy aborts atonic seizures in 100% and decrease generalized tonic-clonic seizures in 83% of patients.[52] Total callosotomy may decrease seizure frequency in patients that fail partial callosotomy. In patients with total callosotomy the largest seizure reduction was seen in tonic-clonic (68%) and tonic (57%) seizures.[52] Ictal EEG patterns after callosotomy became more focal. Seven out of 18 patients with anterior callosotomy and five out of ten patients with complete callosotomy had a more focal seizure onset after disconnective surgery.[53] However, this procedure is strictly palliative and does not cure seizures. The main advantage is the abortion of atonic seizures in order to decrease the number of falls and to enable patients to reduce injury by a more focal seizure onset.[43]

Selection of the type of callosotomy (complete or anterior) is dependent on (anticipated) language function. Complete disconnection leads to neuropsychological deficits including dissociation of both hemispheres (split brain syndrome) with lack of the language dominant hemisphere to access information in the nondominant hemisphere. Additionally, patients may develop apraxia of the nondominant hand to verbal commands and present with difficulties with bimanual coordination.[54,55] Anterior callosotomy, alternatively, leads to fewer deficits with slowing of speech and decreased use of the dominant limbs and

may be the first choice in intellectually higher functioning children, with the option to expand the procedure to a complete disconnection.

Vagus nerve stimulation is discussed separately in Chapter 127.

Frequent etiologies in pediatric epilepsy patients

Sturge-Weber syndrome

Sturge-Weber presents sporadically and is in up to 80% of patients associated with seizures.[56] Besides epilepsy, leptomeningeal angioma and associated cortical changes, patients present with a facial port wine stain in the area of the first trigeminal branch, and with glaucoma.[57] Kossoff *et al.* reviewed the literature on hemispherectomy in 45 patients with Sturge-Weber syndrome and 36 (80%) became seizure free.[56] This number is very similar to the 81% seizure free patients in 32 additionally reported patients in this series.[56]

Tuberous sclerosis complex

Tuberous sclerosis is an utosomal dominant phakomatosis with variable penetrance.[58] Initial presentation consists of seizures in 92% of patients.[59] Additionally, patients usually present with mental retardation. Main pathological substrate are hamartomatous tubers that can present in multiple organs, and frequently multiple tubers are seen within the brain. Other pathological manifestations include giant cell astrocytomas. Patients may be candidates for epilepsy surgery, if a single circumscribed epileptogenic lesion can be identified. PET may be helpful to identify the epileptogenic zone.[60] Multiple cerebral tubers are not a contraindication and seizure freedom is still possible if the epileptogenic tuber can be identified and resected.[61–63]

Malformation of cortical development

First described by Taylor *et al.* in 1971,[64] malformation of cortical development now accounts for up to 25% of patients undergoing epilepsy surgery.[65] Predominantly focal, multilobar or hemispheric malformation patterns such as hemimegalencephaly may be considered for epilepsy surgery, whereas patients with more diffuse malformations such as lissencephaly are less likely surgical candidates. Several neuroimaging features, such as blurring of the gray-white matter junction, focal cortical thickening and aberrant gyral cortical patterns, and white matter hyperintensity on T2 weighted or flair images or hypointensity on T1 images may or may not be present on MRI.[66]

Rasmussen's encephalitis

Focal chronic encephalitis (Rasmussen's syndrome) is characterized by progressive hemiparesis, hemianopia, and pharmacologically intractable seizures.[67] Seizures may progress to epilepsia partialis continua. Neuroimaging reveals progressive unilateral hemispheric atrophy and pathology is suggestive of inflammation. The etiology of this condition is not known, but an autoimmune disease is suspected, and this is supported by temporary improvement of symptoms with immunomodulatory treatment. However, the only curative treatment is hemispherectomy in patients with unilateral symptoms.[68]

Mesial temporal sclerosis

The first focal resections besides hemispherectomies in children were performed in temporal lobe epilepsy patients.[69] In this series of nine patients, mesial temporal sclerosis was found in seven out of nine patients, with four out of nine patients becoming seizure free and additional two patients that were almost seizure free.[69] Seizure freedom after temporal lobe epilepsy surgery in children ranges from 54–83%, with many of these patients presenting with mesial temporal sclerosis.[5,70–73] However, long-term seizure freedom declined on long-term follow up from 80% after two years to 66% after 15 years.[74] A similar decline has been observed in adult patients.[75] Nevertheless epilepsy surgery in temporal lobe epilepsy remains superior to medical therapy.[12]

Developmental tumors

Epileptic seizures are frequently the first presentation of developmental tumors such as gangliogliomas, gangliocytom as, and dysembryoplastic neuroepithelial tumors (DNET). Interestingly, in DNETs the epileptogenic zone is frequently not the tumor itself but surrounding malformation of cortical development associated with the DNET.[76] In a series of children with gangliogliomas, initial presentation consisted of seizures in 50% of patients. They are also frequent etiological findings in patients undergoing epilepsy surgery ranging from 0–40%.[9,11,77–81] Surgical intervention in patients with gangliogliomas rendered 78% of patients seizure free and additional 18% had reduced seizure frequency after surgery.[82] In a series of nine pediatric patients with DNETs, seven became seizure free after resection and the other two had markedly reduced seizure frequency.[76] Low-grade gliomas may also have an excellent prognosis with seizure freedom in up to 96%, if tumors can be completely resected.[83] Shorter duration of seizures may be predictive of good outcome in these patients.[83]

Hypoxic-ischemic injuries

Pre- and perinatal hypoxia and unilateral vascular insults frequently leads to infarction with or without porencephaly. Patients often present with seizures, hemiparesis and varying degrees of developmental motor or speech delay depending on the site of the lesion. Patients presenting with pre-existing hemiparesis were among the first candidates considered for epilepsy surgery, although no pathology has been provided in this series.[40] Seizure free outcome after hemispherectomy ranges from 73–84%, with a better outcome in patients undergoing functional hemispherectomy as compared to anatomical hemispherectomy.[84–87]

Vascular malformations

Up to 40% of patients with vascular malformations present with seizures as initial symptom.[88] Cavernous angiomas are the most epileptogenic vascular malformation, whereas data on pediatric patients with venous angiomas and capillary teleangiectasis is rare.[88] On MRI, cavernous angiomas present as typical round or oval lesions with mixed signal intensity ('popcorn' lesions) and with a surrounding hypointense parenchymal ring on gradient-echo and T2-weighted images related to hemosiderin deposition.

In a series of 11 children undergoing resection of the cavernous angioma because of intractable epilepsy, all became

seizure free.[89] Another series of 51 children reports seizure freedom in 70%.[90]

Seizure outcome after epilepsy surgery

Infants

Although infants were included in the first reported series of hemispherecomies,[40] it took another 40 years until the first experience with epilepsy surgery in infants was reported in detail.[6,7] In 1993, Chugani *et al.*[8] report 23 infants and children with cortical resection ($n = 15$) or hemispherectomy ($n = 8$) due to infantile spasms. At follow-up after on average 28 months, 15 children became seizure free, four had major reduction in seizure frequency and seizure frequency did not change in four children after epilepsy.[8] Out of 12 infants reported by our center, six became seizure free and another three had only rare seizures after on average 32 months of follow-up.[10] Duchowny *et al.* followed 26 infants for at least 1 year after epilepsy surgery and found 16 seizure free, four with greater than 90% seizure reduction, and six with some improvement in seizure frequency.[9] Most recently our center analyzed results of epilepsy surgery of patients under the age of 6 months.[91] Eleven out of 15 patients were seizure free (Engel class I), and three additional infants were much improved. Epilepsy surgery cmplications in this high-risk group included aseptic meningitis in three and a middle cerebral artery stroke in the region of the epileptogenic zone in a patient with pre-existing hemiparesis. Overall outcome was favorable and antiepileptic medications were significantly reduced.[91]

Children and adolescents

Few epilepsy surgery series focus specifically on this age group, but several studies include patients in this age range. The largest series to date reported 136 patients, of which 68% of patients were seizure free after a mean follow-up of 3.6 years.[5] Of note, this series also included infants. Patients with temporal lobe resections (78%) had better outcomes than patients with extratemporal resections (54%). This series demonstrated that etiology and not location of surgery was most important for seizure freedom, with higher rates of seizure freedom in patients with low-grade tumors (82%) than in patients with malformation of cortical development (52%).[5] This is also supported by Gilliam *et al.* who reported 33 patients between 1 and 12 years of age and an overall seizure freedom rate of 57%. Postoperative seizure freedom rate in patients with temporal lobe resections was lower as compared to frontal lobe resections, suggesting other influences on seizure freedom than resection site.[3] Other series including children and adults demonstrate similar results (Table 131.1).[4] Based on different patient populations other studies with fewer patients found similar results, with some variation in percentage of seizure frequency based on etiology, age group, duration of follow up, outcome parameters and resection site (Table 131.2). These results are more encouraging than response to newer antiepileptic medications leading rarely to seizure freedom and reducing seizure frequency by 50% in only 30% of patients.[92] Additionally, the chances of improvement after failure of two or more antiepileptic medications is 5% or less.[13]

Preoperative predictors of seizure outcome

Paolicchi *et al.*[35] followed a cohort of 75 patients under the age of 12 years and tried to determine predictors for outcome at least one year after focal resection. The only significant predictor of good outcome was completeness of resection of the epileptogenic lesion. This was defined as resection of a structural lesion and of an area with interictal and ictal intracranial EEG findings. 92% of patients undergoing complete resection of the epileptogenic lesion subsequently became seizure free. Patients with multilobar resections had a worse outcome as compared to the rest of the cohort with only 22% seizure free patients.[35]

Tonini *et al.* performed a metaanalysis of 47 selected articles in adults and children. Studies after 1984 with a sample size of at least 30 patients, at least 90% of cases with MRI, follow up for at least one year and outcome parameter defined as seizure remission were included. Positive predictors for seizure remission included febrile seizures, mesial temporal sclerosis, tumors, abnormal MRI, EEG/MRI concordance and extensive surgical resection, whereas intracranial monitoring and postoperative epileptiform discharges were negative predictors (Table 131.2).[4] Based on this meta-analysis, neuromigrational defects, CNS infections, vascular lesions, interictal spikes, and the side of the resection did not predict outcome.[4]

Mani *et al.* found acute postoperative seizures within 24 hours after epilepsy surgery predictive of recurrent seizures. Patients with acute postoperative seizures were 73% less likely to be seizure free after 6 months, 78% less likely to be seizure free at 12 months, and 87% less likely to be seizure free after 24 months.[93] Acute postoperative seizures were seen more frequently after extratemporal resection as compared to hemispherectomy.[93]

Age-related risks and contraindications of epilepsy surgery

Mortality

Due to their smaller body weight and lower blood volumes and due to usually more extensive resections, such as hemispherectomies or multilobar resections epilepsy surgery in children has some significant risks. Mortality in pediatric epilepsy surgery series ranges between 1 and 2%. In the Cleveland Clinic series, two out of 149 patients died immediately after surgery (1.3%).[5] Another series reports one death in a case series of 83 patients (1.2%).[35] Earlier series in younger children from established epilepsy centers had even higher mortality rates with one death in eight reported cases in a study from 1988.[6] Other series from established pediatric tertiary epilepsy centers report slightly higher numbers in children undergoing hemispherectomy (4 perioperative deaths in 58 children undergoing hemispherectomy).[94] Mortality from epilepsy surgery should be weighed against risks of injury or SUDEP due to ongoing uncontrolled seizures. In a study on SUDEP in children with learning difficulties, the incidence of sudden death was estimated at 1:295 per year.[95]

Table 131.1 Selected epilepsy surgery series in children

Author	Year	N	Types of surgeries	Pathology, imaging, or presumed etiology	Design	Age at surgery (y/o)	Follow up	Seizure free (%)	Comments
Krynauw[40]	1950	12	Hemispherectomy	NR	R	2–21 y	Few wks to 4 y	100% (10/10)	10/12 with seizures; one death
Cairns and Davidson[41]	1951	3	Hemispherectomy	NR	R	7–20 y	1 y	100% (3/3)	
Penfield[42]	1952	4	Hemispherectomy	NR	R	NR	1 y (?)	3/3 (100%)	No follow up reported on remaining case

Table 131.1 Selected epilepsy surgery series in children—cont'd

Author	Year	N	Types of surgeries	Pathology, imaging, or presumed etiology	Design	Age at surgery (y/o)	Follow up	Seizure free (%)	Comments
Robinson *et al.*[112]	2000	22	AHS (22)	MRI: hippocampal changes (12); normal (7); lesion (1); bilateral abnormal (2)	R	9–21 y	1 y	Engel I: 15/21 (71%); 11/17 (65%) at 2 yrs	IQ improvement
Miranda and Smith[113]	2001	50	TLE (50)	Dual path (10); no additional information	R	6–18 y (mean 13.3 y)	Mean 9 m (0.5–79 m)	33/50 seizure free	Focus on neuropsychological changes
Kuehn *et al.*[128]	2002	26	TLE (20); ETLE (6)	NR	R	Mean 12.9 y	0.4–1.25 y	15 seizure free (58%)	Focus on neuropsychological changes
Sherman *et al.*[129]	2003	22	Hemispherectomy (2), TLE (11), frontal (6), parietal (2), CC (1)	Cryptogenic (15); MCD (4); infection (2); tumor (2)	R	6–17 y	NR	11/22 Engel I (50%)	IQ comparison between surgical and nonsurgical group
Pulsifer *et al.*[130]	2004	71	Hemispherectomy (71)	Rasmussen (37); MCD (27); Vascular (7)	R	0.25–20.6 y	2.4–37.5 y	46/71 seizure free (65%)	Neuropsychological assessment
Smith *et al.*[72]	2004	30	TLE (18), ETLE (8), MLB (4)	MCD (7); MTS/MCD (6); tumor (7); gliosis (4); TSC (2); Rasmussen (1); arachnoid cyst (1); normal (2)	P	1 y	6–18 m	17/30 Engel I (56.7%)	Focus on cognitive and psychosocial function
Sinclair[100]	2005	15	Posterior resections (parietal 9, occipital 6)	MCD (4); stroke (2); normal (2); Astro (2); TSC (2); GGL (1); cyst (1); DNET (1)	R	1.5–16 y	Mean 15.9 m for NP (NR)	7/15 Engel I	9/15 Engel I or II
Gleissner[78]	2006	66	AH (8), LB/LX & AH (21); LB/LX (33); MST (4)	MTS (9); Tumor (27); MCD (16); venous malformation (2); other (8); normal (4)	R	4–16 y	1 y	67–78% seizure free	Comparison of three different IQ groups
Riney[131]	2006	29	Hemispherectomy (27); MLB (2)	MCD (12); Vascular (15); Rasmussen (2); Dual path: MTS (21/29)	R	4.5–204 m	NR	NR	Focus on hippocampal abnormalities

Abbreviations: AH – amygdalohippocampectomies; CC – corpus callosotomy; LB – lobectomies; LX – lesionectomies; MST – multiple subpial transections; MCD – malformation of cortical development; DNET – dysembryoplastic neuroepithelial tumor; GGL -ganglioglioma; GCT – gangliocytoma; GNH – glianeuronal hamartoma; HS – hippocampal sclerosis; PPA – peri/postnatal lesion; SWS – Sturge-Weber syndrome

Table 131.2 Predictors of epilepsy surgery outcome (adapted from Tonini *et al.*, Epilepsy Research, 2004[4])

Positive predictors for seizure remission	Odds ratio	Confidence interval
Febrile seizures	0.48	0.27–0.83
Mesial temporal sclerosis	0.47	0.35–0.64
Tumors	0.58	0.42–0.80
Abnormal MRI	0.44	0.29–0.65
EEG/MRI concordance	0.52	0.32–0.83
Extensive surgical resection	0.24	0.16–0.36
Negative predictors for seizure remission		
Postoperative discharges	2.41	1.37–4.27
Intracranial monitoring	2.72	1.60–4.60

Morbidity

Several complications may be related to the surgical intervention, such as hemorrhage, infection, and hydrocephalus as well as neurological deficits. In an epilepsy surgery series on 708 patients, approximately 3% of patients had postoperative surgical complications.[96]

Additional morbidity may be related to loss of eloquent cortex. Resection of the primary motor area in the precentral gyrus and perirolandic region leads to contralateral motor deficits, but due to bihemispheric innervation, facial motor function and contralateral proximal motor function can recover.[97] Although sensory lesions rarely lead to disability, removal of the primary sensory area in the postcentral gyrus, in particular the hand area, may cause loss of fine finger movements[98] and should therefore be avoided if possible. However, even in patients after hemispherectomy, secondary somatosensory areas and other cortical regions in the intact hemisphere continue to mediate sensory function.[99] Visual field defects occur after parieto-occipital resections or after resection of Meyer's loop in the posterior temporal lobe.[100]

Memory decline after temporal lobe epilepsy surgery has been described, and patients with normal mesial temporal structures on presurgical MRI and high baseline memory function may be at a higher risk.[101] Postsurgical memory outcome is most likely dependent on the reserve capacity of the contralateral not resected hippocampal structures and the functional adequacy of the hippocampus that will be resected, as evidenced by pathology and volumetric studies.[101]

Resection of language dominant areas is rare, but partial or complete resection may be warranted in highly selected patients with brain tumors and Rasmussen's encephalitis. Plasticity of the language cortex in children is an advantage and partial language transfer to the intact hemisphere may be possible in particular in patients with Rasmussen's encephalitis and in patients with initially bilateral language until teenage years.[32]

Additional benefits of epilepsy surgery in infants and children

Development and cognition

Cognitive development may be vulnerable to side effects of seizures and antiepileptic treatment, especially at an early age. Patients with epilepsy are considered to be at threefold higher risk of cognitive or mental problems as compared to the general population.[102] In a population based study, learning disability has been detected in 76% of adult patients with childhood onset epilepsy.[103] In addition to effects on cognition, childhood-onset temporal lobe epilepsy also seems to be associated with white-matter tissue volume loss and other structural brain abnormalities.[104] Several authors report a relationship between the severity of the intellectual disability and the seizure outcome.[103,105–108]

In a series of 12 infants undergoing focal resections or hemispherectomies at our center marked 'catch-up' developmental progress was noted after epilepsy surgery in almost all patients.[10] This was confirmed in a larger series on 24 infants undergoing epilepsy surgery.[109] Pre- and postoperative Bayley Scales of Infant Development were documented and a developmental quotient as compared to biological age was calculated. All children had some degree of developmental delay prior to surgery. Developmental quotient improved after surgery, and improvement was predicted by developmental function prior to epilepsy surgery.[109] Similar results were also found by Asarnow *et al.*,[110] who assessed developmental outcome with the Vineland Adaptive Behavior Scales after 2 years. Developmental outcome was best for infants undergoing surgery at a younger age and who had better developmental baselines prior to surgery.[110] An early epilepsy surgery intervention is also associated with better long-term psychological outcome, and may be warranted in order to utilize the greater amount of plasticity in infants and children and to prevent secondary epileptogenesis.

Review of intellectual outcome in older children and adolescents after temporal lobe epilepsy surgery demonstrated several studies demonstrating an increase of the nonverbal intelligence quotient as compared with verbal intelligence after surgery.[34,111–113]

Cost

The overall direct cost of epilepsy is usually higher in children than in adults.[114] Two studies analyzed the cost of epilepsy surgery in children. In a Swedish study conducted 1980–1992,[115] in the year after surgery annual costs per case were reduced by $11 525 US in direct costs and $42 000 US in indirect costs. Additionally, number of physician contacts and emergency room visits decreased in all patients, even in the patients with ongoing seizures.[115] In a Canadian study, Keene *et al.*[116] analyzed cost efficacy of cortical resection in 64 children with medically intractable epilepsy. The costs of the patients undergoing surgical resection were higher as compared to the medically treated group during the first 14 years, but then slowly declined and after 14 years the surgically treated group was cheaper.[116]

Conclusion

Overall seizure freedom after epilepsy surgery is approximately 60% (Table 136.1) and is comparable with outcome in major adult epilepsy surgery series. Advantages of epilepsy surgery in children include a greater amount of plasticity and improvement of behavioral deficits with impact on neuro-development. Timing of epilepsy surgery is important and risks versus benefits of an early surgical intervention have to be weighed in every patient separately. Further advances in diagnostic tools such as functional imaging and genetics as well as surgical techniques may well lead to improved surgical candidate identification and diagnosis of the epileptogenic zone, with reduction in complications and improved seizure outcome. Other less invasive surgical techniques such as brain stimulation and microcatheter and electrode applications may also gain additional importance in the future.

132 Hemispherectomy: post-surgical seizure frequency

I Tuxhorn, H Holthausen, P Kotagal, and H Pannek

Introduction

Postoperative seizure control following cerebral hemispherectomy (CH) for intractable seizures is similar to that in cases of pediatric temporal lobe epilepsy. The good seizure outcome after CH has been well documented since it was first introduced for the treatment of severe seizures arising from one hemisphere over 50 years ago. In recent years surgical technique has focused less on brain resection and more on disconnection of the epileptogenic cortex to improve perioperative complications and long-term morbidity.

Although most patients benefit with improved seizure control after CH, seizure-free outcome is only reported in 60–80% in most studies which raises the question of which factors are prognostically significant for good outcome. The surgical technique and pathologic substrate causing the epilepsy probably are the two most important factors that will affect surgical outcome.

In this chapter we will give a brief historical review of the development of surgical technique and present the available data from various studies of large CH series from different US and international centers that have looked at the question of which factors influence postoperative seizure frequency.

In addition we will present some individual case material from our centres illustrating some of the anatomical, surgical and epilepsy-related factors that may contribute to post-surgical seizures after CH.

History of hemispheric surgery for epilepsy

Hemispherectomy has been termed the ultimate focal resection and has become an established neurosurgical procedure to treat seizures arising diffusely from one hemisphere.[1] After McKenzie performed the first successful hemispherectomy in 1938 for seizure control in a patient with infantile hemiplegia which was followed by a hiatus of 12 years Krynauw, a South African neurosurgeon in 1950 reported his series of 12 hemispherectomies achieving 80% seizure-free outcome in his patients with infantile hemiparesis.[2] These initially positive experiences were duplicated by other authors in larger patient series and by 1968 the results of 420 hemispherectomized patients were published.[3] In addition the good seizure outcome (80% seizure free, 14% substantial seizure reduction, 5% no change and 32% off medicine) of 50 further hemispherectomy cases from a single center were reported by Wilson in 1970.[4]

At the same time, first reports of mortalities associated with late complications of hydrocephalus secondary to superficial, cerebral hemosiderosis (SCH) transiently dampened further enthusiasm for this procedure to treat hemispheric epilepsy.[5,6] These reports led to successive modifications of the neurosurgical technique from the extensive anatomic excision of the hemisphere (anatomic hemispherectomy) to sparing of most of the white matter by only excising the epileptic cortex (hemidecortication), followed by various disconnective techniques disrupting all afferent and efferent fibres but essentially leaving in place most of the cerebral structures including cortex and white matter, which has been termed a functional hemispherectomy.[7]

Nowadays most centers perform modifications of the functional technique which has undergone further refinements to minimize tissue excision which is usually limited to the temporal lobe including the mesial structures and central insular cortex. Recently new approaches and techniques to optimize the functional disconnection (hemispherotomy) of the hemisphere via two different approaches – the vertex approach[8] or the peri-insular approach – have been published.[9,10] In the latter approach the operculum is excised and the white matter is transected perpendicularly through the circular sulcus of the insula and a complete parasaggital callosotomy is performed from within the lateral ventricle.[7]

Results post hemispherectomy

The overall seizure outcome after hemispherectomy has been reported from various centers and generally ranges between 50–80% seizure-free outcome and significant reductions of seizure frequency and intensity (Engel II and III) in up to 90% of the operated groups. Only a small proportion of patients do not benefit from the procedure. The main pathologies described from most centers include hemimegalencephaly and other hemispheric malformations of cortical development e.g., schizencephaly, unilateral pachygyria/polymicrogyria, Sturge-Weber syndrome, Rasmussen's encephalitis and a variety of acquired encephaloclastic lesions.

The hemispherectomy surgical techniques vary from center to center but may be grouped as anatomic resections, functional hemispherectomies and the newer modifications termed hemispherotomy with either a lateral or vertex approach to disconnect the epileptogenic hemispheral cortex.

Table 132.1 Common etiologies in hemispheric epilepsy

Sturge-Weber Syndrome
Rasmussen's Encephalitis
Porencephaly – Hemiatrophy after ischemia and vascular insults
Hemimegalencephaly
Non-hemimegalencephalic migrational disorders

A large meta-analysis of 333 hemispherectomied patients was analysed in 1997 and published in the proceedings of the Bethel-Cleveland International Symposium on pediatric epilepsy surgery.[11] The data from 11 centres were pooled and an attempt was made to stratify prognostic factors most likely affecting seizure control after hemispherectomy.

Overall, the newer techniques with emphasis on disconnection were as good as or slightly better than the older large resective techniques with the clear additional benefit of improved perisurgical morbidity. In the same analysis it could be shown that postoperative seizure outcome was influenced by the underlying pathology. Sturge-Weber syndrome patients were seizure free in up to 82%, whereas only 56% of dysplasia cases became seizure free. In the study no postoperative imaging data was available to assess the degree of disconnection but the relevance of a meticulous disconnection of the frontal and posterior regions was emphasized in this analysis. Improved seizure frequency with a 68% seizure-free outcome in cases with hemimegalencephaly who underwent a complete paracallosotomy as part of the hemispherotomy procedure without entry into the ventricular system was reported from the Bethel series.[11] Analysis of the preoperative parameters including age of onset, duration of epilepsy, as well as electrographic data with widespread interictal sharp waves and evidence of ictal spread to the good hemisphere did not show any influence on the outcome results.[11]

Figure 132.1 Sagittal MRI post-hemispherotomy in HMG showing complete anterior to posterior paracallosal disconnection. The infant had catastrophic epilepsy and APOS in the first postoperative week and is now seizure free for 1 year.

Hemispherectomy for catastrophic epilepsy in infants

Severe hemispheric epilepsy frequently manifests in the first 2 years of life and ideally hemispherectomies should be performed as soon as possible in this young group of patients to reduce medical morbidity and the risk of status-related mortality. In a newer systematic study of 18 infants operated under the age of 3 years incompleteness of dissection was the only variable statistically associated with persistent seizures after surgery. The type of surgical procedure, pathology category, persistence of insular cortex and bilateral interictal epileptiform activity was not associated with persistent seizures after surgery.[12] Although only a small patient group of 18 children was studied, pre- and postoperative MRI data was available to methodically look at the degree of disconnection with each applied surgical procedure which included anatomic hemispherectomy, functional hemispherectomy and modified hemispherectomy. In this study hemispherotomy with emphasis mainly on dissective technique was not perfomed.[12]

Further analysis of the group of patients (37%) with persistent seizures demonstrated that the presence of fronto-basal brain tissue was a clear source of persistent seizures and two patients subsequently became seizure free after reoperation to complete the disconnection. All patients had surgical

procedures with disconnection through the lateral ventricles. The authors emphasize the difficulty of performing complete disconnections of the frontal horizontal fibres in children with large distorted hemimegalencephalic malformations and that disconnection of the frontal cortex from the mesial structures of the temporal lobe is the most challenging step to achieve in this neurosurgical procedure. Incomplete disconnection of the corpus callosum was only noted in one of 12 incompletely disconnected procedures reported in these series while no incomplete posterior disconnections were reported.

The authors comment on the potential value of intraoperative imaging for these cases but clearly point out the anatomic limitations leading to incomplete fronto-orbital disconnections: the fronto-basal region is intimately related and limited in its posterior aspect by the hypothalamus and the anterior perforated substance which is the exit and entry site for the lenticulostriate arteries and veins and also marks the site of the most anterior inferior portion of the basal ganglia. If these functionally critical structures which do not differentiate well from the cortical gray matter of the frontal lobe are disrupted by the surgeon, resection may result in severe morbidity or death. Therefore the anterior cerebral artery which unfortunately shows anatomic variation is a highly respected anatomic landmark that prevents the surgeon from disrupting these cerebral structures and therefore any 'frontal lobe' brain tissue lying posterior to a more 'anterior variant' of the ACA will be left behind and lead to an incomplete resection. This leads the authors to conclude that in some cases a complete disconnection cannot be performed safely for anatomical reasons and further attempts to remove the remaining frontal cortex can lead to unsuccessful results.[12]

The sequential stages in the surgical method, technical pitfalls, and complications of peri-insular hemispherectomy are characterized by Villemure *et al.* in a recent paper reporting on the outcome in 43 children[13] – 90% were classified as Engel 1 and the incidence of vascular complications and hydrocephalus was very low due to preservation of the cortical vessels and minimal disturbance of the subarachnoid space.

The results reported in these studies emphasizes the importance of accurate patient selection of cases with clear unilateral hemispheric disease and the crucial role of the surgeon's experience for improving surgical strategy and technique.

Prognostic role of acute postoperative seizures

Acute postoperative seizures (APOSs) have been defined as seizure events occurring early within the first 7–10 days after surgery. These have been studied quite systematically in patients with temporal lobe epilepsy as prognostic events determining long-term seizure control. In 114 patients undergoing hemispherectomy APOSs were studies retrospectively and found to occur in 22.6% of patients.[14] Patients with >5 APOSs after hemispherectomy had a more prolonged and complicated hospital course and worse postsurgery seizure control, more AED use and higher reoperation rate than patients without or up to 5 APOSs. Thus the number of APOSs was found to be a valuable predictor of postsurgery seizure control and a useful parameter to counsel patients or families about prognosis after hemispherectomy. In the same study the seizure types observed were described as focal tonic-clonic, unilateral tonic head and eye movements, staring and eye rolling, mouth twitching, myoclonic shoulder twitching, and tonic extension of both extremities. In addition, extensive spasms and a frightened look were also described. In general, the APOSs compared to the pre-surgical seizure type in over 78% of the patients examined. The clear predictive value of the number of APOSs (>5) for post hemispherectomy seizure control may be related to the fact that the younger patients undergoing CH have multiple seizures every day before surgery compared to adult temporal lobe patients who usually only have a few seizures per week. In addition, APOSs tended to occur more in patients with lower pre-surgical Vineland DQ scores. The authors recommend that video-EEG telemetry after hemispherectomy should document whether patients

have a habitual seizure versus a non-seizure event, whether the seizure was typical of the pre-surgical events and whether abnormal EEG findings were noted over the non-resected brain or hemisphere that might support the concept of induced secondary epileptogenesis.[14] These findings were duplicated in a more recent study in which APOSs were analysed in extratemporal resections and hemispherectomy patients.[15] Only 13% of the hemispherectomy patients had APOSs compared to 37% of the extratemporal resective cases and similar to the previous study the presence of APOSs was highly predictive for long-term seizure control which was only seen in 15% of children with APOSs compared to 63% of those without APOSs.[15]

Post CH seizures – newer studies analyzing the influence of pathology and surgical technique

Postoperative seizures were reported in a recent study of 30 patients operated over a time span from 1987 to 2003 in which the effect of surgical technique and pathology on seizure frequency and general morbidity were analyzed.[16] Of 21 patients who could be followed-up for one year 17 remain seizure free or had a 90% seizure reduction and the four patients who continued to have seizures had a recurrence within the first few days after surgery. Two of these patients were reported to have an incomplete disconnection of the corpus callosum, the etiologies were Rasmussen's encephalitis and malformation of cortical development. In the total series only two patients did not improve significantly after surgery.[16]

The authors discuss the relevance of pathology and surgical technique as main factors for postoperative seizure control based on their study and further series in the literature.[17–20] The authors found incomplete disconnections in 18.5% of their cases which is the same incidence reported previously from the UCLA series.[21] In another series using modified perinsular hemispherotomy 9% incomplete disconnection was reported,[22] while Mittal reported no incomplete disconnections in their series of transsylvian keyhole functional hemispherectomy.[20] In a large series reported from Johns Hopkins[18] five out of 111 patients who underwent hemidecortication had repeat surgery for persistent seizures as residual tissue could be identified on MRI. In the Bethel series of 105 hemispherectomies 9 patients (9%) had reoperations for incomplete disconnections, however the rate of incomplete disconnections is higher as only children that had poor postoperative seizure control had a second surgery.[11] Incomplete disconnections may occur with all techniques and relate to the pathology and specific anatomical features of malformed hemispheres so that thick cortical mantles and large distorted hemispheres require good surgical technique and experience of the neurosurgeon to achieve complete disconnection so that the expertize of the neurosurgeon is very important for outcome.[13] The authors concluded that hemispherectomies are procedures where pathology and surgical technique interact narrowly to determine post-surgical prognosis and morbidity.

The UCLA series spanning surgeries from 1986 to 1995 reports excellent seizure control and motor function in 50 patients with more than 1 year follow-up of 90% of seizure reduction.[21] Late postoperative seizure breakthrough required reoperation and further disconnection in five of 27 functional hemispherectomy patients and three of 27 anatomical hemispherectomy patients. In more detail 74% (37) were completely or nearly seizure free with no more than occasional seizures after one year, seven additional patients (14%) showed a greater than 90% reduction in seizure frequency and 10% had a moderate reduction, while one patient showed no improvement. Therefore 88% of the patients had extremely favourable results with greater that 90% seizure reduction. The study presents no MRI data. The authors also discuss technique issues and based on their results and experience they recommend anatomical hemispherectomy in patients with a small lateral ventricle on the affected side because this small window of access increases the difficulties in the disconnection portion of the functional technique. They also state that the presence of large cysts or very marked atrophy is an argument for an anatomic procedure as there is much less disconnection through brain tissue. An anatomic hemispherectomy is also favoured in patients with dysplastic syndromes in which the tissue may become hemorrhagic. They counterbalance the increased risk of hydrocephalus in their argumentation and recommend that functional hemispherectomy should be favoured in patients with a large lateral ventricle present on the affected side, because this facilitates an access for disconnection. By this argument children with middle cerebral artery infarcts are good candidates for the hemispherotomy procedure and particularly where adhesions and scar tissue may obstruct access to the large cerebral arteries which is necessary when performing an anatomic resection. From their experience and data analyses these authors conclude that anatomical functional and modified anatomical hemispherectomy provides an excellent seizure control in young hemiplegic children with intractable epilepsy. They do suggest that the choice and type of hemispherectomy should be individualised with safety and efficacy with regard to seizure control being the primary factors to be considered.

In a follow-up study from the same centre 2-year postsurgery seizure control is reported for a larger series of 115 patients as follows: 78.6% were seizure free at 6 months ($n=112$), 76.3% at one year ($n=97$), 70% at 2 years ($n=88$), and 58% at 5 years ($n=50$). There is a decline in seizure-free patients between 2–5 years postsurgery, which is quite similar to that reported in other cases of extratemporal pediatric epilepsy surgery. The authors note that fewer HME patients were seizure free in follow-up compared to other pathology categories but the differences were not statistically significant, age at surgery and duration of seizure did not correlate with seizure control. The authors comment that the HME cases were surgically the most challenging and of the pathology groups undergoing surgery had the lowest post surgery seizure control which however was higher (58.3%) than in previously reported studies (37%).[23]

In a parallel study from the same centre a comparison of three techniques by pathologic substrates was evaluated in the same group of patients and the factors stratified in the way they affected seizure control: heir conclusion was that the pathologic substrate is less influential with regard to post-hemispherectomy seizure control than other factors such as follow-up length, duration of seizure at surgery, completeness of disconnection of cortex and subcortical structures in patients with cortical dysplasia and Rasmussen's encephalitis.[24]

Long-term seizure control post-hemispherectomy

Seventeen patients treated with hemispherectomy from 1950 to 1971 with a seizure-free or near seizure-free outcome in half of 16 patients (94%) who were followed up long-term up to 38 years were reported by Davies.[25]

Similarly, the long-term follow-up[26] of eight patients showed excellent seizure control, improved neuropsychologic functioning, but a relatively high rate of early postoperative hydrocephalus and CT scan was found valuable to diagnose late complications. The authors emphasize the marked reduction in seizure frequency and improved behaviour, however, with little change in intellect or postoperative hemiplegia.

Seizure-free rates between 50–65% have been reported in studies with 5 or more years follow-up after hemispherectomy, compared with 67 to 88% in reports with shorter follow-up periods.[25] Late recurrences of seizures between 2–5 years are known to occur in pediatric patients after extratemporal resections, however the reasons for late seizure recurrence are not well studied but the phenomenon needs to be considered when comparing seizure control in different clinical series – follow-up duration is an important factor that needs to be considered. The authors, in addition, discuss the effect of including the basal ganglia and thalamus in the resection/disconnection for post-hemispherectomy seizure control, especially in patients with cortical dysplasia and Rasmussen's encephalitis. Studies clearly show that in patients where the basal ganglia and thalamus are preserved the seizure-free rates are lower, reported between 31–67%.[27–29] In studies where deeper structures were removed or disconnected the seizure-free rates are higher, 67–87%.[22,24,30,31]

Recently the favourable long-term seizure outcome results and low complication rate of 83 children who had vertical parasagittal hemispherotomy were reported by Delalande.[32] Similarly the first adult series of 9 patients with follow-ups of up to 30 years was reported with 83% remaining seizure free in the long term and no mortality reported over this period.[33]

133a Psychiatric outcome of epilepsy surgery

AM Kanner and AJ Balabanov

Introduction

Patients with medically intractable epilepsy are at risk for mood, anxiety, psychotic, and attention deficit disorders (ADHD) (see also Chapter 94). For example, lifetime prevalence rates of depressive disorders range between 30–50%, those of anxiety disorders between 10 and 30% and those of ADHD between 20 and 30%.[1–4] It is not surprising that prevalence rates of these psychiatric disorders are relatively high in patients being considered for epilepsy surgery. In a review of the literature Koch-Stoecker found prevalencerates ranging from 43 to 80% among seven case series.[5] In the case series from the Bethel Epilepsy Center, 43% of patients met criteria for a psychiatric syndrome according to the criteria described in the *Diagnostic and Statistical Manual of Mental Disorder*, Third Edition, Revised, while an additional 29% met criteria for a psychiatric syndrome and a personality disorder.

Recognition of post-surgical psychiatric complications of epilepsy surgery goes back to more than 50 years. For example, in 1957, Hill *et al*. described post-surgical depressive episodes occurring independently of seizure outcome and remitted within 18 months.[6] For a long time, most of the data were obtained in case series at The Guy Maudsley Hospital in London, United Kingdom;[6,7] nonetheless, in the last 15 years there has been a marked increase in the number of published studies.

Psychiatric issues related to epilepsy surgery are complex and can be grouped into four main questions: (1) What are the prevalence rates and clinical manifestations of post-surgical psychiatric complications and what is their relation to post-surgical seizure outcome? (2) To what degree do pre-surgical psychiatric comorbidities contribute to post-surgical psychiatric complications? (3) What is the impact of pre-surgical psychiatric comorbidities on post-surgical seizure outcome and psychosocial adjustment? (4) What is the impact of epilepsy surgery on the course of pre-surgical psychiatric comorbidities? The purpose of this chapter is to address these four questions.

Post-surgical psychiatric complications

Post-surgical psychiatric complications can be the expression of (i) a de novo psychiatric disorder, (ii) a *recurrence* of psychiatric disorder that had been in remission for a period of time prior to surgery, (iii) an *exacerbation* in severity of a psychiatric disorder that was present in a subclinical form or that was mild enough in severity that had gone unrecognized by patient, family and clinician or that was identified because of a more careful evaluation of the patient.

The most frequent post-surgical psychiatric complications include; (i) depressive and anxiety disorders, (ii) psychotic disorder, (iii) psychogenic nonepileptic events (PNEE) and other types of somatoform disorders. A study completed at the Rush Epilepsy Center will serve to illustrate the various forms in which post-surgical psychiatric complications present.[8] The study included 99 consecutive patients, 59 men and 40 women that had undergone an antero-temporal lobectomy and had a minimal post-surgical follow-up period of 2 years (median follow-up duration: 7 years; range, 2–13 years). Their mean age was 31±10.7 years (range, 8–59 years) and the mean duration of their seizure disorder was 19.9±8.8 years (range, 4–40 years). A post-surgical psychiatric complication was rated as; (i) a *de novo episode/disorder*, (ii) an *exacerbation* in severity, or (iii) a *recurrence* of a pre-surgical disorder. Any of these complications were rated as *persistent* if they had failed to remit despite several treatment strategies that included pharmacologic trials and psychotherapy. Psychiatric disorders that were present before and after surgery and did not change in their severity after surgery were rated as *unchanged*, while those that remitted after surgery were rated *improved*.

Among the 99 patients, 62 had temporal lobe epilepsy (TLE) secondary to mesial temporal sclerosis (MTS), 18 had lesional TLE and 19 idiopathic TLE, documented with volumetric measurements of mesial structures. Fifty-five patients (55.6%) had a lifetime psychiatric history before surgery, 46 of whom had a mood disorder which consisted of depression alone in 22 patients, and mixed depression and anxiety disorders in 24 while three had in addition ADHD. Among these 46 patients, 26 had experienced a major depressive disorder, 14 a dysthymic disorder and six bipolar illness. Nine patients had other psychiatric disorders that included ADHD or pure anxiety disorder. Among the 99 patients, 44 (44.5%) met our criteria for post-surgical psychiatric complications: nine patients (11%) with de novo depressive/anxiety disorders and four patients (4%) with de novo psychotic episodes. Thirty one patients experienced an *exacerbation* in severity of pre-surgical depressive/anxiety disorders; these complications occurred during the first 12 months after surgery in all patients. In addition, seven of these 31 patients developed de novo PNEE. At the last contact, the post-surgical psychiatric

complication of 14 patients (13.5%) had failed to remit despite multiple pharmacologic trials; two of these patients had developed a de novo post-surgical depressive disorder.

Univariate analyses identified persistent seizures, pre-surgical psychiatric history and a left temporal seizure focus as predictors of post-surgical psychiatric complications. Multivariate regression models, however, identified a pre-surgical history of depression and a left sided seizure focus as predictors of post-surgical psychiatric complications, but not post-surgical seizure outcome. Interestingly enough, having failed to obtain gainful employment after surgery was not a predictor of post-surgical psychiatric complications (see below).

Post-surgical depressive and anxiety disorders

The prevalence rates of post-surgical depressive disorders vary widely among the different studies ranging from 5% up to 63%, with a mean of 26%. In a study of 274 patients, Bruton *et al*. found a 20-fold increase in the prevalence rate of depression after surgery[9] varying in severity from mild dysphoric to major depressive episodes associated with suicidal attempts. More often than not, these post-surgical complications are an expression of a *recurrence* or *exacerbation* of pre-surgical comorbid disorders. Furthermore, de novo psychiatric disorders are less frequent and are also likely to occur in the first six months after surgery. Here are some examples.

Wrench *et al*. published a study of 62 patients who underwent epilepsy surgery; 43 had an ATL and 19 an extratemporal lobectomy ETL.[10] Both groups had comparable pre-surgical histories of depression and anxiety (33% and 23% respectively for ATL and 53% and 18% respectively for ETL). At 1 month after surgery, symptoms of anxiety and/or depression were reported by 66% of ATL patients and 19% of ETL. At 3 months, 54% of ATL and 33% of TL patients were still symptomatic with 30% of ATL and 17% of ETL patients still experiencing a depressive episode. Furthermore, at the 3-month evaluation 13% of ATL patients had developed a de novo depression and 15% a de novo anxiety disorder, while 18% had developed other type of de novo psychiatric disorders. In contrast, only 17% of ETL patients had developed de novo anxiety, but not depression or other psychopathology. At 3 months follow-up, there was no significant association between post-surgical psychopathology and seizure outcome. Glosser *et al*. published a study of 44 patients who underwent an ATL; in the first month after surgery, 12 patients (31%) developed de novo depression and/or anxiety disorders or recurrence of a disorder that had been in remission during the six months preceding the surgical procedure.[11] By 6 months, they were still symptomatic but significantly improved and by 1 year, all but two patients had become free of symptoms. In a study of 49 patients who underwent an ATL and were followed for a period of almost 11 years, Altshuler found that five (10%) developed de novo depressive episodes, four within the first post-surgical year.[12] Similar findings were reported by Ring *et al*. in a study of 60 consecutive patients who underwent an ATL and had a psychiatric evaluation prior to surgery, at six weeks and three months after surgery.[13] At 6 weeks, 45% of all patients were experiencing emotional lability that reflected a de novo psychiatric complication in half of the patients. By 3 months, the emotional lability and symptoms of anxiety had remitted or improved significantly but not so the depressive states. Blumer *et al*., reported a much higher prevalence rates of de novo psychiatric complications in a study of 50 consecutive patients, 44 of who underwent an ATL and six a frontal lobe resection;[14] 14 patients (32%) developed de novo psychiatric disorders presenting as an interictal dysphoric disorder in six patients, depressive episodes in two and a psychotic disorder in six, while only three patients (7%) experienced an *exacerbation* of a pre-surgical interictal dysphoric disorder. In all but two patients the psychiatric complications occurred within 2 months after surgery. All psychiatric complications remitted with psychotropic treatment. Blumer *et al*. associated the development of post-surgical psychiatric complications with persistent seizures.

The role played by the side of surgery on the risk of developing post-surgical depressive disorders has been also investigated. Quigg *et al* studied the relation between the laterality of the seizure focus and the risk of depression before surgery and 1 year post-surgically among 107 patients, 90 of who underwent an ATL and 17 an ETL.[15] Higher pre-surgical depressive comorbidity and right-sided surgery were significant predictors of more severe postoperative depressive symptoms. Worse preoperative depressive traits predicted worse postoperative scores on scales measuring symptoms of depression. Although the side of surgery did not predict worse post-surgical symptoms of depression, there was a trend for patients with right-sided foci. Findings for the ATL subgroup ($n = 90$) were similar to those of the overall sample. These authors concluded that patients undergoing epilepsy surgery in the right hemispheric, especially those with high pre-surgical depression-related morbidity, may be particularly susceptible to clinical depression. These data differ with the findings of our study in which left-sided focus was a predictor for post-surgical depressive episodes.[8]

Pre-surgical *ictal* fear or panic has been also associated with post-surgical psychiatric complications. For example, Kohler *et al*. studied the association of ictal fear with mood and anxiety disorders before and 1 year after ATL.[16] They compared 22 patients with ictal fear with two matched groups of patients with other type of auras and no auras at all. Pre-surgical and post-surgical evaluations at one to two months and one year after ATL were carried out to identify mood and anxiety disorders and the use of psychotropic medication. The majority of patients in the three groups experienced mood and anxiety disorders before surgery with comparable frequencies. Mood and anxiety disorders declined in the two control groups, but not in the ictal fear group after surgery. Postoperative mood and anxiety disorders were more common in patients with persistent seizures and in those in the ictal fear group who were seizure free. Furthermore, a majority of patients with ictal fear required the use of psychotropic medication after surgery.

In addition, Kanemoto *et al*. have identified an association between pre-surgical postictal psychotic episodes (PIPE) and post-surgical mood disorders in a study of 52 patients who underwent an ATL. Post-surgical mood disorders presented as manic and depressive episodes during the first two post-surgical years.[17]

Post-surgical psychosis

The prevalence rates of post-surgical psychotic complications have been estimated to range between 1% and 10% among patients undergoing ATL. Unfortunately, the data of post-surgical psychotic studies are significantly less robust than those of post-surgical mood and anxiety disorders and consist more often than not of small case series or anecdotal reports. Several case series have include a mixture of patients with pre-surgical and de novo post-surgical psychotic disorders.

De novo post-surgical psychotic episodes may present as schizophreniform-like disorders, manic episodes and postictal psychotic episodes. In the study carried out at Rush Epilepsy Center cited above, Kanner *et al.* identified a de novo psychotic episode in four patients within the first 6 months after surgery consisting of a manic episode in two and a paranoid episode in the other two patients.[8] Symptoms remitted in two patients with pharmacotherapy without the need of hospitalization while the other two had to be hospitalized in a psychiatric unit. In one patient, symptoms remitted after the first admission, while the second patient had to be hospitalized twice. Two of these patients had lesional epilepsy caused by dysembrioplastic neuroepithelioma (DNET) in one and a ganglioglioma in the second.

Shaw *et al.* identified 11 patients who developed de novo post-surgical schizophreniform psychosis among 320 consecutive patients (3.2%) who underwent an ATL.[18] Psychotic symptomatology became apparent within the first year in all patients. These 11 patients were compared to a control group of 33 patients. Psychotic patients were more likely to have bilateral epileptiform activity, a smaller amygdala in the nonoperated side and pathologies other than MTS.

Stevens identified a de novo psychotic disorder in two patients within the first 12 months after surgery among a group of 14 patients who had undergone an ATL and who were followed for a period of 20–30 years.[19] Both patients were seizure-free. In a study of 57 consecutive patients who underwent an ATL, Leinonen *et al.*, identified five (8.8%) who developed postoperative psychotic episodes.[20] Two (3.5%) patients had experienced PIPE before surgery which they continued to have post-surgically. Among the other three patients, two (3.5%) experienced a definite and one (1.8%) a probable de novo schizophreniform psychotic disorder. Among 74 patients who underwent an ATL, Jensen and Larsen identified nine who developed a de novo psychotic disorder.[21] Six of the latter nine patients began experiencing psychotic symptoms after they became seizurefree.

Some investigators, have associated the risk of post-surgical psychotic episodes with a right temporal seizure focus. For example, Mace *et al.*[22] reported seven consecutive patients who developed a de novo psychotic disorder following an ATL, six in the right: one developed a delusional depression and four a schizophrenic-like psychosis, while one patient was diagnosed with Capgras' syndrome. Nonetheless, the relation between side of seizure focus and the risk of developing post-surgical psychosis cannot be established on the bases of these small case series.

As in the study by Kanner *et al.*[8] other authors have associated the presence of gangliogliomas or dysembrioplastic neuroepitheliomas with the development of de novo post-surgical psychotic disorders. Andermann *et al.* reported six patients who experienced a de novo psychotic disorder in six patients from four centers.[23] The psychotic disorders consisted of schizophreniform-like episodes with paranoid and depressive symptomatology. These investigators estimated a risk of 2.5% for the development of de novo psychosis (1 of 39) in patients with this type of lesions that undergo an ATL. Such association remains to be established in larger studies, however.

As stated above, *post-surgical manic* episodes can be psychiatric complications of ATL. For example, Carran *et al.* reported 16 patients who developed a de novo manic episode following an ATL.[24] These patients were identified from a case series of 415 consecutive patients (i.e., 3.8% of patients) who had undergone an ATL at the Comprehensive Epilepsy Center of Jefferson University Medical Center. These patients were compared to a control group of asymptomatic patients matched for age and gender and a second group of 30 patients who experienced a post-surgical depression. The manic episode occurred within the first year after the ATL and was short-lived in all but one patient. Compared to the two control groups, patients with post-surgical mania were more likely to display bilateral electrographic abnormalities, to have a right temporal seizure focus, though this difference did not reach significance when compared to the depressed group. Both post-surgical symptomatic patients were more likely to have experienced GTC seizures before surgery and to fail to achieve seizure freedom post-surgically.

Postictal psychotic episodes can also occur de novo after ATL. Christodoulou *et al.*[25] reported three cases (1%) among 282 consecutive patients who had undergone an ATL. All three patients had seizures predominantly from the contralateral (nonsurgical) site or had bilateral independent seizures, while none of the patients who failed surgery but continued to have seizures from the site of the surgery developed de novo PIPE. This supports the conclusion that patients with PIPE (chronic or de novo) have bilateral independent temporal lobe dysfunction.[26] Manchanda *et al.* identified four patients (1.3%) who developed a de novo PIPE among a group of 298 consecutive patients who had undergone an ATL.[27] All four patients had a right sided resection and had no preoperative psychiatric history.

It has been established in several studies that patients with PIPE are at significantly greater risk of having bilateral independent ictal foci.[26,28–30] In a study completed at the Rush Epilepsy Center, the occurrence of PIPE predicted the presence of bilateral independent ictal foci with an 89% probability.[26] By the same token, patients with recurrent PIPE are at significant risk of developing interictal psychosis. To minimize this risk, clinicians must carefully weigh the possibility of offering 'palliative' surgery to patients with PIPE and bilateral ictal foci, particularly those with MTS, provided that most seizures originate from the side of the MTS and the neuropsychological data are concordant with the intended surgical target.

Post-surgical psychogenic nonepileptic events

Ferguson and Rayport were the first authors that described the occurrence of post-surgical de novo PNEE in1965.[31] The development of these events has been attributed to the 'stress' associated with a 'seizure-free' life in patients with chronic epilepsy that are not 'emotionally, physically or economically ready' to face their own or their families increased expectations.

While this 'hypothesis' makes intuitive sense, the available data does not seem to support it. Here is some of the evidence.

The prevalence rates of post-surgically PNEE are relatively low, ranging between 1.8–10% among the different case series. For example, in the study carriedout at the Rush Epilepsy Center cited above, 7% of the patients developed de novo PNEE[8] (Kanner *et al*., submitted). A pre-surgical (lifetime) psychiatric history was associated with the development of post-surgical PNEE but was not found to be a predictive variable in univariate analyses. Interestingly enough, PNEE were not reported in seizure-free patients; in fact, persistent seizures were significantly associated with the development of de novo PNEE. Furthermore, failure to obtain gainful employment was not associated with the development of PNEE.

Ney *et al*. reported the occurrence of post-surgical PNEE among 96 patients who underwent epilepsy surgery over a period of 11 years.[32] Five patients (5.2%) developed de novo post-surgical PNEE. Low full-scale IQ, preoperative psychiatric comorbidity and major surgical complications were identified as risk factors. Glosser *et al*. identified 22 patients with post-surgical PNEE corresponding to a prevalence rate just below 10%.[33] Most of these patients were women with primary right-hemisphere seizure foci and onset of their epileptic seizures after adolescence. In this study, preoperative psychiatric diagnoses were not related to increased risk of PNEE. Reuber *et al*. identified 13 patients with both epileptic and PNEE and investigated their post-surgical outcome:[34] 11 of the 13 patients had significant clinical improvement post-surgically. However, in two out of 13 patients the severity of the PNEE (including pseudo-status epilepticus) increased postoperatively despite a significant improvement of their epileptic seizures. Both patients had a pre-surgical psychiatric history. V-EEG monitoring is required in order to make the diagnosis. Once diagnosed, the PNEE are usually self limited, however psychiatric help with cognitive therapy and counseling might also be needed.

Post-surgical somatoform disorder

This type of psychiatric complication is either rare or underrecognized. To-date there has been one case series of ten patients who developed somatoform disorder (other than PNEE) after ATL.[35] Seven of the ten patients developed an undifferentiated somatoform disorder, one had pain and body dysmorphia, another had pain disorder, and another had body dysmorphia alone. Somatoform disorder was significantly more common among patients who underwent a right ATL ($n = 9$).

Treatment of post-surgical psychiatric complications

Depression and anxiety disorders

The treatment of post-surgical depression includes the use of pharmacotherapy, psychotherapy, particularly cognitive behavior therapy or a combination of both treatment modalities can be considered. In patients with de novo depressive disorders, it is of the essence to rule out any prior history of manic or hypomanic disorder or a family history of bipolar illness before starting an antidepressant drug, as these agents may worsen the course of a bipolar disorder if given without concomitant mood stabilizing agents.[36] The use of antidepressant drugs of the selective serotonin reuptake inhibitor (SSRI) family are the agents of choice in the management of depressive and anxiety episodes in patients with epilepsy.[37] The use of SSRIs in the treatment of anxiety disorders includes panic, generalized anxiety and obsessive compulsive disorders.[37] Some of the depressive disorders can be very severe and may not respond to pharmacotherapy. In such cases, the use of electroshock therapy (ECT) can be considered. Krahn *et al*. reported one such case of a 25-year-old woman who developed a psychotic depression one year after undergoing a left ATL.[38] ECT resulted in symptom remission without any impact on the seizure disorder.

Psychotic disorders

These require the use of antipsychotic drugs; this class of drugs can lower the seizure threshold and thus, should be started at low doses, titrated up slowly and kept at as low a dose as possible. Among the older antipsychotic drugs, haloperidol remains the safest with respect to the risk of seizure occurrence.[39] Among the newer antipsychotic drugs (also known as atypical antipsychotic agents) all have a lower risk of causing seizures with the exception of clozapine.[40] Quietapine is a drug favored by many clinicians as being the safest; although, no controlled data is available. Of note, quietapine has been one of the antipsychotic drugs not to have been found to cause slowing of the electrographic recordings' background activity.

Impact of epilepsy surgery on pre-surgical psychiatric disorders

Anxiety and depressive disorders following ATL and ETR

Epilepsy surgery appears to decrease the prevalence of psychiatric comorbidities at follow-up evaluations. In the study carried out at the Rush Epilepsy Center, a lifetime psychiatric history prior to surgery had been identified in 55 patients of whom 51 were symptomatic at the time of the psychiatric evaluation.[8] At the last contact, 14 continued to be symptomatic despite multiple treatment strategies and an additional 14 patients were symptomfree on psychotropic medication. Thus, epilepsy surgery resulted in total remission off psychotropic medication in 45% of patients. Among the 44 patients reported by Glosser *et al*., six (15%) were symptomatic before surgery and became asymptomatic post-surgically.[11] Twenty-one patients were unchanged in their psychiatric status: eight who were symptomatic and 13 who were asymptomatic before surgery. While the overall prevalence of psychiatric disorders had not changed 6 months after surgery, the symptom severity measured with the Brief Psychiatric Rating Scale had improved significantly. In the study reported by Altshuler *et al*., 17 of 49 patients (35%) had a lifetime history of at least one major depressive episode.[12] Eight of these patients never experienced another major depressive episode post-surgically. In this study, like in our study, the only predictor for post-surgical depressive disorder was a pre-surgical history of depression. Devinsky *et al*. reported the results of a study of 360 patients from seven epilepsy centers in the USA

who underwent epilepsy surgery; 89% had an ATL.[41] Psychiatric syndromes were identified at baseline and two years after surgery with the structured interview Composite International Diagnostic Interview (CIDI). Pre-surgically, 75 patients (22%) met criteria for a diagnosis of depression, 59 (18%) of anxiety disorders and 12 (4%) of other psychiatric disorders including bipolar illness and schizophrenia. At the two-year post-surgical evaluation, only 26 patients (9%) met diagnostic criteria for depression and 20 (10%) for anxiety, while three patients (1%) met criteria for other psychiatric diagnoses. Thus epilepsy surgery had resulted in symptom remission in more than 50% of patients. In this study, the presence of an anxiety or depressive disorder post-surgically was not associated with seizure outcome.

Psychotic disorders

The decision to consider epilepsy surgery in patients with refractory epilepsy and comorbid psychotic disorders has been the source of much controversy. Indeed, some epilepsy centers consider the existence of a psychotic disorder as a contraindication for epilepsy surgery while others do not, as long as the patient can cooperate during the pre-surgical evaluation and has a clear understanding of the therapeutic expectations and risks of the surgical procedure. The impact of ATL on the post-surgical course of the psychotic disorder has varied from unchanged (in a majority of cases) to improved psychotic status and/or level of functioning.[42–47] Yet, several reports have suggested that, in the long term, psychiatric symptoms such as irritability and aggressive behavior can improve following ATL. For example, in a study of 74 patients who underwent an ATL, Jensen and Larsen identified 11 with a psychotic disorder *pre-surgically*.[21] The surgical procedure had no impact on the psychotic disorders that were present pre-surgically. In a study of 52 patients, Kanemoto *et al*. reported recurrence of psychosis in more than two-thirds of the patients with preoperative history of interictal psychosis. Some of the patients (7/12) remained in acute psychosis for a long time.[44] In a series of five patients with a chronic psychotic disorder who underwent an ATL, Reutens *et al*.[45] reported an excellent seizure outcome in all patients. The surgical procedure did not modify the psychotic disorder post-surgically, but the absence of seizures facilitated their level of functioning. Marchetti *et al*. reported six patients with pre-surgical interictal psychosis who underwent an ATL.[46] Five of the six patients achieved a seizure-free outcome and there was no worsening of their psychotic disorder, with relative improvement in the mental conditions of five patients. These same authors reported an additional case of a 45-year-old female patient with a 30-year history of epilepsy and recurrent postictal psychotic episodes since the age of 35 which evolved to a chronic refractory interictal psychosis.[47] Following a right ATL she became seizurefree with remission of the psychotic disorder. All of these case series exemplify that patients with interictal psychosis can successfully complete a pre-surgical evaluation.

Epileptic encephalopathies

The term of 'epileptic encephalopathies' is used to refer to psychiatric and cognitive disturbances whose onset can be traced back to that of the seizure disorders and which can be expected to improve and at times totally remit with the abolition of the epileptic activity. In some epileptic encephalopathies, clinical seizures are rare or not identified but EEG recordings display abundant epileptiform activity. One example of this type of encephalopathy is the acquired epileptic aphasia of childhood (also known as Landau-Kleffner syndrome (LKS), in which severe language and psychiatric disturbances are the major expression of the epileptic disorder and cure of the seizure disorder often is followed by their *partial to full* recovery[48] (see also Chapter 43). Hypothalamic hamartomas with gelastic epilepsy (HHGE) is another example of an epileptic encephalopathy but which is associated with a pharmacoresistant seizure disorder. It presents characteristically with severe psychiatric and cognitive disturbances associated with the onset of a variety of epileptic seizures but particularly gelastic seizures, and also including complex partial, secondarily generalized tonic-clonic seizures, and at times atonic or tonic seizures.[49] Epilepsy surgery has become one of the treatment modalities of these two epileptic encephalopathies and the severe psychiatric and cognitive disturbances appear to remit or improve significantly with the successful cessation of epileptic activity. Unfortunately, the pre and post-surgical psychiatric disturbances have not been evaluated in a systematic manner in either of these two disorders and in most patient series the reports of improvement have been based on parents' reports and not on structured interviews or diagnostic instruments. Thus, the absence of such data precludes a totally objective assessment of the impact of surgical treatment on the pre-surgical psychiatric manifestations and post-surgical changes of these disorders but some data are available and worth reviewing.

Landau–Kleffner syndrome

The surgical technique employed in LKS has consisted primarily of multiple subpial transection (MST) of the epileptogenic area, which typically involves intra and perisylvian cortex.[50] Kanner *et al*. reviewed the post-surgical outcome of 22 children with LKS who underwent epilepsy surgery at the Rush Epilepsy Center between the years 1990–2003 (for more details see Chapter 43).[51] Among the 22 children, 14 were boys and eight girls who were 6.95±1.95 years old at the time of surgery. The mean age of onset of LKS was 4.3±1.4 and the mean duration of the disease before surgery was 2.5±1.3 years; 21 had nonfunctional language for a period of at least 18 months; one child had functional language but had been experiencing frequent and recurrent language regressions that failed to be prevented with pharmacotherapy that included multiple AEDs trials and steroids. Behavioral problems were reported in 19 children; clinical seizures were also identified in 19 patients. In 14 patients (63.6%) only MST of intra and/or perisylvian cortex was performed. In seven (32%) a combination of MST and resection of temporal lobe structures was carried out, while one child underwent a resection of the planum temporale in the right hemisphere of a right-handed boy. Among the 19 children with clinical seizures before surgery, 15 (79%) became seizure free, two had rare seizures, one had >90%, and one had >90% seizure frequency reduction. The presence of epileptiform activity (but not a CSWS pattern) in the last EEG was not associated with a worse post-surgical

language recovery. On the other hand, recurrence of language disturbances occurred in three patients who had a recurrence of a CSWS pattern after surgery.

Post-surgical neuropsychological and speech evaluations were carried out after a mean period of 34.1±19.9 (7–75 months). The mean *baseline* score of the language test used for evaluation of expressive vocabulary, the Expressive One Word Picture Vocabulary Test-Revised (EOWPVT-R, expressed as age equivalent in months old) was 12.8±9.0 months, while the mean *baseline* score of the Peabody Picture Vocabulary Test-Revised (PPVT-R) which is used for evaluation of receptive language was 14.6±12.9 months. At the last formal speech evaluation, the mean EOWPVT and PPVT scores displayed significant increments to 144±72.9 months and 144±73.8 months, respectively with mean gains of 124±60.1 months and 129±59.2 months respectively. In addition, there was a significant correlation between the duration of post-surgical follow-up and the gains made on the PPVT ($r = 0.56$, $p = 0.02$) and a statistical trend for the EOWPVT ($r = 0.4$, $p = 0.09$). At that time, 20 of the 22 patients were still receiving speech therapy. Following a mean post-surgical follow-up period of 48.3±30.2 months, 16 children (72%) had regained functional language as defined by the ability to use complex sentences and understand what was being said to them. Despite these significant gains, only nine of these children (41%) were in a regular class without a need of assistance or further speech therapy. Finally, behavioral improvement was reported in 17 of the 22 patients (77%) by the parents, though there was no significant association between recovery of functional language and reported behavioral improvement.

Encephalopathy due to HHGE

Three surgical techniques have been advocated for the treatment of HHGE, including resection of the hypothalamic hamartoma, radiation with gamma knife and disconnection or destruction of the hamartoma with stereotactic radiofrequency.[49,52–54]

The behavioral and cognitive changes reported in these patients are quite variable. In most patients, behavioral difficulties are characterized by aggressive behavior, uninhibited tendencies, and clinical pictures indistinguishable from attention deficit with hyperactivity, and irritability. Up to 30% of patients may have autistic features. In those patients who appear to have normal cognition, insidious changes often develop before puberty.[49] In most patients, gelastic events often are the only seizure manifestation during the first 5–10 years of life. However, most patients develop other seizure types before puberty. The frequency of the gelastic seizures may be as high as 100 attacks per day. The frequency of other seizures is variable, but often they occur weekly. Of note, some patients who have frequent gelastic seizures do not deteriorate, whereas others with other types of epileptic seizures have worse outcome. The association between seizures and behavioral changes is not clear as the number of seizures in this syndrome often is difficult to estimate. However, depth EEG recordings from the hamartoma often demonstrate almost continuous discharges with or without secondary spread. It is possible that this almost continuous epileptic activity causes considerable cortical and subcortical dysfunction. For parents, the behavioral and cognitive problems often become more important than the seizures.

At least 11 case series of patients with HHGE treated with one of the three techniques cited above and totaling more than 120 patients have been published in the literature in the last 10 years. There is a consensus among the various investigators that successful lesioning or removal of the hamartoma leads to major improvements in cognitive performance and behavior. Most astonishing is the rapid cognitive and behavioral changes observed in these patients. Of the 11 case series published, data from seven are included in Table 133a.1 and presents cognitive and behavioral information on cognitive and behavioral changes post-surgically.[55–61] Five of the series consisted of resection of the HH and one of stereotactic surgery with gamma knife and one with interstitial radiation. Improvement of cognitive and psychiatric disturbances was observed in a majority of patients.

Impact of pre- and post-surgical psychiatric illness on post-surgical seizure outcome

Most of the studies that have investigated the relationship between post-surgical psychiatric disturbances and seizure outcome have found a significant association between persistent post-surgical seizures and post-surgical depressive disorders. Furthermore, Vickery *et al.* have also demonstrated an

Table 133a.1 Surgical case series with data on post-surgical cognitive and psychiatric changes

		Pre-surgical disturbances		Improvement post-surgically			
Authors	N	Cognitive disturbances	Psychiatric disturbances	Cognitive disturbances	Psychiatric disturbances	Seizures	Surgical procedure
Rosenfeld (2003)	5	5	5	5	5	5	Resection
Fohlen (2003)	18	18	18	17	17	17	Resection

Regis (2005)	25	25	0	9	9	18	Gamma knife

association between persistent seizures, including persistence of only auras and poor quality of life post-surgical.[62,63] Indeed, compared to patients who are completely seizurefree including free of auras had significantly higher scores on the Quality of Life in Epilepsy Inventory-89 (QOLIE-89) than those with only auras. The negative impact of persistent auras on the quality of life may be mediated by the need to be kept on AEDs or even the use of higher doses of AEDs to assuage the concern of recurrent seizures. Nonetheless, these data are counterintuitive since patients with auras but no disabling seizures can function normally in all areas. In fact, in a study by Kanner *et al.*, a pre-surgical lifetime psychiatric history of depression was the strongest predictor of persistent auras (in the absence of disabling seizures) on the one hand, and of post-surgical psychiatric complications, particularly depression on the other[64] and (Kanner *et al.*, submitted). Thus, these data raise the question of whether the worse QOLIE-89 scores in patients with persistent auras are driven by a concurrent mood disorder and not (only) by the auras.

A few studies have suggested that a *pre-surgical* psychiatric history is associated with a worse post-surgical seizure outcome. For example, in a study of 121 patients who underwent an ATL, Anhoury *et al.* reported a worse post-surgical seizure outcome for patients with a lifetime psychiatric history compared with those without.[65] Koch-Stoker investigated the post-surgical seizure outcome among 100 consecutive patients who underwent an ATL; 78 had a pre-surgical lifetime psychiatric history. Among patients without comorbid psychiatric history, 89% were seizure free after surgery while this occurred in only 43% of patients with pre-surgical psychiatric history (unpublished data). In the study cited above, Kanner *et al.*[64] used a logistic regression model to identify predictors of post-surgical seizure outcome in the 99 consecutive patients who had undergone an ATL. Covariates included: (i) cause of TLE (MTS, lesional TLE and idiopathic TLE); (ii) history of secondarily generalized tonic-clonic seizures (never, only at the onset of the seizure disorder, 1–2/year, >2year); (iii) duration of seizure disorder; (iv) lifetime history of depression (may have included major depressive disorder, dysthymia). As already mentioned above, a lifetime history of depression was the *sole* predictor of persistent auras in the absence of disabling seizures. In addition, the cause of the temporal lobe epilepsy and a lifetime history of depression were both significant predictors of failure to achieve freedom from disabling seizures. When the outcome variable was no disabling seizures in the last 2 years, the cause of TLE was the strongest predictor, while a lifetime history of depression yielded a statistical trend. These data raise another question – 'Is it possible that a psychiatric history, particularly depression is an 'indicator' of a more severe form of epilepsy?'

Psychosocial outcome

Family dynamics

Epilepsy surgery is expected to have a positive significant impact on the patient's life. With the achievement of seizure freedom, patients can become more independent, not only as it pertains to their ability to drive but in other areas of their life. Paradoxically, in some cases seizure freedom can have a negative impact on family dynamics. Indeed, some family members become accustomed to the patients' limitations and dependency on others and have difficulties allowing the patient to become more independent and see their role in life (unconsciously) as that of a 'caretaker' without which they cannot 'function'. Unfortunately, these dysfunctional family dynamics are not rare in families of patients with a chronic illness like epilepsy and invariable are bound to lead to conflict when patients try to become more independent. In fact, divorce is not an uncommon 'complication' of successful epilepsy surgery. Thus, all couples and families need to be evaluated for the eventual risk of this type of family problems.

Gainful employment

Obtaining gainful employment or getting a better job are some of the obvious goals of a successful surgical treatment. Unfortunately, such is not always the case. A review of the literature reveals that the main factors associated with post-surgical employment are: reduction of seizures or seizure freedom, pre-surgical cognitive ability, psychiatric comorbidity, pre-surgical employment and improvement of neuropsychological function.[66] In a study of 88 adult patients who underwent an ATL at the Rush Epilepsy Center, the predictors of post-surgical gainful employment included: working before surgery, achieving a seizure-free state, a negative lifetime history of depression and being a woman.[67] Lendt *et al.* found that a young age at the time of the surgery and improvement of the general neuropsychological functioning and especially attention are associated with employment after the surgery.[68] In another study, Reeves *et al.* found that being a student or working full time within a year before the surgery, driving after the surgery and obtaining further education after the surgery were associated with full time work postoperatively.[69] Clearly, these data are indicative of the need to carry out vocational evaluations before surgery among unemployed patients.

Disclosure of post-surgical psychiatric complications

As shown above, epilepsy surgery is associated with post-surgical psychiatric complications which should be openly discussed with patients and family members with as much detail as the other surgical risks. Indeed, patients should be advised of the risk of post-surgical depressive and anxiety episodes occurring within the first 12 months, with a higher symptom incidence in the first 3–6 months and a tendency to remit by 12 to 24 months. This is especially true when the patient has a previous history of mood disorder and the symptoms are actually an expression of a recurrence or exacerbation of pre-surgical depressive and/or anxiety disorders, while de novo mood/anxiety disorders are significantly less frequent. In patients undergoing ATL de novo depressive and anxiety disorders can be expected in 10–15% and a risk of 10–15% of persistent mood and anxiety disorders should be disclosed. Patients undergoing extratemporal resections have a lower risk of developing post-surgical psychiatric complications compared to patients undergoing an ATL, though the data available on post-surgical complications after ETL are rather sparse and more studies are needed to establish the

actual risk. With respect to the potential risk of post-surgical psychotic complications, patients and family members should be advised that while de novo post-surgical psychotic complications have been estimated to range between 1–10% following an ATL, the actual frequency remains to be established.

Concluding remarks

The data reviewed in this chapter clearly indicates that patients undergoing epilepsy surgery are at risk of developing psychiatric complications during the first post-surgical 12 months. While in a majority of patients, symptom remission is expected, 10–15% of patients may continue experiencing psychiatric symptoms that may fail to respond to multiple treatments. On the other hand, epilepsy surgery is expected to improve the course of psychiatric disorders, particularly anxiety and depressive disorders in more than 50% of patients. This is another advantage of epilepsy surgery which is rarely discussed with patients and families, in part because of a failure to include a psychiatric evaluation in most pre-surgical evaluations. Finally, the suggestion that pre-surgical psychiatric disorders may be predictive of post-surgical seizure outcome requires further research as it may help identify common pathogenic mechanisms between psychiatric and epileptic disorders.

133b Sudden unexpected death in epileptic patients after epilepsy surgery

D Schmidt and P Ryvlin

Introduction

People with epilepsy have a reduced life expectancy.[1] Mortality has been consistently shown to be 2–3 times higher in people with epilepsy than in the general population (for a review see Tellez-Zentano and Wiebe, 2005)[2] and even higher in populations with more severe epilepsy or associated disorders.[3–5] This increased mortality is attributable to both the underlying disease and to epilepsy itself, and, in rare cases, to fatal side effects of medical or surgical treatment. Common causes of death include pneumonia and other medical illnesses, suicide, seizure-related death and sudden unexpected death (SUDEP). The latter two causes account for between one–fourth and two-thirds of all deaths,[6] making SUDEP the most common cause of death in patients with epilepsy.[7] Reducing mortality is an important aim of epilepsy management.[8] Given that epilepsy surgery is the only intervention to render large proportions of patients with drug resistant epilepsy seizurefree with or without antiepileptic drugs,[9] it is of interest to examine the potential of epilepsy surgery to reduce seizure-related mortality. In this chapter, we focus on the question if epilepsy surgery is able to reduce the incidence of SUDEP in refractory epilepsy.

Definition of SUDEP

To establish the presence of SUDEP, an expert panel in 1997 [10] suggested all of the following criteria: (a) a diagnosis of epilepsy; (b) death occurring unexpectedly while in a reasonable state of health; (c) death occurring suddenly; (d) death occurring during normal activities and benign circumstances; (e) not finding an obvious medical cause of death during postmortem examination; (f) death not resulting from trauma, asphyxia due to aspiration or intractable status epilepticus. SUDEP is considered 'definite' when all criteria are met, and 'probable' when there are no postmortem data. Other definitions of SUDEP exist.[11,12] Some authors use Nashef and Brown's definition of SUDEP,[11] i.e., 'sudden, unexpected, nontraumatic and drowning death in an individual with epilepsy with or without evidence for a seizure and excluding documented status epilepticus, where postmortem examination does not reveal a cause of death'. All definitions share the problem of accurate classification due to insufficient information about the circumstances surrounding death, and to the infrequent practice of postmortem examinations.

SUDEP in surgical candidates and operated patients

A review of 19 studies looking at overall mortality in epilepsy determined that the proportion of SUDEP among all causes of death in surgical candidates or operated patients ranged from 40–77%.[2] The annual incidence of SUDEP was highest in studies of patients who had epilepsy surgery or were surgical candidates (2.2:1000–10:1000) or were undergoing vagus nerve stimulation therapy (4:1000), with a median of 3.6:1000 patient-years.[2] Accordingly, in a review pooling data from all drug-resistant epilepsy series providing detailed numbers of SUDEP and patient-years of follow-up, we found a total of 154 SUDEP among 41, 439 person-years, resulting in a mean annual SUDEP incidence of 3.7/1000.[13] A high number of AEDs, high frequency of seizures, and long duration of epilepsy were found to be more commonly found in high-risk than in low risk populations.[2] In addition, uncontrolled tonic-clonic seizures have been associated with a higher risk of seizure-related death and SUDEP.[6,14] The role of seizures in the pathophysiology of SUDEP is therefore briefly discussed in the next paragraph.

Seizures and SUDEP

Although a detailed account of the pathophysiology of SUDEP is beyond the scope of this chapter, a large body of evidence suggests that SUDEP, although unexpected, is not fully unexplained any more.[15] SUDEP is seizure related in the majority of witnessed cases.[14,16–19] Two major mechanisms have been implicated, one is obstructive or central apnea and neurogenic pulmonary edema.[11,18,20–24] The other is ictal cardiac dysfunction, either through ictal asystole, or ictal cardiac ischemia.[25–29] The cardiac hypothesis of SUDEP has been strenghtened by the detection of potentially fatal asystole in three out of 20 patients with drug-resistant partial epilepsy when examined by implantable loop EKG.[31] Furthermore an

incidence of 0.4 % of ictal asystole has been documented in 1244 video-EEG recordings.[31] Thus, it is not unreasonable to expect that improving seizure control or disease changes associated with better seizure control after epilepsy surgery might reduce mortality. In the following paragraph, we briefly review the evidence that the incidence of SUDEP is actually reduced after surgery for epilepsy.

Does epilepsy surgery lower the incidence of SUDEP?

The impact of resective epilepsy surgery on mortality has been evaluated in several series comparing pre- and postoperative mortality rates (Table 133b.1). Three of these series have concentrated on temporal lobe surgery and demonstrated that the postoperative mortality rate was normal in seizure free patients, whereas it was significantly higher, and comparable to that observed in drug resistant epilepsy cohorts, in patients with poor seizure outcome after surgery.[6,32–33] The authors implied that had surgery not been performed, the patients would have continued to suffer excess mortality, dying at rates similar to patients whose seizures persisted.[6,32–33] This result suggests that successful surgery is associated with dramatic reduction of the risk of epilepsy-related death. However, the authors cautioned that they cannot exclude the possibility that the different responses of their patients to surgery could indicate underlying biological differences that are related to mortality rates.[6,32–33] In fact, other series could not confirm the above findings, and reported comparable death rates in patients with and without postoperative seizure control.[34,33]

In addition, a number of confounding factors need to be considered when examining the relationship between seizure control and mortality after epilepsy surgery. If, for example, mortality is reduced after surgery only in those with complete seizure control, or epilepsy surgery increases mortality in those who remain uncontrolled or the minority with worse control after surgery, the net group effect of surgery on mortality may be small. Furthermore, if the subgroup that responds to surgery had no increased seizure-related mortality to begin with, surgery may have had no effect on mortality even when improving seizure control. Also, theoretically, all-cause mortality may be related to the underlying cause of the epilepsy, and surgery might not be able to completely remove the cause and thus be not able to lower mortality. Finally, reports of survival after epilepsy surgery have been heterogeneous in sample selection, observation periods, analytic methods, choice of comparison groups, and based on small numbers of deaths.[6,34–37] Also, patients were not stratified according to their pre-surgical risk factors for SUDEP or seizure-related death.

Another attempt to study the impact of resective epilepsy surgery on mortality, is to compare cohorts of surgically and medically treated patients. Seven studies have addressed this issue, using various methodologies, and again providing controversial results (Table 133b.2). Only two of the seven series reported a significantly lower death rate in operated patients as compared with those medically treated.[35,39] However, the result by Vickrey and co-workers could be partly explained by preoperative differences between the two populations, including the type of epilepsy (mainly nonlocalized in the medical group and temporal in the operated patients) and the baseline seizure frequency which was significantly higher in the non operated patients.[35] Furthermore, the other five series failed to demonstrate a difference in mortality between operated and nonoperated patients.[37,32,38–42] In the next paragraph we examine the evidence that surgery was in fact responsible for the lower mortality rate reported in some studies.

Table 133b.1 Impact of resective surgery on mortality: seizure-free versus not seizure-free patients

Study population (no. of patients)	SMR: seizure-free patients	SMR: not seizure-free patients	Authors
596 total, 355 TLE	228 at 2 years: 5 died, SMR=3.8 (3 SUDEP);	255 at 2 years: 6 died, SMR=4.3 (3 SUDEP)	Nilsson *et al*. (2003) (ns)
196 total, 106 TLE	69 at 2 years, SMR = 6; no difference	100 at 2 years, SMR = 7.8	Stavem and Guldvog (2005) (ns)
393 TLE	199, no death; significantly lower	194, 11 died, SMR = 4.7 (9 epilepsy related)	Sperling *et al*. (1999) ($p = 0.05$)
215 TLE	148 patients, follow-up: 1–15 years: 3 died, SMR = 1.7 (CI: 0.35–5.0), 1 SUDEP, 1 cancer, 1 suicide; significantly lower	67 patients follow-up: 1-15 years: 8 died, SMR = 7.4 CI: 3.1–14.5); 5 Seizure/ SUDEP, 3 accident/ suicide	Salanova *et al*. (2002) (no Overlap of CI, significant difference)
299 surgical patients	11/13 who died were not seizure free (4 SUDEP (definite and probable), 7 seizure-related)	3/13 who died were seizure free (2 SUDEP, 1 killed by vehicle, seizure-related)	Hennessey *et al*. (1999) (difference)
398 surgical patients	313 with Engel outcome score I, death and SUDEP rate per person-year: 1/535, 0	85 patients with Engel outcome score II–IV, death and SUDEP rate per person-year: 1/81.3, 1/97.6	Sinha *et al*. (2005), ($p = 0.36$)

Abbreviations. SMR = standard mortality ratio per 1000 patient years, SUDEP = sudden unexplained death I epilepsy, TLE = temporal lobe epilepsy.

Table 133b.2 Impact of surgery on mortality: operated versus nonoperated patients

Study population (no. of patients)	SMR: operated patients	SMR: nonoperated patients	Authors
202 surgical vs. 46 nonsurgical patients	14 died (7%) at 6 yr. follow-up	9 died (20%) at average follow-up of 6 yr.	Vickrey *et al*. 1995 ($p<0.01$). Reviewer commentary: cause of death not rigorously ascertained, higher proportion of ongoing seizures in those who died.
196 total, 106 TLE	69 at 2 years, SMR = 6	100 at 2 years, SMR = 7.8	Stavem and Guldvog (2005) (ns)
596 operated patients and 212 nonsurgery patients	596, 14 died, 6 in SUDEP. SMR 4.9 (CI 2.7–8.3). SUDEP incidence 2.4 per 1000 person-years	212, 5 died, 4 in SUDEP, SUDEP incidence: 6.3 per 1000 person-years. SMR for all causes: 7.9 (CI 2.6–8.1)	Nilsson *et al*. (2003) (ns). Reviewer commentary: None of the SUDEP patients was seizure free.
324 TLE	316 at 4.5 years: 12 died, SMR = 1.7 (2 SUDEP, 2 status/seizure related, 1 head injury after falling, 2 medical illness, 2 suicide, 3 cause unknown)	116 at 2 years: 8 died, SMR = 7.4 (2 SUDEP, 1 status, 1 homocide, 1 drowning and medical illness, 2 unknown cause)	Radhakrishnan *et al*. 2005 (abstract) (ns) All cause mortality, $p = 0.218$, for seizure related death only $p = 0.416$)
201 surgical vs. 185 nonsurgical patients			Guldvog *et al*. (1991) (no difference in proportion of patients alive in both groups)
398 surgical vs. 707 patients rejected for surgery	313 with Engel outcome score I (Group A), death and SUDEP rate per person year: 1/535, 0 (Group A). 85 patients with Engel outcome score II–IV, death and SUDEP rate per person year: 1/81.3, 1/97.6 (Group B)	707 patients rejected for surgery (Group C), death and SUDEP rate per person year: 1/59.7, 1/77.2 (Group C)	Sinha *et al*. 775 surgical patients vs. non surgical patients (number not given)	SUDEP rate 0.79/1000 patient years	SUDEP rate 1.1/1000 patient years	Walczak *et al*. (1999) (ns).

Is epilepsy surgery responsible for lower SUDEP rates after surgery? post-hoc or propter-hoc?

It is apparent from the above studies that no consensus emerges regarding the impact of surgery on mortality. As already pointed out, several differences in methodology, type of control population and surgical candidates, are likely to explain the discordant findings observed in the literature. Taking all available data into account, it appears that the main effect which might hold on is the lower risk of seizure-related death in seizure-free patients after temporal lobe surgery, as compared to those who failed to respond to such surgical procedure. However, other series could not confirm the above findings, and found comparable death rates in patients with and without postoperative seizure control.[34,33] Is the lower long-term mortality, in particular SUDEP, reported in some studies, compelling evidence that surgery is in fact responsible for lowering mortality? The attribution of the mortality-lowering effect of surgery rests on the implicit assumption, that prior to surgery, responder and nonresponder to surgery carried a similar risk of mortality. If, for example, those who respond to surgery have a priori a lower mortality, a better postsurgical mortality outcome in surgical responders is no proof for the effect of surgery on mortality. Theoretically, clinical predictors of unfavorable postoperative seizure outcome might also be associated with a higher risk of death, preoperatively. Is there any suggestive evidence that responders may have a lower mortality risk to begin with? In fact, secondary generalized seizures, for example, appear to represent a risk factor for both SUDEP and surgical failure in TLE.[18,19,43–45] Another piece of indirect evidence that patients with a favorable outcome regarding seizures after surgery may have a priori a lower risk of SUDEP comes from Sweden.[46] The authors studied autonomic cardiac control by measuring the heart rate variability prior to surgery and correlated their finding with surgical seizure outcome. Before surgery, the heart rate variability was significantly lower in the patients with ultimately poor outcome (Engel class II–IV) compared with patients with good outcome (Engel Class I). Reduced heart rate variability is a known risk factor for sudden death in nonepileptic patients

with various cardiovascular conditions,[47] and might also be associated with an increased risk for SUDEP.[46] According to these data, surgery candidates with a good outcome may a priori have a lower risk of SUDEP and further suggest that the lower incidence of SUDEP reported after successful surgery may not necessarily be a consequence of the operation.[46]

Support for the view that preoperative differences in risk for cardiovascular death or for SUDEP might exist in patients undergoing resective surgery, comes form a series of publications by Hilz and coworkers.[48,49] They reported that following temporal lobe surgery, there is a reduction of sympathetic cardiovascular modulation and baroreflex sensitivity.[48] More specifically, they suggested that temporal lobe surgery seems to stabilize the cardiovascular control in epilepsy patients by reducing the risk of sympathetically mediated tachyarrhythmias and excessive bradycardiac counter-regulation, both of which might be relevant for the occurrence of SUDEP.[48] In a subsequent publication, Hilz and co-workers studied 16 patients before and after temporal lobe epilepsy surgery and found that sympathetic modulation decreased after surgery in eight patients with good outcome, defined as no seizures in the 10 months after surgery, while it further increased in the group of eight patients with poor surgical outcome.[54] These data support the hypothesis that patients with good seizure outcome (which have been shown to have an improved mortality risk after surgery, as reviewed above) may have had a lower preoperative risk for SUDEP to begin with, and as a consequence it is difficult to attribute the postoperative benefit in mortality outcome to the epilepsy surgery.

The authors have proposed at least two mechanisms to explain the differences in autonomic modulation between patients with good and those with poor outcome of surgery.[49] One, central relay areas of autonomic control areas, such as the amygdala, hippocampus, fronto-orbital cortex, insular cortex, paraventricular or hypothalamic regions are either in close proximity to the epileptogenic zone or part of the pathologic tissue accounting for seizure generation and/or epileptogenesis. Two, interictal EEG activity spreading towards neighboring centers of autonomic control may also interfere with autonomic modulation.[49] The first hypothesis is consistent with the concept of temporal-plus epilepsy which refers to an epileptogenic zone that primarily encompasses the temporal lobe but extends outside the boundary of a standard resection, thus displaying electro-clinical and MRI features highly suggestive of TLE, including signs of hippocampal sclerosis, while usually not responding to anterior temporal lobectomy.[50] The perisylvian region is often involved in this form of epilepsy,[50,51] including two brain structures that might play an important role in the pathophysiology of SUDEP, the insula and the frontal operculum. Electrical stimulation of the precentral operculum has proved to elicit apnoea in patients with epilepsy,[52] whereas insults to the insular cortex appear to promote cerebrogenic sudden death.[53] However, despite clear indications that the insular cortex regulates cardiovascular function in animals and humans,[26,53] only scarce data are yet available regarding its implication in severe ictal arrhythmias or SUDEP.[54–56]

Coming back to our discussion that preoperative differences in risk for SUDEP might exist, it is of particular interest that the eight patients with good outcome of surgery had shown better results in spectral powers of autonomic heart rat modulation *prior* to surgery than those with poor outcome.[49] Although the number of patients was small and the postoperative follow-up was short, these results seem to support our hypothesis that postsurgical reduction in SUDEP rates might be preferentially seen in those with a lower risk for SUDEP prior to surgery. Conversely, augmented sympathetic modulation was seen in patients with persistent seizures after surgery.[49] The authors also suggest that these data indicate an increased cardiovascular risk or risk in SUDEP in patients with poor outcome of epilepsy surgery.[49] Furthermore, anecdotal reports of SUDEP after successful anterior temporal lobectomy suggest that the mechanism leading to SUDEP cannot be halted by successful epilepsy surgery in all cases.[57] In the series by Hennessy *et al.* (1999), the mortality including SUDEP rate of patients with right sided mesial temporal sclerosis remained considerably elevated after surgery (SMR 32, 95% confidence intervals: 24.7–40.5, SUDEP 1: 134 patient-years). In that respect it is of interest to note that in a series from Austria, surgical candidates with right mesial temporal sclerosis had the highest rate of ictal and postictal tachycardia.[58]

If, in fact, the preoperative risk of death is higher in patients who will eventually fail to respond to temporal lobe surgery as compared to the other patients, one could reconcile the positive findings reported in temporal lobe surgery series and the negative results of studies which have compared surgically and medically-treated patients. However, it remains unclear if epilepsy surgery contributes to improved long-term survival in cohorts with severe epilepsy. This controversy has recently been underscored in a review article.[13] Unfortunately, testing this hypothesis remains elusive at the present time mainly for two reasons. One, we cannot precisely anticipate the postoperative seizure outcome prior to surgery as discussed by Ryvlin and Kahane (2005). Two, no large series of surgical outcome exist which have included a stratification for low or high pre-surgical risk for SUDEP.[50]

Neurostimulation and SUDEP

In a cohort of 1819 patients drawn from the pre-FDA approval clinical research trials and the manufacturer's records undergoing vagus nerve stimulation (VNS) for treatment of refractory epilepsy. In the 1819 patients who were followed for 3176 patient-years from implantation, the SUDEP rates were 4.1 per 1000 patient years.[59] The mortality and SUDEP rates are similar to those reported from clinical trials of new drugs and cohorts of severe epilepsy. However when the authors stratified the data by duration of use, the rate of SUDEP was 5.5 per 1000 over the first two years, but only 1.7 per 1000 thereafter.[59] The authors concluded that the lower SUDEP rates after two years of VNS were intriguing, but required further study.[59] If responders to VNS carry a lower risk of SUDEP prior to implantation they have not been examined, to our knowledge.

Conclusions and summary

Several, but not all, series have reported reduced death and SUDEP rates in patients rendered seizure free by epilepsy surgery, whereas those who continue to suffer recurrent seizures postoperatively had an increased mortality comparable to that

observed in medically-treated drug resistant epilepsy or patients rejected for epilepsy surgery. However, in view of many confounding factors, most notably the emerging evidence that those with good seizure outcome after surgery may have lower death and SUDEP risk to begin with, i.e., prior to surgery, the exact contribution of epilepsy surgery for the lower rate of SUDEP observed after surgery needs to be determined. Another unresolved issue is whether some surgical patients will have an increased risk of SUDEP compared to nonsurgical controls with refractory epilepsy. Finally, it is tempting to speculate that the mechanisms responsible for surgical intractability may also regulate the risk of seizure-related mortality, particularly of SUDEP. Once we are able to better predict surgical seizure outcome, we may also gain a better understanding of the mechanism(s) involved in lowering the risk of SUDEP after surgery.

134 Psychosocial outcome and quality of life outcome

NK So and CB Dodrill

Introduction

Common questions asked by patients before epilepsy surgery can be separated into those on the potential for a positive outcome and those on the risk of an adverse effect. Positive outcomes include seizure control, the possibility of a reduction or withdrawal of antiepileptic medications, retention of employment or the hope of new employment and a better job, the ability to drive, improvement in independent function in the community, and a better social relationship with family and friends. Adverse effects include pain and suffering, neurological deficits, impairment of memory and cognition, negative change in mood and personality, loss of independence and death.

This chapter deals with one of the most important outcomes of epilepsy surgery, the impacts of this surgery upon one's quality of life (QOL), especially in a social context. So important is this area, that one could even argue that if the surgery does not have a positive impact upon the quality of the patient's life that indeed it has failed.

We begin this chapter with a review of some of the most salient studies dealing with epilepsy surgery and quality of life overall. We then go on to specific topics of interest within the psychosocial and QOL domains, and we present some of our own data, not heretofore published, to support the conclusions we have drawn. Finally, we offer some guidelines to where research in this area might profitably go in the future.

Basic studies of general interest

What do we know of the concerns of patients with epilepsy outside of the routine clinical encounter? In particular, what do we know about psychosocial and QOL concerns? A Concerns Index has been developed with the Epilepsy Foundation of America, and studied in patients both before and after epilepsy surgery.[1] The Concerns Index was developed in two parts. First 81 patients with chronic epilepsy listed concerns in order of importance. Then experts selected items to construct a 20-item questionnaire. There are pertinent questions on driving, injury from seizures, job status, cognitive function, mood state and social function. Sixteen of 20 concerns were significantly reduced in a group of patients who had received anterior temporal resections, against a comparison group of patients awaiting surgery. However, the Concerns Index does not answer what epilepsy surgery patients actually seek out as the desired goals of surgery.

In fact, the desired goals expressed by patients about to undergo epilepsy surgery seem both logical and consistent across the world. One study from Australia specifically asked epilepsy surgery candidates 'What is the main reason you have sought surgical intervention?'[2] In order of descending rank, patients ranked firstly seizure control (62%), then driving (45%), new activities (38%), employment opportunities (35%), as the main goals for seeking surgery. In the Bonn series,[3] the top 4 motives for surgery in descending order were: seizure control, independence, medication reduction, and improvement in vocational performance. In an Irish study,[4] the most frequently cited aims for surgery in 69 preoperative patients were: gains in employment, driving, independence, improved socialization, and medication reduction.

In a study from the United Kingdom, the expectations of 70 presurgical candidates were studied by asking how they believed they would be on several self-report scales if surgery were successful in stopping their seizures.[5] Preoperative patients had expectations that they would be in better control, and have better memory, more happiness, more independence, more interest in life, more hope, and to be more skillful and to be of greater value after successful surgery. The preoperative profiles were then compared to the self-ratings of 22 seizure-free patients 1 year after actual surgery. It showed that the presurgical expectations exceeded that reported by successful surgery patients 1 year after operation for several areas, such as interest in life, happiness, independence, and memory. This is a reminder that as in many areas of human psychology, expectations may exceed actual experience and that it could be important to counsel patients accordingly.

Outcomes after surgery can be divided into those based on observable measures, and those that are self-perceived. To understand the full impact of epilepsy surgery, both are needed. By observable measures we mean a quantity or status that some person other than the patient can appreciate. They include the core outcomes of seizure control, vocational and educational status, driving status, neuropsychological performance, neuropsychiatric behavioral changes, morbidity, and mortality.

However, other aspects of outcome, such as a patient's own sense of independence, or success in social relationships, are not so easy to quantify in the eyes of an observer. Similarly, the sense of self-worth is one that can only be made by the subject. Hence the measurement of self-perceived health status has become an important science.[6,7] Separate from numerical measures of disease burden, health-related quality of life

(QOL) scales look at self-perceived sense of wellbeing in the major domains of physical health, mental health, social function, and general health. These are based on self-report questionnaires as distinct from classifications by an observer or investigator. It is beyond the scope of this chapter to discuss the background and processes leading to the development of the major measuring instruments in use except to point out that they need to satisfy the requirements of reliability, validity, and practicality. Reliability is the ability to measure variance that is not due to random error. Validity is the degree that the measure reflects the quality being assessed and not some other. Practicality or feasibility concerns the application of the instrument in real life, and includes the use of questions that can be clearly understood, and a form of administration that is not too burdensome.

The different measurement instruments and scales in use for assessing quality of life outcome after epilepsy surgery can be broadly separated into three groups. First, generic scales used in general health research which are not disease specific. Probably the most well known is the SF-36 of the RAND General Health Scales. Others include some of the instruments developed by the World Health Organization, such as the Quality of Life Assessment (WHOQOL) in its various forms. Second, are epilepsy specific scales. The first to be developed and used extensively was the Washington Psychosocial Seizure Inventory (WPSI).[8] Adapted with epilepsy-specific questions, but built on the RAND SF-36 is the Epilepsy Surgery Inventory (ESI-55),[9] containing 11 subscales covering a range of functions. Of the 55 items, 36 belong in the RAND SF-36, while 19 are specific to epilepsy concerns. Another more extensive instrument is the Quality of in Life in Epilepsy (QOLIE)-89,[10] which contains 89 questions. It includes the RAND SF-36 items, as well as selected items from ESI-55, and further expanded with additional questions. Others are sometimes specific to established use in different countries or regions, such as the Quality of Life Assessment Schedule (QOLAS), or EuroQol (EQ-5D).[11] Third, are those borrowed from other disciplines but thought also important in patients with epilepsy. Many are from the mental health world, such as the Beck Inventories for Depression (BDI), and for Anxiety (BAI), Hospital Anxiety and Depression Scales (HAD), Katz Adjustment Scales (KAS), Minnesota Multiphasic Personality Inventory (MMPI), the Brief Psychiatric Rating Scale, and numerous others.

Course of postoperative change

Changes in psychosocial and QOL functioning as demonstrated on any of the measures, whether observable or self-perceived, can certainly be expected to evolve over time. At what time point or points, should we gather the data? Is there a necessary time latency before changes become evident? The preoperative to postoperative interval over which measures were compared varied tremendously from as short as 2 weeks[12] to more than 30 years.[13] More commonly, intervals chosen were at 1, 2 and 5 years, when patients were contacted both for information on seizure control and psychosocial outcomes.

At 3 months after surgery, some patients still have not completed basic healing, may have headaches and other symptoms related to surgery, and may still lack stamina to return to all customary activities. This may seem too short an interval to determine postsurgical outcomes. Nevertheless, some studies had shown a divergence from preoperative quality of life even 3 months after surgery.[14,15] It is unclear whether expectations for a positive outcome rather than actual life changes could have accounted for that. It is clearly too early to talk about gains in employment or independence just 3 months after surgery. Even at 6 months, while surgical healing is likely complete and most patients have resumed customary activities, there is question whether it may be premature to determine psychosocial outcome. For instance, while the commonest seizure-free interval required by driving licensing authorities in the US is 6 months, some require 12 months of seizure control before driving is permitted. Successful employment is another area that can take a longer time frame. The study by McLachlan *et al.*[16] looked at QOL (ESI-55) at 6, 12, and 24 months in a group of patients who had undergone anterior temporal resection as compared to a medically managed group with similar disease severity. The study showed that significant differences in mean and several subscales in self-reported QOL between surgical and medical groups were greater at 24 months follow-up than at 6 or 12 months. A group time effect was also reported by Markand *et al.*[17] There was greater improvement at 2-years than at 1-year follow-up. It is possible that changes in psychosocial status can continue after 24 months. By 5 and 10 years after surgery, a period of stability is more likely to have been established. At the other extreme, when follow-up extends to 30 or more years, new uncontrolled variables can be introduced, such as the appearance of new comorbid conditions that can contaminate the effect of surgery. In the case of children who received surgical treatment while still at school and receiving vocational training, there is a need for longer follow-up studies to learn of the impact of surgery on the maturing brain and personal development.

Bladin and Wilson in Australia,[18,19] have stressed that the patient undergoes major adjustments after a major medical intervention that epilepsy surgery represents. The very relief obtained after seizure control is attained, transforming a life of chronic illness to one of relative well-being, can itself lead to new challenges. This challenge, 'the burden of normality', can lead to maladaptive psychosocial changes that are not anticipated. They reported that 35% of patients rendered seizure free experienced problems related to changing family dynamics, sometimes resulting in divorce. Another 20% of patients and families reported behavioral problems in dealing with the seizure-free state. Indeed, for many patients in whom epilepsy started relatively early in their life, their whole life had been on hold or constrained. Educational learning and life skills have been frequently compromised, and it may or may not have been possible to develop normal social relationships or work habits in the years of intractable epilepsy. Many have in addition to intractable epilepsy significant cognitive impairments that affect performance and judgment. The loss of disability income and social support can become a stressor. What has passed for the presurgical fabric of life may be a construct rather different from that in normal individuals without chronic illnesses. When that presurgical fabric of accommodation is transformed by complete seizure control, the set of complicated adaptations may unravel.

Seizure relief and other predictors of outcome

A reasonable expectation is that any improvement in psychosocial functioning and QOL after epilepsy surgery will reflect relief from seizures. Indeed, relief from seizures has been posited to be so important that unless there is complete relief, significant improvement in psychosocial functioning cannot be expected.[20,21] As can be seen in Table 134.2 and in a later section, this relationship has been repeated affirmed in many studies. Furthermore, when seizure-outcome groups are stratified, the changes in QOL are graduated, with the best outcome in the completely seizure-free (and aura-free) group, next in those with residual auras, who in turn do better than those with a few seizures each year.[15,17,22]

Other presurgical factors that might influence postoperative psychosocial outcome have not been consistently examined. In particular, the strong correlation between neuropsychological measures of mood and QOL measures[23] makes one wonder how premorbid mood status determines outcome after surgery. The reverse has been studied. One study found that preoperative scores on the emotional adjustment scale of the WPSI were highly correlated with subsequent depression.[24] Higher age at surgery was found to be negatively correlated with QOL measures in one study,[15] but not in another.[22] A single study reported that a higher presurgical IQ score correlated with better psychosocial outcome.[25]

It is also of interest to ask if subjects with high self-ratings in function are the ones most likely to report continued wellbeing. This seems to be trend in employment, those already in employment before surgery are most likely to remain employed or to make gains in work status.

Long-term outcome 5 and 10 years after surgery at University of Washington

The University of Washington (UW) Regional Epilepsy Center prospectively performed neurological, neuropsychological, psychosocial, and EEG evaluations on 108 adults (age 16 and over; 55 women, 53 men; 94 right-handed, 14 left-handed; 107 Caucasian) with surgery on the left in 55 cases and on the right in 53 cases. Seventy-four of these patients were re-evaluated 5 years (± 6 months) after their surgeries and the remaining 34 patients were evaluated 10 years (± 6 months) after their surgeries. Preoperatively and at follow-up, patients were administered the Washington Psychosocial Seizure Inventory. Patients were divided across seizure outcome groups (Seizure free – no seizures whatever in the last 2 years of follow-up (n=53 total for both 5- and 10-year groups); significantly improved – at least a 75% improvement in the last 2 years of follow-up in comparison with the 2 years prior to surgery (n=30); not significantly improved – less than a 75% improvement in seizure frequency (n=25).

With the 5-year and 10-year groups combined, the preoperative and postoperative scores for the seizure-free patients on the WPSI are shown in Figure 134.1 using the paired Student *t* statistic applied to each variable independently with

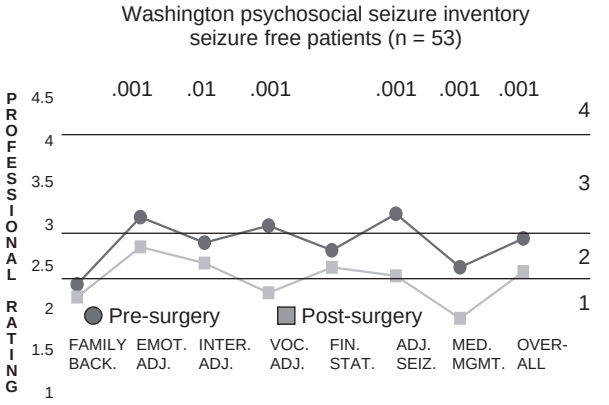

Figure 134.1 Preoperative and 5–10-year postoperative scores on the WPSI for the 53 patients who became seizure free. Improvements (lower scores) were noted on six of the eight clinical scales of the WPSI at the.01 level or better.

statistical significance set at the.01 level or better. Statically better (lower) scores were obtained on six of the eight WPSI scales with substantial differences noted in all psychosocial areas except for family background and financial status. As would be expected, these are the areas that would be most difficult to change after surgery.

Figure 134.2 presents the results on the significantly improved patients. As can be seen, there are fewer statistically significant changes demonstrated on the WPSI and they were at levels less confidently associated with change from a statistical viewpoint. Nevertheless, they are convincingly greater changes than those of the not significantly improved group which are presented in Figure 134.3 where the changes seem to be little more than random fluctuations from one time to the next.

One can see that the results presented here are at deviance from other studies which showed no improvement in psychosocial function after surgery unless relief from surgery was complete. Several factors may be operative here, illustrating the complexity of their interactions. Those studies that have argued for complete seizure relief as the only important determinant have tended to lack the numbers to do detailed

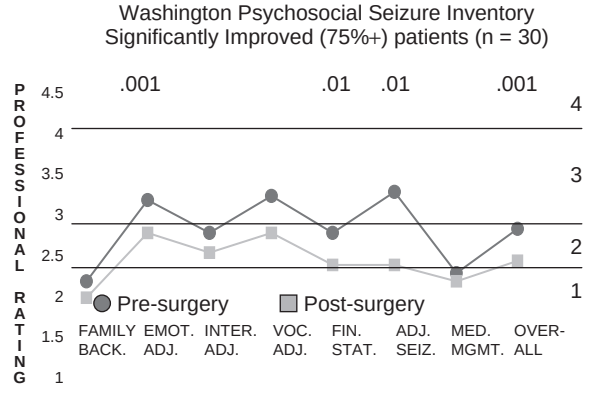

Figure 134.2 Preoperative and 5–10-year postoperative scores on the WPSI for the 30 patients who had significant improvement in their seizure frequencies (at least 75%). Improvements (lower scores) were noted on four of the eight clinical scales of the WPSI at the.01 level or better.

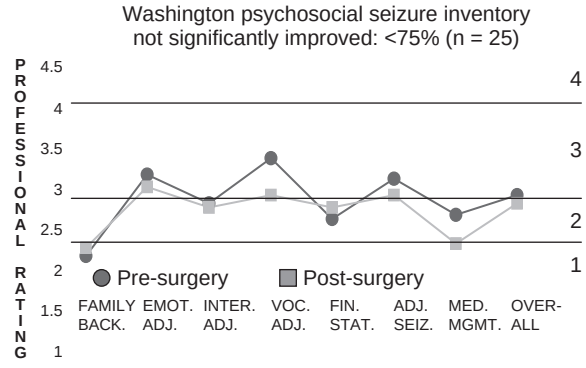

Figure 134.3 Preoperative and 5–10-year postoperative scores on the WPSI for the 25 patients who had no significant improvement in their seizure frequencies (less than 75%). Improvements (lower scores) were not observed on any of the eight clinical scales of the WPSI at the.01 level or better.

stratification of seizure status or did not take the extra steps to do so. We already mentioned other studies which showed that QOL improvements were incremental over a range of seizure outcomes.[15,21,22] Two other factors are specific to the UW study. One is the extended length of postoperative follow-up of 5 and 10 years. This is anticipated to produce a more stable state that takes into account some earlier years of adjustment. Another is the type of psychosocial measure used. The WPSI was developed on an empirical basis, with every item anchored in performance in everyday life as judged by professionals.[8] It was specifically not developed on the basis of an approach whereupon items are placed in groups based upon apparent content. It was also not developed on the basis of factor-analysis, a subjectively-based procedure which is not externally anchored, with factor names which are also not empirically anchored. As a consequence, less obvious changes in functioning may be missed.

Medication status after surgery

In general, patients who have had surgery, are either receiving fewer antiepileptic medications or are more likely to be on no medications in the postoperative period (Table 134.1). This is not too surprising, and undoubtedly strongly biased by patients who have been able to stop medications after becoming completely seizure free. Even though there is no set common protocol to discontinue antiepileptic drugs, particularly in light of follow-up information which showed that medication discontinuation carries a real risk of seizure relapse in those who initially appeared seizure free, many patients would nevertheless act on their own and taper and go off medical therapy when they judge themselves to be free of seizures. Even cautious clinicians who might not suggest to their patients that they should discontinue medications would still agree to a reduction in the number or dosage of drugs when patients are doing well.

Employment

Many but not all studies reported gains in employment status after epilepsy surgery. The most compelling were those that also compared surgically treated patients with a nonsurgical control group.[1,13,25,27,30,32] Whenever additional enquiries had been made on the determinants that may influence employment after surgery, two have consistently been affirmed. One is that the employment status after surgery is correlated to whether the individual has been working, full-time or at least part-time before surgery.[3,26,29] The other is that a gain in employment is strongly influenced by the seizure outcome, and that only seizure-free individuals are likely to maintain or gain new employment (Table 134.1). One study not only looked at improvements in employment and psychosocial status, but also at deterioration and reported that 94% of

Table 134.1 Effects of epilepsy surgery on antiepileptic medication (AED) status and employment status

Study	Medication status	Employment status
Augustine *et al*. 1984[26]	(not studied)	Improved employment Unemployment related to preoperative unemployment, disability payments, psychiatric disease
Guldvog *et al*. 1991*[13]	More likely off AEDs	Improved working ability in surgery group
Vickrey *et al*. 1995*[27]	Reduced AED	Non-significant trend towards improved employment
Sperling *et al*. 1995[28]	(not studied)	Improved in seizure-free patients And younger age at surgery
McLachlan *et al*. 1997*[16]	Reduced AED	(not studied)
Reeves *et al*. 1997[29]	(not studied)	Trend for improvement, correlated with ongoing education and full-time employment before surgery
Lendt, *et al*. 1997[3]	(not studied)	Overall improvement, Correlatied with seizure-free status
Kellet *et al*. 1997*[30]	(not studied)	Improved in surgery group if seizure free
Gilliam *et al*. 1999*[1]	Seizure-free more likely off AED	No significant improvement
Markand *et al*. 2000*[17]	Reduced AED	(not studied)
Jones *et al*. 2002*[25]	(not studies)	Improved in surgery group Best when seizure free
Lowe *et al*. 2004[31]	Seizure-free more likely off AED	(not studied)

*with a non-surgical comparison group

patients who suffered deterioration had continued seizures after surgery.[3]

In one study,[29] being a student before surgery or obtaining further education after surgery were factors associated with employment after surgery. In two studies,[3,28] age at surgery influenced outcome in that patients who remained unemployed after surgery were more likely to have been operated on later compared to those who became employed. This is a pointer perhaps to the importance of early intervention to permit not only the restoration of physical wellbeing, but also to allow a younger person the chance to gain or regain the educational and social skills that are a prerequisite to successful employment. By contrast, those already on disability payments before surgery were less likely to be employed afterwards.[26] It is not clear if those on disability payment before had more severe disease, more severe limitation in skills, or whether being established on disability payment itself served as a disincentive to return to the workforce.

School and education

Long-term studies of children or adolescents who received epilepsy surgery are relatively small in number and very different in design.[33] It is difficult to draw conclusions on the effect of surgery on the educational and psychosocial outcome of children and adolescents based on these reports. Only two used a QOL questionnaire with both preoperative and postoperative assessments but did not specifically discuss educational outcomes.[34,35] The largest series of 50 patients who had temporal lobectomy in childhood from Mayo Clinic reported that 34 were either in school or employed at the time of follow-up.[36] Guldvog reported on the educational attainments of a cohort from Norway who had epilepsy surgery, as compared with a matching medically treated group.[13] In looking just at patients who were still receiving education at the time of intervention, there was no significant difference in the length of education attained in the two groups. If anything, more surgically treated patients dropped out of school before having completed 7 years of education as compared to medical controls.

The lack of clarity in the literature more likely reflects on deficient data rather than lack of an effect. Many who have guided youngsters through successful surgery have been impressed by the transformation in behavior and attention that makes for enhanced learning at school. For those treated at a later stage in formal education, it could mean the difference between success or failure in graduation and certification.

Driving

Several studies specifically gathered information on driving status before and after surgery. This might be considered a relatively trivial matter in parts of the world where public transport is the norm. However, the privilege of driving is a vital part of independent living and a basis for work in most parts of North America. The Mayo Clinic series reported that the percentage of patients driving went from 20% preoperatively to 79% postoperatively.[29] Gilliam reported that 60% of patients were driving after surgery, while only 27% were able to do so preoperatively.[1] Again the seizure outcome after surgery is the major determinant, since all driving authorities base the decision to issue a license on establishment of seizure control. Thus while 64% of patients who were seizure free successfully got a license postoperatively, none of the patients who continued to have seizures were able to do so.[37]

Neuropsychiatric status

The Multi-Center Study on Epilepsy Surgery has provided the largest cohort of patients followed for psychiatric status before and after epilepsy surgery.[38] A total of 360 patients made self-reports using the Beck Depression Inventory, and the Beck Anxiety Inventory, and were administered the Composite International Diagnostic Interview, before surgery, and at 3, 12, and 24 months after surgery. The study confirmed significant overall improvement in symptoms of depression and anxiety after surgery, in keeping with prior reports. The decline in self-reported depression and anxiety was apparent as early as 3 months after surgery. Symptoms of depression and anxiety, present in 22.1% and 24.7% of preoperative patients respectively, declined by almost 50% postoperatively. Seizure control was significantly ($p=.02$) correlated with rates of postoperative depression: moderate to severe depression was present in 8.2% of seizure-free patients as against 17.6% of patients with continuing seizures. There is a similar but not statistically significant trend ($p=.09$) for postoperative anxiety. Localization or lateralization of the seizure focus were not correlated with depression or anxiety before or after operation.

The overall improvement in depression and anxiety after surgery can yet overlook two developments. First, a transient increase in symptoms in the first few weeks to months after surgery which fortunately resolve just as rapidly, with or without the use of psychotropic medications. Second, development of de novo psychiatric illnesses. One study reported that close to 50% of patients developed depression, anxiety, or mood lability in the the first few weeks after surgery. Bladin reported that 54% developed anxiety in the postoperative period.[17] Many of the patients improved within the first year. Certainly patients should be counseled before surgery that depression and anxiety can arise in the postoperative period, and offered treatment when indicated.

The literature on the de novo development of major psychiatric illness after epilepsy surgery is a long one. It includes historical hypotheses that are controversial. One is the concept of 'forced normalization' that describes the emergence of psychosis after the cessation of seizures, and others relate to the correlation of psychopathology to brain laterality, with schizophreniform symptoms linked to the dominant hemisphere, while mania and depression were linked to the nondominant hemisphere. Many of the observations were in the form of uncontrolled case series. Thus the frequency or incidence of such problems was unclear in the earlier reports. The latest Multi-Center Study yielded a de novo rate of 7.9% for depression, 9% for anxiety, and 1.1% for psychosis (mania, schizophrenia) in postoperative patients who did not have these manifestations before.[38] However, another series of 100 consecutive patients who had temporal lobe resections at a major center in Germany,[39] gave a somewhat higher incidence of de novo psychosis (11%), although the rate of

major depression (9%) was similar to that in the Multi-Center Study. The patients who developed postoperative psychosis were all rated to have had personality disorders before surgery, and some had persisting seizures while others were seizure free.

In the Norwegian study that compared 201 surgical patients to a medical control group of 185 patients, 6.7% of the surgical group developed de novo psychosis, while none occurred in the medical group. It is not clear whether the lower rate of postsurgical psychosis in the Multi-Center Study from the USA reflects different patient selection criteria between the USA and Europe, or differences in methodology in psychiatric evaluation.

Mortality

Patients with refractory epilepsy such as those who are candidates for surgical treatment are known to be at an increased risk for death. Often these are in the form of sudden unexplained death (or SUDEP) in addition to known accidents, suicide, or concurrent illness. Although the range of estimates for mortality can be large, the standard mortality ratio for patients with uncontrolled seizures at referral centers is close to 5, translating into an overall mortality of 1.3 per 100 person-years.[41]

In the Norwegian study, the survival of surgery patients was compared to those of medical controls.[40] There was no difference between the groups. However the effect of complete seizure control was not analyzed. A UCLA cohort of surgical versus non-surgical patients showed that surgically treated patients had significantly reduced mortality.[42] The most complete follow-up data on mortality after epilepsy surgery had been that reported by Sperling over the years.[43,44] In both the 1999 and 2005 reports, patients with recurrent seizures had significantly higher mortality (1.14–1.37 per 100 person-years) as compared with those who were seizure free (except for auras). Seizure-free patients had a mortality rate similar to that of the age- and sex-matched population at large. In short, persistent seizures after surgery are associated with an increased mortality rate similar to that of medically refractory patients, while successful epilepsy surgery normalized the risk.

Outcomes from quality of life scales

There has been a growth of interest in the assessment of quality of life by self-report questionnaires in the last decade. Selected findings from studies reporting on larger sample sizes are included in Table 134.2.

Table 134.2 Effects of epilepsy surgery on quality of life (QOL) measurements

Study	Surgery (n)	Control (n)	Measure	Follow-up	Results
Dodrill 1987[45]	60	–	WPSI	1 yr	Improvement in 5/8 scales
Vickrey 1995a[27]	202	46	ESI-55 KAS	Mean 5.8 yrs	Improvement in 5/11 scales
Vickrey 1995b[21]	133	–	ESI-55	> 1 yr	Improvement: seizure-free aura-free > aura-free > continuing seizures
McLachlan 1997[16]	51	21	ESI-55	6, 12, 24 months	Improvement in 6/11 scales at 24 m, better than at 6 or 12 m. Improved when seizure free or 90% reduction. Decline in others
Kellet 1997[30]	94	36	Various	> 1 yr	Improvement when seizure free v 10 seizures a year or no surgery
Malmgren 1997[46]	103	–	SF-36 HAD	> 2 yrs mean 4 yrs	Correlation with seizure outcome Seizure free: improved 7/8 scales
Wheelock 1998[21]	79	–	MMPI WPSI	2 m 1 yr	Improved only when seizure free
Gilliam 1999[1]	125	71	ESI-55	> 1 yr	Improved 8/11 scales Correlation with mood, employment, driving, AED use but not seizure status
Selai 2000[11]	25	15	QOLAS ESI-55 EQ-5D	Mean 1 yr	Improved 2/3 ESI-55 composite scores and QOLAS when seizure free or >75% seizure reduction
Markand 2000[17]	53	37	QOLIE-89	1, 2 yrs	Improved 10/17 scales Greater improvement at 2 yrs v 1 yr Seizure free aura free best outcome
Wiebe 2001[14]	40	40	QLIE-89	1 yr	Surgery group improved more than medical group
Spencer 2003[15]	231	–	QOLIE-89 BAI, BDI	> 2 yrs	Improvement apparent at 3 mo's Correlation with seizure outcome
Lowe 2004[31]	50	–	QOLIE-89	>2 yrs	Improvement when seizure free

For abbreviations of QOL instruments, see pages 5,6

All studies have shown an improvement in usually more than one quality of life domains. Some have shown an improvement as early as 3 months,[14,15] while two reports noted that improvement was greater at 24 months than at earlier time points.[16,17] Half of the studies employed a 'control' or comparison group of patients who did not have surgery: either because they did not have a localizable epileptogenic zone amenable for surgery, or because candidates declined surgery or were still awaiting surgery. All except one study[1] that specifically looked at the relationship between postoperative seizure control and QOL outcomes revealed a correlation between postoperative seizure status and QOL measurements: namely that a seizure-free status, or very few seizures, were correlated with higher QOL scores. The most detailed analysis of postoperative seizure outcome status with QOL measurements was that by Vickery based on UCLA data.[22] It showed significantly higher QOL scores in patients who were completely free of seizures and auras (Engel Class Ia), as compared to those who had residual auras, who in term were separable in QOL measures from those with 2–12 seizures a year, and from those with >12 seizures a year. The latter had the lowest scores. Of interest, the study found no difference in QOL measure amongst seizure-free patients whether they remained on antiepileptic medications or not. That seizure-free and aura-free patients had the most pronounced improvement in QOL was confirmed by another study.[17]

There have been gratifyingly few indicators pointing to deterioration in psychosocial functioning after surgery, but it could be that this has not been looked into carefully. In order to answer this and other questions an ideal study would comprise both a surgery and medical treatment arm, with sequential QOL measures over time, starting at baseline before intervention. The one study that satisfied this design did not have the details to address this issue.[14] Anecdotal clinical experience suggests that deterioration in psychosocial function does unfortunately occur in a minority of patients, usually in those who have failed to obtain satisfactory seizure control sometimes with compounding neurological or cognitive deficits. Partial support comes from the Bonn series that found socioeconomic deterioration when it occurs to be related to insufficient seizure control.[3] Markand[17] found the only significant decline in QOL scores from baseline in patients with persisting seizures (not including auras) and that was in the social support domain of the QOLIE-89.

Summary

There is now a wealth of data that can be called on when counseling patients going through surgical evaluation and treatment. In addition to and in consequence of an improvement in seizure control, patients can rightfully anticipate an improvement in the potential to participate in the full range of life activities, which can extend to work and driving. As would seem to be obvious, seizure-free patients would no longer be exposed to the risk of sudden death as compared to those with continuing seizures. How long it takes for the positive benefits of epilepsy surgery to become apparent remains a subject of enquiry. Although some studies showed an improvement as early as 3 months after surgery, gains in life functions and employment will likely take much longer. Despite the consensus for positive change after successful surgery, we need to be mindful that there are others who can be unsettled or challenged by changes that come about after surgery.

135 Neuropsychological outcome

WB Barr

Introduction

It is known that up to 60–80% of those patients undergoing surgical treatment for partial epilepsy with a well-defined seizure focus will become seizure free following surgery.[1] However, it is also acknowledged that 25–40% of these individuals will also experience a postoperative decline in memory, language, or some other aspect of cognitive functioning. This chapter will review an evolving literature demonstrating how results from presurgical neuropsychological testing, combined with demographic variables and other neurodiagnostic findings, are useful for predicting which patients are at greatest risk for developing a postoperative drop in neuropsychological functioning. The current review will, in a manner that is consistent with the available literature, emphasize findings from studies of adults undergoing temporal lobe resection.

Neuropsychological testing, as a methodology, has provided valuable information regarding the effects of epilepsy surgery. This type of testing has proven critical to the operation of any epilepsy center. Findings from the original Maudsley series, published over 50 years ago, demonstrated postoperative memory changes in a subset of patients undergoing temporal lobectomy.[2,3] More details regarding the nature of these memory changes have described in an elegant series of studies performed by Brenda Milner and her colleagues at the Montreal Neurological Institute.[4,5] These studies brought attention to the fact that not all patients experience the same cognitive outcome from surgery and that a number of surgical variables, such as side and extent of the surgical resection, can be used to predict what types of deficits might be observed afterwards. Studies from the 1970s and 1980s demonstrated that the degree of postsurgical deficit often related to surgical outcome, as defined by a reduction in seizure frequency.[6] An interesting finding provided by Novelly and colleagues at Yale University, indicated that postsurgical deficits associated with functions of the surgical hemisphere were, in some cases, accompanied by concurrent improvement in functions in the opposite hemisphere.[7]

The fact is that most types of epilepsy surgery involve resection of brain areas considered important for normal memory processing. Emphasis has thus been placed on predicting memory outcome, with results indicating that a considerable number of patients may experience a decline in some aspect of language or cognitive functioning following standard procedures for anterior temporal lobectomy (ATL). Development of global amnestic syndromes was reported in some early series[8,9], but the occurrence of such devastating impairments in memory is now estimated to appear in less than 1% of cases after utilizing a number of methods to prevent its occurrence.[10] Predicting other types of neuropsychological deficits is generally based on brain topography and what is known about the functional neuroanatomy of the brain. Changes in executive functions and behavior are generally predicted when surgery is performed on the frontal lobes. Deficits in other functions, such as perception and higher-order sensory functions are seen in some cases involving surgery of more posterior brain regions.

Postoperative deficits in language and related functions are a natural concern when one is performing surgery on traditional 'language zones' of the dominant hemisphere. Many surgical centers make great efforts to ascertain the site and nature of cortical language representation using procedures such as the intracarotid amobarbital procedure (IAP) or intracranial language mapping either intraoperatively or through stimulation of subdural grids. Many are now also using newer techniques such as functional magnetic resonance imaging (fMRI) and magnetoencephalograpy (MEG) for evaluating hemispheric representation of language.

The prediction of postoperative memory decline has received the most attention and has been guided by two basic theoretical approaches, with both based on findings from neuropsychological research. One is based on Milner's[11] initial observation that material-specific memory deficits in verbal and nonverbal memory will be observed following surgery on the left (dominant) and right (nondominant) temporal lobes respectively. The second is based on a model developed by Chelune,[12] predicting that the degree of postoperative memory deficit, as well as seizure outcome itself, will be determined by the 'functional adequacy' of the tissue to be resected.

An analysis of material-specific memory findings, as predicted by Milner's model, is included in nearly every neuropsychological study of postoperative outcome. The conclusion drawn from recent reviews of the literature is that there is strong empirical support for the link between surgery on the left temporal lobe and postoperative deficits in verbal memory.[13] However, there is substantially less support for the proposed relationship between nonverbal memory impairment and surgery on the right temporal lobe.[13,14] Effects sizes from a recent meta-analytic study of verbal and nonverbal memory scores from Wechsler Memory Scale are depicted in Figure 135.1. The findings from a variety of sources thus demonstrate that patients undergoing surgical resection of the language dominant hemisphere are at the greatest level of

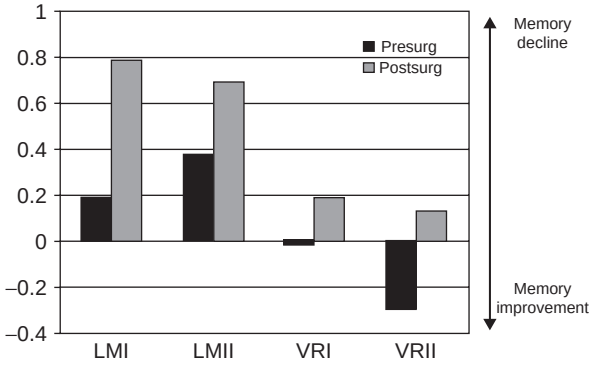

Figure 135.1 Effect sizes from 33 studies assessing verbal and nonverbal memory performances before and after temporal lobectomy (Adapted from Lee, Yip, and Jones-Gotman).[13]

risk for undergoing an identifiable decline in postoperative memory functioning.

For years, it was unclear whether prediction on postoperative cognitive outcome should be based on observation of the functioning of the side that was to be resected or the side that would remain following surgery. Initial studies using the IAP focused on information on functioning from the side contralateral to surgery to predict whether a patient was at risk for developing a postsurgical amnestic syndrome. However, results from subsequent studies using neuropsychological testing in conjunction with information from the IAP, neuroimaging, and histological analyses, has indicated that the functions of the side to be resected is an important factor to consider in predicting a patient's postoperative level of functioning. According to Chelune's functional adequacy model, the degree of postoperative memory decline can be predicted by examining the integrity of the proposed surgical zone, as defined by integration of a number of predictive variables.[12]

Initial evidence for the functional adequacy model was based on findings that significant decrements on memory testing following temporal lobe resection were observed in those patients with higher levels of performance on presurgical testing.[15,16] Results of subsequent research[17] demonstrated that patients with the highest levels of memory performance, in particular, showed greater decline in memory performance in the 6 months following surgery. Less significant decline in functioning was observed in patients with lower levels of presurgical memory functioning. The authors argued that these findings were not simply the result of a statistical 'regression to the mean', but rather a tendency for the most functional patients at baseline to be more vulnerable to experiencing postoperative memory loss.

The functional adequacy has now been supported by findings from a number of other neuropsychological studies.[18–21] The theory has also received support from a number of neuroimaging and IAP-Wada studies, which will be reviewed below. It is now generally accepted that this model, combined with other factors, is effective in predicting a patient's neuropsychological outcome from surgery.[22] A brief listing of these factors is provided in Table 135.1. The following sections will review further characteristics of neuropsychological functioning following epilepsy surgery as well as other factors that can be used to predict outcome.

Table 135.1 Factors important for predicting outcome from epilepsy surgery (from Elger, Helmstaedter, and Kurthen)[22]

1. The 'functional adequacy' of the tissue to be resected, as determined by EEG, neuroimaging, and neuropsychological testing.
2. The degree of 'mental reserve', as reflected by patient's age, educational attainment, and level of presurgical intellectual functioning.
3. The degree of postoperative seizure control, particularly the frequency of generalized tonic-clonic seizures.

Profile of change in postoperative neuropsychological functions

Clinicians and patients are interested in knowing which cognitive functions are at risk for decline following surgery. The following section provides a review of what is known about changes in various aspects of neuropsychological functions following surgery:

General intelligence

One of the earliest findings from neuropsychological studies is that epilepsy surgery results in very little change in overall intellectual functioning.[23] Some studies have found an IQ increases in some patients following surgery, particularly in those that become seizure free. However, from a psychometric standpoint, changes in 6–8 IQ points are required to constitute a significant change, and changes of that magnitude are rarely observed after surgery.

The view that patients with lower levels of intelligence do not benefit from surgery has been dispelled by research findings showing similar levels of seizure reduction in both low and high IQ groups.[23,24] Patients with higher levels of preoperative intellectual functioning and memory performance do tend to experience a greater degree of net decline following surgery, although they also continue to exhibit a higher level of postoperative functioning than do patients with lower levels of presurgical functioning.[25] This finding has been considered supportive of the model of 'cognitive reserve' that has gained acceptance in the research fields of dementia and traumatic brain injury.[26,27]

Memory

Memory decline is a primary concern when considering neuropsychological outcome from epilepsy surgery. A number of studies have shown that memory change is commonly reported in patients following surgical resection of the temporal lobe and such change exerts a significant impact on a patient's perception of quality of life.[28] Studies using neuropsychological testing have demonstrated that if a patient undergoes a decline in functioning after surgery, it is most likely to occur in the realm of verbal memory.[13,17] Similar to what has been observed in IQ studies, the findings generally show that patients with higher levels of memory performance before surgery will undergo a greater degree of decline afterward.[23]

There has been some evidence of improvement in some memory skills following surgery, particularly for those functions associated with the hemisphere contralateral to the surgery.[7]

Decrements in postoperative memory functioning have been observed using a range of verbal memory tasks. Several studies have shown that the paragraph-recall (Logical Memory) subtest from the Wechsler Memory Scales (WMS) provides one of the most sensitive measures of postoperative memory change.[13,29,30] Other studies have demonstrated that measures of acquisition and delayed recall from measures, such as the California Verbal Learning Test, Rey Auditory Verbal Learning Test, and Selective Reminding Test, are also sensitive to identifying postoperative changes in memory performance.[17,31,32] Additional success has been obtained from testing the ability to learn and retain word pairs, as provided in Paired Associate subtest from the WMS.[16,28,33,34]

Using findings based on the study of Patient H.M. as a prototype, it was initially thought that memory disturbance resulting from unilateral temporal lobectomy was characterized primarily in terms of 'rapid forgetting' or as a deficit in memory 'consolidation'.[33,34] However, findings from contemporary studies using more refined assessment techniques have determined that the decline in verbal memory following left anterior temporal resection is more multifaceted, as it is also characterized by prominent impairments in encoding and retrieval stages of memory processing.[35] Others have described a specific effect on relational memory.[36] Deficits in memory processing are also known to occur in patients undergoing frontal lobe resection, although the pattern of disturbance is qualitatively different as these patients are more prone to having difficulties with selection or retrieval processes and more prone to making intrusion or perseverative errors than patients undergoing temporal lobe resection.[37,38]

As mentioned above, there has been much less support for the presence of visual memory impairment resulting from surgery performed on the nondominant hemisphere. It has been thought that a number of factors contribute to the lack of findings of a decline in nonverbal memory functioning following right ATL, including limited theoretical knowledge of the right temporal lobe's role in memory processing as well as the sensitivity of most commonly used measures for assessing visual memory.[39,41]

Little success has resulted from using traditional measures of figural memory, such as the WMS designs or Rey's complex figure, to identify memory changes in patients undergoing surgical resection of the nondominant hemisphere.[13,14,42] However, findings from recent studies have indicated that the latest version of the Wechsler Memory Scale (WMS-III) may be more sensitive than other commonly used measures to identifying material specific memory impairment following unilateral ATL,[43] although it does not appear sensitive to identifying lateralized deficits in patients prior to surgery.[44] This study demonstrated that a combination of findings from the Verbal Paired Associates, Faces, and Family Pictures subtests can be used to discriminate right and left ATL patients with 81.3% accuracy.[43] Mixed findings have been obtained from studies using figural learning paradigms, analogous to verbal list-learning tasks, where designs ranging in complexity are reproduced after viewing them over repeated trials.[14,45–48]

Some success in identifying material-specific decline in nonverbal memory functions has been demonstrated using specialized test methods. Based on findings from the primate literature, it has been hypothesized that memory dysfunction following resection of the nondominant temporal lobe will reflect a disturbance of the ventral processing stream, which has related to processing object, as opposed to spatial, information.[39] Given the proximity to the fusiform face area,[49] processing and retaining facial information would be expected to be particularly affected. In fact, studies using facial recognition paradigms have shown the emergence of subtle deficits in facial perception following right temporal lobe resection.[50] Difficulties with remembering unfamiliar faces, both before and after right temporal lobe resection, have been reported in numerous studies.[14,39,51–53] It has been shown that the primary impairment is related more to memory than to perceptual processing of the faces.[54] One study has demonstrated the specificity of this deficit, as demonstrated by a decline in facial, but not spatial, memory following right temporal lobe resection.[55] However, in spite of these observations, a number of studies have demonstrated spatial memory deficits using a variety of innovative paradigms.[56–58]

While most attention is placed on postsurgical evaluation of possible deficits in new learning, a number of studies have demonstrated difficulties with recalling remote knowledge following anterior temporal lobe resection. Several studies have shown deficits in recognizing and naming familiar faces, such as those of celebrities such as politicians, actors, musicians, and athletes.[59–62] A recent study has shown that patients undergoing left ATL may develop difficulties with naming famous individuals depicted in pictures, while those undergoing right ATL appear to have a more basic difficulty with the perceptual aspects of identifying those depicted in the photograph.[60]

Recent interest has also turned to the examining changes in processing and retaining emotional stimuli in patients undergoing temporal lobe resection.[63] Studies have shown that patients undergoing right ATL may develop a specific reduction in their startle response or in their ability to perform in a fear conditioning paradigm.[64,65] These observations have carried into memory paradigms, where is has been demonstrated that patients undergoing resection of the amygdala exhibit a specific reduction in the ability to learn and retain emotionally charged information.[66–70]

Language

Prevention of postoperative language impairment is a concern, particularly when surgery involves the language-dominant hemisphere. Surgery performed on the dominant temporal lobe is most commonly associated with postoperative naming deficits, as typically measured by tests of confrontation naming and verbal fluency. While impairments on other language tasks, such as sentence repetition or auditory comprehension may be encountered, they are seen far less often.

A decline in naming performance is thought to occur in approximately 30–40% of patients undergoing surgery on the language dominant hemisphere.[71,72] Naming decline is not limited to those undergoing extensive resection of the lateral cortex as a relationship between naming impairment and excision of the hippocampus has been demonstrated.[73]

Surgical studies have placed far less emphasis on assessment of naming deficits than on changes in verbal memory functions. Demographic predictors of naming decline appear to be similar to those used for evaluating the risk of memory loss. A specific risk to postoperative naming abilities has been found for those patients undergoing left hemisphere surgery with a later age of onset or an absence of early risk factors for seizures and negative findings on neuroimaging.[73,74]

Assessing changes in naming performance following surgery is typically performed through use of a picture recognition paradigm, such as the Boston Naming Test. However, results from recent studies have indicated that naming changes might be identified more accurately using auditory naming tasks as opposed to visual naming paradigms.[75–77] Results of studies attempting to characterize the type of postoperative naming impairment have been somewhat conflicting. One study found that left ATL is associated with a category specific impairment in naming nonliving as opposed to living things, whereas another study showed the opposite findings.[78,79] Other studies have found that retrieval of object names is affected more than verb naming and words learned at a later age are more likely to be affected those acquired early in life following left temporal lobe surgery.[80,81]

Studies on postoperative language change have also shown decreases in verbal fluency following both left and right unilateral temporal lobectomy.[82] Fluency, as defined in these studies, is assessed through paradigms requiring a generation of word lists beginning with either a specific letter of the alphabet or coming from a predefined semantic category, such as animal names. A decrease in verbal fluency is observed in some patients following surgery to the dominant frontal lobe.[83] Improvement in verbal fluency has been observed in some patients following frontal lobe resection, particularly in cases obtaining good postoperative seizure control.[81,84]

Other neuropsychological functions

Studies using standard neuropsychological measures of motor and sensory functions have found very little change in patients undergoing resection of the temporal lobe. Findings from one study found presurgical baseline impairment in somatosensory functions, with some apparent improvement observed in a subset of patients following surgery.[85] Changes in olfactory functions have been observed after anterior temporal lobectomy, with no consistent association with the side of the resection.[86] Patients undergoing right temporal lobe excision exhibit less accurate recognition of emotion and less change in response to emotional stimuli than do left temporal lobe patients.[66,87]

There are no consistent findings demonstrating deficits in visual perceptual or spatial functions associated with right anterior temporal lobe resection.[88,89] Specific impairment in facial recognition has been observed in one study, although the size of the overall effect was mild.[50] Patients undergoing right temporal lobe surgery have been found to have greater difficulty integrating spatial information while walking a linear path.[90] Development of spatial neglect is rarely seen following temporal lobe resection. However, it has been observed following surgery to the parietal cortices of the right hemisphere.[91] Other studies have demonstrated changes in auditory perception, most notably directional pitch and spatial location, following surgical resection of the right temporal lobe.[92–94]

Greater attention has been placed on assessment of executive functions before and after surgery. In general, patients undergoing frontal lobe resection generally exhibit decline on measures of executive functions.[37] Those with resection of premotor or SMA regions exhibit specific decreases in response maintenance and inhibition, while those with surgery on the left hemisphere also exhibit some decline on language tasks.[23,83] Studies using newer measures of frontal lobe functioning from the Delis-Kaplan Executive Functioning System have demonstrated particular deficits in set-shifting, nonverbal fluency, and response inhibition in frontal lobe surgical patients.[95–97] A decline in spatial working memory has also been reported in patients undergoing frontal lobe surgery.[98]

A number of studies have found impairment in executive functions in patients with temporal lobe epilepsy, contrary to predictions based on early studies finding a double dissociation between frontal and temporal lobe resection groups.[99] Deficits in performance on the Wisconsin Card Sorting Test, a traditional measure of 'frontal lobe functions' has been observed in patients with temporal lobe dysfunction presurgically, with some of these patients exhibiting a normalization in performance following anterior temporal lobe resection.[100,101] It has been hypothesized that the postsurgical improvement is related to a removal of nociferous cortex affecting remote frontal lobe functions.[102] A recent observation if improvement in verbal fluency performance following temporal lobe resection is interpreted supports that hypothesis.[84]

Predictors of neuropsychological decline

It is clear that a number of factors are required to accurately predict postoperative changes in cognitive functioning. The level of evidence has now reached a point where one can use information from neuropsychological tests, obtained presurgically, combined with other surgical and neurodiagnostic values, to predict which patients are at risk for neuropsychological decline.[22] A listing of some of the most commonly known factors for predicting decline are listed in Table 135.2. More details regarding demographic, surgical, and neurodiagnostic predictors of cognitive decline are provided below.

Table 135.2 Predictors of poor cognitive outcome from surgery on the language-dominant hemisphere (from Elger, Helmstaedter, and Kurthen)[22]

1. Persistent seizures.
2. Intact memory performance preoperatively.
3. Extent of surgical resection.
4. Notable collateral brain damage after surgery.
5. Low reserve capacity.

Demographic variables

Developmental factors, including age at the time of surgery and the stage of development at the time of seizure onset, are important factors for predicting postoperative cognitive decline. Most of what is known about postoperative outcome is based on studies of individuals ranging in age from 20 to 45 years, which is the group most likely to undergo surgical intervention. The risk of cognitive decline following surgery appears to be lower in children below the age of 16 years than in adults.[103] At the other end of the age spectrum, older individuals appear to experience greater memory loss, consistent with a profile of accelerated aging.[25] Continuing decline in memory performance may be seen in some individuals ten years or more following surgery.[28] The postoperative deficit in verbal memory in patients rendered seizure free is similar to what is observed over time in nonsurgical patients that are continuing to experience seizures.[25]

Age of onset of epilepsy is thought to interact with both functional and structural indices in a manner consistent with predictions of the functional adequacy model.[12,104] Those with a younger age of onset will have experienced pathology at an earlier stage of development and will have experienced seizures for a longer period of time. This will lead to a greater state of neurological compromise accompanied by more severe and widespread cognitive impairment. However, this would also cause a redistribution of function to other brain areas, which would lead to a less severe deficit following surgery.

In contrast, individuals who develop epilepsy later in life are not as compromised from a neurological standpoint and do not exhibit the same degree of cognitive dysfunction preoperatively. In these individuals, surgery would involve removal of more functional brain tissue, leading to development of a greater level of deficit postoperatively. Support for these findings with age was present in some early studies, but at least one recent study has failed to find a link between severe hippocampal pathology, memory decline, and early onset of seizures.[104]

Another general finding is that, with increasing age, cognitive deficits become more specific and less reversible with surgery. It has been suggested that the pattern of findings involving age of onset are more consistent for cognitive functions associated with neocortical zones than for those associated with the mesial temporal lobe.[23] For example, findings have suggested that more severe naming deficits are observed in older patients. Other studies examining demographic factors have suggested that women, in general, exhibit less severe cognitive decline following surgery than men.[105]

Surgical variables

A relationship between postoperative memory decline and continued seizures has been observed inconsistently across studies.[28] However, the general finding is that postoperative improvement in memory is seen most frequently in patients with greater than 75% seizure reduction.[7,16,106]

The type of surgical procedure has not borne out as a consistent influence on postoperative memory functioning in temporal lobectomy patients. A number of studies have found that a more selective resection of the anterior temporal lobe leads to less severe postoperative deficit than a standard anterior temporal lobe resection.[48,106–109] However, one study has shown that there is no difference in outcome between various surgical approaches.[48] Another multicenter study demonstrated no influence of tailored temporal lobe resections for preventing naming changes in surgical cases involving the language dominant hemisphere.[110] Surgical removal of the superior temporal gyrus during left temporal lobe surgery has been found to have no specific influence on postoperative naming performance.[111]

Much less is known about the neuropsychological outcome of other types of epilepsy surgery. One study found that patients undergoing frontal lobe resection are prone to developing deficits in executive functions after surgery, whereas patients undergoing temporal lobe resection experience relative improvement in these functions.[37] Mild changes in performance IQ, as measured by the WAIS-R, has been reported following surgery to the posterior cortices, irrespective of side.[112] Preliminary data have indicated that a reduced risk of postoperative neuropsychological decline is not associated when gamma knife surgery is used as a treatment for temporal lobe epilepsy.[113]

In cases of callosotomy, one must be prepared for the possible emergence of the well-described 'split-brain' syndrome, particularly features of the alien hand syndrome. However, it has been shown that language is more likely to undergo a decline following callosotomy than any other function.[23] The occurrence of severe language impairment, in the form of postoperative mutism, is known to occur in some patients with atypical patterns of hemispheric language dominance.[114] It is thus critical to ascertain a candidate's pattern of language dominance through the IAP or fMRI prior to surgery. Improvement in social functions has been observed as a positive finding in some cases following callosotomy, with the greatest level of improvement observed in patients that were younger at the time of surgery.[115]

Hemispherectomy has been demonstrated to be an effective treatment for patients with hemimegalencephaly or with Rasumussen or Sturge-Weber syndromes. It is generally assumed that in surgeries involving the left hemisphere, language has moved to the right side, making postoperative language changes unlikely. Research findings have shown that this is most often the case, but some children do continue to be prone to language changes following surgery.[116] Improvements in IQ and attention following hemispherectomy have been reported in some series.[23]

Neurodiagnostic variables

Many studies have demonstrated that a multidisciplinary model, using a combination of neurodiagnostic, demographic, and performance-based factors, is most effective for predicting neuropsychological outcome from epilepsy surgery.[19,117,118] Results from neuropathological studies have consistently demonstrated that memory outcome is impacted significantly by the preoperative presence of hippocampal sclerosis (HS) on the side to be resected.[71,119,120] Individuals with severe unilateral HS tend to exhibit lower levels of preoperative memory functioning and are likely to exhibit less decline in memory performance following surgery.[121]

Neuroimaging findings

The functional adequacy model has been supported by results of studies using MRI measures of hippocampal pathology.[122,123] The findings show that removal of a nonatrophic left hippocampus is generally associated with the greatest degree of memory decline, although it is also possible to observe memory loss in some patients with the most severe presurgical levels of HS.[35] It is now known that surgery performed on individuals with bilateral hippocampal pathology does not necessarily cause global amnesia. However, greater rates of memory decline are seen in those patients with bilateral hippocampal atrophy who undergo surgery on the dominant left temporal lobe.[35] These and other findings indicate that the functional integrity of the left temporal lobe plays a critical role in predicting memory outcome, independent of the presence of structural pathology.[124,125]

Functional adequacy has been predicted through results of magnetic resonance spectroscopy (MRS).[126,127] Functional MRI (fMRI) has been shown to be useful for predicting postoperative naming.[128] Studies using functional imaging methods have indicated that both FDG-PET and fMRI can be helpful in predicting postoperative memory impairment.[129,130] In the case of FDG-PET, a lack of left side hypometabolism predicted the onset of memory loss in patients undergoing left ATL.[131]

Intracarotid amobarbital procedure (IAP)

IAP memory scores, combined with MRI measures of hippocampal volume, have been shown together to be related to the degree of memory change following temporal lobectomy.[132] However, it has been suggested that these variables are used most optimally for prediction of verbal as opposed to nonverbal memory changes.[133] A recent study has demonstrated a significant negative correlation between IAP scores ipsilateral to the surgical resection and postoperative memory change, consistent with predictions based on the functional adequacy model.[134] There has been some suggestion that, in cases with right hemisphere language dominance, verbal memory functions might also shift to the right hemisphere, resulting in the observation of less severe memory decline after surgery.

Language mapping

While an emphasis has been placed on language mapping prior to dominant hemisphere surgery,[135] results from studies using both grid and intraoperative brain mapping procedures have been variable. Some studies have shown that standard ATL without stimulation mapping is safe for long-term language functions.[136] One multicenter study found that the rate of postoperative naming decline was not influenced by the availability of mapping data.[110] Removal of basal temporal zones found to be patent for language functioning on mapping have not been associated with consistent decrements in postoperative language abilities.[137] However, others have recently found that identification of mapping sites critical for auditory descriptive naming is important for predicting both auditory and visual naming outcome.[138] A more distributed region of language functions has been described in patients with decreased intelligence and lower levels of educational attainment.[139] Results from mapping studies using magnetoencephalograpy (MEG), have suggested a reorganization of hemispheric language representation following dominant hemisphere resection.[140]

Recent methodological advances

One of the criticisms of neuropsychological research is that it has typically focused on results of group analyses, making it difficult to translate the results into manner that can be useful in counseling patients. There has also been a view that focusing on analysis of group differences following surgery may mask many of the differences between patients undergoing left and right temporal lobe resection.

There has been a recent trend moving from group methods of analysis towards predicting the risk of postoperative change in individual patients. To optimize the prediction of individual risk, investigators have been using statistical methods, such as the reliable change index (RCI) and standardized regression-based (SRB) methods to control for the reliability of the instruments, practice effects, and regression to the mean. These measures are readily obtained through studies of test-retest changes observed in non-surgical patients.[30,141–144]

Experience shows that RCI's are the most easy to use in a clinical setting, with a level of expected change observed on retesting translated into 95% confidence intervals. Modifications to the original RCI formula are made, correcting for practice effects.[144] Values for some of the most commonly used neuropsychological tests are provided in Tables 135.3 and 135.4. Clinicians are encouraged to use these values to determine whether significant changes in neuropsychological test scores are observed in individual patients following surgery.

Results from postsurgical studies using RCI and SRB methodology are summarized in Table 135.5. When patients are considering surgery, they can now be informed, on the basis of results from these studies, that the risk for postoperative decline in verbal memory ranges from 28–49% in patients undergoing left temporal lobe surgery while the risk for decline patients undergoing right temporal lobe surgery ranges from 7–33%, depending on the memory measure that is used to assess outcome.[72]

Other studies have revealed greater degrees of risk in patients undergoing left anterior temporal lobe resection with minimal evidence of hippocampal sclerosis on MRI.[104] Another study found that bilateral hippocampal atrophy, in the presence of left temporal lobe seizures, increases the risk of memory decline following left temporal lobectomy.[35] Bilateral hippocampal atrophy did not provide a risk to patients undergoing right temporal lobectomy. One study has shown that patients with MTS and normal preoperative memory performance are still at risk for developing memory changes following surgery.[124] Using indices from the CVLT, 17% exhibited a drop on acquisition scores, while 65% experienced a decline in verbal retrieval. This point was made again in a case report where intact preoperative memory performance in the presence of numerous signs of hippocampal sclerosis resulted in a significant postoperative decline in memory.[125] The results from the studies using methodology for assessing change have thus provided evidence that results from presurgical testing provide a critical predictor of

neuropsychological outcome independent of information obtained from neuroimaging.

Conclusion

A number of important advances have been made over the past 50 years in assessing neuropsychological outcome from epilepsy surgery. Most attention is place on the prevention of declines in naming and verbal memory, which are most likely to be seen in a sizeable minority of patients following surgical procedures conducted on the language-dominant hemisphere. Current practices involve a model utilizing presurgical neuropsychological testing, along with information obtained from neuroimaging and the IAP, to assess a given patient's risk for postoperative decline. Patients with evidence of intact cognitive functions on the site to be resected are considered at greatest risk for postoperative memory decline, independent from structural imaging findings. Studies using newer statistical approaches to evaluating neuropsychological change are providing clinicians with information that makes it easier to counsel individual patients on the risk of developing postsurgical changes in memory and language.

136 Temporal lobe epilepsy surgery: surgical complications

D Sasaki-Adams and EJ Hadar

Introduction

No professional man gets greater pleasure from the record of his successes than a surgeon. How delightful when the uninformed refer to them as miracles! And how inaccurate! But no one regrets his failures more ...[1]

Surgical complications are perhaps the most humbling of all mistakes. The role of this chapter is to delineate the most frequent complications encountered in surgery for temporal lobe epilepsy. In addressing the potential pitfalls of this surgical procedure, perhaps one can hope to determine means to avoid them. During the last century, a considerable amount of general knowledge has been gained in surgical evaluation for temporal lobe epilepsy. The implications and outcomes have been fine tuned over the past 50 years at many epilepsy centers to make temporal lobe resection for medically intractable disease the most common surgical procedure for epilepsy worldwide.[2–11] The benefits of this surgery have revolutionized the prospect of epilepsy being a potentially curable disease. Surgical resection for medically refractory seizures has demonstrated very promising results with respect to seizure control. A multitude of studies have estimated a 60–70% rate of seizure freedom and up to an 85% rate of significant reduction in seizure frequency.[3,4,11] A prospective randomized controlled trial found 64% of patients who underwent surgical resection were seizure free compared to only 8% in the medical group on optimal medical therapy.[11] They concluded that surgery was superior to prolonged medical therapy. However, one must remember in counseling patients for surgical intervention, that complications do occur and can be life altering.

The temporal lobe performs a myriad of functions including integration of such higher level functions as language, musical appreciation, emotion, and memory. Its location bordering the frontal, parietal, occipital lobes makes it ideal for acting to coordinate and process multivariate information. Likewise, its mesial structures, including the hippocampus, are deeply involved in episodic memory processing. Additionally, one must remember that the temporal lobe borders the vascular supply of essential relay stations including the thalamus, internal capsule, and basal ganglia. Interference of these pathways, either by temporal lobe pathology or surgical intervention, can result in significant loss of function. The optic tract and visual pathways traverse the temporal lobe making a visual field deficit a possible outcome to disturbance of this area. Lastly, several cranial nerves approximate the mesial portion of the temporal lobe as is evidenced by the typical sign of a third nerve palsy with uncal herniation.

The temporal lobe acts to coordinate sensory information and synthesize it as it relates to higher level cognitive function. For example, in recalling a memory, one can often remember the specific situation in fine detail. With such an integral processing station, it is no surprise that surgery in this region can be associated with a multitude of complications. Temporal lobe epilepsy, in its natural progression, is often associated with many of the neuropsychological complications described here. Patients with longstanding temporal lobe epilepsy often will demonstrate a cognitive decline with difficulties in language, memory, and psychosocial functioning.

The chapter will begin by discussing the intricate anatomy of the temporal lobe and providing a brief overview of the various surgical approaches. An understanding of the resection bed's proximity to a multitude of essential anatomical pathways and structures will assist in explaining some of the various complications that are commonly encountered. We will then embark on a brief overview of the most commonly described surgical complications associated with general craniotomy. The remaining portion of the chapter will focus on the various neurological complications that have been documented. The neurological sequelae will be subdivided into motor, sensory, visual field, and cranial nerve deficits. We will then discuss neuropsychological complications including language, memory, and general cognitive disturbances. Lastly, we will address various psychiatric complications which have been observed following temporal lobe surgery for epilepsy.

Anatomy

The anatomy of the temporal lobe, including the mesial structures, is quite complex and requires a three dimensional understanding of its relationship to the rest of the brain before embarking on surgical intervention.[12] It is separated from the frontal lobe superiorly by the Sylvian fissure. One can follow the Sylvian fissure medially until it ends at the circular sulcus. This structure separates the insula from the temporal stem which comprises the white matter outflow tracts of the temporal lobe. Inferior and medial to the temporal stem lies the temporal horn of the lateral ventricle. The mesial structures of the temporal lobe reside along the medial aspect of the ventricle.

The complex anatomy of the mesial temporal structures and their proximity to the brain stem and other critical vascular and neuronal structures makes surgery in this region challenging. The mesial structures start at the parahippocampal gyrus and extend medially curling upwards contiguous with

the hippocampus. The hippocampal sulcus separates the parahippocampal gyrus from the hippocampus proper. The ambient cistern lies between the mesial temporal lobe and the brain stem. The posterior cerebral artery, posterior communicating artery, basal vein of Rosenthal, and the third nerve pass through this cistern. The hippocampus and the limbic lobe are C-shaped structures which extend posteriorly and follow the course of the lateral ventricle and corpus callosum. The hippocampus comprises the medial wall of the temporal horn of the lateral ventricle. The fornix, which is the outflow tract of the hippocampus, extends posteriorly and follows the course of the ventricular system to the mammillary bodies. The choroidal fissure delineates the hippocampus and fornix from the diencephalon, optic tract, and basal ganglia medially. The amygdala is contiguous with the basal ganglia and lies just anterior to the head of the hippocampus. Please see Wen and Rhoton's section describing surgical anatomy for more detail.[13]

Approaches

In the context of temporal lobe surgery for epilepsy, most surgical strategies are aimed at resection of the hippocampus and associated mesial structures. Hippocampal exposure is usually accomplished via the ventricular system and access to the ventricle has been described through multiple approaches.[8,14–19] Each approach necessitates some type of tissue disruption and each has its described advantages and disadvantages. These are described in detail elsewhere in this book.

Surgical complications

Surgical complications in this chapter include those complications associated with general craniotomy for all indications. Many centers quote different complication rates with respect to postoperative hematoma, infarct, retraction injury, wound complications, and infection as have been observed in their individual institutions.[2,3,9–11,20] These types of complications vary with the experience of the center, the resources of the institution, and the degree to which these are reported and recorded. Generally, infection is felt to be the highest surgical risk estimated in 1–5% of cases with the risk increasing with prolonged intracranial monitoring.[2,20] In a study evaluating risk of craniotomy and postoperative infection and role of antibiotic prophylaxis in 4578 craniotomies, it was found that the overall rate of infection was 6.6%.[20] Several studies have been done to correlate increased risk of infection with chronic invasive subdural grid and subdural electrode monitoring.[21,22] In a review and prospective analysis of 38 patients who underwent craniotomy for electrode implantation, clinical infection was observed in 7.9% of patients, with a 13.2% positive culture rate indicating that laboratory results do not always correlate with clinical outcome.[22] In a retrospective analysis of 198 monitoring sessions in 187 patients, the overall rate of infection was found to be 12.1%.[21] These studies suggest that the risk of infection increases significantly with preresection craniotomy for intracranial monitoring. Hematoma and infarct are seen far less often; in less than 3 % of cases.[2,9,21] Upon review of the 449 therapeutic procedures performed in Sweden between 1990 and 1995, infection was observed in 5.1%, hematoma in 0.4%, deep venous thrombosis in 0.4%, hydrocephalus in 0.7%, and CSF leak in 0.7%.[9] In a retrospective analysis of a series of 429 consecutive patients operated on during 6.5 years in the University of Bonn epilepsy program, a total of 33 surgical complications were encountered, 7.5% stemming from temporal lobe resections.[2] Of those described, deep vein thrombosis and pulmonary embolism were observed in 2% of patients. Postoperative meningitis was observed in 1%, with postoperative wound infection seen in 2.8%. A retrospective analysis of 215 patients who underwent temporal lobectomy for medically intractable epilepsy found no surgical mortality, but 1.3% of the patients harbored an infection of the bone flap.[10]

In summary, when considering the general risks associated with craniotomy in this region, one must appreciate the individual experience of the home institutions where these operations are performed as well as the unique nature of these procedures. The risk of infection is often higher than that for a routine craniotomy as many of these patients undergo placement of subdural grids for prolonged intracranial monitoring prior to the definitive surgical resection. In routine craniotomy without subdural grid monitoring, the risk can be estimated for most centers as between 1 and 3%. This risk increases with preresection monitoring to 8–12%. The risk of serious complications such as hematoma and infarct appear to occur on the order of 1–2%, but may vary according to the home institution's individual experience. Preoperative medical evaluation and perioperative monitoring are essential in reducing risk for developing such complications as deep venous thrombosis, pulmonary embolism, and perioperative myocardial infarction and should be utilized routinely. Additionally, perioperative antibiotic prophylaxis should be considered in an effort to reduce infection risk as well as strict adherence to a wound care regimen.

Neurological complications

Motor deficits

Hemiparesis of the contralateral side following surgery for temporal lobe epilepsy has been well described in the literature. In the manuscript, "Manipulation Hemiplegia", Penfield, Lende, and Rasmussen eloquently describe this complication and propose various theories for its etiology.[23] All operations carried out in the temporal regions by Penfield between 1948 and 1955 were retrospectively reviewed to include 161 in total with 8 incidents of hemiparesis accounting for 5%. Additionally, complete homonymous hemianopsia was also produced in all cases. Hemihypesthesias were also present. The hemiplegia improved to some extent in all cases. It was hypothesized that this triad of symptoms was attributable to injury of the internal capsule and associated structures where the corticospinal tracts, optic radiations, and thalamic radiations could be affected. It was proposed that this injury was likely vascular. It was further felt to be the result of injury to the anterior perforating arteries. It has since been attributed to injury to the anterior choroidal artery which supplies the optic tract, ventral thalamus, part of the striatum, and part of the posterior limb of the internal capsule.

Since Penfield's intial observations, numerous other institutions have documented postoperative motor deficits following temporal lobe surgery for medically intractable epilepsy. In 1975, Jensen reported his results from a survey covering 2,282 published temporal lobe resections around the world performed from 1928–1973 with respect to seizure control outcome and complications.[24] They found persistent hemiparesis in 2.4% and transient hemiparesis in 4.2% of temporal lobe resections respectively. In a retrospective analysis reviewing complications in 654 procedures recorded in the Swedish National Epilepsy Surgery Register between 1990 and 1995, hemiparesis was observed in 2.2%.[9] Of the 247 temporal lobe resections, one patient was observed to have hemiparesis after a temporal lobe resection excluding the hippocampus and four occurred after temporal lobe resection including the mesial structures. This was felt to support the theory that hemiparesis occurred as a result of injury of the anterior choroidal artery.

In Behrens' report, hemiparesis was the most frequent neurological complication being observed in 1.8% of the temporal lobe resection group.[2] Upon review, it was found that in two cases, manipulation of the anterior choroidal artery led to infarction of the internal capsule as documented on postoperative computed tomography scans. In a cohort of 215 patients, two patients suffered from a postoperative hemiparesis.[10] A regression analysis was performed in an attempt to identify potential risk factors for this potential complication. These two patients were greater than the mean age of 34 suggesting the possibility of advanced age as a risk factor for developing this complication.

In review of the above studies, hemiplegia and associated deficits following injury to the anterior choroidal artery and perforant vessels appears to occur on the average of 2%. Long-term studies have not been conducted to determine the percentage of patients with this complication who develop improvement. Subjectively, upon gross review of the literature, it would appear, that in a majority of cases of this type of complication, the hemiplegia is transient and tends to improve over several months to a year. Whether advanced age could be a risk factor for the development of this complication remains unclear.

Visual field deficits

Surgery for temporal lobe epilepsy afforded a new outlet for studying the route of optic radiations through the middle cranial fossa. Prior to temporal lobe resections for epilepsy, anatomical studies of visual field defects were limited to surgery for neoplastic resection as illustrated in Cushing's series, or by Meyer's studies of secondary degeneration following vascular or traumatic lesions.[25,26] Soon after the initial descriptions of temporal lobe resections for epilepsy were published, several case series examining the effect of the surgery on visual fields were presented. In the initial reports, it became evident that a majority of patients demonstrated a partial homonymous contralateral visual field defect limited to the upper quadrant. This was felt to be a reflection of the degree of the surgical resection and likely attributable to injury to Meyer's loop; the lateral most portion of temporal optic radiations. Penfield in 1954 stated, that if the excision was limited to less than 6 cm of the temporal lobe, no visual field defect was observed and resection of greater than 6 cm was associated with a partial visual field defect and greater than 8 cm was associated with a complete homonymous hemianopsia.[8] In contrast, Falconer's experience in 40 patients did not demonstrate a clear association with the degree of visual field defect with respect to the extent of the temporal lobe dissection.[5,27]

In 1958, two case series were published from Montreal Neurological Institute and Guy's de Maudsley Neurosurgical Institute in London.[28,29] In the former, 41 patients who underwent temporal lobe resection in an effort to elucidate the architecture of the optic radiations in the temporal lobe were examined pre- and postoperatively with perimetry visual field testing.[27,28] They found that there was no increased risk to central vision, visual acuity, or blind-spot margins. They found visual field defects in 82% of the patients. All were found to be quadrantic in nature. Ten were found to be congruous and 23 were incongruous with the defect closer approaching the fixation point in the eye on the side of the surgery. Additionally, they noted a slanting inferior margin of some of the defects expanding to a homonymous hemianopsia rather than a pure quandrantanopsia. They then embarked on a review of the existing literature describing the optic radiations of the temporal lobe. They concluded that the visual defects encountered were due to the effects of surgical ablation and not edema of the temporal portion of the visual radiation, as the deficits persisted 4 and 9 months postoperatively. Falconer and Wilson from London studied the visual field changes in 50 consecutive patients treated by anterior temporal lobectomy.[27] They found the chances of developing an upper quadrantic defect was on the order of 5 to 1. They determined that there was no significant difference in the range of the extent of the hemianopsia with regard to the extent of the dissection between 4.5 and 8 cm from the temporal pole extending posteriorly. All of their results demonstrated a congruous visual field defect, in contrast to the results reported by Van Buren and Baldwin.

Ten years following these two illustrative manuscripts, Marino and Rasmussen performed a more detailed review examining 50 patients operated upon for temporal lobe epilepsy at the Montreal Neurological Institute between 1962 and 1967.[30] Preoperative perimetry and tangent screen tests were normal in all patients in this series. It was found that 58% of the patient exhibited partial or complete quadrantic defects. The smallest defect being a small triangular sector near the vertical meridian with the most severe being a complete homonymous hemianopsia. It was found that in 34% in whom no field defects were noted, temporal lobe removals extended between 4 and 8 cm. They found a poor correlation between the extent of the defects and the extent of temporal lobe resection. This lended support to the idea of the presence of considerable variability in the formation of the optic radiations between patients. They reported the visual field defects were congruous in 79% of patients.

More recently, several large reviews have been undertaken to study the various complications associated with the procedure. In the review of the Swedish National Epilepsy Surgery Register of 449 procedures performed between September 1990 to 1995, two patients were found to have experienced hemianopsia.[9] In Jensen's review of 868 cases, visual field deficits reported ranged from 2.9–93% with an average of 50.9%.[24] After the two extremes reported were eliminated, it was found that visual field defects occurred at a frequency of

46% with the majority being partial hemianopsias and only 4% were complete homonymous hemianopsias. In a study of 215 patients, only one patient demonstrated a hemianopsia equaling 0.4%.[10] In Wiebe's prospective randomized trial quadrantic visual field defects occurred in 55% of patients in the surgical group.[11] However, these were asymptomatic and were only evident on detailed visual field testing. A recent study was carried out at the National Hospital in London to evaluate the extent of visual field defects and to discuss its implication in passing the British driving examination.[31] Of patients who had undergone temporal lobe surgery,[24] underwent postoperative evaluation with both Goldmann and Humphrey perimeter testing. It was noted that a field deficit was found in 54% of patients using the Goldmann test and 46% using the Humphrey analysis. In 25% of these patients, the defect was large enough to fail the vision criteria set forth by the British driving regulations, prompting the role of preoperative discussion of this side-effect prior to surgical resection.

The majority of these studies thus far have attributed the visual field defects to an injury to the optic radiations which traverse the temporal lobe. The superior quadrantanopsia appears to be associated with a primary injury to Meyer's loop, whereas a complete homonymous hemianopsia has been attributed to removal of a greater extent of the temporal lobe as well as disruption of the optic radiations as they course medially and inferiorly. It would make sense that there would be a variance in the incidence of visual field deficits with respect to differing surgical approaches. A study comparing the standard anterior temporal lobectomy (ATL) approach with selective amygdalohippocampectomy (SAH) with respect to visual field deficits was carried out by Egan *et al.*[32] Twenty-nine patients were enrolled, with 14 undergoing SAH and 15 ATL. The patients were tested using Goldman perimetry 1 month postoperatively. Approximately 75% were found to have a superior quandrantanopsia. There was no statistical difference between the two approaches. It was postulated that the visual field defect occured during ATL when the temporal tip is removed. In SAH, it was explained that visual field defects occurred as the suction device and retractors are driven through the optic radiations en route to resection of the medial temporal lobe.

In conclusion, visual field defects following surgery for temporal lobe epilepsy range from minor triangular defects to complete homonymous hemianopsias. In the majority of cases, the patients demonstrated a superior quadrantanopsia and were unaware of their deficit as it was diagnosed only with detailed visual field testing. The range of patients to exhibit visual field defects ranges from 46% to 82% in earlier studies. A quote of a 50% chance of possibly incurring a visual field defect is reasonable when counseling patients for this procedure. The extent of the visual defect does not appear to clearly correlate with the degree of dissection or approach of the surgery. The optic radiations, which make up the most lateral aspect of Meyer's loop appear to be most susceptible to injury. However, in the majority of cases, the patients who were found to have a superior quadrantanopsia on detailed testing were unaware of their deficit. In those few cases of patients who suffer a more extensive hemianopsia, it may be related to the amount of resection or individual variance on the course of the optic radiations as they encompass the temporal lobe and appears to with a frequency of 4–12%.

Cranial nerve deficits

The cranial nerves most often implicated in potential complications following surgery for temporal lobe epilepsy are the oculomotor CN III and the trochlear CN IV nerves. The oculomotor nerve passes through the ambient cistern bordering the medial aspect of the temporal lobe en route to the cavernous sinus. The trochlear nerve innervates the superior oblique muscle of the orbit. It exits the brain stem dorsally and decussates in the superior medullary velum. It then courses lateral to the cerebral peduncles and passes between the posterior cerebral and superior cerebellar arteries just lateral to CN III as it runs medial to the temporal lobe before entering the cavernous sinus.

Several studies have demonstrated cranial nerve palsies following temporal lobe surgery.

Rydenhag *et al.* documented two trochlear nerve and two oculomotor nerve palsies following mesial temporal lobe resections upon their review of 247 temporal lobe resections.[9] Third nerve palsy was seen transiently in four of 279 cases reviewed by Behren's *et al.*[2] In Salanova's study of 215 patients, seven manifested transient cranial nerve palsies with nerves III or IV following temporal lobectomy.[10] This accounted for 3.2% of their series and was observed to have resolved in several weeks. Jacobsen *et al.* reviewed 22 cases of patients who underwent anterior temporal lobectomy for treatment of epilepsy at the Marshfield clinic between 1987 through 1993 and found three cases of transient postoperative diplopia.[33] Detailed neurological examination was performed which demonstrated ipsilateral trochlear nerve palsies. Postoperative imaging did not demonstrate any evidence of infarction. It was felt that this complication was likely secondary to traction. The trochlear nerve is the thinnest cranial nerve residing in the lateral wall of the cavernous sinus and may be vulnerable to mechanical distortions of the lateral wall which may occur during temporal lobe resection. The authors felt that trochlear nerve palsies may be underdiagnosed due to their difficulty in diagnosis and that the prevalence may be higher than initially supposed. Thus, after review of the literature, it would appear that the risk for developing a cranial nerve palsy of either the oculomotor or trochlear nerve is on the order of 1.5–3%. Additionally, this deficit appears to be transient in the majority of cases which would correlate with a possible retraction injury as opposed to direct injury to the nerve or vascular compromise.

Language deficits

The role of language in the temporal lobe can be appreciated by observing certain seizure semiologies. Often persons are completely aphasic during a seizure or exhibit abnormal language with perseveration and paraphasic errors. The posterior superior portion of the temporal lobe has been mapped as Wernicke's area; with lesioning of that area associated with a receptive aphasia. The inferior frontal gyrus overlying the superior temporal lobe is implicated in Broca's area, the lesioning of which is associated with an expressive aphasia. The two are believed to be connected via the arcuate fasciculus where lesions have been characterized as producing a conductive aphasia. Numerous studies have demonstrated language difficulty following surgery of the temporal lobe. Many centers report a transient aphasia characterized by

dysnomia following temporal lobectomy for epilepsy.[34–38] However, the more long-term impact on temporal lobe resection on language function has been less clearly elucidated. The role of this section will provide a broad overview of the temporal lobe's function in language and to outline the most common complications encountered following surgery in this area.

In the initial surgeries for temporal lobe epilespy, intraoperative language mapping was employed routinely as well as an attempt to avoid the superior temporal gyrus secondary to the risk of injury to Wernicke's area. In recent years, the role for language mapping has been debated. Hermann conducted a prospective analysis of 29 patients who underwent partial resection of the anterior temporal lobe utilizing intraoperative mapping.[35] No significant loss in either dominant or nondominant-sided resections with respect to language function was observed. Anecdotally, improved seizure control was observed in patients from this study who were unable to tolerate intraoperative mapping for various reasons. As a result, Hermann carried out a follow-up study with 64 consecutive patients who underwent anterior temporal lobe resection without intraoperative language mapping.[36] The patients were administered the multilingual aphasia test preoperatively and 6 months postoperatively. A median of 4.25 cm of lateral dominant temporal cortex or 4.5 cm of nondominant temporal cortex was removed including resection of the superior temporal gyrus. No measurable compromise was appreciated when comparing preoperative and postoperative scores. In fact, dominant temporal lobectomy patients were seen to have gained in language comprehension function postoperatively.

The surgical approach has been implicated as a means for protecting language function. It has been argued that sparing the superior temporal gyrus results in less postoperative dysnomia. It has also been implied that preoperative or intraoperative language mapping results in less difficulty with language post operatively. In a large multicenter study, four surgical approaches were examined with respect to visual confrontation naming following Wada proven language dominant left temporal lobectomy for epilepsy.[39] A total of 217 patients underwent surgery either via tailored resection with intraoperative mapping, tailored resection with extraoperative mapping, standard resection with sparing of the superior temporal gyrus, and standard resections including excision of the superior temporal gyrus. They found that in all surgical groups there was significant decline in visual confrontation naming as assessed by the Boston Naming Test by an average of 8%. They saw no significant change between naming outcomes as a function of surgical approach.

Contrastly, Ojemann conducted a study of 117 patients undergoing Wada proven left language dominant hemispheric resections for various reasons where language mapping was undertaken.[40] It was found that essential areas for language were often organized in a 1–2 cm mosaic pattern of discrete areas of language function. Mosaics essential for language were usually located in the frontal cortex or in the temporoparietal cortex. These findings were often highly localized and reproducible within a given patient but were not found uniformly in a group analysis. These findings imply a great degree of variability within localization of essential naming and language function to suggest a role for language mapping. Since its inception the role for intraoperative mapping and partitioning of the superior temporal gyrus has been debated. Currently, temporal lobe epilepsy surgery has expanded so that many centers no longer perform tailored resection according to language mapping nor do they routinely spare the superior temporal gyrus.

Dysnomia appears to be the most common deficit encountered in language function following surgery for temporal lobe epilepsy. Hermann published a study to evaluate the presence of dysnomia following dominant anterior temporal lobectomy.[41] Patients with Wada proven left hemisphere speech dominance with intractable nonlesional epilepsy and full-scale IQ > 69, underwent anterior temporal lobectomy without functional mapping at the University of Tennessee, and were evaluated with respect to language. These patients were administered a standard aphasia battery preoperatively and 6 months postoperatively. The primary area of interest was a visual naming subtest. The extent of lateral dominant resection averaged 4.3 cm from the temporal tip. No significant difference in the mean preoperative to postoperative score was seen for the right temporal lobectomy group. Left temporal lobectomy patients experienced a 23–27% decline from their preoperative performance. A study by Martin *et al.* showed in a total of 101 Wada proven left language dominant patients who underwent anterior temporal lobectomy for medically intractable epilepsy showed that nearly 50% of the left-sided resected patients experienced clinically meaningful declines with respect to the Boston Naming Test.[42] This contrasted with right-sided resected patients who showed no significant decline on the Boston Naming Test.

Following, these and other studies which demonstrated a clear decline in postoperative naming ability after resection of the Wada proven language dominant temporal lobe, many studies have been aimed at predicting risk factors for developing this difficulty. Stafiniak *et al.* evaluated 45 patients who underwent anterior temporal lobecomy for medically refractory epilepsy.[38] All patients received comprehensive neuropsychological evaluations preoperatively and 3 weeks after surgery. After left dominant lobectomy 60% of patients with no early risk factors such as early neurologic insult via infection or trauma, or febrile seizure demonstrated a > 25% decline in naming. However, none of the patients without early risk factors experienced a postoperative decline in naming. None of the patients who underwent right-sided surgery experienced a naming decline postoperatively. This study would suggest that perhaps patients with a neurological insult early in life are able to collateralize language ability to some extent allowing for decreased risk for dysnomia postoperatively. Bell studied 26 patients with Wada proven left-sided language dominance who underwent left anterior temporal lobectomy with respect to naming performance.[43] The age of onset of epilepsy was the only predictor of postoperative dysfunction. Patients who developed epilepsy at an earlier age were more likely to exhibit less difficulty with naming postoperatively. Patients who had felt that they had learned the particular word in question at a later age were more likely to have difficulty naming it in the time prescribed during the Boston Naming Test on their postoperative evaluation. In a multicenter trial to compare surgical approach with language difficulty postoperatively, one risk factor which was identified was the age at onset of epilepsy. Patients who developed seizure onset at a later age demonstrated increased difficulty in naming.[44]

The above studies demonstrate a postoperative decline in naming ability following dominant temporal lobe resection. However, the stability of this deficit over time has been less clearly observed. Stafaniak *et al.* evaluated 41 patients with respect to dysnomia following surgery for temporal lobe epilepsy and found that four of the six patients who experienced an average decline of 61% in naming ability pre- to postoperatively improved to a mean decline of 18% at 1 year follow-up.[38] This finding suggests that this naming deficit often shows significant improvement over time. In a prospective study by Davies *et al.*, 95 consecutive patients undergoing standard anterior temporal lobectomy for intractable complex seizures were studied with respect to language functioning.[34] Patients underwent a neuropsychological evaluation to assess naming of objects preoperatively and 1 year postoperatively. Comparison of the preoperative scores showed a significantly lower score for the left-side dominant group for several of the language measures. At the 1 year follow-up, left-sided lobectomy patients demonstrated a significant improvement in verbal fluency and performance IQ. Right-sided temporal lobectomy patients also showed a significant improvement with respect to verbal fluency and performance IQ. In these resections, the superior temporal gyrus was resected without evidence for detriment to language function. In fact, this study seemed to support that the surgical resection allowed for improvement in language fluency and performance IQ. This may be a result of improved seizure control, or perhaps, the idea of relieving abnormal circuitry to allow normal circuitry to develop and progress.

Functional magnetic resonance imaging has prompted a new cadre of non-invasive means to study language organization. In one study designed to evaluate reading skills in patients who underwent left-sided language dominant temporal lobectomy for medically intractable epilepsy compared patients to age matched controls.[45] Those patients who demonstrated higher level reading skills postoperatively were more likely to recruit right hemispheric activity, specifically the in the right inferior frontal gyrus, right hippocampus, and right inferior temporal gyrus. The introduction of magnetoencephalograms has also added to the abundant studies underway to determine language localization. In a recent study by Pataria *et al.*, 12 patients were examined using MEG who underwent left temporal lobectomy.[46] They found that patients who exhibited bihemispheric recruitment preoperatively for language tasks were more likely to show increased right hemispheric activity postoperatively.

The temporal lobe's function in language has long been recognized as is evidenced by Wernicke's and Brodman's mapping studies. Temporal lobe epilepsy is often associated with semiology whereby the patients demonstrate language difficulty during seizures. The implications of temporal lobe resection on language ability have been somewhat surprising. Initially, it was felt that resections should be undertaken with intraoperative mapping and careful preservation of the superior temporal gyrus. Numerous studies have demonstrated no significant difference between outcomes in language function when intraoperative mapping is not utilized or the superior temporal gyrus is resected. However, there may exist individual variance between patients to support utilization of intraoperative mapping per Ojemann's argument which must be considered when counseling patients of surgical risk of language difficulty. Additionally, though many studies have demonstrated a significant problem with dysnomia following surgery, it would appear that this is often a transient deficit which resolves in the first 12 months postoperatively. It was also found that patients with Wada proven language dominance on the side of the resection were more likely to suffer language difficulty postoperatively than those who underwent non-language dominant resections. Additional risk factors for language difficulty aside from dominant hemisphere resections included later age of epilepsy onset. New imaging analyses have shown that possibly patients who recruit the opposite hemisphere are better able to compensate for language difficulty postoperatively. Taken together, these data may lend support to the idea that patients who develop epilepsy at a younger age and who may exhibit a higher degree of plasticity, are at an advantage as they may be able to develop bihemispheric projections to support language function. This would argue proposal of surgical intervention in the younger population with medically intractable epilepsy. In conclusion, patients considering surgery for temporal lobe epilepsy need to understand the risk of language difficulty postoperatively. This risk appears to be increased in patients undergoing resection in the Wada proven dominant hemisphere, later age of onset of epilepsy, and absence of childhood neurological insult such as infection, trauma, or febrile seizures. Additionally, it would appear that, in a majority of patients, perioperative language difficulty is a transient phenomenon which demonstrates significant improvement 1 year following surgery.

Memory deficits

Since the inception of temporal lobe epilepsy surgery, a correlation has been observed between resection of the mesial structures and memory. Unfortunately, much of the knowledge that has been gained in this regard has been at the expense of surgical complications. Penfield and Scoville described several case reports of patients who underwent either unilateral hippocampal resection for temporal lobe epilepsy or bilateral resection for psychiatric illness, and developed severe anterograde amnesia.[47,48] In all of these patients, there was evidence of difficulty in acquiring new memories to the extent that these patients were no longer able to carry out their activities of daily living. In those patients who underwent unilateral resection, it was found postoperatively that the opposite hippocampus exhibited a destructive lesion. After careful analysis of these patients, it was concluded that bilateral hippocampal dysfunction was correlated with this severe form of amnesia.

The Wada test was introduced in Japan by Juhn Wada in 1949 and initiated into Western medical literature in 1960.[49] The test involves injection of sodium amytal into each carotid artery to induce a temporal loss of function in the injected hemisphere. Lanugage is then assessed by monitoring the EEG-slowing and associated hemiparesis. Memory is assessed 10 minutes following injection and following return of EEG behavior to baseline. This test was initially utilized in 20 patients being evaluated for epilepsy surgery in Japan in an effort to determine language hemisphere dominance. However, after it was determined that memory likely also demonstrated some degree of lateralization, Branch and Milner published a retrospective analysis of 50 patients being evaluated for surgical resection at the Montreal Neurological Institute.[50] They hypothesized that no memory defect should

be seen after unilateral amytal injection unless there was a poorly functioning hippocampal formation on the contralateral side. They found memory disturbance in 13% of patients. This study led to the idea of utilizing the Wada test as a means of assessing the ability of the contralateral hemisphere to support memory independently when planning for resection of ipsilateral mesial temporal structures. The Wada test is employed on a routine basis in most epilepsy centers in an effort to prevent devastating memory loss following hippocampal resection. Rausch describes outcome data for 214 patients at UCLA who underwent anterior temporal lobectomy.[51] All patients underwent Wada testing prior to procedure and demonstrated 67% of correct responses when sodium amytal was injected on the side ipsilateral to the resection. No significant postoperative memory decline was demonstrated after resection. Jones-Gotman evaluated the results of patients who failed Wada memory tests compared to those who had passed (found to support memory in the contralateral hemisphere) and who had undergone temporal lobectomy.[52] Seventy-two patients were included in the sample; 11 who had failed the preoperative Wada test contralateral to the planned resection. Substantial postoperative losses with respect to long-term memory deficits 1 year after surgery were observed in those patients. In conclusion, the Wada test aids in determining whether or not memory can be adequately supported by the hemisphere contralateral to the planned resection.

The hippocampal formation appears to correlate with episodic memory functioning used in day-to-day living as opposed to semantic memory which refers to knowledge of a more encyclopedic variety. Patients with temporal lobe epilepsy have been found to have progressive memory decline with respect to normal controls.[53,54] Likewise after surgical resection, further decline has been reported. Despite a great deal of progress, the pathways of memory formation, consolidation, and retrieval have not been completely elucidated and appear to demonstrate considerable variability between subjects. Regardless, numerous studies implicate the neocortex of the temporal lobe in short-term or working memory functioning. Contrastly, the hippocampus has been implicated in memory consolidation.[53–55] Hermann *et al*. report on a series 57 patients with full scale IQ > 69, medically resistant temporal lobe epilepsy, with Wada proven left hemisphere dominance.[55] All subjects were given the California Verbal Learning Test preoperatively and 6 months postoperatively. This test provides information on overall recall ability, rate of learning, and indices of forgetting in addition to characterizing between different types of memory consolidation. This test involves oral presentation of a 'shopping' list of 16 items followed by five immediate recall trials. They found that patients who underwent a right-sided resection showed greater recall of words from the middle of the list, were able to utilize semantic clustering and demonstrated an overall greater ability to recall verbal material after a short delay. The patients undergoing left-sided temporal resection showed a lower proportion of words recalled from the middle of the list and exhibited more errors in free recall. The left-sided resected patients were more inefficient in their memory strategy. Given a list of 30 or more words, they were less able to remember words towards the top of the list and appeared to try to remember them by serial connection rather than semantic clustering. This means that they would attempt to recall the words by remembering the order in which they were presented rather than making associations to connect the various words together. This study lends support to the theory that the language dominant hemisphere hippocampus is important in allowing the person to cement memories into functional quanta.

Multiple studies including volumetric as well as histologic analyses have been done to demonstrate the role of the hippocampus in verbal memory functioning. A study by Trenarry *et al*. compared preoperative MRI-based hippocampal volumes with pre- and postoperative performance on an assortment of memory tests in 80 patients who underwent temporal lobectomy for medically intractable epilepsy.[56] The average hippocampal volume was noted to be smaller on the side ipsilateral to the resection which correlates with the numerous patients exhibiting mesial temporal sclerosis as a pathologic entity. They found that greater atrophy of the left hippocampal formation when compared to the right was associated with improved verbal and visual memory following a left temporal lobectomy. Contrastly, resection of a non-atrophic normal sized hippocampus resulted in verbal and visual memory decline. This data lends support to the idea that the hippocampus may be involved in both verbal and visual memory consolidation. Previous studies have shown that hippoampal cell loss in the CA1 region is observed reliably in patients with hippocampal sclerosis. Rausch and Babb evaluated 25 patients who underwent temporal lobe surgery for medically intractable epilepsy and found that the degree of hippocampal neuron loss was significantly related to memory function.[57] Preoperatively, patients with left temporal lobe seizures with severe neuron loss, defined as greater than 80% cell loss when compared to controls, performed worse than those with less than 80% cell loss. Postoperatively both sets of patients with left-sided resections decreased their performance on word pair tasks and delayed recall.

Numerous studies have been done to demonstrate postoperative memory decline following surgery for temporal lobe epilepsy. Chelune *et al*. conducted a prospective analysis of 42 patients with medically intractable epilepsy who underwent temporal lobectomy with Wada proven left-sided language dominance.[58] The patients were tested 3 months prior to their surgeries and at 6 months postoperatively. They found a significant decline in verbal memory tasks with those patients scoring the highest preoperatively demonstrating the most significant decline. A decrease in 1.5 standard deviations was evident in the verbal memory score. Rausch *et al*. compared 44 patients who underwent temporal lobectomy with eight patients who were found not to be surgical candidates.[54] All participants underwent cognitive testing preoperatively, 1 year postoperatively, and at least 9 years later. All patients had language dominance in the left hemisphere confirmed by Wada testing. Ninety Percent of patients were found to exhibit hippocampal sclerosis on pathologic analysis. They found that the group of patients who underwent left temporal lobectomy demonstrated decreased performance in verbal memory scores when compared with preoperative scores. Patients who underwent right temporal lobectomy showed increases in verbal memory scores. Long-term follow-up demonstrated progression in decline in verbal memory for both patients undergoing right- and left-sided resections as well as those patients who did not undergo surgery. These results support that left-sided temporal lobectomy for left-sided language

dominant patients is associated with a decline in verbal memory functioning postoperatively. However, the study implies that patients with temporal lobe epilepsy may exhibit a more rapid decline in memory functioning than would be expected in the general population. Helmstaedter *et al.* enrolled a total of 144 patients who underwent temporal lobectomy.[53] Participants were matched with respect to sex, age, seizure frequency, and IQ. Patients who failed the Wada test or who showed right hemisphere language dominance were not included. They found that left-sided temporal lobe epilepsy patients did significantly worse on preoperative performance measures of short and long delayed recall than patients with epilepsy localized to the right temporal lobe. Short and long delayed recall were impaired in only 34–40% of patients with right temporal lobe epilepsy compared to 70–80% of patients with left temporal lobe epilepsy. Postoperatively, no significant change was appreciated in any measure of verbal memory in right temporal lobe resections. Left temporal lobe resections by contrast showed marked negative effects on learning, recognition, and recall. The deficits observed were most pronounced in tests of memory acquisition and recognition.

The lateral neocortex has been implicated more in naming and short-term working memory tasks. The mesial temporal lobe and hippocampus specifically has been associated with long-term memory consolidation and retrieval. A study by Helmstaedter *et al.* sought to confirm this representation by comparing the type of memory deficits suffered by persons undergoing lateral versus mesial resections for epilepsy surgery.[54] They examined 47 patients with medically intractable temporal lobe epilepsy localized to the left hemisphere who underwent standard anterior temporal lobectomy, cortical lesionectomy, and selective amygdalohippocampectomy. Memory was assessed preoperatively and 3 and 12 months postoperatively using a variant of the Rey Auditory Verbal Learning Test. This test was designed to assess different aspects of declarative memory including working memory by means of immediate recall as well as long-term aspects such as consolidation and retrieval by asking for free recall following distraction, delayed recall, and recognition. The results were compared to 175 matched controls with no history of a central nervous system disease. A significant decrease in delayed free recall and an increase in recognition errors in patients who underwent anterior temporal lobectomy and selective amygdalohippocampectomy when compared to the cortical lesionectomy group. They also found a significant effect in patients who underwent temporal lobectomy with respect to selective amygdalohippocampectomy with a further deterioration in total immediate recall. A repeat analysis 12 months postoperatively was consistent with 3-month data to suggest stability of the outcome over time. These data support the hypothesis that the mesial temporal structures are correlated with long-term memory retrieval and consolidation while the lateral temporal lobe is more implicated in working memory. This study implies that perhaps anterior temporal lobectomy results in a deficit in both working memory and long-term memory whereas selective amygdalohippocampectomy may offer some preservation of working memory. However, a study of 140 patients who underwent selective amygdalohippocampectomy demonstrated a significant decline in all aspects of verbal learning and memory.[60] The results were standardized according to normative data of 200 healthy controls. Patients underwent a neuropsychological examination of verbal and visual memory functions preoperatively and 3 months postoperatively. Left-sided resected patients scored 2–3 standard deviations below the mean postoperatively. These deteriorations involved verbal memory learning, delayed free recall, and recognition. The authors found no recovery of postoperative verbal memory declines as clinically meaningful losses were evident in 33–50% of patients at the 1 year follow-up.[61]

Tailored resection for temporal lobectomy has been proposed in patients to preserve both language and memory function. A study by Ojemann and Dodrill demonstrated memory centers localized in the lateral neocortex of the temporal lobe.[62] In a study of 14 adults who underwent left temporal lobectomy with intraoperative mapping, the Weshler Verbal Memory Scale was employed to study memory function pre- and postoperatively. The score decreased an average of 22% at 1 month and 11% at 1 year. In the mapping studies, they found the presence of temporo-parietal zones of memory sites which largely bordered naming sites. They then correlated the presence of these sites with the proximity to the resection bed. They found that the presence of these sites within the resection zone was present in five of six patients who demonstrated a significant memory decline postoperatively indicative of an 80% predictive ability.

Numerous studies have been done in an attempt to elucidate which patients may be at greater risk for postoperative memory decline. One study found that later age at onset of epilepsy and older chronologic age were risk factors for memory deficits.[63] Two hundred three patients were assessed using the California Verbal learning Test preoperatively and 6 months postoperatively following anterior temporal lobe resection. In this study, higher postoperative scores correlated with higher preoperative scores, younger chronologic age, higher full-scale IQ, female sex, and right-sided resection. To explain the variance in higher preoperative scores being associated with higher postoperative scores, they suggest that, when all other preoperative variables are held constant, a person with higher intelligence is better able to compensate. In a multiple regression analysis performed on 144 patients who underwent anterior temporal lobectomy several factors were felt to be predictors of postoperative deterioration.[53] High presurgical performance level, older age, longer duration of epilepsy, extensive en bloc resection, preexisting deficits in memory performance and preoperative secondarily generalized seizures were all associated with a decline in memory function postoperatively. The effect with respect to age appeared to correlate well with an age of 30 years at the time of surgery. Only 17% of patients aged > 30 demonstrated stable or improved memory performance postoperatively. A further analysis to evaluate the role of regression based outcome methodology was employed on a cohort of 101 patients found a significant performance decline in 25–50% of patients with left-sided resections.[42] However, they noted a significant range of memory outcome within groups to support the great deal of variability found in numerous other studies. In a study by Hermann *et al.*, 60% of patients with left anterior temporal lobectomy experienced postoperative decrease in verbal memory but 38% showed improvement illustrating the great deal of individual variance between patients with respect to functional outcomes.

In summary, the role of the temporal lobe in memory function is both complex and critical. The Wada test is an important tool which has been developed to determine the ability for the contralateral hemisphere to adequately support memory following temporal lobe and hippocampal resection. However, even when one is careful to offer surgery only to those patients who have favorable Wada test results, memory deficits remain a significant complication observed following this surgery. In patients with left-sided language dominance, the risk of memory dysfunction postoperatively appears to be greater than those who undergo right-sided resection. The presence of preoperative memory deficit in setting of mesial temporal sclerosis may mitigate the risk of a decline in verbal memory postoperatively. The deficits that are observed following temporal lobectomy are characterized by difficulty with working memory and memory consolidation. Resection of the lateral neocortex appears to result in a deficit of working memory whereas resection of the mesial structures results in difficulty with memory consolidation. These deficits often require the patient to adopt different strategies for memory consolidation such as outward documentation to assist them in their day-to-day living. Postoperative neuropsychological testing, in addition to studying the types and degree of memory difficulty observed following temporal lobe resection, provides a tool for the patient and patient's family to identify particular weaknesses which then may be addressed. Older age at epilepsy onset, older chronologic age, higher preoperative functioning, and left-sided resections appear to be risk factors for memory deficits postoperatively. Taken together, these data illustrate particular trends which may correlate to predictive analysis of postoperative memory decline but that for each individual there exists a great deal of variance.

Cognitive deficits

Cognitive difficulty has been noted in patients with temporal lobe epilepsy when compared to controls. Progression of the disease is associated with progressive cognitive impairment prompting a role for medical or surgical control of seizures. The question of whether the extent of the neocortical resection correlated to the degree of cognitive impairment was addressed by Lutz *et al*. comparing 80 randomized patients who either underwent transylvian approach or transcortical approach for mesial resection.[64] All patients received comprehensive neuropsychological testing of verbal, non-verbal memory, attention, and executive functions before and 6 and 12 months following surgery. It was found that 75% of patients became seizure free with no appreciable difference observed with regard to surgical approach. Repeated multivariate analysis of variance measures demonstrated no statistical difference between cognitive outcomes with the exception of phonemic fluency which was improved after transcortical but not after transsylvian approach. This improvement in verbal fluency with the transcortical approach has traditionally been attributed to seizure freedom postoperatively. However, the authors felt that the improvement with the transcortical approach may be a reflection of this function being more closely associated with frontal lobe manipulation. Verbal fluency could be regarded more as an executive function and, as such, has its seat in the frontal lobe. The frontal lobe is manipulated with retraction more with the transylvian approach than with the transcortical approach.

In a study by Wachi et. al., 26 patients who underwent anterior temporal lobectomy including excision of the hippocampus were evaluated with a battery of neuropsychological tests pre- and postoperatively.[65] They found a uniform improvement in cognitive functioning following resection. A significant increase was observed in verbal IQ from 85.1 to 89.3. Performance IQ also increased from 89 to 95 1 year postoperatively. Full-scale IQ scores also were observed to increase at 1 year after surgery from 85.5 to 88.5. There was no significant difference between memory function as determined using story recall test, Benton's visual retention test, Rey-Osterreith complex figure test, and the WMS-R between preoperative analysis and postoperative analysis. These improvements were felt to be reflective of an overall decrease in seizure frequency with 62% of the patients being seizure free. However, the study was made of a small sample size and statistically significant comparisons could not be made between left- and right-sided resection.

The role of tailored resection with respect to cognitive preservation was undertaken by Leitjen *et al*.[66] Eighty patients with pathologically proven mesial temporal lobe sclerosis underwent surgery. These patients underwent a standard neuropsychological test battery 6 months prior to and 6 months after the surgery including verbal IQ (VIQ), performance IQ (PIQ), visual naming, and a complex figure test. Sixty-one percent of the patients demonstrated neocortical spikes on the intraoperative ECoG. Interestingly, patients with left-sided resections with neocortical spikes demonstrated a slightly improved VIQ preoperatively than their counterparts without spikes. They found an improvement in PIQ in patients who underwent tailored resection, but not in any other modality. It was felt that this was in contrast to their initial hypothesis that neocortical spikes were indicative of dysfunctional tissue and that removal of such spikes would allow for a better cognitive performance outcome, especially in regard to language function thought to be harbored in the neocortex of the temporal lobe.

Taken together, these studies support that improved seizure frequency results in overall improvement in visual and performance IQ following surgery for temporal lobe epilepsy. A complete resection of the mesial structures without regard to intraoperative mapping may allow for greater seizure control and thus correlate with improved outcome in cognitive functioning.

Psychiatric deficits

Epilepsy in itself has been associated with a higher incidence of a major depressive illness and suicide. It is estimated that the suicide rate in epilepsy patients is five times that of the general population.[67,68] One study found that up to 50% of patients with epilepsy suffer from depressive syndromes.[69] Patients with temporal lobe epilepsy have been found to have an even higher risk of depression.[63] Temporal lobe epilepsy, in particular, has been associated with a variety of psychological disturbances both before and after resective procedures. The proximity to the limbic structures has been implicated as a possible reason for higher incidence in mood and psychiatric disturbances. The amygdala in particular has been associated with processing of fear response. In one study of 28 patients who had undergone anterior temporal lobectomy, a postoperative impairment was found in recognizing facial expressions

of fear, anger, sadness, and disgust.[70] In a prospective randomized controlled trial of 80 patients who either underwent temporal lobectomy or received optimal medical therapy the rate of depression was fairly equally represented between both groups.[11] Eighteen percent of patients were diagnosed with depression in the surgical group compared to 20% of patients in the medical groups indicating the increased prevalence of this problem in this population. Since the landmark study by Kluver and Bucy describing a state of hypersexualuality, loss of fear, hyperphagia, and generalized apathy following bilateral temporal lobectomy, various psychiatric derangements have been attributed to the temporal lobe.[71] Disturbances in mood, emotional responses, and even schizophrenic-type illnesses have been localized to the temporal lobe. Blumer's report, based on a series of 50 patients who underwent temporal lobectomy and were followed for an average of 17 years sought to examine the type of psychiatric sequelae of the surgery.[68] Fifty patients experienced an exacerbation or onset of a chronic schizophrenia-like psychosis. Ten percent also demonstrated angry and aggressive behavioral outbreaks. Many patients preoperatively demonstrated hyposexuality. These patients were observed to have developed normal sexual arousal and occasional hypersexuality postoperatively. Fenwich *et al.* conducted a literature review and circulated a questionnaire to multiple centers around the world to study the current practice and outcomes of surgery with regard to psychiatric complications.[72] In comparing three separate series, there was a rate of developing a schizophrenia-type psychosis in 15.4%, which is greatly increased from the stated 1% lifetime incidence documented for the general population. A retrospective analysis was performed by Inoue and Mihara to assess the presence of psychiatric morbidity in association with epilepsy surgery.[73] Their subjects consisted of 226 patients who underwent surgical therapy between 1983 and 1997. Seventy-eight percent of the patients exhibited psychiatric disorders before and after surgery. Of those 61 patients who demonstrated psychiatric disturbances before surgery, one-third of them resolved following surgery. Nine patients were found to have transient affective disorder immediately postoperatively which resolved in 1–2 months. Eight patients developed a chronic psychiatric disorder de novo following surgery. Of these, six were found to have psychosis and two developed behavioral disorders. This study suggests that about a third of persons with psychiatric disorders prior to surgery will experience resolution of their symptoms postoperatively, while the rest will persist. It also suggests, that in a select minority of patients, a de novo psychiatric disturbance will become manifest after surgery. Shaw, interested in the association between temporal lobe surgery and postoperative schizophrenia-like psychosis, performed a retrospective analysis of a series of 320 surgical patients.[74] They identified 11 patients who developed a schizophrenia-type psychotic illness postoperatively and compared them with 33 control subjects who remained free of psychosis. The psychotic illness was characterized by the presence of persecutory delusions and auditory hallucinations. They found no clear association between postoperative seizure activity and the development of psychotic symptoms. However, they did find that those patients were more likely to demonstrate pathologies other than mesial temporal sclerosis as five of the 11 had lesions such as vascular hamartoma, DNET, ganglionglioma, and abscess. Additionally, they found that the psychotic patients were more likely to demonstrate bilateral EEG abnormalities.

Christodoulou *et al.* made an interesting observation in reviewing a case series of 282 consecutive patients who underwent temporal lobe resections for epilepsy.[75] Fifty-six patients demonstrated persistent or recurrent seizures postoperatively. Three of these patients developed a chronic psychotic illness. Upon further study, it was found that all three of these patients demonstrated a new seizure type postoperatively arising from the side contralateral to the resection. This appears to support the theory that patients prone to psychotic breaks may have some inherent involvement of both hemispheres, perhaps brought out by resection of one side of the mesial temporal structures.

Epilepsy surgery has also been associated with a higher predisposition to somatic-type disorders. A retrospective review of 325 anterior temporal lobectomies performed between 1991 and 2000 at New York University Hospital found 10 patients (3%), who developed somatoform disorder.[76] These were characterized by body dysmorphia and pain disorder. Nine of the ten had undergone right resections which correlate with previous data implicating the right temporal lobe in psychotic corrolaries. It is difficult to assess objectively the psychiatric complications of temporal lobectomy for epilepsy as many of these patients demonstrated abnormal psychiatric profiles preoperatively. In general, it is felt that a majority of patients develop stronger emotional ties, family relationships, and become more functionally independent following the procedure likely secondary to its improvement in seizure control. However, for a select few, it may predispose them to developing a severe psychotic illness similar to schizophrenia. It is recommended that potential candidates for resective surgery be considered for a psychiatric assessment prior to the procedure to ensure that they are receiving optimal therapy prior to any potential surgical intervention.

Conclusion

In conclusion, surgery for medically intractable temporal lobe epilepsy is associated with a broad variety of complications. When counseling prospective candidates for this procedure, one must keep in mind the intricate structure and relationship of the temporal lobe with its surroundings as well as the variety of functions intrinsic to the temporal lobe itself.

The surgical complications most frequently encountered include hematoma and infection. The risks of craniotomy vary between institutions and should be quoted as such. In general, a risk of postoperative infection is on the order of 2–5%. Risk reduction is achieved by employing sterile technique and perioperative antibiotics. The risk of a clinically significant hematoma is on the order of 1–2% which may necessitate a need for a repeat craniotomy for hematoma evacuation. Wound complications such as dehiscence, superficial wound infections, and CSF leak all have been seen with routine craniotomies as well as with temporal lobe epilepsy surgery. Wounds should be monitored closely postoperatively and a strict wound care regimen should be followed.

In consideration of the potential neurological complications, one must recall the more rare deficits such as injury to

the anterior choroidal artery and resultant hemiplegia as well as the routinely observed contralateral upper quadrantanopsia seen postoperatively. Motor deficits postoperatively appear to be secondary to vascular injury. Risk factors for vascular disease such as increasing age, hypertension, hypercholesteromia may all be considered not only for risk to specific vessels but also in regard to the patient's overall surgical risk. The risk for a potential visual field defect is on the order of 50%. The majority of patients are unaware of this deficit, but in up to 12% of patients, a more significant and disabling defect such as a complete homonymous hemianopsia may develop. Cranial nerve palsies of the third and fourth cranial nerve can occasionally be observed postoperatively. These may be quite bothersome for the patient but usually are transient in nature.

The potential adverse effects on language and memory were discussed in detail. The temporal lobe harbors various regions associated with language function such as Wernicke's area and other regions identified with intraoperative mapping studies, and resection of the language dominant temporal lobe can result in a significant dysnomia. This appears to improve with increasing postoperative period and may resolve entirely. Older age at onset of epilepsy appears to be a risk factor which may be associated with poorer postoperative language function. Many patients demonstrate improvement in language which is likely multifactorial but may be associated with overall seizure control. The possible detriment to memory function is significant and can be severe. The ability for the contralateral hippocampal formation to independently support memory should be evaluated preoperatively and surgical resection planned accordingly. The type of memory most affected appears to be episodic memory consolidation. Patients who develop postoperative memory deficits appear to exhibit difficulty with employing strategies for recalling information attributable to the events of daily living that is not in their immediate memory banks. This type of deficit appears to be stable with time. Patients may benefit from learning various means to cope with this outcome.

Lastly, the psychological sequelae of this surgery were discussed. Temporal lobe epilepsy of its own right is associated with an increased incidence in psychiatric morbidity including mood disorders, somatic disorders, as well as psychotic disturbances. The risk of introducing a new psychiatric illness is fairly rare, but there is a clear association between development of a postoperative psychotic illness similar to schizophrenia and surgery for temporal lobe epilepsy. Neuropsychological analysis should be considered prior to surgery to ensure that the patient is enrolled in optimal treatment paradigms.

This chapter serves as a basic outline of the potential pitfalls associated with surgery for temporal lobe epilepsy. One must remember that in addressing the risks and benefits of this surgical procedure, each patient should be assessed as an individual. The percentages and data presented here serve only as guidelines. The neurosurgeon and neurologist involved will need to balance each patient with respect to individual risk for surgery, potential neurological complications, potential cognitive complications, as well as psychiatric complications. The surgical approach and the use of mapping need to be considered on an individual basis. In doing so, one can hope to provide the best hope for a good surgical outcome unfettered with complications.

137 Neocortical focal epilepsy surgery: surgical complications

JA González-Martínez and WE Bingaman

Introduction

The main goal of the pre- and intraoperative evaluation for epilepsy surgery is to identify possible candidates in whom surgical intervention will totally or partially control seizures without increasing neurological deficits or general morbidity. The neurosurgeon is dependent on this evaluation, to identify potential candidates for epilepsy surgery, for developing a safe operative strategy, and to minimize complications. For that reason, this chapter will concentrate on the topic 'surgical complications in neocortical focal epilepsy surgery' addressing complications from diagnostic and therapeutic procedures.

In general, we can divide complications in focal neocortical epilepsy surgery based on pathophysiological mechanisms:

Surgical complications
- Infection
- Hematoma
- Brain swelling
- Hydrocephalus
- Vascular compromise (arterial or venous)

Injury to eloquent areas of the brain causing neurological impairment
- Hemiparesis
- Hemiplegia
- Visual field defect
- Aphasia
- Alexia
- Neuropsychological impairment (deficits in cognition, memory, language, attention, and concentration).

Psychosocial impairment
- Family and interpersonal relationships
- Self esteem
- Vocational/educational

Psychiatric impairment
- Depression
- Anxiety
- Psychosis

In regard to surgical procedures related to neocortical focal epilepsy, we can additionally classify complications due to focal neocortical resections in:

Diagnostic procedures
- Complications associated with subdural grid and strip electrodes, depth electrodes and stereoelectroencephalography (SEEG).

Therapeutic procedures – resective surgery
- Complications associated with frontal (mesial and lateral) resections
- Complications associated with temporal lobe resections
- Complications associated with parietal and occipital resections.

Procedural complications

Diagnostic procedures: subdural grids/strip electrodes, depths electrodes, and SEEG complications

When noninvasive studies remain nonconcordant or inconclusive regarding the localization and the extent of the seizure onset zone and/or the eloquent cortex, invasive studies using subdural grids, strips or depths electrodes may be needed.[1–3] Jayakar and colleagues proposed the following relative indications for the evaluation with invasive monitoring: normal structural imaging, extratemporal location, divergent noninvasive data, encroachment on eloquent cortex, tuberous sclerosis, and cortical dysplasia.[3] Rosenow and Lüders[4] recommended the use of invasive monitoring only in patients with focal epilepsy (single focus) in whom there is a clear hypothesis regarding the location of the epileptogenic zone (derived from noninvasive studies).

The intracranial placement of subdural grid electrodes via craniotomy has received increasing acceptance over the past decade. Invasive electroencephalogram (EEG) monitoring by subdural grid electrodes facilitates prolonged electrographic assessment as well as extraoperative functional brain mapping. Also, it is particular important in pediatric cases in which awake surgery and intraoperative functional mapping is often difficult.

The principal complications of grid electrode implantation include infection and subdural hematoma formation

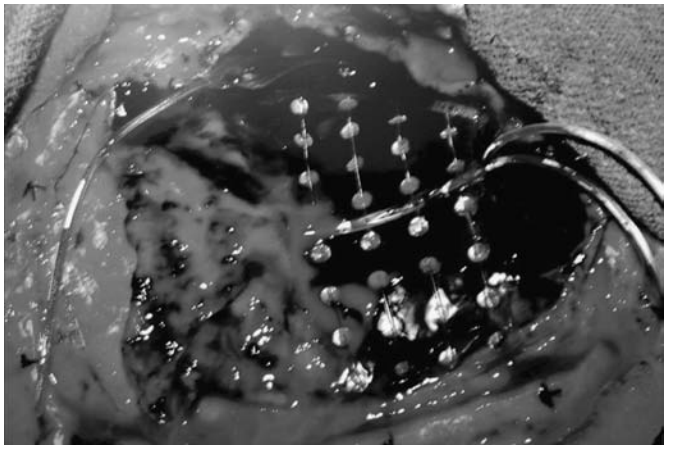

Figure 137.1 Intraoperative aspect of large subdural hematoma located underneath the subdural grid.

(Figure 137.1), which may be associated with neurological deficits, elevations of intracranial pressure, and even death.[5–7]

Other complications may include brain swelling and arterial or venous infarctions (Figure 137.2). In a recent series, of the two hundred twenty-eight cases from nine centers, the reported complications included infection, hemorrhage with transient deficit, increased preexisting hemiparesis, aseptic necrosis of the bone flap, and transient elevations in intracranial pressure.[8] In an individual series from the Cleveland Clinic, an initial infection rate of 22% declined to 7% when subcutaneous tunneling of electrode cables was instituted.[9] More recently, routine use of perioperative antibiotics and water-tight dural closure with sutures at cable exit sites has been advocated in our group.[10] Since these modifications were introduced, the infection rate has declined markedly.

Figure 137.2 Complication of subdural grid placement: Venous infarction located in the left frontal lobe region after subdural grid placement. Postoperative CT after subdural grid removal and bone decompression.

In the absence of a multicenter, prospective complications survey, anecdotal reports of subdural hematoma formation, increased intracranial pressure (ICP), and death following grid placement have been documented in the literature.[11] Some centers recommend routine, perioperative decadron and mannitol administration over the 2–3 days after surgery, dural grafting, or leaving out the bone flap during the period of monitoring as responses to the threat of increased intracranial pressure. Circumferential dural incision, linning of the outer grid surface with hemostatic agents, and tapering of valproic acid are also recommended to reduce hematoma formation.[12] There is no data with respect to the relative value of any of these practices in preventing individual complications.

Regarding subdural strip implantation, the epilepsy surgery literature suggests that subdural strip electrode insertion may be safer than depth electrode placement.[7,13–15] No examples of significant hemorrhagic complications associated with prolonged neurological deficit or death have been reported so far. Localized infections occur at a slightly lower frequency when compared with depth recordings and usually respond to antibiotic therapy alone. In a recent series of three hundred fifty patients, two cases of meningitis, one brain abscess associated with hemiparesis, and three superficial wound infections were reported.[16] In two additional reports studying 122 patients, no hemorrhagic, neurologic, or infectious complications occurred following strip electrode placement.[17,18]

Different techniques of invasive monitoring exist and each has its advantages and disadvantages. Chronically implanted subdural electrodes allow recording from large superficial cortical areas, but they provide limited coverage of deeper structures, such as the hippocampus, the interhemispheric region or cortex within sulci. Intracerebral electrodes have the advantage of excellent sampling from mesial structures and from deep cortical areas, with the disadvantage of providing information from a limited volume of tissue. Combined use of subdural and intracerebral electrodes also has been advocated. In a recent publication, Cossu *et al.*[19] presented a retrospective study of a large series of patients (211 patients) who underwent stereoelectroencephalography (SEEG) evaluation. SEEG provided additional guidance towards epileptic focus resection in 183 patients (87%), resulting in a seizure-free outcome in 44% of the cases, and an overall significant improvement in 82%. Major complications occurred in less than 1% of the patients, with an overall hemorrhagic event risk of 4.2%. Other complications included one brain abscess, not resulting in permanent deficit, one episode of focal cortical edema, and one retained broken electrode. The authors concluded that SEEG is a useful and relatively safe tool in the presurgical evaluation of focal epilepsy.[19]

As highlighted by others, important issues relating to depth electrode placement and associated complications include: (1) the relative safety of lateral, parasagittal, and tangential methods of insertion, (2) the relative safety of flexible versus rigid electrodes, (3) the role of computer-assisted work-stations in the improvement of stereotactic accuracy and the reduction of vessel injury, and (4) the effect upon infectious complications of length of monitoring, antibiotic prophylaxis, tunneling of electrode leads, and methods of electrode removal.[19]

Resective surgery complications: temporal neocortical focal resections

In general, there are at least four different surgical approaches to treat mesial temporal lobe epilepsy. These approaches include: (a) en bloc temporal resection or standard temporal lobectomy, (b) awake temporal lobectomy with tailored resection, (c) amygdalohippocampectomy, and (d) radical hippocampectomy. Each technique represents a different approach to the identification and resection of the epileptogenic zone. Because this chapter is focused on complications in neocortical epilepsy surgery, complications related to mesial temporal lobe resections will not be discussed.

In an extensive review of the literature performed by Pilcher and Ojemann regarding complications of anterior temporal lobectomy, mortality occurred in less than 1%, mainly caused by hemorrhage, infarction, pulmonary complications and sudden death. Other complications included hemiparesis (transient or permanent) in 2–4%, minimal visual field defects in more than 50%, and severe field defects (hemianopsia) in 2–4%. Infections (meningitis, abscess), epidural hematoma, and III nerve palsy (transient) occurred in less than 2%. Neurobehavioral complications included transitory anomia (less than 1 week) in 20% of the patients, persistent dysphasia in 1–3%, and transitory psychosis/depression in 2–20%.[12]

Penfield reported a 2.5% hemiplegia in an early Montreal Neurological Institute (MNI) series. He attributed this complication to excessive manipulation of branches of the middle cerebral artery (MCA) during the trans-sylvian resection of insular cortex.[20] Alternative explanations included direct capsular injury with insular resection as well as compromise of the lenticulostriate vessels and the anterior choroidal artery.

Visual field deficits occur following temporal lobe resections in approximately 50% of operated patients. These deficits are often incongruous or worse in the ipsilateral eye, due to the anterolateral location of ipsilateral fibers overlying the anterior portion of the temporal horn (Meyer's loop). Severe visual field deficits considered disabling by patients are less frequent and were reported in 8% in our previous series.[9] Rasmussen *et al*. suggested that by limiting the extent of the superolateral ventricular opening to 1 cm, quadrantic deficits could be avoided entirely.[21–23] Other studies also suggested that the magnitude of the visual field deficit was entirely related to the extension of the ventricular opening, mainly in the ventricular roof in the temporal horn. Alternatively, direct surgical injury to the optic tract, lateral geniculate nucleus, or optic radiation in the posterior temporal lobe white matter can also cause visual field deficits.

Postoperative anomia or dysphasia is not uncommon following dominant temporal lobectomy. These aphasias are largely resolved after 1 week. Transitory dysphasias are reported in up to 30% of operated patients in the setting of awake surgery with intraoperative language mapping. Removal of the anterior temporal or inferior-basal language sites may explain this phenomenon.[12] Other explanations include resection of cortex within 1–2 cm from essential language areas, brain retraction, and disruption of white matter pathways connecting language areas.

According to Crandall and colleagues, persistent language disorders were found in three of 53 patients undergoing temporal lobe resection.[24] In another series, five of 25 patients were aphasic at the time of discharge (Katz *et al*. 1989).[25] In the MNI series, using intraoperative language mapping, two of 250 patients were reported to have long-lasting aphasia after surgery.[21–23] In both cases, aggressive resection near essential speech areas was performed. In the Seattle series, removal of brain within 1–2 cm of essential sites established by intraoperative mapping was associated with mild language deficits.[26–28]

The 'tailored operation' is designed to use language mapping techniques to identify and protect neocortical language sites. In a comparison of 'standard' versus tailored temporal lobectomies performed by a single surgeon, a slight increase in postoperative dysnomia was identified 6 months after surgery following a 'standard' operation.[29]

Therapeutic procedures: extratemporal neocortical focal resections

The extratemporal epilepsies considered for resective therapy are less frequent, more variable in their presentation, and are associated with a less favorable seizure outcome postoperatively than is the temporal lobe epilepsies. Additionally, the epileptogenic zone is more likely to involve eloquent cortex and intraoperative or extraoperative brain mapping is often necessary. All of these factors have a direct impact upon the complications of extratemporal neocortical focal resections, especially the functional consequences of adequate removal of the epileptogenic zone in eloquent cortex. In a systematic fashion, we can divide extratemporal focal resections into frontal, central, parietal and occipital resections.

Frontal resections

The frontal lobe encompasses one-third of the cerebral cortex volume, yet, despite its large size, the frequency of surgically treated frontal lobe epilepsy is small as compared to temporal lobe epilepsy. This varies between 18%[30,31] and 5.5% in larger series. This may be due to the inherent complexity, variable presentation, presence of eloquent cortex, and difficulty with EEG localization often seen with frontal lobe epilepsies.

The manifestations of frontal lobe epilepsy can be divided into three major subgroups:[32–34] Supplementary motor seizures, complex partial seizures and focal motor seizures. The localization of an ictal onset area is difficult in frontal lobe epilepsy and is facilitated when a lesion is present on imaging.[30]

Anatomically, Broca's area is located in the inferior frontal gyrus at *pars triangularis* and *pars opercularis* of the dominant frontal lobe, and this region is generally avoided when dominant frontal resections are performed under general anesthesia. The cortical representation of essential language sites may be quite variable and brain mapping techniques are often utilized to tailor frontal resections and avoid language complications. These investigations may identify zones of language cortex quite separate from Broca's area within middle,

superior, and even parasagittal frontal cortex in the region of the supplementary motor area.

Transitory aphasic syndromes are often caused when resections are carried within 1–1.5 cm of these essential language areas.[26,27] Long lasting expressive aphasia can follow resection or operative injury (vascular compromise) to language sites in the posterior inferior frontal gyrus. Any resection involving frontal cortex, but especially parasagittal cortex (superior frontal gyrus), may cause compromise of draining frontal veins with associated postoperative edema and potentially venous infarction leading to postoperative language and motor deficits.

The supplementary motor area (SMA), defined by Penfield and Welch[35] is located in the mesial superior frontal cortex of the lower extremity, superior to the cingulate gyrus. Functional studies have shown that this area is activated during initiation of movement and vocalization. Stimulation of this area leads to a fencing posture with bilateral motor movement. The SMA is extensively and somatotopically connected to the corpus callosum, resulting in fast spread of the ictal discharges to the contralateral side, making lateralization of the ictal onset zone difficult.[36] Resection of the supplementary motor area may produce a supplementary motor cortex syndrome characterized by mutism (dominant SMA cortex), and contralateral neglect with a hemiparesis characterized by diminished spontaneous movement which gradually resolves over several weeks.[37,38] On long term follow-up, gross motor deficits are rare.

The orbito-frontal area is limited laterally by the orbitofrontal sulcus, medially by the olfactory sulcus, anteriorly and superiorly by the frontomarginal sulcus, and posteriorly by the anterior perforated area. The orbito-frontal cortex is extensively connected with the anterior and mesial temporal lobe, cingulum, and opercular area and thus frequently misdiagnosed as anterior temporal seizures.[39] Adequate sampling of these structures using invasive electrodes is recommended. On the nondominant side, extensive resection of the orbitofrontal cortex can be performed without deficit. The intersection of the optic nerve and the olfactory nerve and the anterior face of the M1 segment of the middle cerebral artery are used as the posterior anatomical landmarks of the resection. On the dominant side, mapping of Broca's area should be performed.

The cognitive effects of extensive frontal resections are clinically insignificant with minimal consequences in daily life activities.[40] Furthermore, provided that a careful subpial technique is employed with preservation of the vascular supply to motor cortex, frontal excisions may be safely carried up to the pial bank of the precentral gyrus. Care must be taken, however, not to undermine the motor cortex if the resection is extended into the white matter.

Central resections (perirolandic)

Central type epilepsy or seizures arising from the primary motor and sensory area are relatively infrequently encountered in surgical series. In patients with preserved motor function, these epilepsies present considerable challenges. A more aggressive approach to the perirolandic epilepsies is gaining acceptance with improved surgical techniques such as extraoperative functional mapping of central cortex, intra-operative mapping by direct cortical stimulation, and microsurgical technique.

Resection of the face motor cortex

The partial resection of the nondominant face motor cortex may be safely performed, resulting in a transitory contralateral facial asymmetry. Complete removal may be associated with perioral weakness and dysarthria in some patients. The superior resection margin should extend no higher than 2–3 mm below the lowest elicited thumb response. In the dominant hemisphere, some surgeons report postoperative dysarthrias and dysphasias following face motor cortex excision. Nevertheless, Rasmussen *et al*. reported that complete removal of dominant face motor and sensory cortex may be safely performed provided that manipulation of underlying white matter or ascending vascular supply is avoided.[21–23] It is our experience that essential motor language sites may be found just anterior to motor tongue cortex in the inferior or even middle frontal gyrus. Certainly, mapping of these areas is mandatory to avoid a postoperative deficit after dominant frontal lobe resections involving the lower perirolandic cortex.

Resection of the hand/leg motor cortex

The resection of the primary hand motor cortex produces a permanent deficit of fine motor control and should be avoided if useful hand function is present preoperatively. Resection of the primary leg motor cortex will elicit an immediate flaccid leg paralysis followed by gradual partial recovery of ambulatory capacity over months.[21–23] Proximal limb function is likely to recover however distal ankle and foot permanent weakness are often present, requiring use of orthoses for safe ambulation.

Resection of the sensory cortex

The resections of leg or face sensory cortex cause permanent but clinically insignificant deficit of proprioception in the leg or two-point discrimination in the lower face.[41] In contrast, resection of hand sensory cortex is followed by important functional impairment, with the majority of patients showing deficits of pressure sensitivity, two-point discrimination, point localization, position sense, and tactual object recognition, which makes functional use of the involved hand difficult.[41]

Parietal resections

Seizures originating in the parietal lobe account for up to 6% of reported series but very few articles reporting complications in parietal resections are available in the literature. A large proportion of patients exhibit an aura, most commonly somatosensory.[33] Pain, vertiginous sensation, aphasia, or disturbance of body image is suggestive of parietal origin. The ictal manifestations are varied and reflect the quick spread to the frontal lobe in superior parietal epilepsies and to the temporal lobe in inferior parietal cases.[42] Interictal and ictal scalp EEG recordings were not reliable markers for parietal lobe epilepsy. In two recent series, surgery resulted in

satisfactory seizure control. Salanova *et al.* reported the MNI experience of 79 patients with nontumoral parietal lobe epilepsy. Of these, 45.5% were seizure free, 19% had rare seizures, and 21.5% had worthwhile improvement. Persistent dysphasia was noted in two patients, a Gerstmann's syndrome in one, and contralateral weakness in three cases.

Large parietal resections may be undertaken posterior to the central cortex in the nondominant hemisphere without causing a sensorimotor deficit and with a rate of hemiparesis of approximately 0.5%.[21–23] A non-dominant parietal syndrome may follow these resections in some individuals. In the dominant hemisphere, language mapping must be used to avoid postoperative language deficits. When resections are extended into the parietal operculum, contralateral lower quadrantic or, hemianopic visual field deficits (rare) may occur as resections are performed beyond the depths of the sulci into the white matter.[8,21–23]

Occipital resections

Occipital lobe seizures are rare, representing just 1% of epilepsy surgery patients in the MNI series.[33] Early clinical manifestations of elementary visual hallucinations, ictal amaurosis, eye movement sensations, and blinking are highly suggestive of an occipital origin.[42] In infra-calcarine cases, quick spread to the temporal lobe can produce symptomatology typical of mesial temporal lobe epilepsy. An imaging abnormality is found in a large proportion of cases.[42] In patients with hemianopsia, resective surgery carries minimal risk. On the dominant hemisphere, the speech related cortex should be identified and spared. The management of patients with intact vision is challenging. When a circumscribed lesion is found, lesionectomy can yield satisfactory results. In non-lesional cases, the ictal onset area should be precisely localized using invasive electrodes.[43] These are used in addition to mapping of the calcarine cortex and speech related cortex. With this strategy, visual deficts can be minimized. Resections of the dominant basal temporal lobe should be carefully planned as this can yield an alexia without agraphia deficit.[1,2]

Contralateral homonymous hemianopsia often follow resections in this area, despite careful extraoperative mapping of cortical function. If vision is intact preoperatively, calcarine cortex and optic radiations must be spared as much as possible if the occurrence of an hemianopsia is to be avoided. The use of intraoperative visual evoked potential (VEP), intraoperative direct stimulation, and radiological techniques to map the geniculocalcarine projections (diffusion tensor imaging or DTI) are still under investigation.

If adequate data from invasive monitoring is available to suggest that the superior calcarine gyrus may be spared, an inferior calcarine gyrus resection with or without an aggressive resection of mesial temporal lobe structures will result only in a superior quadrantic deficit associated with minimal disability. Excision to within 2 cm of Wernicke's area in the domimant hemisphere may elicit persistent dyslexia.[21–23] Therefore, exposure at craniotomy should be adequate to provide access to the postcentral gyrus and parieto-temporal language areas, which will serve as the anterior limits of resection.

Conclusions

A valid appreciation of the complications of epilepsy surgery is fundamental to balance the risks and benefits of diagnostic and therapeutic procedures. Unfortunately, the medical literature available on this topic does not reflect contemporary surgical practice. Available data is derived from the surgical experience of a few highly experienced surgeons working in well-established comprehensive epilepsy centers and used patient selection criteria and operative approaches which have since been modified or radically changed.

Although a prospective trial to study the risks of invasive monitoring and other surgery related complications is not feasible, more literature on contemporary outcomes and complications using modern day surgical techniques is necessary. As the number and complexity of patients referred for epilepsy surgery continue to increase, surgeons are obligated to accurately report complications occurring from surgical treatment. As this chapter has outlined, complications are quite variable depending largely on the region of the brain operated. Armed with this knowledge, the surgeon and patient can truly make informed decisions regarding the risks and rewards of cortical resections to treat medically intractable epilepsy.

Post-surgical management

138 Early post-surgical management of patients with epilepsy

I Melamed and AA Cohen-Gadol

Introduction

Post-operative management of patients who have undergone epilepsy surgery should be tailored based on the needs of each individual patient but is similar to those who have undergone other types of major craniotomies. There are certain common factors that should be considered in the early post-operative management of patients who undergo epilepsy surgery. These include prevention and control of post-operative seizures, infection, cerebral swelling, and new expanding mass lesions such as a hematoma. Thorough communication with the patient and family is especially important to decrease their anxiety and make them comfortable about the need for additional interventions and the prognosis.

The patients undergoing surgery for intractable epilepsy also form a unique subset of patients with very specific needs that should be addressed in the immediate post-operative period. One of the specific needs of major importance pertains to prevention and control of post-operative seizures. Therefore, the major portion of this chapter is dedicated to management of early post-operative seizures for patients who undergo epilepsy surgery. We will also briefly discuss the relevant post-operative psychosocial issues among this patient group.

Management of post-operative infection and hematoma

With recent advances in epileptogenic focus localization and microsurgical techniques, epilepsy surgery has become relatively safe. In the report for temporal lobe and localized neocortical resection for epilepsy, Engel and his associates summarized a total of 556 patients from seven institutions in whom the morbidity and mortality of resective procedures were addressed.[1] In this group, there were two deaths (0.4%). These were not a direct result of surgery but occurred within 1 month of surgery. Two subdural hematomas were reported but those did not lead to a permanent morbidity. There were 34 patients with new neurological deficits (6%). These included 17 mild aphasias, five 3rd or 4th cranial nerve palsies, ten visual field deficits, greater than a quadrant, and 12 instances of hemiparesis. Sixteen (3%) of these 34 patients had deficits that were transient, resolving within 3 months, while 18 (3%) had permanent deficits. There were 26 (5%) instances of infection, nine (35%) of which were wound infections.

The use of prophylactic antibiotics to prevent infection is routine and an intravenous antibiotic of choice (usually Kefzol) is continued for 24 hours after surgery. The use of glucocorticosteroids to prevent and control cerebral swelling is less routine and is tailored according to the preference of the surgeon. It is interesting to note that one of the first studies to note the use of steroids in reducing post-operative cerebral edema was conducted among patients who had undergone temporal lobe resective epilepsy surgery.[2] Most patients would benefit from gastric ulcer prophylaxis (especially if they are taking steroids), as well as deep vein thrombosis prophylaxis.

Patients who undergo an intracranial monitoring study using subdural grids, strips or depth electrodes may be at increased risk of infection. Intravenous antibiotics are most commonly continued during the course of their study until the electrodes are removed and resective surgery is conducted (antibiotics are usually continued for an additional 24 hours after the last surgery). For patients who harbor intracranial electrodes, signs of infection including persistent fever, cerebrospinal fluid drainage from the wound, and decreased level of consciousness require work-up to rule out CSF infection. If the suspicion for infection is high, removal of electrodes urgently is indicated.

Expanding hematomas may form around or underneath subdural grids or strips causing mass effect and an altered neurological status. Is this case, a head computed tomography (CT) imaging may assist with the diagnosis; however, the artifact caused by the electrodes on this form of study may interfere with an adequate visualization of the hematoma. If mass effect and distortion of ventricles/midline structures is noted and is responsible for the neurological decline, emergent evacuation of hematoma is indicated.

If the patient has signs of CSF space infection more than a week post-operative ly, a head CT with contrast to rule out cerebritis (early cerebral abscess) or subdural empyema is reasonable. In addition, a lumbar puncture will exclude post-operative meningitis. An acutely decreased level of consciousness will certainly make the performance of the work-up more emergent.

Management of acute post-operative seizures

Acute post-operative seizures (APOS) (those occurring within 7–10 days of surgery) occur in 20–28% of patients who undergo epilepsy surgery.[3–5] Up to 12.6% of patients who undergo a

craniotomy may suffer from an APOS despite not having any seizures before surgery.[6] The APOS are defined as 'early' if the seizures were present in the first 24 post-operative hours or 'late' if the seizures occurred between post-operative days 2–7. Others have called acute post-operative seizures as 'neighborhood' seizures within one month post-surgery (Commission on Neurosurgery of the International League against Epilepsy, 2001).[7]

Possible etiologies for APOS include: subtherapeutic drug levels, fevers, metabolic disturbances such as acidosis or hyponatremia and/or residual unresected epileptogenic focus.[5] Such seizures can also signify the presence of a post-operative complication such as hemorrhage or infection. The seizure itself should be treated and a search for reversible etiologies such as those listed above should be initiated.

In the absence of any underlying acute structural and metabolic post-operative etiologies that is remediable, acute post-operative habitual seizures (same seizure semiology as the pre-operative period) can be distressing psychologically to the patient, family and surgeon and therefore an understanding of their prognostic influence on long-term seizure control is of great importance. Several studies have shown that patients with seizures within the first week after surgery have a greater likelihood of suffering from recurrent seizures.[4,8–10] However, others state that APOSs have no significant bearing on the overall outcome from seizure surgery.[11,12]

Malla and co-workers,[4] in their paper on acute post-operative seizures following anterior temporal lobectomy, suggested that only patients who had APOS similar to their pre-operative habitual seizures were less likely to have an excellent outcome than patients without APOS. In this study, 160 consecutive patients who underwent an anterior temporal lobectomy and amygadalohippocampectomy at the Mayo Clinic (Rochester, MN) for nonlesional temporal lobe epilepsy were included. The patients were divided into groups based on the type of seizure they experienced, presence of risk factors, and whether the seizure occurred early (within 24 hours) or later (day 2–7) in the post-operative course. Thirty-two patients developed APOS. Five of these patients had identifiable risk factors for APOS such as subtherapeutic drug levels or infection. During the last follow up visit 20/32 (62.5%) patients had excellent results (they were seizure free or had experienced one seizure after the discontinuation of medication), while 96/128 (75%) of the patients without APOS had excellent results. Seven of the patients with early APOS had habitual seizures. Of those seven, only one (14.3%) had excellent outcome at the last follow-up. Interestingly there were no statistically significant differences in outcome between early and late APOS, or between patients with and patients without precipitating factors identified for their APOS. Therefore recurrent habitual seizures during the acute post-operative period may indicate that the epileptogenic focus has not been adequately resected. Such information may be used for patient counseling. On the other hand, patients suffering from APOS which are not the same as their habitual pre-operative seizures should therefore be reassured of a good long-term chance of seizure freedom.

In the pediatric population,[5] another study of patients 18 years or younger who underwent epilepsy surgery documented a 63–78% lower chance of seizure freedom among patients who suffered from APOS as opposed to those who did not. In this study, a multivariate analysis showed that APOS was an independent predictor of a less-favorable outcome. Nevertheless, 51% of the patients with APOS were seizure free at the last follow-up. In this study, subtherapeutic drug levels were not a significant risk factor for the occurrence of APOS, however; fever was a 'key post-operative risk factor', defined as two consecutive readings (taken every 4 hours apart) if >38 degrees. A history of febrile seizures was not associated with an increased chance of APOS.

In another study of pediatric patients at UCLA who underwent hemispherectomy, Mathern[3] found that the incidence of five or more acute post-operative seizures predicted longer seizure duration before surgery, longer hospital course, later oral food intake, more frequent lumbar punctures, worse overall seizure control at 0.5 and one year after surgery, more antiepileptic drug use at 2 and 5 years after surgery, and higher reoperation rate. The authors in this study did not find any difference between the patients with 0 and 1–5 APOS. The timing of the APOS did not predict outcome. The cause of recurrent post-operative seizures in these patients may have been the capability of the opposite intact hemisphere to generate seizures that were not appreciated before surgery.

The relationship of APOS and long-term seizure outcome may also be dependent upon the epilepsy syndrome and resection location. The incidence of APOS may be slightly higher among adult extratemporal resections (average 42%; range 26–46%) as compared with pediatric and adult temporal lobe epilepsy patients (average 30%, range 17–49%.) For the patients who have undergone extratemporal resections, the importance of APOS in predicting long-term seizure freedom is less clear. A study reported that APOS among patients who have undergone frontal lobe resection has no prognostic significance [13] while others have found less favorable seizure outcome among patients who have undergone extratemporal resection and have suffered from APOS.[5,8]

Lüders[8] found that seizure recurrence was significantly higher when seizures occurred during the first week after surgery. Although seizure recurrence increased progressively with longer follow-ups, the 6-month post-operative seizure outcome was an excellent predictor of long-term outcome. Lüders therefore recommended that, seizure frequency should be reported at fixed follow-up periods, e.g., at 6 months and 1, 2, 5, and 10 years. This reporting strategy will allow comparison of outcomes between different studies.[9]

Others have suggested that early APOS (within 24 hours of surgery) may be less important in long-term prognostication of seizure outcome. This is the time when the effect of anesthesia and surgical manipulation on cerebral physiology is greatest, increasing the risk of a seizure.[14] In general, the occurrence of APOS should be interpreted cautiously and individually for each patient. Although the presence of seizures post-operatively may signify a lower chance of long-term seizure freedom, one must remember that a significant majority of these patients do become seizure free.

Several limitations are present in the majority of the studies which have studied the importance of APOS. Video-EEG monitoring is not routinely performed subsequent to surgery.

The care takers who report the ictal behavior may not be qualified for such purpose. Often, the family member may observe an APOS and may not be able to adequately identify the post-operative seizure semiology.

Post-operative management of antiepileptic drugs

The effects of anesthesia, stress of surgery as well as missing doses of medications have been known to cause varying changes in the blood levels of antiepileptic drugs (AEDs) in patients who have recently undergone epilepsy surgery. This phenomenon exposes the post-operative patient to an increased risk of a seizure. The seizure may cause uncontrollable spikes in blood pressure, causing intracerebral hemorrhage in the resection bed during the early post-operative period as well as prevent rapid patient's post-operative recovery and mobilization. Therefore, prevention of post-operative seizures is of special importance.

Effstorm, Friel and their associates have demonstrated a reduction in drug levels following surgery among the patients on stable doses of medications.[15,16] Friel *et al.* followed drug levels of 12 patients treated with phenytoin, carbamazepine and valproate. In the six patients on phenytoin and the six on carbamazepine, there was a significant reduction in serum levels at 48 hours post-operatively compared to those immediately pre-operatively.[16] However, in the five patients treated with valproate there was no significant change. In another study, the toxic levels of carbamazepine observed after surgery for subdural grid placement may suggest that the metabolism of carbamazepine can actually become slower following surgery.[17] It is thus recommended that the levels of AED medications be followed closely during the first 48 hrs after surgery to avoid sub- and/or supratherapeutic drug levels which in turn can lead to post-operative seizures or toxic reactions, respectively.

AEDs should not be tapered during the immediate post-operative period despite a lack of seizures. The time-line for tapering or discontinuing AEDs after successful surgery is not clear. The patients who undergo epilepsy surgery typically require fewer AEDs than those who did not have surgery.[18] Schiller *et al.*[19] retrospectively studied 210 patients after temporal and extratemporal resections for epilepsy at the Mayo Clinic (Rochester, MN). In this group of patients, the medications were tapered sequentially with a varied taper typically lasting 6–25 months. The medications were altered in 180 of the 210 patients. AEDs were tapered and discontinued in 84 (40%) and reduced in 96 (46%). Discontinuation of the AED treatment was associated with recurrent seizures in 22 of the 84 patients. Reinstitution of the AED treatment resulted in seizure control in 20 of the 22 patients. The remaining two patients developed medically refractory epilepsy despite AED therapy. Thirteen of 96 (14%) who reduced the number or dose of AED medications had recurrent seizures. In trying to define the patients who would be at an increased risk of seizure recurrence after medication adjustment, these authors investigated numerous factors. Patients with a normal pre-operative MRI study showed a tendency for higher seizure recurrence. Nevertheless, this difference did not reach statistical significance. No difference was observed in seizure relapse between patients with and without epileptic spikes in the post-operative EEG studies. Furthermore, reviewing the length of medical therapy after surgery, the authors could not find any correlation between the duration of seizure-free post-operative AED treatment and seizure recurrence after AED withdrawal. Thus, this study could not find a way to predict who would have recurrent seizures after AED adjustments. It would seem wise to wait at least 6 months in order to allow the patient to recover from surgery and assure successful surgical outcome before discussing tapering medications.

Post-operative psychosocial issues

Epilepsy has had a long historical association with psychiatric and behavioral disturbances. It has been estimated that about 20% of temporal lobe epilepsy patients have depression. Wrench *et al.* studied the effects of seizure surgery on mood disturbances.[20] This study included 43 patients who underwent temporal resections, and 17 patients who underwent extratemporal resections. Prior to surgery, each patient was seen by a psychiatrist, while after surgery each patient was screened by the treating clinical neuropsychologist and referred for psychiatric assessment where indicated. Before surgery 57% of the patients had previous psychiatric history to include depression, anxiety, postictal psychosis, personality disorder, anorexia nervosa, dysthymia, substance dependence, and delusional disorder. At discharge from the hospital, 32% of the patients were experiencing psychiatric difficulties. At one month, reports of psychiatric difficulties increased to 52% among patients who underwent temporal resections, significantly greater than extratemporal patients. No association was found between the outcome of the surgery and general psychopathology, depression or anxiety. Other studies have also documented that temporal lobectomy patients have a tendency to develop symptoms of mood disturbance within six weeks of their post-operative period.[21,22] The patients who are at a higher risk for such disturbances might benefit from pre- and post-operative counseling.

Conclusions

Acute or early post-operative seizures can be emotionally devastating to the patients and their families due to the possible negative impact of these acute seizures on long-term seizure outcome following epilepsy surgery. The precise impact of acute post-operative seizures on the long-term outcome of epilepsy surgery has remained controversial. The available studies have predicted a negative or no impact on final outcome of surgery in patients who suffer from acute post-operative seizures compared to those who remain seizure free early in the post-operative period. The appropriate post-operative care can help in the management of these patients and assist them on their way to recovery from this epilepsy disorder.

139 Post-surgical pharmacotherapy: discontinuation of anticonvulsants

AS Tanner and D Schmidt

Introduction

Resective surgery for epilepsy is currently offered to a wide variety of patients with different kinds of focal medically refractory epilepsy in centers around the world. Specifically, temporal lobectomy is now well established as effective in patients with intractable temporal lobe epilepsy.[1] The body of literature on resective epilepsy surgery, heavily concentrated on temporal resections on adult patients, has shown a wide range of seizure-freedom rates for all procedures, (33–90%)[2] with the highest rates after anterior temporal lobectomy for medial temporal lobe epilepsy.[1] While several series reported in the literature have included small numbers of patients and have used different follow up periods, methodologies and study designs[2] most of them agree on the long-term benefit of temporal lobectomy for the treatment of refractory epilepsy. Reported figures show rates of seizure freedom that range between 53–80% during the first year postoperatively, 53–58% at year two, and 52–55% at year five.[2]

For patients that have undergone neocortical resections this figure is shown to be somewhat lower than for temporal resections, and around 50% at two years.[3] For children, studies report that around 70% of pediatric patients with temporal lobe epilepsy[4] and 54–82% of patients with pathologies such as Rasmussen's encephalitis, hemiplegia, or Sturge-Weber are seizure free after surgery[5]. Many patients (anywhere between 10% and 60%), however, relapse after epilepsy surgery and evidence shows that most of these relapses occur early after surgery (within the first two years)[6,7] although later recurrences have been reported.[7,8] Some of the factors cited as predictors for relapse include longer preoperative illness, normal pathology[8] and the presence of secondarily generalized seizures before surgery.[7] A factor that has only recently been explored is the role that antiepileptic drugs (AEDs) play after epilepsy surgery especially in relationship to the risk of relapse.[9] This is an extremely important and relevant variable not only because of obvious importance when counseling patients and planning therapeutic decisions after surgery, but because of the expectation from patients that freedom from drugs follows surgery.[10] The literature on these topics is unfortunately not as abundant as in other areas of epilepsy surgery. Reasons for this may include the inherent difficulties in assessing outcomes after discontinuation AEDs, in designing adequate clinical trials that address this particular issue and the lack of universal guidelines. We will review the relevant literature in this chapter.

Discontinuation of AEDs: relevant literature

Most of the literature in AED discontinuation after resective surgery again relates to temporal lobe epilepsy.[1,2,6,7,11–16] Few papers address this issue on neocortical, extratemporal and all types of resections in children.[3–5,17–24] Schiller and his colleagues[21] reported in 2000 a series of 210 patients that underwent either a taper or discontinuation of AEDs after epilepsy surgery. The majority of these patients were adults, and most of them underwent temporal lobe resections. After 1 year of seizure freedom (including patients with isolated auras), patients were divided into a group that reduced but not withdrew AEDs, and a group that tapered and discontinued AEDs; they were compared to a 'control group' of patients that were seizure free after surgery and did not alter their medication regimen. Their retrospective study revealed seizure recurrence in 14% and 36% of patients by the end of 2 and 5 years respectively after complete AED withdrawal, and recurrence of 9% and 14% of patients who partially reduced AED treatment by the end of 2 and 5 years. (Table 139.1) There were no statistical differences on the clinical features between the groups that partially discontinued AEDs with the control group. Reinstitution of AEDs resulted in seizure control in 91% of patient who relapse after complete AED withdrawal. Among the variables that they studied abnormal preoperative MRI carried a higher tendency for seizure recurrence. They did find that seizure recurrence was unrelated to the duration of the seizure-free post-operative AED treatment.

In a recent publication, Kim[13] and his colleagues reported on a series of patients that underwent AED discontinuation. They included patients of all ages and a majority undergoing temporal lobectomy for hippocampal sclerosis. Altogether, 33% of patients who attempted AED tapering experienced seizure relapse in the course of discontinuation. The seizure recurrence rate was not different in patients that had become seizure free immediately after surgery than on those who became seizure free sometime after surgery. The majority of patients (70%) regained seizure freedom after reinstitution of AEDs.

Schmidt *et al.*[22] analyzed six retrospective series of patients undergoing planned AED discontinuation under medical supervision. Their review showed an average relapse rate of 34% for all surgeries, most often temporal lobe resections with recurrence rates increasing with the length of follow-up.

Table 139.1 Discontinuation of antiepileptic drugs: relevant literature

Study (Reference number)	Number of patients age/ gender	Procedures included	Design	Follow-up	Proportion of surgical patients seizure free after discontinuation of AEDs
Schiller *et al.*[21]	*N* = 210 Age mean: 31.9; range: 9–55. 107 f; 103 m	Temporal lobe resections: 89.5% Extratemporal resection: 10.5%	Retrospective	Mean: 5.1±0.3 range: 3–8 Years	57/84 (67%) after complete discontinuation; 83/96 (86%) after partially reducing AEDs
Kim *et al.*[13]	*N* = 88 Age mean: 27.3; range: 11–41 49 f; 39 m	Temporal lobectomy: 100%	Retrospective	Mean: 77.4 months range: 36–144	37/66 (56%)
Wieser *et al.*[15]	*N* = 376 Age mean: 32±11 166 f; 210 m	Temporal lobe resections: 100% (selective amygdalohippocampectomies)	Retrospective	Median: 7.5±05.7 Range: 1–25	92/111 (82.9%)
Berg *et* al.[25]	*N* = 129 Age median: 36 years	Temporal lobe: neocortical and medial temporal	Prospective	Not stated	88/129 (68%)
Lachhwani *et al.*[18]	*N* = 97 Age mean: 11 Range: 3 months –18 years	Temporal and extra-temporal resections	Retrospective	Median: 37 Range: 1–134 months	57/68 (84%)

Interestingly, among all patients analyzed, only 48% of seizure-free adult patients discontinued AEDs, whereas 71% of seizure-free children did so. Their findings suggested that there was no benefit in waiting to attempt AED tapering (1 year in children and 2 in adults), and that the occurrence of rare seizures or auras did not preclude successful AED discontinuation. In accordance with other studies and observations, more then 90% of adult patients with seizure recurrence regained seizure control after reinstitution of AEDs. This study failed to find a strong association between relapse after AED withdrawal and factors such as age of onset of epilepsy, duration of epilepsy and preoperative MRI findings.

Wieser and Häne[15,16] reported retrospectively on patients that had undergone amygdalohippocampectomy. In their study the overall risk of relapse associated with AED tapering and withdrawal was 17%; they concluded that in this population monotherapy was an adequate option, and therefore AED reduction to monotherapy could be advisable as early as 1 year postoperatively with discontinuation at year two. In a recent report, Berg and her colleagues from the Multicenter Study of Epilepsy Surgery[25] analyzed the impact of reducing AEDs in subjects who attained a 1-year seizure remission after surgery. The authors found that 41 of 129 patients (32%) relapsed after reducing AEDs. No difference was found between reducing from two to one AED or from one to no AEDs. Delayed remission after surgery was significantly associated with an increase rate of relapse, while continued auras were marginally associated with relapse. Of note, in the series of patients reported by Berg, 45% of patients (73 of 162) in the nonreduction arm also recurred. Overall, 39% of all patients who attained seizure freedom for one year recurred (114 of 301).

The literature addressing AED discontinuation after epilepsy surgery in children is scarce. As indicated earlier, anywhere between 50% and 80% of pediatric patients become seizure-free after surgery for temporal lobe epilepsy, seizures associated with infantile hemiplegia or seizures accompanying tumors.[4,5]

The report by Lachhwani[18] (included in the analysis by Schmidt cited earlier) showed that 16% of patients that underwent AED discontinuation had seizure recurrences. No significant differences were found based on etiology. The majority of these patients regained seizure control after the AEDs were reinstituted.

One related question that patients and physicians have is the long-term seizure prognosis following epilepsy surgery in patients off AEDs.

Long-term surgical seizure outcome off AEDs: relevant literature

Although surgery is often seen as a curative treatment for patients with drug-resistant temporal lobe epilepsy, little information is available regarding how many cases are seizure free for at least five years without taking AEDs. This question was reviewed by Schmidt *et al.*[26] The review included 13 retrospective and five prospective clinical observations published since 1980 provided data on long-term seizure control off AEDs in a total of 1658 patients (Table 139.2). No randomized studies were found. Following temporal lobe surgery, approximately one in four adult patients and approximately one in three children or adolescents were shown to be seizurefree for 5 years without AEDs (25%, mean of eight studies in adults, 95% CI: 21–30%, and 31%, mean of three studies in children, 95% CI: 20–41%). The rate of seizure control off AEDs seemed to be stable after 2 years of follow-up. However, as 55% of patients free of disabling seizures preferred not to discontinue their medication completely as late as 5 years after surgery, it is impossible to know if more patients could have been seizure free, if all had discontinued their medication. No features predictive of surgical cure were detected except for better outcome in children versus adults with hippocampal sclerosis and in patients with typical versus atypical Ammonshorn's sclerosis or tumor in one small study each. In conclusion, the available evidence on seizure outcome off AEDs after temporal lobe surgery is based on nonrandomized studies and, in part, data were collected retrospectively.[11,15,19,26–41] In a single–center study of long-term seizure outcome off AEDs following temporal lobe surgery, which appeared after completion of the above review, Kelley and Theodore[42] reported a similar result. In their analysis one in three patients were seizure free of AEDs when reexamined 10–30 years after surgery.

Discussion

The importance of the quality, quantity and length of AED treatment in patients that have undergone epilepsy surgery goes beyond the pure consideration of seizure freedom versus seizure recurrence: AEDs influence quality of life because of side effects, interactions with other drugs, issues related to contraception, pregnancy, lactation, menopause, bone health as well as financial issues.[43–46] Therefore, understanding their role after epilepsy surgery is vital when treating and counseling these patients for more than one reason.

The current relevant literature suggests that a significant minority of patients (about a third of adults, perhaps a lower percentage in children) will have seizure recurrence upon AED discontinuation after resective surgery for epilepsy. In addition, based on long-term studies, one in three patients can expect to be free of seizures without taking AEDs anymore. Because the goal of many patients considered for epilepsy surgery is to be free of medications, this literature becomes an important tool for discussing this issue after surgery. Fortunately, the literature shows that the vast majority of these patients will regain seizure control once AEDs are restarted, with only a small minority of up to 10% going on to have intractable or recurrent seizures.

Many important issues, however, remain unanswered. Most of the relevant papers addressing AED discontinuation have included in their analysis both patients undergoing temporal and extratemporal resections, and in some cases children and adults alike. This 'lumping' of cases does not allow us to make specific determinations for these different groups, and it can, as a matter of fact, confound the results. Are patients with nonlesional MRIs and neocortical resections at higher risk of recurrence than are patients with lesional cortical epilepsies? Are patients with classical mesial temporal epilepsy at a different risk? If we control for other variables, do all groups have the same risk? Future research has to address this issue in different cohorts of patients. Another point that ought to be considered is whether or not there was bias in

Table 139.2 Long-term surgical seizure outcome off antiepileptic drugs: relevant literature

Study (Reference number)	Number of patients age/gender	Procedures included	Design	Follow up
Adams *et al.*[27]	*N* = 44 Age median: 12.7, range: 2.5–15.8	Anterior temporal lobectomy	Retrospective	
Bien *et al.*[11]	*N* = 148 Age mean: 31.5; range 8.8–63	Temporal lobe resections: anterior temporal lobectomy and amygdalohippocampectomy	Prospective	4.8 years (mean)
Derry *et al.*[28]	*N* = 30 18f; 12m	Temporal lobectomy	Prospective	8.5 years
Elwes *et al.*[29]	*N* = 101 Age median: 23; range 3–53 48f; 54m	Anterior temporal lobectomy	Retrospective	61 months
Gilliam *et al.*[30]	*N* = 196 Age mean:33. 110f; 86m	Anterior temporal lobectomy	Cross-sectional	n/a
Li *et al.*[32]	*N* = 23 Age mean: 29.7	Anterior temporal lobectomy	Prospective	
King *et al.*[31]	*N* = 23 Age mean: 31.5	Anterior temporal lobectomy	Retrospective	1 year
Maher *et al.*[33]	*N* = 93 Age mean: 32 48f; 45m	Temporal lobe resections	Retrospective	2 years
Mathern *et al.*[19]	*N* = 198 (TLE=31) 87f; 111m	Hemispherectomy; lobar and multilobar resections, temporal lobe resections	Retrospective	2 years
McLachlan *et al.*[34]	*N* = 51 Age mean: 31.9 27f; 24m	Anterior temporal lobectomy	Prospective	2 years
Mizrahi *et al.*[35]	*N* = 22 Age mean: 21 11f; 11m	Anterior temporal lobectomy	Retrospective	
So *et al.*[37]	*N* = 184 Age median: 31; range:7–86 years 100f; 84m	Anterior temporal lobectomy	Retrospective	3.4 years (median) Range: 1.1–5.7
Sperling *et al.*[38]	*N* = 89 Age mean: 31.9, range 10–60 years 44f; 45m	Anterior temporal lobectomy	Prospective	5 years
Wieser *et al.*[15]	*N* = 376 Age mean: 32 165f; 211m	Amygdalohippocampectomy	Retrospective	5 years
Williamson *et al.*[40]	*N* = 67 Age and gender n/a	Temporal lobe resections	Retrospective	5.7 years (mean) Range 2–14 years
Oxbury *et al.*[36]	*N* = 50 Age: children group median 14 (8–15), adult group: 22 (16–36) Gender: n/a	Temporal lobe resections	Retrospective	5 years
Velasco *et al.*[39]	*N* = 22 Age mean: 32, range: 15–48 11f; 11m	Anterior temporal lobectomy	Prospective	2 years
York *et al.*[41]	*N* = 145 Age mean:27.9, range: 7–57 82f, 63m	Anterior temporal lobectomy	Retrospective	1 year

selecting the patients that have undergone AED tapering or withdrawal. Were the 'high-risk' patients excluded? Are the risks of recurrence actually higher? Only prospective, carefully designed trials will answer this question as well as issues such as the identification of other predictors of seizure recurrence and of patients 'pre-determined' to recur after surgery regardless of AEDs.

One further consideration is whether different techniques of tapering have confounded the results. Does reduction carry a different risk than discontinuation? A constant among most studies is the lack of unified way to taper and discontinue: the majority will cite that tapering and discontinuing was done at the direction of the treating neurologist. What is the best way to taper? Does this influence recurrence? Again adequately designed trial may answer this. Although some investigators have suggested timelines for tapering, an issue that remains inconclusive is how long AEDs should be kept after surgery.

In conclusion, we now know that a subset of patients initially seizure free after surgery will relapse after AED taper and/or discontinuation, and that upon reinstitution most of them will regain control of their seizures again. However, numerous other issues are yet to be elucidated and future research should focus on addressing this vital information.

140 Post-surgical rehabilitation

R Thorbecke and B Hötger

Why rehabilitation in the context of epilepsy surgery?

For the majority of patients undergoing epilepsy surgery this intervention effects a dramatic change in the course of their illness, i.e., they reach ultimate freedom of seizures. It seems that patients anticipate this and generate expectations respectively aims going beyond the aim of mere seizure relief – e.g., they plan to get a driving license or to begin a new professional career, etc.[1,2]

From the early times of epilepsy surgery in the 1950s until today (also on the professional side) the goal of epilepsy surgery has not only been to stop seizures but in consequence to improve the patient's wellbeing, functioning and their social situation especially with respect to employment and independent life.[3,4]

However, from the first reports on social outcome until today it is obvious that not all patients gain from the procedure as might be expected from the excellent prognosis after surgical intervention. There may be barriers to the attainment of the preoperatively defined goals – e.g., neuropsychological deficits[5,6] or psychiatric disturbances already existing before surgery, or a low potential to discard a sick role with low expectations held over many years.[7–9] There might also be barriers in the patient's environment not perceiving the new possibilities for growth and for taking over more demanding roles.[10]

Rehabilitation in the context of epilepsy surgery means supporting the patient to attain their goals when they decide to have surgical treatment. This may be psychological support for adaptation to a new situation with new and more expectations than during the years before surgery. It may also include social work, counselling to improve one's employment situation. It must however be kept in mind that the expectations connected to the surgery might be unrealistic in relation to the patient's capabilities or formulated not concrete enough to work at their realization.[1] Here rehabilitation means to shape expectations into a more realistic form with the patient – in the best already before surgery.

Plan of this chapter

In the first part the patient's aims tied to surgical interventions are depicted. In the second part the knowledge on outcome of surgical interventions in relation to these aims is reported, discussing at the same time relevant prognostic factors. In respect to rehabilitation, it is important to understand that postoperative seizure status is not the only, and not always the most, important prognostic factor for social outcome. Rather we have to account for the patient's cognitive and behavioral resources to adopt new roles. The Bethel Epilepsy surgery programme has existed for more than 15 years now and, from the beginning, there was a focus on social outcome, its determinants, and how to optimize it. Therefore a section with the Bethel experiences from 1990 – 2004 will be included. In the third part, finally, practical advices for rehabilitation interventions in epilepsy surgery patients stemming from the literature and from the experiences in the Bethel epilepsy surgery program will be reported.

Aims/expectations of patients associated with epilepsy surgery

Several studies have preoperatively investigated expectations with respect to the postoperative psychosocial situation. Baxendale *et al.* asked patients to rate themselves with a self-concept scale, first in a general way and second under the presupposition that the proposed surgery would be successful in eliminating their seizures. It appeared that the patients were expecting to be happier, more in control, and more hopeful, independent and interested in life.[11] Thorbecke, in a similar way asked for expected changes in several social domains. The greatest expectations were present for elimination of seizures followed by improved mobility, employment opportunities, sports, leisure time activities, and more social contacts, and the hope to find a partner. In fact the perception of difficulties in any social domain correlated consistently and highly with the strength of the expectation of change after surgery.[12] Wheelock *et al.* asked patients and significant others for expected life changes following epilepsy surgery. Having more friends, being less dependent on others, others worrying less about the patient, improved marital/family relationships, ability to drive, ability to work, and ability to do more things independently were mentioned most often.[13,14] Taylor *et al.* asked 69 patients who already had decided to get surgery, and who were able to depict their postoperative aims with respect to their cognitive and psychiatric status. The mean number of statements was three (range 1–5). Improved work situation, driving, independence, socializing, relief from taking medication/relief of side effects were the five most often-mentioned aims. Surprisingly there was little expressed interest in improving cognitive functioning.[2]

An interesting question addressed in these studies is what type of expectations have the best chances to be fulfilled. From Wheelock's study comes the finding that those patients whose expectations were fulfilled, postoperatively were more satisfied, and this was associated with better psychosocial functioning.[13,14] Wilson *et al.* asked the patients preoperatively about their expectations in respect to surgery and postoperatively to rate

the success. 'The successful subgroup primarily reported expectations that led to a practical or clearly identifiable result, such as seizure ablation, driving, employment and the initiation of new activities'. In contrast, the unsuccessful subgroup reported less practical expectations (difference for expectations to become employed < 0.05) but more expectations of psychosocial nature and the expectation that the operation would generally enhance their QOL.[1] In Wheelock's and Thorbecke's studies it was the opportunity to do these practical things now which was delineated as postoperative changes.

In all three studies[1,12–14] no differences with age or gender are reported and in all three studies persons who had not become completely seizure free reported less changes. Wheelock *et al.*, and in a similar way Wilson *et al.*, showed that the expectations of those whose seizures were not completely eliminated but improved were only slightly or moderately fulfilled. It is evident that these findings should have practical consequences for pre- and postoperative counselling especially for a better adaptation of those improved but not completely seizure free. An interesting comment in this context comes from Wheelock *et al.* when they compare preoperative evaluation of risks with the behaviour in a game of chance: '… on hearing from their physicians that they have a 70–75% chance of becoming seizure free, patients may automatically place themselves in the positive outcome category rather than acknowledge that they may be among the patients who continue to experience seizures.'[14]

Factors determining social prognosis

Outcome might be very different for different social domains, and different outcomes might be affected by different factors, e.g., seizures having stopped might influence the capability to drive or the possibilities to do certain types of sports in a very direct way, whereas living independently or starting a new career might be much more determined by age, cognitive abilities, and social skills than by mere seizure status.

Overview from the literature

Employment

The majority of studies in the early years of epilepsy surgery between 1960 and 1980 showed dramatic improvements in employment rates after epilepsy surgery.[3,15,16] Up to the eighties such effects were less obvious[17,18] or there were no effects at all.[19–21] In the US multicenter study of epilepsy surgery in a cohort of 396 patients followed for at least 2 years after surgery, there was only a not significant increase of employment from 45–52%.[22] A somewhat different picture evolves in studies using a control group. A Norwegian study demonstrated that persons who are employed at the time of surgery stay longer in the work force than controls,[10] and in a study from the U.S. the rate of persons in full time employment was significantly higher in the surgery group compared with a medical management group.[23] Nevertheless in the surgery group there remained 31% without full-time employment.

In the early studies it seemed clear that improved seizure status was predictive for improved employment situation.[2,16] However, in the more recent studies there is not such a clear picture and it seems that additional factors must be accounted for. In a study by Jones *et al.*, the employment rate of those having become seizure free was higher than for persons who were not seizure free, the difference, however, did not reach significance.[23] Lendt and colleagues found four factors relevant for postoperative employment – preoperative employment, low age at surgery, improvement in general neuropsychological functioning especially attention, and good seizure outcome.[18] Reeves *et al.* observed that being a student or working full time within a year before surgery, driving after surgery, and obtaining further education after surgery were associated with full-time work postoperatively.[20]

These results are not as favourable as expected in view of a patient group in which about 70% of the patients have become seizure free at the time of follow-up. So it is not surprising that the need of rehabilitation efforts, especially in the vocational domain, is underlined in the more recent studies. 'Vocational rehabilitation efforts should be enhanced and should include those who were working prior to surgery but unemployed at follow-up.'[27] To make progress in this direction, however, would need a careful analysis of barriers to gainful employment in the patient such as already preoperatively existing cognitive deficits and psychiatric disturbances as well as barriers in the environment, e.g., when the patient's enlarged work abilities after surgery are not perceived.[10]

Independent living

To live more independently is one aim expressed by patients in all studies addressing aims/expectations (see above). Also, professionals are interested in the effects of epilepsy surgery on independent living for economical reasons. There is, however, a dearth of data allowing some conclusion in this direction. In older studies highly significant gains with respect to independent living were reported.[24] There were, however, no control groups. A study from Norway showed a strong decrease in the need to be looked after in the surgically-treated patients at the end of the mean follow-up interval of 17 years. In the control group however the same course could be observed although seizure frequency at follow up was significantly higher.[10] Thus the decrease in supervision reflected rather a general attitude change towards independent living of persons with disabilities or the subjects simply growing older than true changes resulting from surgery. There are also difficulties in finding a definition of independent living which is independent from cultural norms.[25–27]

> In the controlled study of Jones *et al.* independent living was defined as not requiring assistance in any of three activities of daily living (e.g., organizing and taking medications, keeping appointments, and showering) and as living alone, with a roommate(s), or with significant other(s) (not living with parents or living in an assisted-living arrangement). The proportions living independently were, for the surgery group pre 53%, post 85%, for the control group pre 39%, post 48% ($p < 0.001$). Possible prognostic factors were not evaluated.[23]

The Bethel experiences are reported below. For rehabilitation purposes some general findings on independent living in PWE might be helpful (delineated in Thorbecke's review 2001):[26,27] epilepsy might only be of importance if there are frequent and severe (grand mal) seizures. Decisive factors seem to be additional disabilities, e.g., physical limitations like hemiparesis and cognitive deficits.

Driving

Reeves *et al.* reported that in their series 79% of 112 patients were driving postsurgically which is in good accord with 80% having an excellent seizure outcome. In this study driving after surgery was one important predictor for full-time work at follow-up.[20] In the study of Jones *et al.* 67% of the patients were driving 5 years after surgery in contrast to only 22% of the controls ($p<0.001$), freedom of seizures being a significant predictor.[23]

Although to overcome driving restrictions is one of the most important aims of patients deciding to undergo surgery, there may be complications which prevent them postoperatively from driving. In a study on effects of visual field defects and epilepsy control seven out of 13 patients were seizure free and also seven out of 13 had visual fields that would allow them to drive. However only five met both criteria, significantly altering the percentage of patients who were actually eligible to drive.[28] The authors concluded that the probability of driving should be discussed at length prior to any temporal lobe surgery (see also).[29]

At least in countries were a formal examination is necessary to get a driving license it might be that already preoperative or postoperative cognitive deficits may hinder the patient to pass it successfully. This should be discussed with patients at risk prior to surgery.

Family relationships, social contacts and significant others

There is only little information on this domain. Mihara *et al.* asked patients and families to rate satisfaction with different social domains pre- and postoperatively independently from each other and then computed change scores. The assessments of patients and their families concurred well. About 2/3 of the patients and somewhat less of the family members rated emotional wellbeing and leisure time activities as improved 2 years after surgery. There were, however, much lower changes in respect to social contacts, family relations and in respect to financial status.[30,31]

Bladin *et al.*, when doing a rating together with patients and families found nonfamilial relationships improved nearly at the same degree as Mihara *et al.* Changes in family relationships were reported however much lesser, the majority of the 107 interviewed saying that relations remained unchanged.[19] In both studies changes were influenced by seizure outcome. In both studies, however, it was not clear if the quality of preoperatively already-existing relationships had improved or new postoperative contacts had been initiated. Anyway, from both studies it can be inferred that 10–15% of the patients also postoperatively had major difficulties in nonfamily relationships, respectively social contacts.

Langfitt *et al.* in an extensive study in which the family interactions of 43 patients 2–3 years after surgery were videotaped, looked for family predictors of social adjustment i.e., functioning in the areas of work/school, social/leisure time, and family relationships. Predominant affect in the family and, to a lesser degree, seizure outcome explained 50% of the variance in social adjustment. The correlations were especially high for the group of patients who had not become seizure free. The authors underline the importance of family support for this patient group, which has much more difficulties, to rely on a social network outside their family.[32]

Bladin, in his study on psychosocial difficulties after TLR, observed 4 years after surgery a level of 6% divorce which was unremarkable against a general divorce rate of 1:3.[19] Carran *et al.* reported the proportion of married patients pre- and postoperatively not to differ significantly from each other – 37% versus 43%. However 33 of 190 patients had changed marital status postoperatively with 21 who became married, and 12 who became divorced.[33] Although the divorce rate seems to be low the divorces reported might be related to surgery, e g., if the patient preoperatively had sustained the relationship only because of the dependency in consequence of the seizures and, after having become seizure free, escapes.[19]

Psychological wellbeing

It is now well established that TLR improves HRQL.[34] However this hold only for those patients who have become completely seizure free. In patients who still have auras (Engel class IB) no improvements could be observed[35–38] although there was substantial seizure reduction. However such a

> Failure is a judgement based on preoperative expectations. To reduce the seizure frequency by half, or to eliminate one of two seizure types could be seen as favourable outcomes if they had been agreed-upon goals prior to surgery.[39]

These authors contend that these problems could be prevented by formulating clear and realistic expectations preoperatively.

There are other factors apart from seizure status decisive for postoperative quality of life. Personality traits like neuroticism,[40,41] learned helplessness, a measure closely related to depression,[35,36] and learned resourcefulness which refers to a personality style that not only buffers negative effects of stress, but which also prompts the initiation of corrective personal change strategies such as the use of thoughts to control emotion, application of problem solving strategies, and delaying immediate gratification influence HROL independently from seizure outcome.[42] Depression is the strongest predictor for HRQOL explaining up to 45% of HRQL independently from seizure status.[43] Depressive syndromes (dysthymic disorders, major depression) may be found up to half of the patients preoperatively, and de novo mood disorders in about 10% postoperatively, the latter mostly being of transient nature[44] (see Chapter 95). From this it becomes obvious that apart from seizure outcome a close psychiatric follow-up in the first 2 years postoperatively may be decisive for the outcome as judged by the patient in quality of life terms.

Finally there is the small group of patients with no improvement at all. This group may deteriorate in HRQOL in comparison to the baseline preoperatively.[4] A surprising finding is that the overwhelming majority of patients who did not become seizure free say that they would have surgery again in a comparable situation[23] i.e., they are not at odds with the unsuccessful therapeutic trial. Nevertheless this is the group needing the most intensive medical, psychiatric/psychotherapeutic, and social-work support postoperatively.

Difficulties to adapt to a situation without seizures (burden of normality)

Bladin and Wilson in recent years repeatedly reported on difficulties associated with the cessation of seizures after surgery,

e.g., inability to cope with a new situation imposing less social constraints but at the same time making new demands – inappropriate, self-indulgent behavior in consequence of this, or being at odds with ones fate because surgery came too late.[9] Such phenomena have loas been observed and gave the starting point for rehabilitation in epilepsy surgery.[7,15,45] Wilson *et al*. observed these phenomena with an increasing frequency in up to 30% of the patients until 2 years postoperatively.[46] From the features described it is, however, not clear for what proportion of the patients they are of clinical relevance. Wheelock also reported such difficulties in seizure free patients but the frequency was low. She conceded however that her sample ($n = 32$) might have been too small to give an adequate estimation.[13,14]

A further difficulty is that from the newer reports of Wilson *et al.* it is not clear who is especially prone for the described difficulties in adaptation. In the older reports[45] it seemed that patients with preoperative personality disorders and/or extremely unrealistic expectations were especially susceptible to such reactions. In our experience, patients with few resources for adaptation i.e., a dearth of social skills and cognitive impairments preoperatively especially with an IQ in the range of a learning disability preferably develop these maladaptive reactions.

Experiences from the Bethel epilepsy surgery programme

In the preceding section it was shown that there is a lack of studies dealing with the social situation of epilepsy patients after surgery. Especially pre- and postoperative changes in the patients' objective social situation have not often been analyzed. We did a follow-up on social outcome in our program twice – for patients getting ATL between 1991 and 1996 [26,27] and between 1998 and 2004.[47] Here we report some results of the second follow-up.

Patients and methods

This study was undertaken in 115 patients with temporal lobe epilepsy who were treated in the epilepsy surgery program Bethel between 1998 and 2004. The patients' demographic features are presented in Table 140.1.

All patients were interviewed by a social worker pre- and postoperatively and were asked to fill out the PESOS-Questionnaire before surgery and two years after that. The PESOS-Questionnaire (PESOS = Performance, Sociodemographic aspects, Subjective evaluation/estimation) is a tool which was developed in the Epilepsy Center Bethel to assess the impact of epilepsy, the epilepsy related quality of life and the psychosocial problems of epilepsy patients.[48] Additionally patients rated their quality of life on a seven point Lickert-Scale 6 months after surgery.

Neuropsychological testing was conducted pre- and 6 months postsurgically. The standard test battery consisted of tests which are indicators for verbal and nonverbal memory, attention, ability to explore, spatial constructive abilities, short-term and working memory, cognitive flexibility and intelligence. Sixty-five patients were included in a specific rehabilitation programme focusing on work related integration. The focus on rehabilitation in Bethel has existed from the beginning, but a special rehabilitation unit was not installed before 1997.

Table 140.1 Bethel program – basic data

Sex m/f	53/62
Right temporal lobe epilepsy/ left temporal lobe epilepsy	68/47
Age mean years (SD); range	35.04 (10.6); 15–60
Duration of epilepsy mean years (SD); range	21.97 (12.0); 1–53
Surgery: right TLE/left TLE/ lesionectomy	62/46/7
Seizure outcome: Engel class I/II/III/IV	79/17/11/8

Patients who suffered from a progredient tumor were excluded from the study.

Results

Changes in specific social domains

To be able to analyze postoperative changes in the above-defined categories we dichotomized patients' answers. There was a significant improvement of the patients' objective social situation in most domains (Table 140.2). In comparison to the results observed in our first follow up[26,27] the results were even more promising.

Table 140.2 Differences prepost for the whole group

Social domain	Pre		Post		*p*	
Accidents	22.3%	(31%)	2.7%	(8%)	< 0.001	(< 0.001)
Not driving	91.0%	(96%)	59.3%	(70%)	< 0.001	(< 0.001)
Not leaving without accompanying person	10.6%	(23%)	2.7%	(7%)	0.006	(0.0002)
No sports	51.5%	(65%)	34.8%	(58%)	0.001	(n.s.)
Unemployment	19.8%	(19%)	8.9%	15%	0.013	(n.s.)
Disability pension	13.9%	(15%)	14.9%	(23%)	n.s.	(n.s.)
Unsatisfactory employment situation	49.5%	(64%)	15.7%	(34%)	< 0.001	(0.0008)
Living with parents	27.0%	(39%)	15.7%	(26%)	0.002	(0.0002)
Social contacts < 1/week	33.3%	(29%)	24.1%	(32%)	n.s.	(n.s.)
No partner	34.9%	(48%)	28.1%	(46%)	< 0.001	(n.s.)

( ): Results Thorbecke (2001).

After describing differences prepost a stepwise logistic regression analysis was done including neuropsychological, social, and clinical variables as predictors for the postoperative score in the analyzed domain. We also included the patients' presurgical score in every domain as a predictor.

Employment

Surgery did not cause a significant change in the amount of people who were in disability pension. In fact only one more person received a disability pension after surgery.

The pre-postsurgical comparison however shows that there was a significant decrease in the unemployment rate after surgery. While about 20% of all patients were out of work before surgery less than half of them (9%) were unemployed afterwards ($p = 0.013$). Furthermore the perceived employment situation improved a lot: while 49.5% called their working situation unsatisfactory presurgically only 15.7% felt the same 6 months after surgery ($p < 0.001$).

To gain a better objective judgement of the patients' employment situation social workers grouped it into four categories: as good as before (employed before and after surgery), as bad as before (out of work before and after surgery), improved (unemployed presurgically, employed postsurgically) and deteriorated (employed before surgery, out of work postsurgically). Housewives were excluded from these categories.

About half of the patients (52.3%) were employed before and after surgery (as good as before), in 5.4% of the cases the negative employment situation had not changed (as bad as before), 22.5% had been out of work before surgery but were employed afterwards (improved) of all patients 19.8% had to cope with a more negative employment situation, e.g., they had been employed before surgery but were out of work or in pension after it.

Work-related problems which epilepsy patients have to deal with decrease after surgery. The PESOS-Questionnaire contains a scale concerning different aspects of problems at work (days on sick leave, slow working speed, memory and attention problems, staying a whole work day, seizures at work). Before surgery 59.1% of the patients said to have such problems, postsurgically comprised only 24.6% ($p = 0.002$)

In the logistic regression analysis (Cox and Snells-$R^2 = 0.405$; Nagelkerkes-$R^2 = 0.723$) the preoperative status was proved as a significant predictor, e.g., patients who received disability pension before surgery were more likely to be still in pension afterwards ($p < 0.001$). An additional predictor was the age at first seizure, a greater proportion of patients with epilepsy onset later than 20 years receiving early disability pension ($p = 0.023$).

The postsurgical employment status and also the subjective perception of the work situation can be best predicted by the presurgical work situation ($p = 0.010$, Cox and Snells-$R^2 = 0.103$; Nagelkerkes-$R^2 = 0.168$).

Mobility

The majority of patients (more than 85%) were independent before and after surgery (i.e., patients left their home without an accompanying person). After surgery even more people were able to leave home without company ($p = 0.006$). In the logistic regression analysis only the presurgical situation was a significant predictor ($p < 0.001$, Cox and Snells-$R^2 = 0.155$; Nagelkerkes-$R^2 = 0.292$).

Sports

In contrast to Thorbecke's results a significant increase in the percentage of people doing sports regularly (48.5% preoperative vs. 65.2% postoperative) could be observed. The analysis for predictors (Cox and Snells-$R^2 = 0.145$; Nagelkerkes-$R^2 = 0.204$) showed an effect of the seizure outcome ($p = 0.042$) and the preoperative frequency of doing sports ($p = 0.004$). Persons who had already been active in sports before surgery and who were seizurefree postsurgically did sports more often.

Independent living

The pre-postsurgical comparison showed that postsurgically fewer patients lived with their parents (27% vs. 15.7%, $p = 0.002$). After surgery more patients called their living situation satisfying: presurgically 15.3% were not satisfied with their living situation, postsurgically only 8.1% thought their living situation was not satisfying.

Significant factors for predicting (Cox and Snells-$R^2 = 0.346$; Nagelkerkes-$R^2 = 0.593$) the postoperative living situation were the patient's age ($p = 0.004$), the presurgical living situation ($p < 0.001$), and the neuropsychological parameter 'nonverbal memory' ($p = 0.013$). Patients who lived independently were significantly older ($F(40) = 2.19$; $p = 0.002$) than patients still living with their parents. Additionally patients who lived at home presurgically were at a greater risk to still live with parents after surgery ($F(1) = 63.97$; $p < 0.001$). People with a poor nonverbal memory performance were more likely to live with their parents.

Social contacts

No significant change in the frequency of social contacts could be observed after surgery. Respectively 76.7 and 85.9% of the patients had social contacts outside the family pre- and postoperatively at least once per week. In contrast there was a significant change in the number of friendships ($p = 0.004$). While preoperatively 29.4% of all patients reported to have very few or no friends, postoperatively only 15.9% made this statement.

There was also a positive change in the subjective evaluation of social contacts. Postsurgically significantly more patients called the quality and number of friendships satisfying ($p < 0.001$). Only 11.6% were not satisfied with their social life after surgery while presurgically 19.5% were not pleased with their social contacts.

Two factors were suitable to predict the postsurgical situation with respect to social contacts: the presurgical frequency of social contacts ($p = 0.024$) and the extent of epilepsy-related fear ($p = 0.046$). Patients who had had more social contacts before surgery and who had a lower level of epilepsy-related fear were more likely to have a high frequency of social contacts (Cox and Snells-$R^2 = 0.095$; Nagelkerkes-$R^2 = 0.143$).

Partnership

In contrast to the results from 2001 there was a significant increase in the percentage of people having a partner

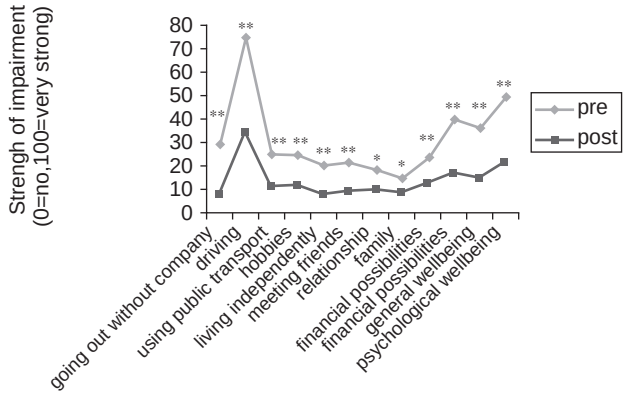

Figure 140.1 Differences pre-post in subjective impairment due to epilepsy.

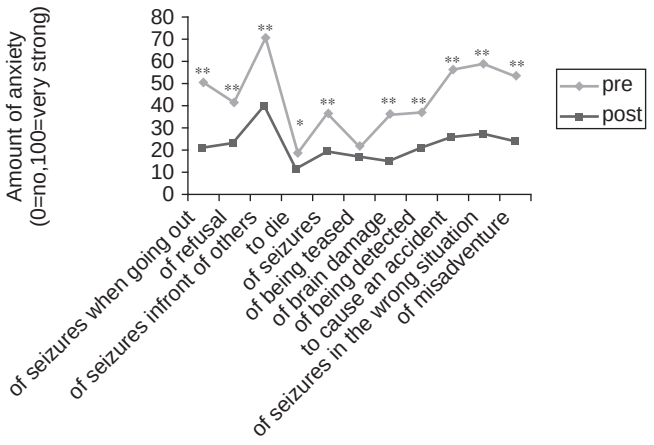

Figure 140.3 Differences pre-post in epilepsy related fear.

($p<0.001$). While presurgically 34.9% of our patients had no partner, only 28.1% had no partner after surgery. In addition to that, less people reported epilepsy-related problems in their relationship (35.3% postsurgically vs. 13.8% presurgically). However, the presurgical status was the only predictor (Cox and Snells-$R^2=0.238$; Nagelkerkes-$R^2=0.352$).

Subjective social situation

The patients' subjective situation was assessed with four scales: impairment due to epilepsy, emotional adaptation to epilepsy, stigmatization and epilepsy-related fear. The pre-postoperative comparison of these scales is presented in Figures 140.1 to 140.3.

Figure 140.1 shows the comparison for the subjective impairment due to epilepsy. A significant reduction of impairment could be observed in every single item of this scale. Thus patients' felt, less restricted in domains such as going out without company, using public transport, etc. Additionally the change in the scale sum score became highly significant ($p<0.001$).

Figure 140.2 shows the results of the pre-postsurgical comparison of two scales: the underlined items belong to the scale 'stigmatization', the other items are part of the scale 'emotional adaptation to epilepsy'. While all pre-postsurgical comparisons became significant ($p<0.001$) with respect to the latter scale only one significant change could be observed when looking at the stigmatization scale: Patients felt more accepted after the surgery ($p<0.001$).

Figure 140.3 shows that the patients did not suffer from epilepsy-related fear as strongly as they did presurgically. Nevertheless the fear of being teased remained.

To conclude, in general quality of life indicators improved significantly. There was however little change in perceived stigmatization.

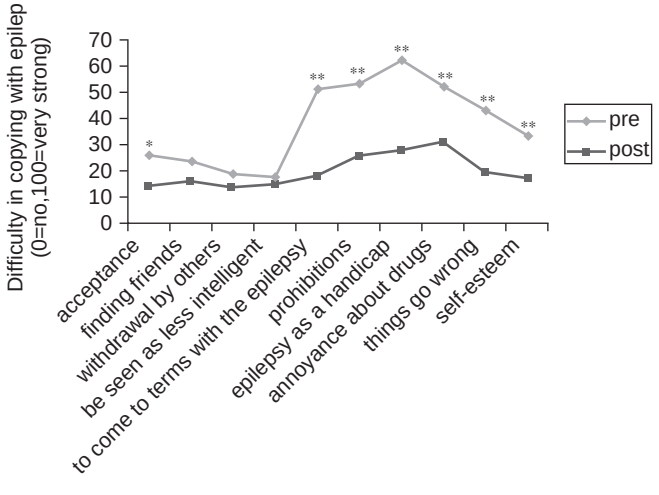

Figure 140.2 Differences prepost in coping with the epilepsy.

Conclusions

The results from our second follow up are in good agreement with our former results[26,27] as well as with results reported by others (see the second section). The patients' objective and subjective social situation in most domains improves after epilepsy surgery. No significant change, however, can be observed in felt stigmatization.

In comparison with our former results, especially the outcome on work related variables is more positive than before. While no difference in the postoperative employment situation could be found in 2001, there is a significant improvement in the second cohort. This improvement could be due to the establishment of a special rehabilitation unit in our centre in 1997 (for a description of the rehabilitation unit see below.

Nevertheless, there are persisting restrictions. First of all, no significant improvement can be observed in the frequency of social contacts. Possibly this result is coherent with the finding that patients still feel stigmatized after surgery. Thus patients with a high degree of felt stigma could be lacking the self-certainty to take the first steps to build up new relationships. Changes in social behaviors perhaps may need more time to have measurable effects. The same holds true for changes in the work situation. While a significant decrease in the unemployment rate can be observed in the second follow-up, the percentage of people who receive a disability pension remains stable.

All in all the studies presented in the previous section and also our own results show that there is a need for rehabilitative

interventions because even surgically-treated patients with a good seizure outcome suffer from social difficulties. The Bethel experience gives hints that rehabilitative care is indeed important and can positively influence patients' social situation after surgery.

Rehabilitation interventions

Pre and postoperative rehabilitation

Preoperative rehabilitation

As we have demonstrated in the second section, the evaluation of outcome by the patient and also individual motivation to work for postoperative improvements of the psychosocial situation depends strongly on preoperative expectations/aims set in connection with the surgical intervention. Therefore rehabilitation should always begin preoperatively with working out realistic expectations together with the patient and family. This seems essential in view of the high proportion of patients with psychiatric and neuropsychological deficits already existing preoperatively. In both follow-up studies from Bethel, about 60 % of the patients had personality disorders (Koch-Stoecker 2001,[44] unpublished data 2005). Preoperative neuropsychological deficits were reported repeatedly by Helmstaedter.[5,6]

In our experience, expectations with respect to social outcome should not be discussed with the patient immediately before surgery because at this time the patient is involved in evaluation of the medical risks informed by the neurosurgeon. An ideal time is after the patient management meeting (see Chapter 104 this volume) because then medical, neuropsychological, psychiatric, and psychosocial work-up is finished so seizure prognosis, and the patient's rehabilitation potential can be assessed. Working out expectations should not only be done by the neurologist, and the patient, but also other team members (neuropsychologist, social worker) should be consulted if their knowledge is relevant. Wilson *et al.*,[1] suggest the following questions to tap expectations:

1. What is the main reason you have sought surgical intervention?
2. Do you see the operation as a chance to change your life?
3. Have you made any postoperative plans?
4. Do you plan engaging in any new activities/hobbies postoperatively?

In our center we discuss expectations with two open-ended questions.

1. What changes in your life do you expect postoperatively if you do not become seizure free, your seizure status however improve strongly?
2. What changes in your life do you expect postoperatively if you become completely seizure free?

In our experience the first question makes it easily possible to single out those patients who assess the surgery a failure if there is not complete seizure relief. Furthermore answers to both questions are a very good starting point for working on concrete expectations.[2] Taylor *et al.* learned from their interviews that people vary greatly in their capacity to formulate an answer when posed a question such as 'How shall you know 2 years from now, that you are better?' and propose an individualized approach without preformulated questions.[2] Anyway, it is important to document the expectations/aims because there might be phases later in which the patient may feel overburdened by new expectations and then it might be helpful to remind him of his own plans from the preoperative workup.

The topics to be addressed when discussing expectations would be:

1. Inform the patient and relatives regarding expected seizure outcome. Also when the patient's chances to become seizure free are very high it should be made clear that there is a possibility, even if small, that seizures may persist after surgery.
2. Discussion of the patient's and his family's individual expectations/aims in relation to surgery. Relying on neuropsychological assessment and the patient's history, e.g. patient's employment career, realistic expectations must be discussed. When the patient, and his family's expectations are unrealistic, e.g., a patient with a learning disability who believes that he can successfully accomplish a high-level professional training postoperatively, first steps of vocational rehabilitation should be done already *before* surgery. Otherwise the difficulties will be masked after unsuccessful operation ('because I have not become completely seizure free it does not work') or he will be frustrated although successfully operated because his expectations are not fulfilled.

Postoperative rehabilitation

Horowitz *et al.*[8] delineated a rehabilitation model with five phases in which the patient detaches himself from his chronic disease. The first phase is described as a *moratorium* during which the old roles are continued or unrealistic expectations arise. It is followed by *reappraisal*, a phase during which new behaviors are tried out or new restrictions arise directed by the fear to provoke seizures. The next phase is called *great expectations*, Excessive expectations may lead to the perception of failure in the patient; the persons in his environment on the other side may react with removal of support or with a rigidification of the role structure. It is the authors' contention that in this phase psychotherapeutic support and support by a social worker is crucial. In the next two phases named *turbulent period with the self* and *gradual adaptation* the authors describe two different endpoints of rehabilitation, one in which the role of the chronically ill person is reinstalled and made permanent; this happens when the construction of a new identity does not succeed and may be accompanied by severe psychiatric reactions; the other in which the person gradually gains more autonomy, and needs less support by his family.

Although this model was designed from experience with only 17 patients in the sixties it also seems to give a frame for understanding the postoperative psychosocial development today. In our experience the first three phases–moratorium, reappraisal, and trying going in new directions–are passed in the first 6–12 months post-surgery, and only in rare cases it takes longer, and it seems that the situation 24 months postoperatively can be taken as the 'outcome of surgery'.

Wilson *et al.*, when describing different ways of postoperative adaptation as 'outcome trajectories' noted early anxiety as a marker for a poor psychosocial outcome and no vocational changes in the first 12 months as indicators for a poor employment outcome 24 months post-operatively.[49]

Situations which require special rehabilitation efforts

We feel that a team composed of the neurologist, psychiatrist, neuropsychologist, and social worker, who have met the patient already preoperatively, is essential for successful rehabilitation.

Situation immediately after surgery

If the patient is seizure free, and there are no neurological complications or noticeable neuropsychological deficits, and emotional adaptation seems adequate, the most important thing is to advise the patient when to return to the workplace or when to takeup duties as a homemaker. It is the experience of other centres (*Wilson trajectories*) and also our own that premature return to work may be followed by complications such as a long sick leave, etc. We inform our patients preoperatively that it may take 3 months until they are able to return to work, and then make an individualized plan postoperatively. It seems that age at surgery is the most important factor for the time needed for postoperative recovery. If possible it may be very helpful to re-enter work stepwise i.e., to start with less hours than normal and then gradually increase the number of work-hours per day.

There are, however, patients who have relapsed immediately after surgery or who have a high risk to do so. Furthermore there are patients who have a high level of anxiety or other psychiatric complications, or who are at risk to deteriorate psychiatrically (see Chapters 144 and 150), patients who had neuropsychological deficits already preoperatively, or whose performance has deteriorated postoperatively, and patients who had preoperatively social or employment difficulties or who are at risk to deteriorate. In our centre in 1997 a short-term inpatient rehabilitation program lasting about three weeks was installed for this group. Medical treatment, psychiatric support, psychotherapeutic counselling, neuropsychological training to learn compensatory strategies for word–finding difficulties, visual field or memory deficits, occupational therapy, sports and recreational therapy, intensive counselling, and a structured patient education program especially designed for postoperative patients are offered.[50]

Continuing psychosocial difficulties several months after surgery

We feel, that at about 6 months after surgery it is possible to assess whether a patient is not progressing according to expectations. This includes patients who have become seizure free and have no psychotic disturbances, but in whom one of the following complicating factors can be indicated: persisting mood disturbances, psychosomatic complaints (see Chapter 144), neuropsychological deficits which may or may not have been present preoperatively, occurrence of role conflicts in the family, work situation having become more difficult because the improved seizure situation is not accounted for by colleagues, and patients who apparently do not use their improved mobility and their new possibilities for leisure-time activities.

We offer an intensive team counselling these patients during a 3-day intake 6 months after surgery. We also offered a weekend workshop for couples in which one partner had had surgery twice. Patients and partners complained about different problems, and conflicts were mostly reported by the partners. Psychoeducational methods including role-play were employed. From this resulted the experience that solutions for conflicts could be found, although this might be difficult. All couples said at the end that they would try out the new ways of communication they had learned to solve conflicts.[51] There are also patients who have not yet returned to their work-place 6 months after surgery, who continue to be unemployed, or who have not become seizure free and now plan to apply for early disability pension. Furthermore there are patients whose early disability pension now finishes, and who need support for work reintegration. If we cannot solve these difficulties during the 3-day intake, we try to get funds for a second intake in our short-term rehabilitation unit. During the intake immediately after surgery the patients get medical treatment, psychiatric support, psychotherapeutic counselling, and neuropsychological training, which are extended to occupational assessment and real work-experience in companies downtown where professions similar to those the patient intends to return to are found. There are also intensive contacts to employers and to the agencies responsible for labour mediation and vocational rehabilitation. In our series with 115 patients with TLR (see section above) we had nine second intakes 6 months after surgery. Five had a successful rehabilitation outcome: two young adults received afterdischarge vocational training, one adult received vocational retraining, two patients were able to return to their workplace, one of them not being seizure free and having severe neuropsychological deficits. The four patients with a negative rehabilitation outcome all had not become seizure free, additionally one had a severe psychiatric complication, and two had deteriorated in their neuropsychological abilities. For one patient the reasons were not clear.

Patients with late relapses

There is a significant risk for late relapses. In a recent study about half of these patients remitted, the others continued to have seizures although in low frequency.[52] Unfortunately there is little research on the social prognosis of this group. From clinical experience we know that there are patients who become resigned, giving comments like 'now I am again an epileptic and must bear the consequences'. Apart from a thorough medical assessment those patients need social-work support and sometimes also psychiatric counselling to prevent their situation from destabilizing.

Conclusions

By going through the literature and by presenting results from our own program we tried to show that a need for rehabilitation interventions before and after epilepsy surgery is consistently described. This review also identifies a number of predictors for social outcome that allow the planning of targeted pre- and postoperative rehabilitation interventions. Depending on the special outcome domain the predictors vary. The results from our program as well as from other studies show

that the majority of the patients postsurgically remain in the same situation as before. However, this is not only true for the well adapted but also for those in an unsatisfactory situation. From our experience it is the small number of patients who are able to improve postoperatively, and the also small group which deteriorates postoperatively which must be the target group for rehabilitation interventions. If there is a thorough preoperative work-up and a close follow-up during the first 6 months postoperatively these patients can be identified and addressed for rehabilitation interventions.

These interventions should rely on the prognostic factors known from literature (third section) and on the practical experiences reported in the fourth section.

Timing would be one important aspect. From the literature it seems that a great deal of rehabilitation counselling has to be done preoperatively to shape the expectations of the patient and relatives and to develop the individual's potential for rehabilitation. In the postoperative course we delineated three occasions for considering rehabilitation support:

1. Immediately after surgery if there is a high risk for psychosocial complications or complications have already occurred.
2. About 6 months after surgery when there are hints that the patient did not profit as much as would have been possible.
3. When the patient relapses after some time without seizures.

SECTION 19

Neuropathology and research related to epilepsy surgery

141 Neuropathology of mesial temporal sclerosis

I Blümcke

Introduction

Mesial temporal sclerosis (MTS) is the major finding in patients with temporal lobe epilepsies (TLE) and histopathologically characterized by segmental neuronal cell loss and gliosis within the hippocampal formation (syn. hippocampal sclerosis, Ammon's horn sclerosis). The majority of hippocampal specimens also reveal alterations within the dentate gyrus, i.e., granule cell dispersion. In addition, variable cell loss can be detected within adjacent cortical regions, including the subiculum, entorhinal cortex, and amygdala. Cortical dyslamination and increased numbers of ectopic white matter neurons within the ipsilateral temporal lobe may also occur in MTS. Neuropathological evaluation of surgical specimens is, therefore, an important diagnostic tool to characterize the morphological substrate of the epileptogenic region. In most patients, clinical histories point to an early onset, such as precipitating events before the age of 4 years, and recent molecular studies targeted developmental pathomechanisms of hippocampal architecture to play a role in the formation of MTS, i.e., loss of Reelin and granule cell dispersion. In contrast, surgical treatment is usually carried out at an end stage of the disease and make any sequential relationship of mesial temporal pathology in TLE patients difficult to obtain. In order to better address underlying etiologies in the heterogeneous group of TLE patients and to stratify post-surgical outcome, a novel clinico-pathological classification system is proposed, which point to early preceding events, respectively the developmental state at which such an event compromises mesial temporal lobe maturation, as a reliable predictor for severe hippocampal pathology.

Clinico-pathological findings in MTS

Histopathological studies in patients with pharmacoresistant TLE have identified mesial temporal sclerosis (MTS, syn., Ammon's horn sclerosis, hippocampal sclerosis) as major pathological finding[1,2] MTS can be detected in approximately 65% of patients with MTLE[1] and 24.8% of a consecutive cohort of 3319 epilepsy patients undergoing surgical resection for various etiologies in Germany (Table 141.1). Although the pathogenesis of MTS remains to be identified, clinical histories follow a characteristic schedule in most patients. In our series of 824 patients obtained from major German epilepsy centers, including the Universities of Berlin, Bonn, Erlangen, and Freiburg as well as the Bielefeld-Bethel clinics, three periods were identified. Approximately 50% of patients presented with an initial precipitating injury before the age of 4 years.[1] In this cohort, complex febrile seizures are the most frequently noted findings. Birth trauma, head injury or meningitis were other early childhood lesions observed in TLE patients. The mean age at onset of spontaneous complex partial seizures is 11.1 years (Table 141.1). As a matter of fact, structural, molecular or functional analysis cannot be obtained during this early and clinically silent period. The diagnosis of MTS can be verified in surgical specimens mainly after a long period of frustrane antiepileptic medication. The mean age at the time of surgery is about 34 years with a medium history of epileptic seizures of almost 23 years (Table 141.1). As in most other series reported so far, both genders were equally affected and a familial history of TLE was very rare indicating that hereditary genetic factors do not play a major role in MTS associated TLE.

Histopathologically, MTS is characterized by segmental pyramidal cell loss in CA1 (Sommer's sector), CA3 and CA4 (endfolium), whereas CA2 pyramidal and dentate gyrus granule cells are most seizure resistant (Figure 141.1). Notwithstanding, several interneuronal cell populations were also affected, i.e., neuropeptide Y- and somatostatin-immunoreactive interneurons and/or mossy cells in the CA4 sector.[3,4] Neuronal cell loss is invariably associated with reactive astrogliosis, which results in stiffening of the tissue and established the traditional term of Ammon's horn sclerosis.[5] An intriguing question relates to the mechanisms of selective neuronal vulnerabilities between these morphologically similar neuronal cell populations. Notwithstanding, this topic is matter of ongoing studies and will not be further discussed in this chapter. Major pathomechanisms include, besides many others, abnormal neuronal circuitries (aberrant mossy fiber sprouting)[6] and molecular rearrangement/plasticity of ion channel and neurotransmitter receptor expression.[7]

Clinico-pathological classification of MTS

Clinical studies assume mesial temporal lobe epilepsies as a heterogenic entity with different etiologies and clinical histories.[8–10] Hence, neuropathological investigations described different patterns of neuronal cell loss within hippocampal subfields and adjacent temporal lobe structures.[4,11,12]

Table 141.1 Clinico-pathological findings in MTLE patients

		Hemisphere					
		Number	Age OP	Gender		Onset	Duration

Evaluation of 1175 patients with mesial temporal lobe epilepsies and surgical resection including the hippocampal formation. All data were obtained from the German Neuropathological Data Base for Epilepsy Surgery. Histopathological evaluation and clinical histories are as following:

MTS: mesial temporal sclerosis; DUAL: dual pathologies; LEAT: long-term epilepsy associated tumors; Vasc.: vascular; NOS: not otherwise specified; Age OP = age of patients at surgery (in years); Hemisphere: L (left), R (right); Gender: F = female, M = male; Onset = age at onset of spontaneous seizure activity (in years); Duration = duration of seizure disorder before surgical treatment (in years).

An intriguing issue is, therefore, to identify determining factors on hippocampal pathology patterns. A reliable neuropathological classification system will also be most helpful to separate distinct pathological subgroups and to better predict post-surgical outcome. A first systematic attempt was published in 1992 by Wyler[11], referring to percentages of neuronal cell loss within identified hippocampal subfields CA1-CA4 (Table 141.2). The Wyler-Score is well established in the neuropathological work-up of MTS and threshold values are defined either by 10% (Wyler score 1 = mild MTS) or 50% of neuronal loss. Classification includes five grades (W0 = normal, W1 = mild, W2 = moderate, W3 = classical hippocampal sclerosis and W4 = severe hippocampal sclerosis). End folium sclerosis is subsumed into W2. In previous investigations, certain difficulties evolved using the Wyler-Score to identify mild hippocampal sclerosis on the basis of 10% neuronal cell loss within CA1 and CA3/CA4. Our own analysis even identified 10% neuronal loss within the first standard deviation of age-matched control individuals. An extension and revision of the Wyler-Score was then published by Proper *et al.*[13] including mossy fiber sprouting. Mossy fiber sprouting as well as reactive gliosis are frequently associated with long-term mesial temporal lobe epilepsy, and were confirmed in a variety of different animal models.[12,14–19] However, any histopathological classification system should be deliberately based on general histopathology techniques and staining protocols applicable in any pathology laboratory worldwide, without further time and cost-intensive or capricious neuroanatomical techniques, i.e., Timm staining for aberrant mossy fiber sprouting.[9]

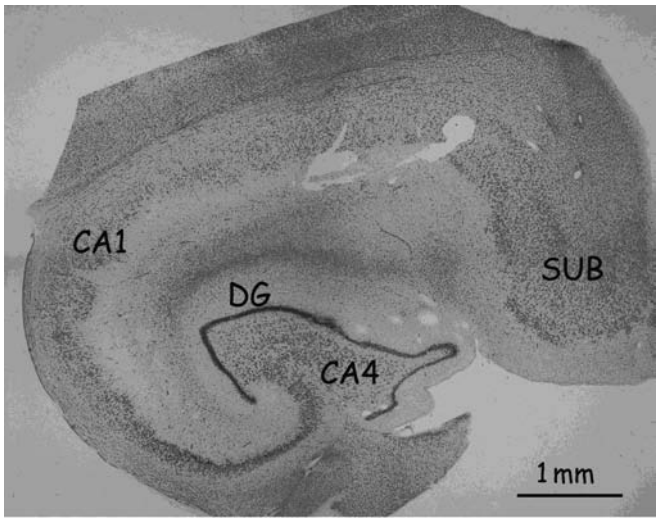
We propose, therefore, a novel clinico-pathological classification system for hippocampal cell loss in patients suffering from mesial temporal lobe epilepsies (MTLE). Five distinct patterns were recognized (Table 141.2) and associate with specific clinical histories and/or post-surgical outcome.[20]

No MTS

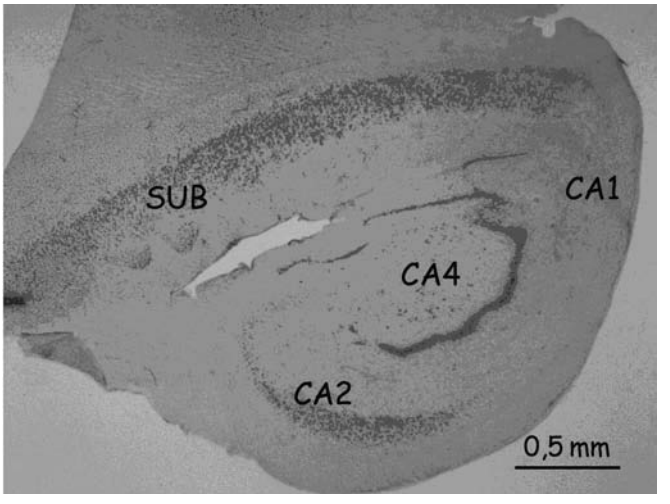
Despite electrophysiological evidence for mesial temporal lobe generation of seizures, a cohort of approximately 19% of MTLE cases do not show microscopical features of neuronal cell loss (Table 141.1; Blümcke *et al.*, 2007)[20] and cell density measurements were not significantly different from age matched autopsy controls (±10% difference in neuronal cell densities are explicable only by the standard deviation obtained from human control values !). We designated this group as no mesial temporal sclerosis (no MTS; Table 141.2). This observation has been frequently reported in neuropathological surveys of similar MTS series.[1,2] The epileptogenic pathomechanisms of hippocampal seizure generation remains to be further determined, and we suggest a mechanism similar to the kindling animal model. Indeed, focal lesions adjacent to the hippocampus can be frequently identified in this cohort of TLE patients (Table 141.1).

MTS type 1a and 1b (classical and severe hippocampal sclerosis)

With 70% of MTS cases, the largest group present with a classical or severe pattern of segmental neuronal cell loss affecting CA1 and CA4. Due to considerable similarities of neuronal cell loss patterns and clinical histories, we designated these two groups as MTS type 1a (20%) and 1b (50%). In our hands, the degree of CA3 and CA2 pyramidal cell loss is likely to differentiate between MTS type 1a (with moderate CA2 cell loss) and MTS type 1b (with severe CA2 cell loss). This distinction is reasonably similar to that described by Wyler *et al.*[11] Correlation with clinical data pointed to an early age of preceding events (< 3 years) as important predictor of this classical and severe hippocampal pathology pattern.



(a)



(b)

Figure 141.1 Neuropathological findings in mesial temporal sclerosis (MTS). Neuropathological hallmarks of MTS represent segmental pyramidal cell loss affecting the CA1 and CA4 sectors (b). In contrast, CA2 pyramidal and dentate gyrus (DG) granule cells are most seizure resistant. a: Histograph of a human hippocampus obtained from autopsy. SUB: Subiculum. Pigment-Darrow Red Staining. Scale bars = 1 mm in a and 0.5 mm in b. Note the significant atrophy of the MTS specimen in b. (See Color plates.)

Atypical MTS type 2 (CA1-sclerosis) and type 3 (endfolium sclerosis)

We identified two atypical variants characterized either by severe neuronal loss restricted to sector CA1 (MTS type 2; 6%) or to the hilar region (MTS type 3, 4%). In MTS type 2, preceding events were documented at a later age (mean six years), whereas in MTS type 3 and normal appearing hippocampus (no MTS) the first event appeared beyond the age of 13 and 16 years, respectively.

The novel MTS classification system allows some prediction of post-surgical outcome (Table 141.3). In our large cohort of TLE patients, the overall six months outcome revealed a rate of 78% seizure freedom, which is in the well-recognized range of earlier reports.[8,10,22–26] The best outcome was achieved, however, in patients presenting with MTS type 1a and MTS type 1b (> 83% seizure freedom), whereas only half of patients with atypical MTS patterns (type 2 and type 3) became seizure free (Table 141.3). Notwithstanding, TLE patients without hippocampal neuronal loss have also a proven benefit from epilepsy surgery.

An intriguing challenge for any neuropathological classification system of CNS diseases is the relationship between cellular/molecular lesion patterns and clinical parameters as well as its predictive value for post-surgical outcome. The age of the first preceding event such as birth trauma, febrile seizures, head trauma, encephalitis or first seizure in the absence of a preceding event was significantly different in the neuropathology groups. Early events occurring in pre-school age under age of 7 years came along with severe neuronal loss in hippocampal subfield CA1. Moreover, earlier events under the age of 3 years presented with more widespread hippocampal damage comprising all hippocampal sectors as well as the dentate gyrus. Occurrence of an event or epilepsy onset (in the absence of an event) during early adolescence did affect only the hilar region and spared also other hippocampal subfields to a greater extent. Events occurring even at later adolescence were associated with a rather normal appearing hippocampal formation. Many reports emphasize the association between initial preceding events and development of MTS. The frequent association with febrile seizures in early childhood supports this hypothesis. Seizures during early childhood are associated with aberrant mossy fibre axon connections without evidence of seizure-induced cell death.[27] Moreover, prolonged seizure discharges stimulate dentate granule cell neurogenesis as a potential repair mechanism, leading to aberrant connections.[14] Such alterations may affect normal brain development and further promote epileptogenesis, whereas seizure activity during later adolescence may strengthen recurrent excitation and induce excitotoxic cell damage, i.e., MTS.[19]

Granule cell dispersion

The population of dentate gyrus granule cells is pathologically affected in the vast majority of patients with MTS (Figure 141.2). Lesional patterns in this anatomical distinct compartment range from granule cell dispersion, which occur in almost 50% of patients[1] to severe cell loss in MTS type 1a and 1b (Table 141.2). Neuropathological criteria for granule cell alterations have not been firmly established.[9] We consider any increase in granule cell lamination above 10 layers with smaller perikarya and larger intercellular gaps as pathologic and compatible with GCD. Ectopic cluster and bilamination within the molecular layer can also be identified, although to a smaller extent. Since granule cell pathology is not internationally standardized by a classification system, clinicopathological studies yielded complementary results. Granule cell dispersion may be associated with early seizure onset or status epilepticus at an initial stage of the disease.[28,29] On the other hand, Mathern *et al.* failed to establish a correlation between dentate granule cell densities and onset of seizures.[30] A positive correlation was found between the presence of granule cell dispersion and the severity of hippocampal neuronal loss.[2,16,31] This finding suggests that the processes of granule cell dispersion and MTS are closely linked. Furthermore, the occasional observation of granule cell dispersion in the absence of

Table 141.2 Histopathological classification systems for MTS

Reference	Pattern	CA1	CA2	CA3	CA4	DG
(Blümcke *et al.*, 2007)						
no MTS	normal	no loss	no loss	no loss	no loss	no loss
MTS type 1a	classic	80%	30%	30%	40%	55%
MTS type 1b	severe	85%	49%	70%	85%	60%
MTS type 2	atypical	80%	20%	20%	25%	20%
MTS type 3	atypical	20%	25%	30%	45%	35%
(Wyler *et al.*, 1992b)						
Wyler Score 0	normal	no loss	no loss	no loss	no loss	–
Wyler Score 1	mild	10%	–	10%	10%	–
Wyler Score 2	moderate	10–50%	–	10–50%	10–50%	–
Wyler Score 3	classic	>50%	<50%	>50%	>50%	–
Wyler Score 4	severe	>50%	>50%	>50%	>50%	involved

Comparison between two MTS classification systems proposed by Wyler *et al.*[11] and by Blümcke and *et al.*[20] Neuronal cell loss is expressed as percentage from control values within hippocampal subfields (CA1–CA4) and dentate gyrus (DG). Semi quantitative analysis should be applied to determine the extent of pyramidal cell loss. Values represent mean percentages of persisting neurons. It is important to note, that standard deviations need to be applied for scoring individual numbers (data not shown). A software analysis system will be available upon request from the author to automatically calculate the new MTS score.

hippocampal cell loss but with widespread cortical malformations would also point towards a malformative origin.[32]

Dual pathologies

In a proportion of patients with MTS, depth electrode recordings and intraoperative electrocorticography characterize more widespread areas of epileptiform activity involving both mesial and lateral temporal lobe regions.[33–35] From neuroimaging and neuropathological studies it is well established that MTS can occur in combination with a second temporal lobe epileptogenic pathology such as cortical dyslamination (i.e., Focal Cortical Dysplasia type I), ectopic white matter neurons or low-grade glio-neuronal tumors.[1,33,36–41] There are also occasional reports of distinct hippocampal malformations occurring with MTS[42] and structural hippocampal abnormalities on MRI which appear to preceed MTS.[43,44] In the German Neuropathological Data Base for Epilepsy Surgery, dual pathologies were identified in approx. 10% of cases (Table 141.1). There is some evidence for less severe hippocampal neuronal loss when a 'dual pathology' is present (i.e., MTS type 3). In these cases, 'kindling' of the hippocampus by the adjacent temporal lobe lesion may play a role. There is some evidence to support the notion that progressive hippocampal atrophy occurs with longer duration of seizures.[45–47] It has been shown, however, that surgical removal of both lesions results in the best post operative seizure outcome for dual pathologies[40] indicating that each component contributes to the genesis of seizures. The coincidence of dual temporal lobe pathologies also raises the important question of a common predisposing malformative process for both lesions. Furthermore, in a larger proportion of TLE cases, less well defined, subtle microscopic malformations may be identified. Such alterations lend further evidence for underlying temporal lobe dysgenesis which renders it more vulnerable to seizures, neuronal injury and ultimately MTS.[48,49]

A major difficulty, however, reflect the poor interrater concordance for the neuropathological classification of dual pathology in MTS patients. We propose, that the term 'dual pathology' is restricted to a combination of MTS and those lesions, which are likely to represent a distinct pathogenic etiology, i.e., MTS and LEAT, MTS and vascular lesions, MTS and glial scars/trauma. White matter neuronal ectopy and cortical dyslamination of the temporal lobe may not inevitably fit to this assumption and need, therefore, careful attention. The same holds true for the frequent association between LEAT and cortical dysplasias, which may not arise from different pathogenic mechanisms.

Table141.3 Correlation between pathology patterns and post-surgical outcome

		Engel 1	Engel 2	Engel 3	Engel 4
no MTS	n	71.0	12.9	9.7	6.5
MTS type 1a	n	85.7	10.7	3.6	–
MTS type 1b	n	83.3	8.9	7.8	–
MTS type 2	n	50.0*	20.0	20.0	10.0
MTS type 3	n	42.9*	14.3	28.6	14.3
Total	n	77.7	10.8	9.0	2.4

Outcome according to Engel's classification was determined with a minimum period of six months after epilepsy surgery. A total of 166 patients were included in this analysis (Blümcke *et al.*, 2007).[20]
*Note the better outcome in MTS type 1a and 1b, whereas only 50% of patients with atypical MTS type 2 and 43% with atypical MTS type 3 became seizure free ($p = 0.051$).

A pathogenetic model for MTS – associated TLE

Molecular-neuropathological studies of surgical specimens obtained from patients with chronic TLE have focused on different pathogenetic mechanisms, such as (i) structural (axonal/dendritic) and molecular reorganization patterns

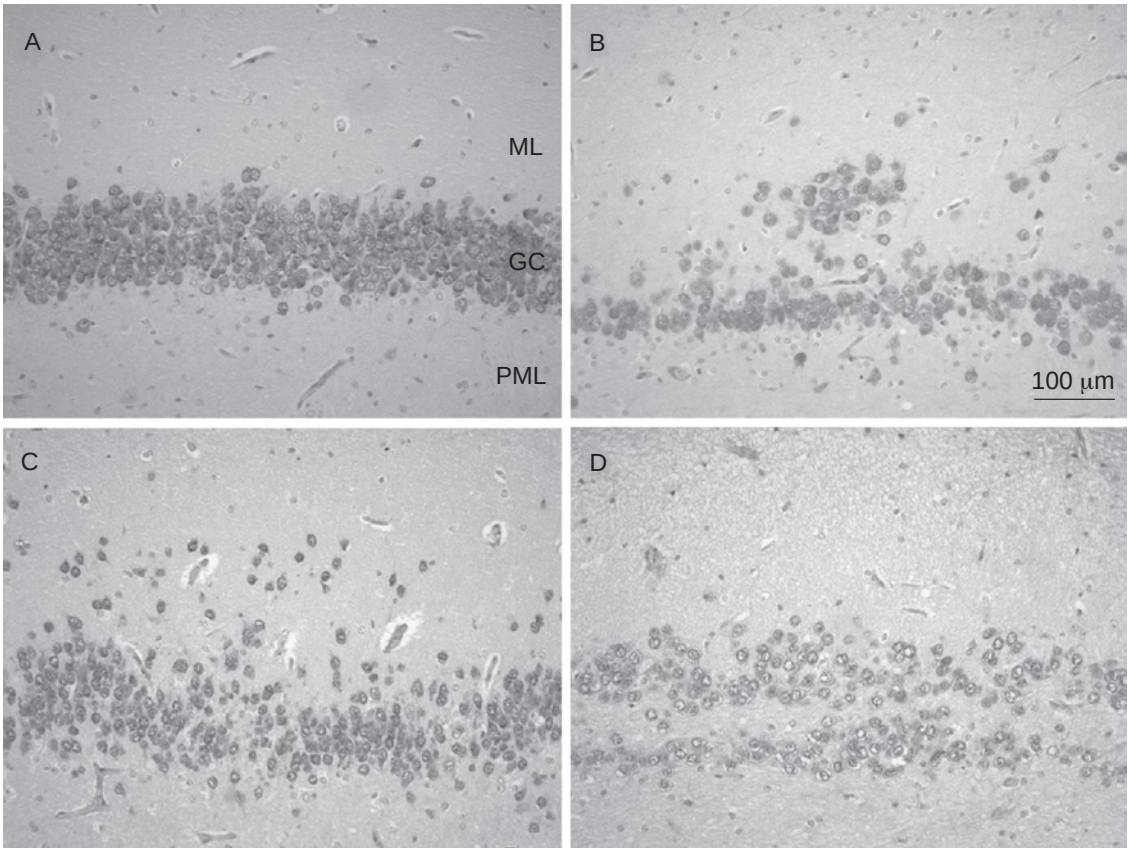


Figure 141.2 The spectrum of granule cell pathology in MTS. Different patterns of granule cell pathologies can be observed in surgical MTS specimens. A: Normal, densely packed granule cell layer of the dentate gyrus (ML – molecular layer; GC – granule cell layer; PML – pleomorphic cell layer). B: A cluster of ectopic granule cell displaced into the molecular layer is depicted. C: A frequent finding comprises granule cell dispersion with a broader thickness of GC and increased gaps between individual neurons. D: In a few patients the granule cell layer present as bilayered structure. Compared to controls, borders to adjacent layers are always less distinguishable in GC pathologies. Scale bar in B = 100 μm (applies also to A, C, and D).

(neurotransmitter receptors, extracellular matrix), (ii) selective neuronal vulnerability (CA1 pyramidal cell loss), (iii) activity dependent changes in neuronal function/synaptic plasticity (voltage dependent ion channels), (iv) gliosis (spatial ion buffering capacity/glutmate receptor expression/gap junctions) as well as (v) epilepsy-associated neurogenesis. A comprehensive model encompassing the chronic disease history in individual patients has, however, been difficult to obtain. Considering the major clinical milestones and molecular-pathological and pathophysiological changes that can be observed at the end stage of the disease (when neurosurgically resected hippocampal specimens are available) the following pathogenic model of MTS associated TLE will be discussed.

We conclude that MTS is an early disorder compromizing normal development of mesial temporal lobe organization with the dentate gyrus as the primarily target.[1] Whether a somatic genetic component plays a role, i.e. affecting neurodevelopmental signaling pathways such as the reelin cascade, can not be excluded yet. However, increased neurogenesis and/or persistence of Cajal-Retzius cells in TLE patients with MTS point towards a prolonged and abnormal maturation period[50,51] and may be regarded as predisposition/susceptibility factor to seizures and neuronal cell loss. This hypothesis is supported by the notion that long-term epilepsies per se do not inevitably damage the hippocampus (repetitively shown in cohorts of TLE patients with poorly controlled seizures).[2]

During a latency period, which usually extends into the 'teenager period', a number of structural and molecular reorganization mechanisms can be assumed. This model is difficult to address in human surgical tissue specimens obtained from an end stage of the disease. However, there is ample evidence from animal models of limbic epilepsy indicating a number of activity dependent reorganization events preceding the onset of spontaneous seizure activity. In particular, neurotransmitter receptor complexes dramatically change their molecular composition in a region-specific manner. Such modulatory changes can functionally reduce seizure threshold levels in the dentate gyrus.[52–54]

Following onset of spontaneous seizure activity within the hippocampal formation and mesial temporal lobe structures during adolescence, secondary changes associated with excitotoxic cell damage may lead to the full-blown pattern of MTS.[1] This model does not rule out that segmental neuronal cell loss can occur already during an earlier period. We do, however, propose that limbic seizure activity on its own cannot induce MTS without preceding anatomical and functional alterations in the hippocampus/dentate gyrus network. This assumption is supported by our studies in lesion-associated TLE, in which patients suffer from low-grade tumors, malformations or vascular lesions (Table 141.1). In these patients, the hippocampus does not unequivocally reveal neuropathological changes (Table 141.2) although seizure semiologies and clinical histories can be very similar to MTS-associated TLE patients.[1]

Our new MTS classification systems fits very well into this model, since most patients with classic or severe MTS (type 1a/1b) suffer from early precipitating injuries. In contrast, atypical patterns with cell loss restricted either to CA1 (MTS type 2) or to the hilus (MTS type 3) associate with later seizure onset.[20] Further studies will be warranted to extend and confirm MTS classification systems and to better stratify the heterogeneous group of TLE patients.

142 Pathology of neocortical epilepsy

M Thom and S Sisodiya

Introduction

A range of focal developmental brain disorders and other cortical abnormalities are now recognized to be highly associated with intractable seizures. Diverse and subtle structural lesions can be identified by neuroimaging and further localized with regions of abnormal activity on EEG and functional imaging and in many cases they may be amenable to surgical resection. One goal of neuropathological examination and study of the tissue removed, above providing a tissue diagnosis, is to investigate more precisely the relationship between the abnormal neuronal and glial cell types identified, and their connections between the lesional and perilesional cortex. This can be correlated with preoperative studies and will continue to improve our knowledge of the cellular basis for seizure onset, which may lead to more directed surgical resections and further improve postoperative quality of life.

Neuropathology methods

Tissues from surgical resections carried out for the treatment of neocortical epilepsy are in general rapidly transported to the neuropathology laboratory fresh from theater in order to allow optimal tissue sampling. Where electrophysiological studies are being carried out on single cells or tissue slices, immediate immersion of the identified cortical region for study into cold, oxygenated, artificial CSF is necessary, from which thick (200–300 μm) vibratome sections are rapidly cut. Neuronal electrophysiological properties, can then be investigated and correlated with cell morphology and local connectivity.[1] Intraoperative marking of electrically abnormal areas identified by subdural grids also allows study of particular histopathological features in the seizure-onset zones in comparison to functionally more normal regions.[2] For structural abnormalities seen on MRI, reliable co-registration and mapping of the pathological changes in the resected specimen also requires careful tissue handling. Following removal, resected brain tissues naturally undergo distortion as well as significant volume changes when subjected to standard tissue fixation, processing and tissue sectioning methods. However, careful orientation and precise slicing of the specimen (Figure 142.1) with reformatting of volumetric MRI images may allow reasonable registration between the specimen and in vivo images.[3] Such methods will become particularly important when investigating more subtle pathological features, for example those in mild dysplasias.

Tissue sampling protocols for neocortical resections in epilepsy will vary between laboratories and with the type of tissue resection carried out. For example the availability of adjacent perilesional or more electrically and structurally 'normal' cortex depends on the underlying condition, operative approach, localization of lesion and functional eloquence of that cortical region. For many epilepsy pathologies, eg., low-grade tumors, complete resection may be more desirable rather than biopsy for the best post-operative outcome and for other lesions (e.g., cavernomas), additional resection of marginal tissue may be beneficial. Ideally, samples for freezing, routine formalin fixation and for electron microscopy should be taken from both the abnormal regions as well as 'more normal' regions. Such archiving of tissues is important both for future diagnosis and molecular research. In most neuropathology laboratories, standard histological stains for the routine diagnosis of neocortical lesions in epilepsy include cresyl violet (Nissl stain) with luxol fast blue to demonstrate abnormalities of the cortical laminar and myeloarchitecture and the presence of abnormal cell types. Immunohistochemistry panels are selected appropriate to the suspected pathology but neuronal markers such as NeuN, phosphorylated and nonphosphorylated neurofilament proteins, glial markers as GFAP and markers of interneuronal groups are more widely used as routine cellular markers in epilepsy neuropathology.

Neocortical neuropathologies in epilepsy

Common neocortical pathologies encountered in some reported epilepsy series, (not including the more frequent temporal lobectomy series reports), are listed in Table 142.1. The most common pathologies include cortical malformations (also discussed in Chapter 148), vascular malformations (Chapter 149), low grade tumors (Chapter 150), inflammatory lesions, in addition to cortical scarring and gliosis.

Focal neocortical malformations

The neuropathology of generalized malforma-tions due to abnormal cortical development are covered in Chapter 148. The main types of focal malformations encountered in epilepsy surgery are divided into three main groups: focal cortical dysplasis, mild dysplasias (mild MCD), and hamartomatous lesions.

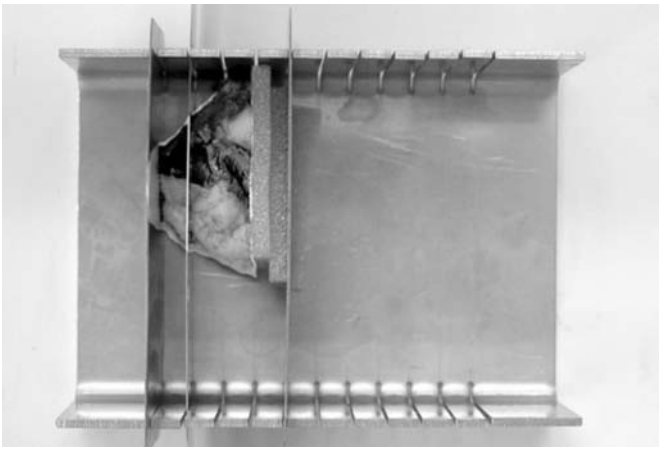

Figure 142.1 Simple metal cradles (7 × 5 cm) can be designed for the handling and slicing of cortical resection specimens in epilepsy to allow even slicing of blocks to correlate with preoperative MRI. In addition, particular regions of the specimen (as shown) can be linked intraoperatively for further localisation of abnormalities.

Focal cortical dysplasia

Focal cortical dysplasia (FCD) describes a type of malformation of cortical development where the abnormality is largely restricted to a region of the cortical plate and characterized by distinctive cyto-architectural changes. These lesions are easily recognized in histological sections but in the past the terminology used has lacked consistency between centers. Recent reappraisal of the nomenclature[4] has resulted in a widely adopted classification system of these lesions in most epilepsy centres which will facilitate their further study. In this system FCD is divided into two types, type I and II, based on the presence of specific neuropathological features as outlined in Table 142.2. Type II FCD, for example is characterized by the presence of abnormal cell types including *dysmorphic neurones* and *balloon cells*.

Macroscopic abnormalities may be present in surgical resections from FCD cases. There may be apparent thickening of the cortical gray matter, blurring of the gray-white border and the tissue may appear firmer. The overall lesion size varies and can be up to several centimetres broad, involving both sulci and gryri. On histological examination, abnormalities of cortical laminar architecture (also called 'dyslamination') are common to all types of FCD with loss of distinction between cortical layers, more easily visualised with Nissl stain or NeuN immunohistochemistry (Figure 142.2). Cortical layer I may often remain relatively cell-free and better defined than other laminae in the region of dysplasia, but may be broader or narrower than normal. The junction between the deep cortical layers and white matter is also typically ill-defined. A lack of radial alignment of neurones compared to normal cortex may also be present in FCD type II. However in FCD I, particularly in childhood epilepsy, an exaggeration of columnar neuronal arrangement has been reported.[5,6] Care should obviously be taken with the interpretation of any perceived cytoarchitectural abnormality in relation to normal regional variations.

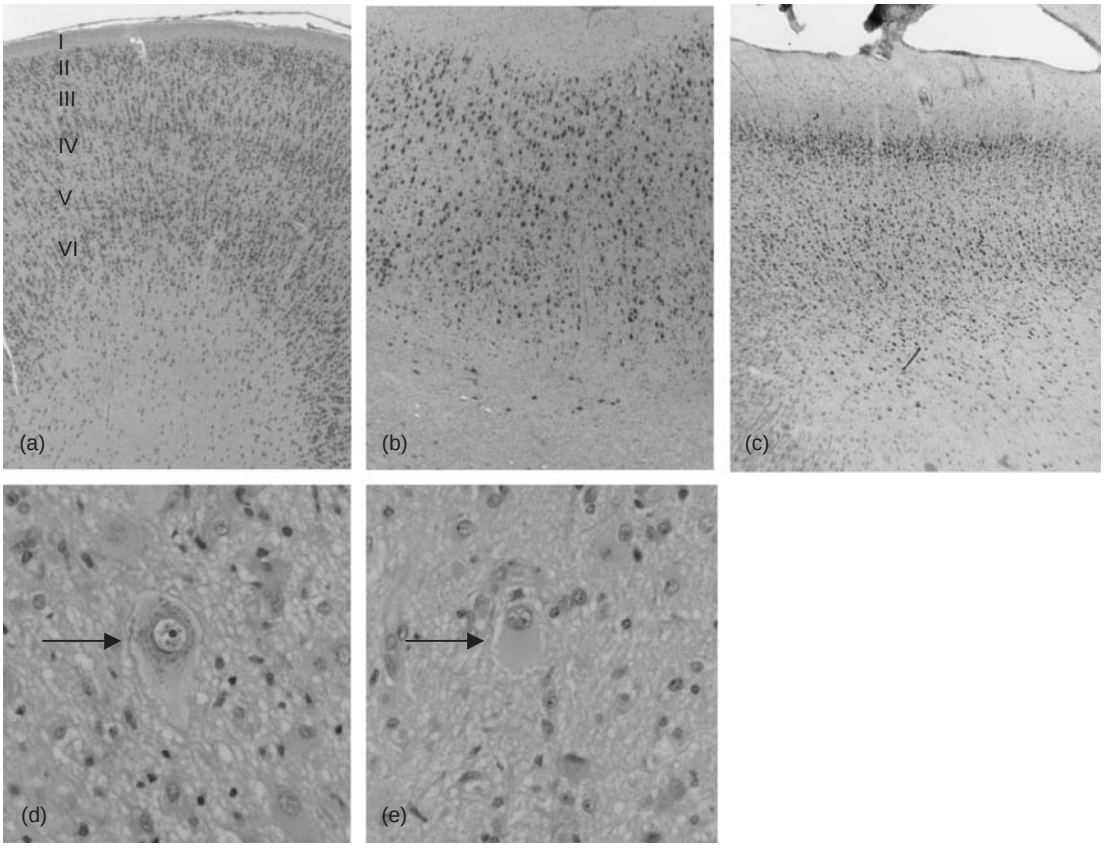

Figure 142.2 FCD type II highlighting changes in the cortical cytoarchitecture as seen with NeuN immunostaining. (a) Normal cortex with distinction between cortical laminae and in (b) in FCD although layer I remains well defined, clear distinction between deeper cortical layers is lost and in (c) a pediatric FCD case, dysplastic neurnones predominate in upper and lower cortical laminae and layer I appears broader than normal. (d) A dysplastic neurone in FCD in H&E preparation and (e) a balloon cell.

Table 142.1 Range of common neuropathological diagnosis in some larger reported epilepsy surgical series which included extratemporal resections (results shown in %)

Series (Ref)	Types of resection	Age of patients	Number of cases (time period)	Major MCD	Focal dysplasias: FCD Mild MCD Hamartomas	Vascular malformations	Low-grade tumours	Hippocampal sclerosis	Old scars/ gliotic/ atrophic lesions	Rasmussen's encephalitis/ others
Goteborg, Sweden 1999[1]	T (25%), F (21%), M (21%)	Children (0–18 years)	108	6%	22%	1%	8.5%	5.5%	53%	0.5%
	T (75%), F (15%)	Adults (18yrs+)	128 (8 years)	1.6%	12.5%	8.5%	10%	14%	51%	2.4%
London, UK 2001[2]	En bloc temporal lobe resection (excluding HS alone)	50% less than 20 years	80 (20 years)	3%	6% 2.5% hamartoma	6. 2%	75% (65% DNT 7.5% GG)	33% (a dual pathology – HS in isolation not included in this series)	–	9.8%
Cleveland, Ohio 2000[3]	Extratemporal neocortical resections	Mean age 21years; range 3 months – 57 years	133 (17 years)	-	37.6% 44.4% (neuronal heterotopia in white matter) 4.5% hamartoma	3%	20.9% (4.5% DNT 5% GG)	–	18%	RE=1.5% No pathology identified= 17%
Grenoble, France 2002[4]	Lesionectomy (11.6%) Corticectomy (49.5%) Combined (38.8%) 81.6% included temporal lobe	Mean age 24.5 years (range 2.5 to 61.2 years).	327 (10 years)	–	18%	4%	28% (18% DNT 8.8% GG)	31% (dual pathology in 5.5%)	5%	RE=1.2% No pathology identified = 15.6%
Bonn, Germany 2002[5]	Focal frontal lobe resections	Adult	68	–	26%	14%	35% (1.4% DNT 11% GG)	–	20%	5%

T = temporal, F = Frontal, M = Multilobar, DNT = dysembryoplastic neuroepithelial tumour, GG = ganglioglioma, HS = hippocampal sclerosis, EFS = end folium sclerosis, RE = Rasmussen's encephalitis, 'en-bloc temporal lobe resection' includes hippocampus and amygdala.

Table 142.2 Pathological features of FCD subtypes as outlined in the system by Palmini *et al.* (2004)

Type	Subtype	Pathology features	MRI	Useful immunohistochemistry panel to aid lesion characterization
FCD type I	IA	Architectural cortical abnormalities ± features of mild MCD	Structural imaging – not usually identified	NeuN – to demonstrate cortical architecture
	IB	Architectural abnormalities and giant (hypertrophic) or immature neurones	Structural imaging – not always identified	*Hypertrophic neurones* Neurofilament proteins; Phosphorylated and nonphosphorylated heavy and light chain (enhanced expression), NeuN
FCD type II	IIA	Architectural abnormalities with dysmorphic neurones but no balloon cells	(May be normal) Increased cortical thickness Blurring of the gray-white junction	*Dysmorphic neurones* Neurofilaments NeuN Developmental proteins; Doublecortin, PSA-NCAM, Nestin, MAP1B
	IIB	Architectural abnormalities with dysmorphic neurones and balloon cells	Above plus Increased signal on T2 or FLAIR (extending toward ventricle in some cases)	*Balloon cells* Variable expression: GFAP, vimentin, neurofilaments, synpatophysin, CD34, CD133, nestin, doublecortin, MAP1B

MCD = Malformation of cortical development.

Abnormalities of the cortical myelo-architecture may also be striking features in FCD, with the presence of excessive and abnormally-orientated cortical myelinated fiber bundles. Myelin rarefaction of the immediate subcortical white matter is also a common finding.

The identification of abnormal cortical neurones and glial cells in FCD define the subtypes (Table 142.2). *Dysmorphic neurones* have an abnormal orientation, dendritic branching pattern and cytoskeletal structure (Figures 142.2 and 142.3). In Cresyl violet stained sections, the Nissl substance of these neurones appears abnormally clumped and eccentric thickening of nuclear membranes is seen. Such neurones may be present in any cortical lamina or may predominate in pyramidal cell layers III and V and are occasionally seen as single cells within apparently normal cortex away from the main lesion, or in clusters trailing into the underlying white matter. The abnormal orientation of these neurones ranges from slight rotation to complete inversion.[1] The dendrites show increased tortuosity but decreased spine density. *Balloon cells* have large round cell bodies with eccentric nuclei and pale pink, glassy cytoplasm on H&E. Multinucleate or giant cell forms are frequent. Cells with mixed balloon cell/ dysmorphic neuronal appearances may also be identified as indeterminate or transitional cell forms. Balloon cells lack axons and dendritic spines and tend to be located in deeper cortical layers, spilling into the white matter, but can be present throughout the cortex, including layer I (Figures 142.2 and 142.3). *Giant or hypertrophic pyramidal neurones* differ from dysplastic neurones in that they retain an overall pyramidal morphology and orientation but may present in any, or throughout all, cortical layers. These cells have abnormally tortuous but shorter dendrites, with increased branching. Their cross-sectional area is significantly larger than normal pyramidal cells.[1] *Immature neurones* are less frequently identified in FCD lesions. These are round or oval cells (diameter 10–12 μm) with a thin rim of cytoplasm and rudimentary dendrites and they may aggregate in clusters.

Although these abnormal cell types are readily recognizable in routine sections, immunohistochemistry may aid their further characterization and classification (Table 142.2 and Figure 142.3). Neurofilament gene expression has been shown to be augmented in FCD neurones[7] and immunopositivity may highlight abnormal morphology, alignment and laminar position (Figure 142.3). Dysmorphic neurones are also highlighted with silver stains, such as Bielchowsky (Figure 142.3) although tau-positive Alzheimer disease-like tangles are only rarely present in these neurones and usually in older patients. In addition, in many abnormal cell types in FCD there is aberrant expression of developmentally-regulated proteins (Table 142.2). Strong cytoplasmic immunopositivity of abnormal neurones in FCD may be seen for nestin[8] whilst balloon cells show variable expression of nestin, vimentin, GFAP, neurofilaments, and MAP1B, an immature MAP isoform.[9] More recent studies have also shown membranous expression of stem cell markers CD34 and CD133 in balloon cell populations located predominantly in the white matter.[10,11] Co-expression of both neuronal and glial markers by abnormal cell types is also another common finding,[9,12] confirming aberrant glial-neuronal differentiation. These findings reflect the likely mal-developmental origins of FCD.

How these abnormal cell types may be involved in the generation of seizure activity is under study. Single cell recordings from dysplastic neurons have demonstrated abnormal intrinsic membrane properties and ion channel functions.[1] Using current clamp techniques in in vitro slice preparations however, no spontaneous epileptiform depolarisations

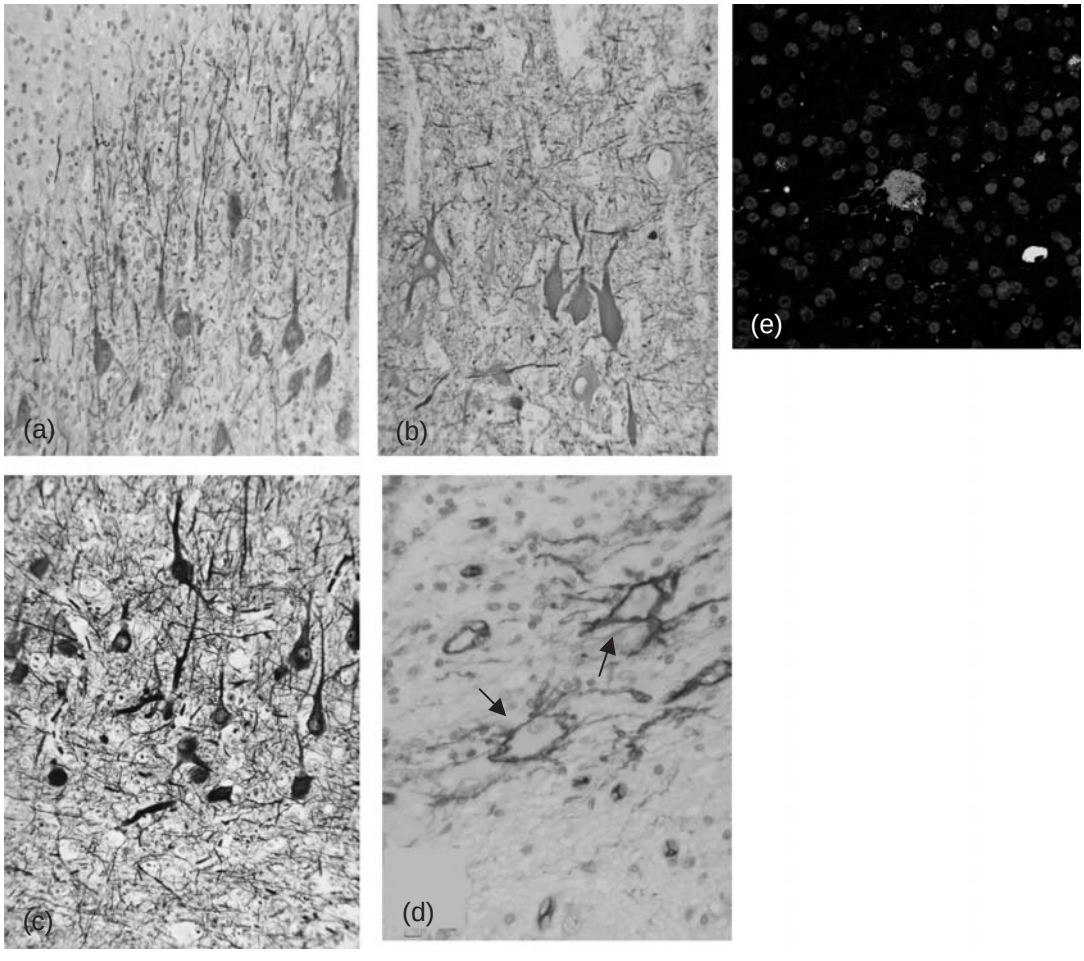

Figure 142.3 Cell types in FCD type IIB. (a) Hyertrophic pyramidal neurones in layer III show strong immunolabelling with nonphosphorylated neurofilament antibodies (SMI32) and in (b) labelling of dysmorphic neurones and numerous processes in the cortex is shown with phosphorylated neurofilament epitope (SMI31). Dysmorphic and hypertrophic neurones in FCD II can also be highlighted with silver stain methods (c). Membranous expression of CD34 on balloon cells in the white matter is a common finding in FCD IIB (d). Proliferative potential of balloon cell populations in FCD type IIB is demonstrated by double labelling for cell cycle marker Mcm2 (nuclear stain, green) and nestin (red) (e). (See Color plates.)

in cytomegalic neurons were noted, suggesting they are unlikely to operate as 'pacemaker' neurons.[13] Balloon cells do not display spontaneous synaptic current or action potentials[1] and lack synaptic contacts[14] suggesting they are relatively inert bystanders. Direct electrocorticographic recordings also support that the centre of the FCD lesion containing balloon cells are less epileptogenic than other regions.[2] In these patients the epileptogenic regions mainly reside in the surrounding regions that are dysplastic but relatively devoid of balloon cells.

The dysmorphic neurons in FCD show increased expression for glutamate receptor subunits, including NMDA receptors.[15] These are heteromeric receptors assembled from NR1, NR2A-D and NR3 subunits and the composition confers specific physiological properties, for example sensitivity to Mg^{2+} blockade. Normal cortical neurons mainly express NR1 and NR2A NMDA receptors. Studies of NMDA receptor subunit expression in large dysmorphic neurons show increased NR1 and NR2 immunolabelling, indicative of a greater number of receptors per cell, although overall receptor density may not be increased.[14] Reports also suggest varying alterations in subunit composition and assembly of NMDA receptors in these cell types in FCD, considered likely to influence their electrophysiological output[16–18] as well as synaptogenesis and possibly neuronal migration during development. AMPA receptor mRNA is also increased in dysplastic neurons.[16,19] A potential role for the differential expression of NR2B in dysplastic neurons was validated in recent in vitro electrophysiological studies in freshly resected human slices; Ifenpordil, a specific inhibitor of the NR2B subunit of the NMDA receptor almost completely suppressed epileptiform discharges in FCD types I and 2A but had no effect on control tissue.[18]

In further support of a local excitatory-inhibitory imbalance in FCD lesions there is evidence for a reduction of number of local inhibitory interneurons and terminals in FCD type II lesions using labelling for GAD, parvalbumin and calbindin.[20,21] $GABA_A$ receptor subunit ($\beta1$, $\beta2$, $\alpha1$, $\alpha2$) mRNAs are decreased in abnormal neurons of FCD[19] as well as in TSC lesions[17] and a reduction in GABA transporter 1 (GAT1) has also been shown in FCD.[20] This potential deficit in inhibitory input may have a role in intrinsic bursting of excitatory neurons. However, other studies propose preserved GABAergic activity in the region of dysplasia[13] and hypertrophic, inhibitory synaptic terminals are often seen to surround dysplastic neurons in ultrastructural studies.[14,20,22] Indeed, recordings from in vitro slice preparations of FCD have implicated a role for GABAergic synchronisation of ictal discharges.[23]

The pathogenesis of FCD is unknown. It is widely considered to represent the result of arrested neuronal migration, abnormal differentiation, progenitor cell proliferation or programmed loss of neurones during cortical development possibly following some localised insult. Abnormal numbers of cortical neurones have been shown in FCD lesions[24,25] with preservation of the proliferative potential of balloon cells (Figure 142.3). FCD is not familial and there is no animal model that exactly resembles the human counterpart. It is plausible that FCD results from a somatic mutation in precursor or progenitor cell populations during development. Single cell analysis has shown that the cells within FCD are not clonally derived but probably arise from mixed populations of progenitor cells.[26] As the histological features of FCD IIB are similar to neocortical tubers of the tuberous sclerosis complex (TSC) (see Chapter 156) several research programs have sought to identify a common genetic link. Sequence alterations (polymorphisms) in the *TSC1* locus and loss of heterozygosity have been identified in FCD type IIB[27] but not in FCD IIA samples[28] potentially implicating TSC genes in balloon-cell containing FCD lesions as distinct from other FCD types. The TSC gene products interact with several intracellular signalling pathways, including Rap1 (binding with ezrin which effects cell adhesion, migration, polarity and cell cycle progression), dysregulation of the insulin signalling mTor/p70SK-S6 pathway (influences cell size and proliferation) and the wnt-1/β-Catenin pathway (implicated in cell survival, cell shape and differentiation, polarity and migration). Molecular studies utilising single cell capture, however, have also disclosed differences between balloon cells and giant cells in FCD and tubers suggesting that the pathological mechanisms in operation are not identical in these lesions.[29–32] Furthermore histological and molecular similarities also exist between FCD and more extensive malformation causing hemimegalencephaly (HME). HME is often sporadic and associated with epilepsy, but occasional linked with syndromes such as linear sebaceous neavus syndrome, proteous syndrome and rarely TSC. Like FCD, activation of the wnt-1/β-catenin pathway has been shown in HME.[29] The reelin and cdk5 signalling pathways have also been implicated in the pathogenesis of FCD, as mice deficient in these proteins display marked cortical laminar abnormalities. Finally there is also an alternative hypothesis, although with relatively less evidence to support it, that FCD is a localised lesion that occurs as a result of cortical structural re-organisation and plasticity following a prior cerebral-cortical insult, for example early cerebral trauma.[33–35]

Mild MCD (malformation of cortical development) in neocortical epilepsy

Mild MCD in epilepsy encompass the more subtle end of the spectrum of focal cortical malformations. These lesions were previously labelled microdysgenesis or architectural dysplasias. Microdysgenesis (or microscopic dysplasia) has been used to cover a wide variety of microscopic minor cyto-architectural cortical abnormalities, including poor distinction between laminar boundaries, an excess of cortical neuronal clusters, an excess of layer I and white-matter neurones and prominent perivascular oligodendroglia-like cell aggregates among others.[36–38] Mild MCD is a term used more discriminately and in the updated Palmini classification, they are divided into two categories: *type I* with ectopic neurones placed in or adjacent to layer I and *type II* with microscopic neuronal heterotopia outside layer I (Figure 142.4). Cortical laminar abnormalities are now included under FCD type IA.

Excess single or 'ectopic' neurones in layer I in mild MCD type I may have varied origins including residual preplate cells from earlier developmental stages (for example, reelin-secreting Cajal-Retzius cells),[39] other early neurones of the marginal zone, abnormally persistent subgranular cell layer neurones, radial migrating GABAergic neurones from the ganglionic eminence or heterotopic cortical plate neurones. In some cases, layer I hypercellularity is readily apparent on qualitative inspection of resected tissues, with occasional formation of nodular aggregates. Quantitative evaluation to distinguish Mild MCD type I from normal cortex may prove of practical value but is time consuming.[21,24,25,39,40] As yet there is no established immunohistochemical panel that can distinguish 'ectopic' from normal layer I neuronal populations and therefore in many cases the diagnosis based on routine stains may be difficult.

Similarly with Mild MCD type II, which includes ectopic single white matter neurones, there are practical diagnostic issues in the separation of pathological 'ectopia' from normal interstitial neurones of the white matter, particularly in the temporal lobe where such cells are more numerous. Possible origins of white matter neurones in mild MCD type II include an excess of residual subplate cells or 'true' heterotopic cortical plate cells. White-matter neurones have mixed morphologies and include pyramidal and small inhibitory interneurones. Several quantitative studies have been carried out, mainly in temporal lobe epilepsy, and confirm higher white matter neuronal densities compared to controls but diagnostic criteria differ between these studies regarding the types of neurones included and the method of quantitative analysis.[38,40–42] Furthermore, in epilepsy, processes such as atrophy and gliosis affect tissue volume and may falsely exaggerate cell number.

Consequently there is less consensus agreement on the diagnosis of mild MCD compared to histologically more easily-recognized forms of FCD. The frequency of mild MCD, in both temporal lobe and neocortical epilepsy is uncertain, with reports suggesting figures of between 16.7–43% in surgical series.[37,43,44] Furthermore as both type I and II mild MCD are typically not visible using current neuroimaging techniques, neuropathology remains the only method of detection. The pathogenesis of mild MCD is unknown. There are some animal models, such as the Ihara rat, which show microdysgenetic features reminiscent of the human trait. As to an underlying genetic basis for Mild MCD, a recent study demonstrated TSC1 genomic sequence polymorphisms in surgical epilepsy specimens showing single white matter neuronal heterotopia and lesions of FCD type I.[28] In contrast to FCD type II, there is as yet little evidence confirming a direct link between mild MCD and cortical epileptogenesis. An excess of layer I neurones with cell hypertrophy was particularly associated with infantile spasms in one study.[24] However, mild MCD-like pathologies have also associated with other behavioral and cognitive conditions without seizures.[4]

Dysplasias adjacent to low grade tumors in epilepsy

Focal dysplasia has also been reported in the context of epileptogenic low-grade glioneuronal tumours, such as DNT and

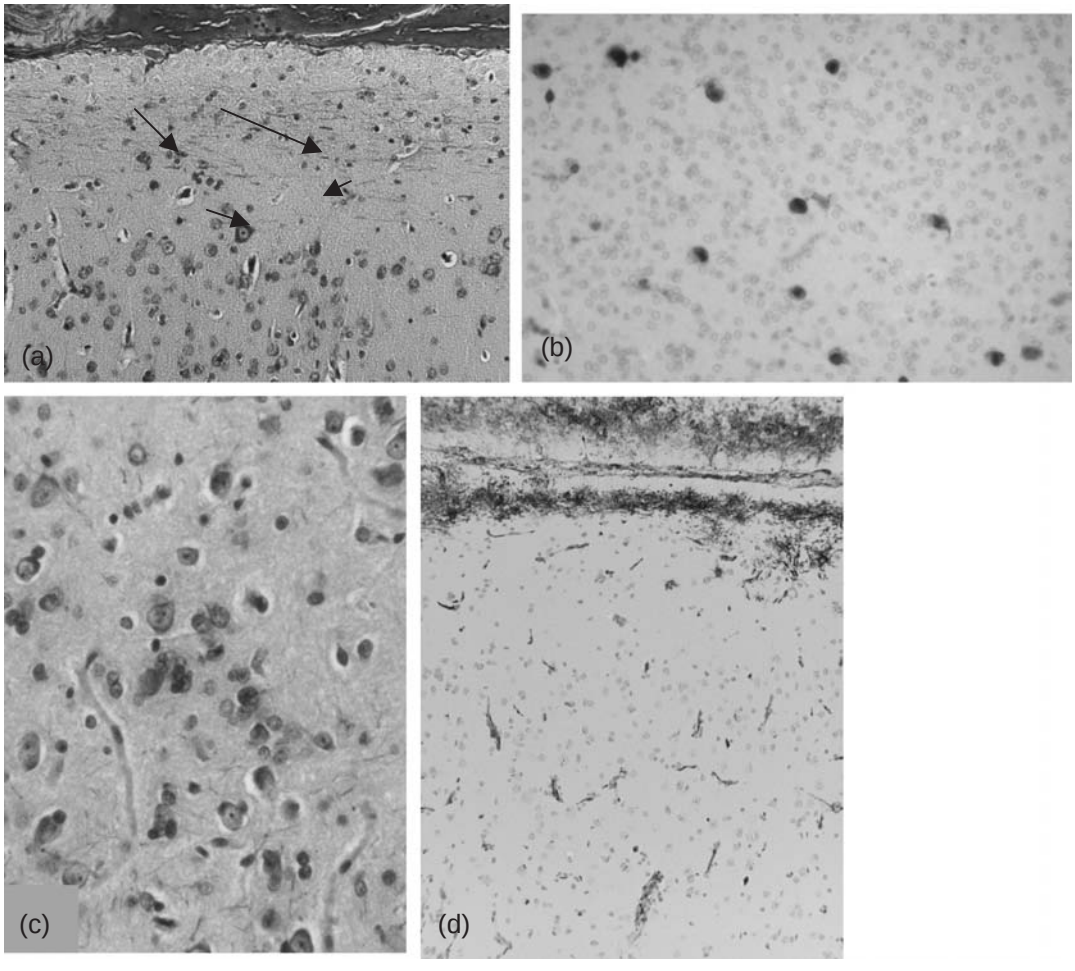

Figure 142.4 Mild MCD. (a) Subtle changes in cortical cytoarchitecture described in Mild MCD include and excess of ectopic neurones in layer I as seen in this Nissl stained section showing a cluster of small neurones (long arrow) and a single large ectopic neurone (short arrow). (b) An excess of single mature neurones in the white matter is one feature of Mild MCD type II, as shown here with NeuN staining. The cortex adjacent to epileptogenic glio-neuronal tumours may show dysplastic features including hamartia like aggregates of immature neurones (c) and an excess of small cells and immature neurones in layer I as highlighted with CD34 staining (d). (See Color plates.)

ganglioglioma, possibly indicating a common biological origin. The type of cortical dysplasia reported varies but is usually cortical/dyslamination (corresponding to FCD type IA). Layer I hypercellularity or a 'subpial cellular band' (mild MCD type I) is also commonly reported[45–47] (Figure 142.4). Clusters of immature neuronal cells mixed with mature neurones and glial cells forming aggregates around 0.2–1 mm across are also common findings in the cortex adjacent to these tumours. These are often referred to as hamartias or 'microdysgenetic nodules'.[48] They may represent tumour precursor lesions and can escape detection on routine H&E but are highlighted with immunolabelling for nestin or the stem cell marker CD34, particularly when in the temporal lobe.[49,50] More severe types of cortical dysplasia, such as balloon cell types of FCD, are rarely reported in association with DNT or ganglioglioma.[47]

The diagnosis of additional cortical dysplasia must be distinguished from disturbance to the cortical architecture resulting from local tumour infiltration. The presence of of cortical dysplasia in the vicinity of glioneuronal tumors raises the possibility of a common biological origin and furthermore the question of the source of the intrinsic epileptogenicity, which is important for surgical management. Intracerebral EEG recordings in ganglioglioma suggest that ictogenesis resides in the itself.[50] The exact mechanisms resulting in hyperexcitability remain to be determined; the prominent mature and immature neuronal component of these tumours is one obvious explanation and expression of several glutamate receptors subtypes on both the neuronal and glial component have been shown[51] and may contribute to proepileptogenic circuits integrating with the adjacent cortex.

Hamartomata in neocortical epilepsy

Hamartomata occurring in epilepsy are a relatively poorly-defined pathological group compared to cortical dysplasias and tumors, being less well represented in epilepsy surgical series. *Glio-neuronal hamartomata* have been described in various cortical locations, particularly temporal and frontal lobes. They are composed of circumscribed masses of mature, but haphazardly arranged, cell types.[52] The imaging characteristics are variable[53,54] but their lack of growth and mitotic activity help to distinguish these lesions from low grade tumors.[52] Following resection recurrence is unusual. The *hypothalamic hamartoma* is a distinct lesion that has a strong association

with intrinsic subcortical epileptogenesis, particularly manifesting with gelastic seizures and may be associated with the development of secondary cortical epileptogenesis[55] and is further discussed in Chapter 43. Unlike the tuberous sclerosis complex, hamartomas or malformative cortical lesions are relatively rarely reported in neurofibromatosis type 1 (NF1) a syndrome in which epilepsy occurs in up to 6% of patients. Neurofibromatosis type 2 (NF2) can be associated with multiple cortical glial micro-hamartomata that are often incidental findings at post mortem, in addition to meningioangiomatosis. *Meningioangiomatosis* (MA) is a presumed hamartomatous developmental lesion, as distinct from meningeal tumours. It is associated with epilepsy, more commonly in sporadic MA (over 80% of patients) than for MA associated with the NF2 complex.[56] MA more commonly occurs in the frontal or temporal lobes forming a superficial or plaque-like hemispheric mass. Histologically it is composed of an intracortical and leptomeningeal collection of small blood vessels and perivascular spindle cells. The intervening cortical parenchyma can appear disorganized and gliotic and neurofibrillary tangles may be present. The more common sporadic form of MA is typically solitary and EEG suggests the epileptogenicity is confined to the adjacent cortex. Indeed, seizures may persist in over half of patients following surgical treatment.[57] It is unexplained as to why patients with MA in NF2 typically do not manifest with seizures.[56]

Rasmussen's encephalitis

Rasmussen's syndrome or encephalitis is a rare, progressive unilateral neurological disorder, typically presenting in childhood with intractable focal seizures (see Chapter 44). Cortical inflammation, neuronal loss and gliosis of one hemisphere are the typical pathological findings in surgical resection specimens, including hemispherectomies. The inflammation is often patchy even in a localized region of the brain. It appears to proceed through various stages of activation representing the presumed immunological destruction of the cortical parenchyma. The early stages are marked by infiltrates of T lymphocytes, microgliosis and astrocytosis (Figure 142.5). In end stages, there is marked neuronal loss, and pan-laminar cortical cavitation.[58] There is a correlation with the pathological stage and the duration of the illness, although within a single specimen regions at non-contiguous stages may be in close proximity. In addition the pathology may be more severe in patients with younger age of onset, suggesting brain maturity may modulate the inflammatory response.[59] The aetiopathogenesis of Rasmussen's encephalitis remains unknown; T-lymphocyte cytotoxicity is currently favored over viral infection.

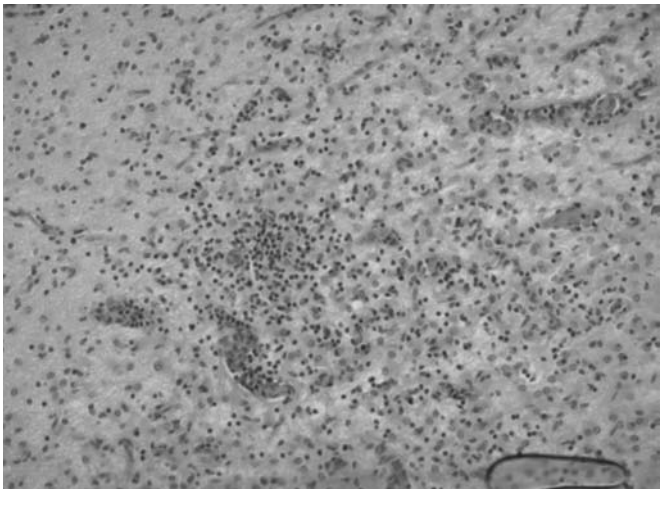

Figure 142.5 Active stage of Rasmussen's encephalitis with infiltrates of lymphocytes in the cortex and early cortical neuronal loss, cavitation, and gliosis.

Nonspecific cortical scarring

The neuropathology of old traumatic scars and cerebral injuries are discussed in Chapter 156. In some neocortical resection specimens subtle degrees of cortical scarring are present and do not appear to be directly attributable to cerebral trauma or perilesional changes and more likely represent tissue changes as a result of seizures themselves. Recurrent generalized seizures or episodes of status epilepticus can result in laminar cortical neuronal loss (Figure147.6) typically involving pyramidal neurones with a corresponding laminar gliosis. Gliosis may also be marked in the subpial region and in the white matter, where perivascular atrophy, vascular degenerative changes and deposits of corpora amylacea are not infrequent findings. The cause of these 'nonspecific' degenerative changes is unknown. Recent studies, however, highlight the importance of not dismissing glial cell proliferations in epilepsy as a mere structural scarring reaction as these cells have important physiological properties. Glutamate released from glial cells can activate neuronal NMDA receptors with the capacity for epileptiform discharges[60] and through establishing local pathological networks, could be a mechanism for synchronising local neuronal activity.[61] Glutamate receptors are also expressed on astrocytes[62] which may also form an extensive syncytium via gap-junctional coupling. Astrocytes have roles in neurotransmitter transport and regulation of levels in the extracellular space. Therefore, proliferation of these glial cells in regions of scarring may potentially play a functional role in neocortical epilepsies and seizure spread.[63]

Molecular and genetic research in epilepsy neuropathology

Access to well-preserved human brain tissue with a detailed history of insults, seizures, and drug exposure, through surgical programs for the treatment of drug-resistant epilepsy, is one of the great advantages researchers in epilepsy have compared to those working in other neurological diseases. Mostly such material consists of varying amounts of tissue, usually including hippocampus, from the temporal lobe, but focal or lobar extratemporal or even hemispherectomy material is sometimes also available. Studies have been undertaken on fresh and fixed tissues, at macroscopic, microscopic, immunohistochemical, electron microscopic, molecular and genomic and functional levels, mainly in hippocampal sclerosis, but also to lesser extents in tumors, brain malformations (including vascular malformations), traumatic brain injury and other pathologies. The range of research is enormous, and

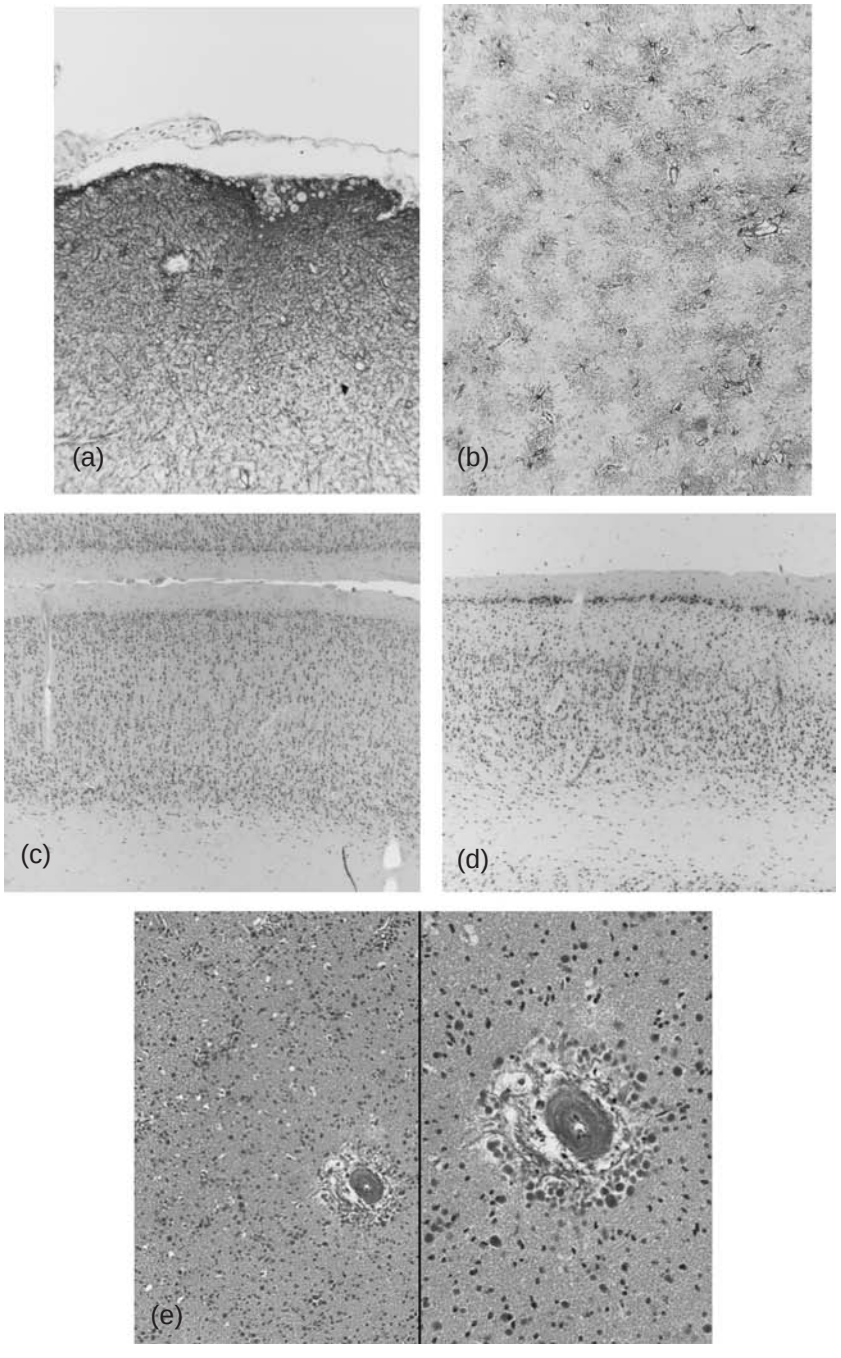

Figure 142.6 Nonspecific cortical changes in patients with epilepsy include regions of superficial cortical and subpial gliosis as seen on GFAP stain (a), areas of cortical gliosis (b). Neuronal loss may be identified in superficial cortical layers (d) compared to normal cortex (c). Marked accumulation of corpora amylacea may be present in the white matter and around small vessels (e) as well as the cortex. (See Color plates.)

only general principles and illustrative brief examples can be given. The interested reader is referred to detailed texts and reviews.[63]

Investigation has revealed a gamut of changes in the two most common surgically-resected pathologies, hippocampal sclerosis (HS) and focal cortical dysplasia (FCD), ranging from changes in entire cell populations, loss of specific immunophenotypic subtypes, alterations in cell morphologies, distributions and processes, disruptions to cellular architecture, genomic expression,[31] protein signatures, processing and function:[16] most of this work has been immunohistochemical, but electron microscopic and functional studies have also contributed.

Genomic investigations are only beginning to be undertaken, and are well illustrated by work from Peter Crino's group. Thus, for example, the possible clonality of origin of cells in FCD has been considered; more recent data raise the possibility of somatic mutation underlying FCD[29] and hemimegalencephaly, with extensive changes in entire cellular pathways such as the mTOR cascade.[30] The use of single-cell laser capture microdissection and single cell mRNA amplification and analysis will become more widely applied, and

integrated with examination of variation in germline DNA, to produce comprehensive pictures of pathophysiology using neuropathological material.

There remain problems. Completely normal comparable brain tissue is very difficult to obtain; most studies that include control tissue use adjacent histologically-normal tissue, but this has its detractors. Almost universally, only a single time point can be examined from one individual, in comparison to animal models: cause and effect, and disease progression, can only be inferred or separated with additional information. There are threats to the availability of tissue from issues of consent, misuse, and legislation, but there is also recognition that these tissues are invaluable for advancing understanding. Undoubtedly, there is still much to be learnt from modern neuropathological analyses of epilepsy brain material.

143 Pathology of malformations of cortical development

R Spreafico and AJ Becker

Cortical development

At the end of the 18th century Camillo Golgi described glial fibers 'radiating' from the central canal towards the periphery of the spinal cord suggesting that '... the key for the solution of many questions is enclosed in the embryogenesis of the nervous central organs'.[1]

Santiago Ramón y Cajal, aware of the works of Golgi, published his first report on the developing cerebral cortex in 1889 stating that cell division occurred preferentially in the 'vicinity of the epithelium', that neuroblasts migrated beneath the outer part of the developing cortex and that radial glia served as scaffold structure for embryonic development.[2]

A particular hallmark regarding mechanisms of cortical development is represented by Rakic's work[3] who clarified the intercellular neuron-glia relationship demonstrating that 'late-generated cells find their way to the cortex by assuming a bipolar shape and moving outward in direct and constant apposition to radial glial processes that span almost the entire width of the telencephalic wall'.

More recent findings provided evidence for distinct nonradial migration routes of certain cell cohorts that migrate parallel to the pial surface. Further novel data indicate that radial cells are capable, by asymmetric division, to give origin to neurons and glial cells, thereby pointing towards the neurogenic potential of radial glial cells.[4–8]

Cell proliferation, migration, differentiation, maturation, as well as programmed cell death represent the fundamental events involved in the developmental shaping of the cerebral cortex.

At the beginning of cortical development, a homogeneous population of undifferentiated cells is present, organized as a pseudostratified columnar epithelium, and called the ventricular zone (VZ). From these undifferentiated cellular population, the neocortex is generated through successive and partially irreversible steps and the final laminated cortex of mammals, including humans, is generated through the formation of transient structures.

After the appearance of the VZ, a new area, called the marginal zone (MZ), is formed just below the pial surface. This area is supposed to be the first functionally active zone of the developing cortex. It constitutes the site of initial synapses formation with brainstem-derived afferents. The MZ also promotes the maturation of early generated neurons in the subpial region, presumably triggering the subsequent migratory events.[9] Thus, the appearance of the MZ marks the initial event of cortical neurogenesis and precedes the formation of all the other cortical layers. The superficial lamina containing the first differentiated neuronal elements is termed primordial plexiform layer (PPL).

Subsequently, after a mitotic cycle, the neuroblasts from the VZ migrate upward and by arrival of the first migratory neurons the PPL is split into two regions. The most dorsal one, close to the pial surface, becomes the prospective layer I; the second one, named the subplate (SP), lies below the newly arrived cohort of neurons forming the cortical plate (CP). The SP is considered the area recipient of fibers incoming from subcortical structures, which establish synapses with the neurons of SP, and represents the waiting compartment for these afferents during CP development. SP neurons are destined to die later on through a process of programmed cell death, and the fibers will then be released to reach their appropriate and final cortical target.

During further developmental stages, the thickness of the CP progressively increases due to the arrival of subsequent waves of migrating neuroblasts. This process follows an inside-out sequence, i.e., the early generated and migrated neurons will form the deep layers of the future neocortex, displaced downward by the neurons generated later and forming the most superficial layers.[9,10] By these mechanisms, layers II through VI are formed.

As mentioned above, two main trajectories, a radial and a tangential route, have been identified for neuronal migration. The process of radial migration implies that newly generated neuroblasts from the proliferative zone migrate to the CP climbing along radially oriented fibers that extend from the ventricle to the pial surface.[6–8,10] Radially migrating neurons give rise primarily to pyramidal neurons (i.e., projection neurons), which are excitatory and utilize glutamate as main neurotransmitter.

Nonradially migrating neurons are generated in the ganglionic eminence, the primordium of the future basal ganglia, located in the ventral forebrain. The cells generated in the ganglionic eminence follow a long tangential migratory route to reach the CP and constitute the majority of non pyramidal neurons (i.e., cortical interneurons), which are GABAergic.[4–6]

These two migratory mechanisms have been extensively studied in animal models; although in principle they are present also in humans, recent data suggest that the population of GABAergic neurons reaching the cortex through tangential migration is only 20–30% of the total inhibitory population resident in the adult neocortex.

Thus, during cortical development, a spatially and ordered sequence of migratory events is accomplished to construct the cerebral cortex. Although the intimate processes leading to the mature cortical structure are not yet completely understood it is evident that both intrinsic (genetic) and environmental mechanisms are involved in corticogenesis and that disturbances of these processes can result in a wide range of alterations, from severe brain malformations to local disruption of cortical structure.

Malformations of cortical development (MCD), recognized as pathologically since the end of the 19th century, constitute a heterogeneous group of focal or diffuse anatomical derangement with pathological features more largely depending on the timing of the defect within the developmental process than on its cause.

The advent of high-resolution imaging techniques, particularly magnetic resonance imaging (MRI), made it possible to diagnose MCD in vivo and, several types of partial epilepsies previously defined as cryptogenetic are now recognized as secondary to cortical lesions. As a consequence correlations between imaging and electroclinical data have increased the number of patient that appear as candidates for surgical treatment.

Neuronal migration disorders (NMDs) are generally considered a subgroup of MCD, and their definition may imply that disruption of migration is the only mechanism on which the malformation is based. However, not all the so-called NMDs have been shown to be due directly to impaired neuronal migration, and other mechanisms are therefore involved.

The cortical malformations previously grouped under the general term of NMDs are currently diversified to reflect the improved knowledge of the pathological substrate, the possible aetiological factors and the relationship between altered structural features of the malformation and type of epilepsy.[11–15]

Lissencephaly

Abnormalities related to cortical development may either affect proliferation and lead to abnormally sized and shaped neuronal and glial cells or be associated with aberrant neuronal migration, which results in abnormal neuronal positioning and compromized cortical architecture.[12] Migration of virtually all cortical neurons is severely affected in lissencephaly. This alteration goes along with an abnormally smooth cerebral surface.[16] Classic lissencephaly shows a prevalence of 11.7 per million births.[17] However, the prevalence of milder forms of the disorder remains undetermined. Initially thought to be an extremely rare disorder going along with severe epilepsy, retardation and early death, MRI reveals individual patients to survive until adulthood.

In normal brain development, the even, agyric cerebral surface, which is present until the 11th week of gestation, is replaced by gyral architectures developing from the area of the sylvian fissure during the following weeks. Gyration is physiologically terminated around the 32nd fetal week. The determination stage for pathological manifestation of a lissencephalic compromised brain development is between fetal weeks 11–13.[18] Transitional forms between lissencephaly/agyria and pachygyria occur. In pachygyria, the cortical architecture appears more advanced compared to agyria.

Different genetic causes underly lissencephalic brain abnormalities, which can lead to substantial alterations with respect to the distribution of the pathological alterations as well as the aberrant cortical architecture. Linkage studies have particularly pointed towards alterations in two genes, i.e., doublecortin (*DCX*) on the X chromosome[19] and *LIS1* on chromosome 17.[20–22] Mutations in *DCX* cause lissencephaly (XLIS) in hemizygous male individuals and subcortical band heterotopia (SBH) in heterozygous females.[23,24] DCX is a microtubule-associated phosphoprotein maintaining cytoskeletal plasticity during axonal outgrowth, neuronal maturation and cell migration.[25] Impaired DCX function in vitro results in interruption of microtubuli. Thereby, the cellular shape and cytoskeletal function as well as cell migration are compromised in vivo.[19,26,27] The combination of high resolution MRI and genetics has recently shown that women with nonsydromical mental retardation, epilepsy and normal MRI may have *DCX* mutations. Women were identified due to male relatives with subcortical band heterotopia or lissencephaly. Therefore, *DCX* may be regarded as candidate gene for women with cryptogenic epilepsy and retardation in the absence of male relatives or a known relevant family history.[28]

Heterozygous deletions of the chromosomal region 17p13. containing *LIS1* underlie extensive phenotypical alterations, summarized as Miller-Dieker syndrome, which comprises severe lissencephaly, craniofacial defects, substantial EEG abnormalities. The syndrome generally is associated with a reduced lifespan. Intragenic deletions or mutations of *LIS1* cause isolated lissencephaly. *LIS1* codes a subunit of the acetylhydroxylase and is expressed by Cajal-Retzius cells.[29,30] Other genes located on chromosome 17p are likely to be involved in the phenotype of the Miller-Dieker syndrome. A recent study has identified at least one gene in this region that influences neuronal migration, YWHAE, which encodes a protein termed 14-3-3ε.[31] It has been pointed out, that the pachy- or a-gyral alterations associated with *LIS1* are pronounced in the posterior occipital area, whereas the structural abnormalities in XLIS are more pronounced in the anterior occipital brain.[23]

LIS1 is expressed and may have a structural role in the adult human brain. It is differentially activated by seizure activity in animal models.[30] *DCX* is regarded to be expressed in the human brain only during development. For both genes, an immediate link between the mutational event and a causative, phenotypic effect has not been shown and does not appear very likely. Epileptic seizures may more probably occur due to complex functional changes resulting from disruption of the normal development of the cortex and white matter and an aberrant neuronal network architecture.

Another form of lissencephaly with an autosomal-recessive transmission mode is caused by deletions in the reelin (*RELN*) gene.[32] In the affected individuals, moderately severe pachygyria is associated with extensive cerebellar hypoplasia. In addition to seizures, severe hypotonia and developmental delay constitute clinical hallmarks of the syndrome.

Type-II-lissencephaly is represented by alterations described as 'pachygyric micropolygyria'.[33] The cerebral surface appears agyric but not smooth. Histologically, abundant and confluent microgyri are present. In the cerebellum multiple cortical

heterotopias are present. Type-II-lissencephaly is frequently associated with oculocerebellomuscular anomalies including the Walker-Warburg-syndrome.[34] or the Fukuyama-type congenital muscular dystrophy.[35,36]

Pathological hallmarks of the lissencephalic brain are absence (agyric) or decreased presence (pachygyric) of convolutions. In pachygyria, the gyri appear flat and smoth. The border between gray and white matter appears unsharp and the cortical organization is severly compromised. With respect to histopathological alterations, two types of lissencephaly are distinguished (Figure 143.1)[37]: *type-I* reveals a thick, only rarely differentiated cortex under a smooth, rather agyric cerebral surface. White matter appears rather thin. The cortical area is composed by four layers:

- A marginal (molecular) layer
- An outer neuronal layer
- A cell-depleted layer with tangentially orientated myelinated fibres
- An inner neuronal layer.

This architecture is typically present in the Miller-Dieker syndrome. The neurons that are compromised in migration may form an additional cortical layer in the white matter, which may result in a double cortex.

The *type-II* lissencephalic phenotype relates to pachygyric alterations, reduced gyration of the cerebral surface and increased width of gyri. The claustrum in most cases is absent. Additional alterations occur in the medulla-cerebellum area, where impaired neural migration in the cerebellar cortex as well as heterotopias of the nucleus olivaris may be present.[18] At the conversion zone of the pachygyric to the normal cortical architecture, the outer neural layer shows a transition to the normal cortex. In contrast, the inner neural layer does not show

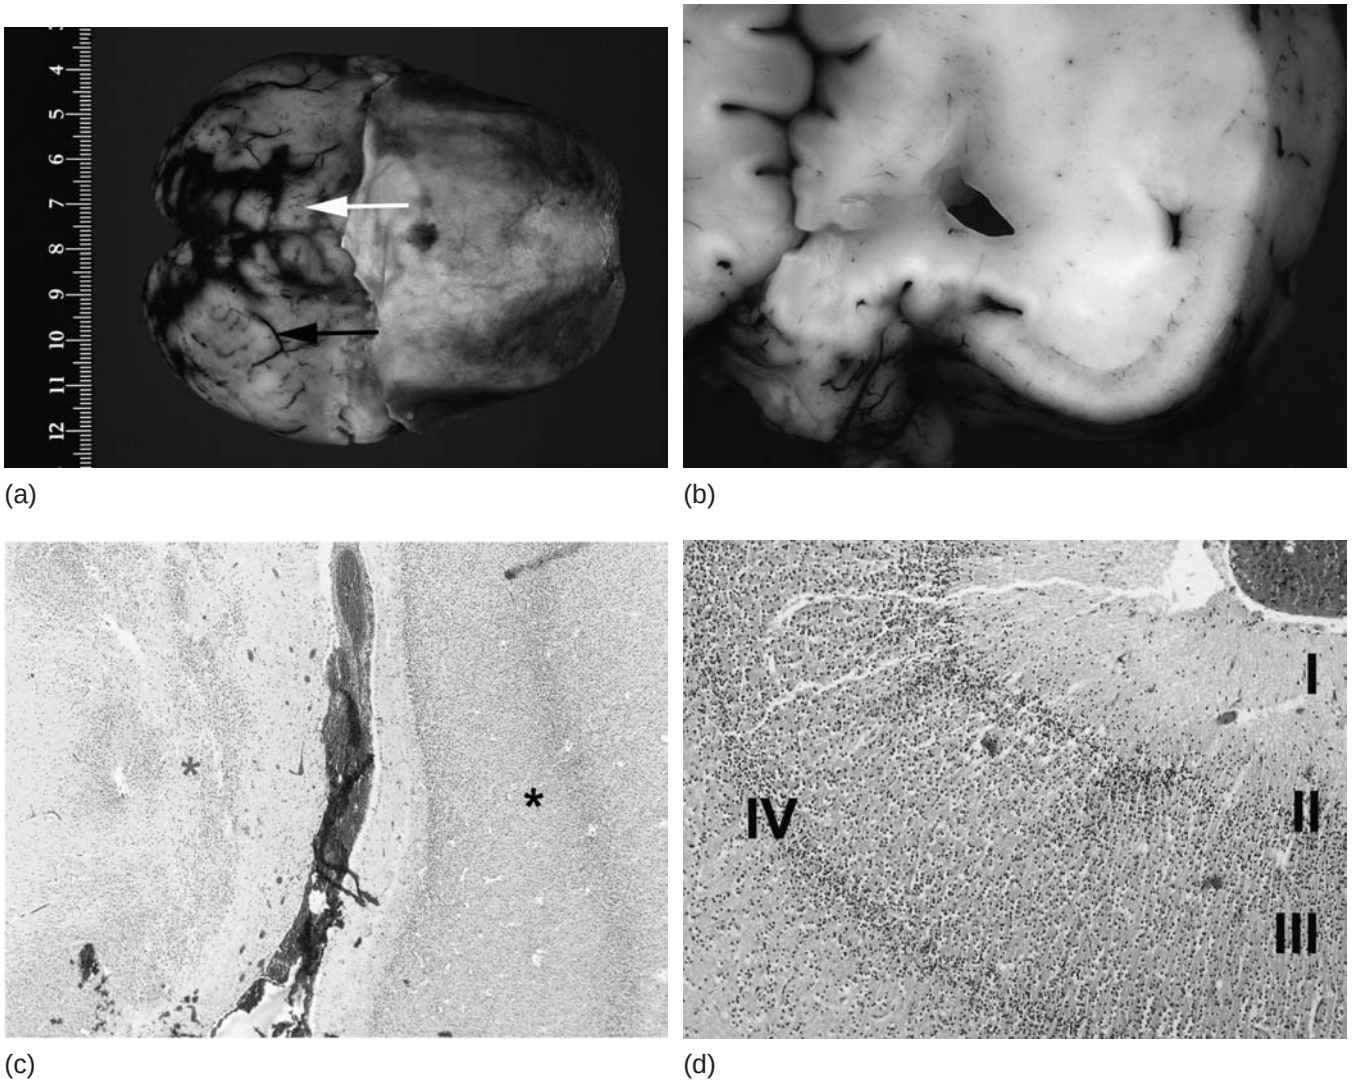

Figure 143.1 Neuropathological findings in lissencephaly. In lissencephaly, the gyri can be flat and smooth, an appearance termed pachygyria (white arrow), or absent, i.e., agyric (black arrow) (a, kindly provided by Volkmar Hans, MD, Bielefeld-Bethel, Germany). On the macroscopic section, a compromised cortical architecture becomes manifest in the agyric areas of the brain (b, kindly provided by Volkmar Hans, MD, Bielefeld-Bethel, Germany). On histological sections, the aberrant architecture of the lissencephalic cortex becomes visible, i.e., lack of cortical organization (gray asterisk) as well as pathological four-layer structure (black asterisk) (c, hematoxilin and eosin, ×100). The characteristic four-layer structure in lissencephaly can differentiated according to a marginal (molecular) layer (I), a outer neuronal layer (II), a cell-depleted layer with tangentially orientated myelinated fibres (III) and an inner neuronal layer (IV) (d, hematoxilin and eosin, ×400).

continuity to the normal cortex. This histological finding may help to differentiate pachygyric alterations from polymicrogyria.

Polymicrogyria

The presence of an excess number of abnormally small gyri that lead to an irregular cortical surface is described by the term polymicrogyria. The outermost cortical layer, i.e., molecular layer, commonly fuses, which results in the appearance of a rather smooth cortical surface. At least two general histological types are observed, the four-layered and the unlayered type. Clearly, a variety of intermediate neuropathological phenotypes exist.

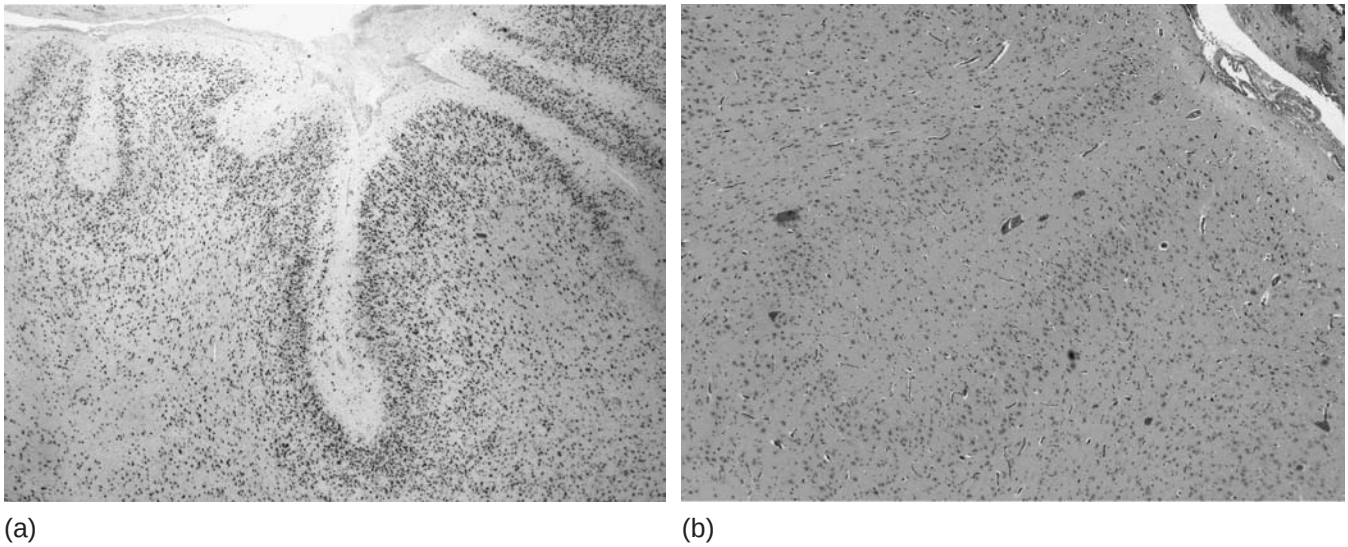
Polymicrogyria may be identified on MRI by excessive cortical gyration in the absence of significant cortical volume and an irregular border between gray and white matter.[15] An important aspect of polymicrogyria is the regional distribution. The malformation may occur unilaterally as well as bilaterally. The manifestation of polymicrogyria at variable brain regions refers to a variety of specific subsyndromes.[38–40] A subsyndrome with distinct clinico-pathological findings and familial recurrence is bilateral perisylvian polymicrogyria, in which the individuals suffer from parallel pseudobulbar palsy, spastic quadraparesis, learning disability and epilepsy.[39,41] There is substantial variation with respect to the extent of polymicrogyria with a wide range of clinical manifestations, from severe encephalopathy with intractable epilepsy to only selective impairment of cognitive function.[42]

Various patterns of inheritance have been described for the different subtypes of polymicrogyria.[41] No individual genes have been linked to any of the bilateral forms with isolated polymicrogyria, although a mutation in *MECP2* was observed in a male patient with bilateral perisylvian disorder and severe neonatal encephalopathy.[43] Further, various linkages to distinct chromosomal regions have been reported.[44,45] A recent hybrid genetic-MRI approach led to the identification of the homeobox gene PAX6 as a factor, in which mutations can result in unilateral polymicrogyria.[46] As observed frequently for other types of cortical malformations, polymicrogyria may be part of multiple congenital anomaly syndromes.[15]

The mechanisms of epileptogenesis related to polymicrogyria are not entirely understood. An experimental model has been used, where a single or few microgyri are generated by a freezing insult. Recent data indicate a widespread region of functional impairment, which extends the visual-ized abnormality in the model.[47,48] Also in patients with polymicrogyria, surrounding cortex appears be involved in epileptogenesis. Therefore, surgical resection of an area of polymicrogyria alone is rarely likely to substantially attenuate or abolish recurrent epileptic seizures.[49,50] Polymicrogyria is, however, not inevitably associated with epilepsy, and it may present as developmental delay or congenital hemiparesis.

In contrast to agyria or pachygyria, gyri are formed in polymicrogyria. However, gyri are atypically organized and lack the physiological laminar cytoarchitectural structure. Polymicrogyria is frequently observed in the vicinity of encephaloclastic lesions such as schizencephaly.[51,52] Exogenic causes of polymicrogyria comprise infections including cytomegaly, toxoplasmosis, rubeola as well as impaired haemodynamic with predelection to the perfusion area of the middle cerebral artery.

Histologically, polymicrogyric lesions show a variety of alterations. On the one side of the spectrum (*type 1*), unlayered polymicrogyria can be observed (Figure 143.2). The molecular layer is continuous and does not follow the convolution profiles. The neurons have a radial distribution and do not show a laminar organization.[53] Microscopically, polymicrogyria (*type 2*) shows a laminar structure composed of four layers:



(a) (b)

Figure 143.2 Neuropathological findings in polymicrogyria. Histopathologically, polymicrogyria comprises a spectrum of alterations. The molecular layer commonly fuses. Polymicrogyria (*type 2*) shows a laminary structure composed of four laminae, i.e., molecular layer, outer neuronal layer, nerve fiber layer, inner neuronal layer (a, NeuN, ×100). In polymicrogyria (*type 1*), the molecular layer is continuous and does not follow the convolution profiles. The neurons have a radial distribution and do not show a laminary organization (b, hematoxilin and eosin, ×400).

- Molecular layer
- Outer neuronal layer
- Nerve fiber layer
- Inner neuronal layer

Apparently, the third layer (nerve fiber) is a result of cellular necrosis and subsequent myelinisation. Occasionally, in the neuronal cell layers granular as well as pyramidal neurons can be observed resembling residuals of the normal six-layer cortical architecture. These two histopathological subtypes do not necessarily have a distinct origin, as both may coexist in contigiuous cortical regions.[54,55]

A main differential diagnosis of polymicrogyria and lissencephaly is given by ulegyria.[56,57] Ulegyria has a prominent scar character with substantial fiber gliosis. Polymicrogyria and lissencephaly lack this extensive astrogliosis. In contrast to ulegyria, there is a dense network of tangentially orientated myelinated fibres in the subpial outer areas of the molecular layer in polymicrogyria.

Schizencephaly

Porencephaly or schizencephaly constitute cystic cortical lesions, which result in open connections between the lateral ventricles and the subarachnoidal space. Schizencephaly is currently grouped with polymicrogyria among the malformations of cortical development (MCD; group IIIA 1,2).[15] Schizencephaly represents a lesion presenting with a transcortical cleft, open or closed (with unapposed or apposed cortical lips, respectively), lined by cortex. Schizencephaly may be further related to regional absence of proliferating neurons and glia or to abnormal cortical organization. Local failure of induction of neuronal migration or focal ischemic necrosis with destruction of the radial glial fibers during early gestation has been hypothesized.[55] Recent studies have pointed to molecular alterations in schizencephaly, suggesting germ line mutations in the EMX_2 homeobox gene in approximately 70% of the cases.[58–60]

With respect to the areas affected, there is a predelection for the central region as well as areas perfused by the middle cerebral artery. Hypoxic damage manifests during fetal development until the end of cortical maturation. There is combination of schizencephaly with polymicrogyria[53] (*type 1*) as well as co-occurrence of schizencephly with radial orientation of the gyri in the vicinity to the cortical defect (*type 2*).[54,61,62] Frequently, schizencephaly occurs bilaterally. However, substantial pathological alterations including the morphological manifestation in form of a porus, is often present only unilaterally. In such cases, abnormal gyration may be observed on the side contralateral to the porus. In some cases the inner glioependymal surface may extend to the external cortical surface, which can appear as a membranous, pale cover. Clefts may be associated with a range of other malformations of, for example, the septum, optic nerve, callosum or hippocampus.[63] Surgical therapy of refractory epilepsy due to schizencephaly has been reported, but is rarely considered in the most number of cases.[49]

In congenital porencephaly, there is a parallel amygdala-hippocampus-atrophy in a high number of cases. With respect to the differential diagnosis of schizencephaly, cystic necroses that are due to inappropriate perfusion at peri- and postnatal stages have to be differentiated. Frequently, these cystic lesions do not exhibit a communication between the inner and outer liquor spaces.

Hemimegalencephaly

Hemimegalencephaly (HME) is a rare, complex brain malformation characterized by enlargement of one hemisphere. In the past it has been included into one of the three major forms of megalencephaly[64,65] and considered as a consequence of aberrant neuronal migration. Although its etiology remains unknown recent molecular genetic studies, imaging and neuropathological data have provided insights in the pathogenesis of this malformation which is actually considered either an early, genetically programmed developmental disorder related to cellular lineage and establishment of symmetry[66] or a primary disorder of proliferation.[67] Barkovich *et al.*[15] include HME among the non-neoplastic malformations due to abnormal neuronal and glial proliferation; two major subgroups are identified: the isolated forms and those associated with neurocutaneous disorders. Sarnat and Flores-Sarnat[68] differentiate, on the basis of morphological and molecular genetic criteria, three main subgroups partially overlapping the Barkovich classification:[15] isolated HME, syndromic HME (associated with other diseases mainly neurocutaneous syndromes) and total HME characterized by associated enlargement of the ipsilateral half of the brain stem and cerebellum.

Being a rare congenital malformation, despite many cases or small series reports, reviews of large cohort of patients is rare in English literature. Tinkle *et al.*[69] in a retrospective study of 15 patients of identified HME reported 53% of nonsyndromic cases and 47% associated with known or suspected syndrome. In a nationwide survey of 44 patients Sasaki *et al.*[70] reported that 36% of the patients had underlying disorders. In their cohort the right hemisphere was mainly affected (66%) with male predominance and no familial cases.

Neurological symptoms are similar in the syndromic and isolated forms[66,70] and characterized by epilepsy, contralateral hemiparesis and psychomotor retardation. Severe epilepsy, often refractory to medical treatment and thus suitable for surgical treatment, is occurring in the vast majority of patients.[71]

Imaging studies are fundamentals for the in vivo study of HME although no substantial differences are present between isolated and syndromic forms. In addition to the evident asymmetry of hemispheres, unilateral thick cortex with broad, flat gyri associated with pachygyria or micropoligyria are evident in the affected hemisphere. Schizencephaly, asymmetry of corpus callosum, heterotopia in white matter can also be observed. White matter abnormalities with loss of gray-white matter differentiation are also present.[66,70,72,73]

Few autoptic cases are reported and the majority of neuropathological studies derive from specimens obtained from multilobar resections or hemispherectomies (Figure 143.3) performed for epilepsy treatment.[73–77] The neuropathological features, like clinical, EEG and MRI aspects, do not allow a differentiation between syndromic and isolated cases and strictly overlaps the gross anatomical abnormalities depicted by imaging studies. Gross specimen inspection shows areas with sulci and gyri of variable configuration (Figure 143.3); thickened gray matter as well as white matter larger than normal volume with blurring of gray-white matter are constantly found.

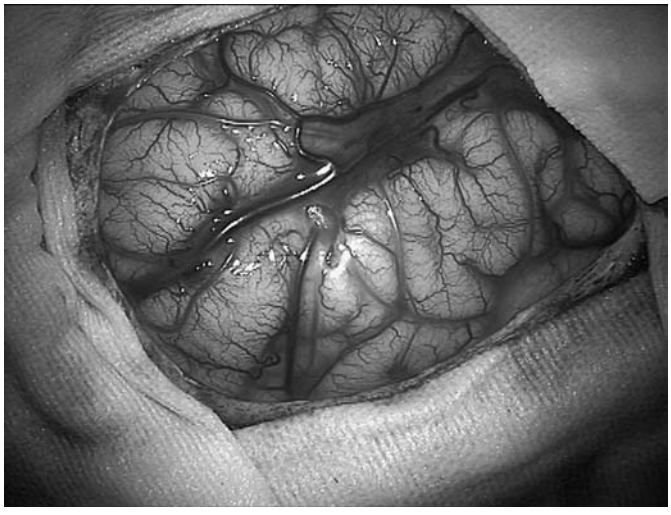


Figure 143.3 Hemimegalencephaly as appears before surgical hemispherotomy; note the broad and irregular gyri. (kindly provided by Prof. G. Broggi).

The lateral ventricle of the enlarged hemisphere is frequently straightened and corpus callosum is frequently asymmetric and thin. At histopathological level a wide spectrum of morphological alterations with combination of different aspects of malformations of cortical development (pachygyria, polymicrogyria and cortical dysplasia with heterotopic neurons in the white matter) can be observed. Dysplastic cortical areas are characterized by cortical dyslamination with columnar arrangement. Large and small neurons are mixed randomly with many disoriented cells. Neuronal cytomegaly with enlarged axons is usually observed so that morphometric analysis demonstrates a significant increase, over controls, in neuronal profile area.[75] The co-occurrence of balloon cells associated with giant dysmorphic neurons are similar to the histopathological findings observed in Taylor's type focal cortical dysplasia (Type IIB in the classification by Palmini *et al.*).[12] Astrocyte proliferation, demonstrated by GFAP immunostaining, is present in both gray and white matter. In some cases dysmielinization is also present in the white matter as suggested by MRI findings. Some ultrastructural data are available but no vascular abnormalities, metabolic storage material or mitochondrial alteration have been observed.[75,77]

Some neurons in HME are expressing markers of cellular immaturity such nestin, MAP1B and vimentin suggesting a defect of cell differentiation or proliferation. Thus its is likely that this developmental malformation may results from somatic gene mutation affecting progenitor cells in one hemisphere during brain development. Recently Crino and coworkers have addressed the molecular pathogenesis of HME.[78,79] by assaying, in eight patients, the expression of 200 cell signalling, growth, angiogenic and transcriptional factor genes with targeted cDNA arrays. The authors found altered expression of 31 mRNAs from four gene families that may lead to aberrant cell growth and hemispheric enlargement in HME.

Heterotopia

The term heterotopia comprises malformations of cortical development characterized by the presence of apparently normal neurons in abnormal position and in general in the subcortical hemispheric white matter. Three main categories are recognized: individual misplaced neurons in the white matter (neuronal heterotopia), nodules of gray matter within the white matter (nodular heterotopia) and band heterotopia (double cortex). In the original classification by Jacob[80] neuronal heterotopia was not considered and only subependymal nodular and band (laminar) forms were included. In the recent classification by Barkovich *et al.*[15] conditions of abundant neurons in the white matter are considered as being due to abnormal neuronal migration. However, classification issues of neuronal heterotopia are still matter of intense debate and authors indicate that the presence of exceeding neurons in the white matter (frequently associated with different forms of MCD) can be ascertained only after accurate morphometric analysis of surgical specimens.[81,82] In this chapter we will focused on the neuropathological aspects of nodular and band heterotopia.

Periventricular nodular heterotopia (PNH)

The incidence of PNH in the general population and in patients with epilepsy is unknown. In a large cohort of 132 epileptic patients with different forms of cortical dysgenesis at the Montreal Neurological Institute, 15% had PNH while Raymond *et al.*[13] reported that 20% of the cases with MCD presented PNH. At the C. Munari Epilepsy Surgery Centre approximately 7% of the patients operated on for intractable epilepsy presented PNH. Only a few autoptic cases are reported however, recent high-resolution imaging techniques allow a precise definition of the macroscopic morphology and extent of nodular heterotopia. Surgical specimens were rare since it was generally considered that epileptic patients with PNH did not respond to surgical treatment; however recent reports suggest that in patients with unilateral heterotopia, surgery can be highly beneficial when epileptogenic zone is carefully identified by refined electroclinical presurgical assessments including invasive recordings.[83,84] The increasing data from genetic studies and MRI (Figure 143.4a) as well as the availability of surgical specimens are determining a continuous refinement of the sub classification system for PNH. Barkovich *et al.*[15] subdivided the PNH into subependymal and subcortical groups. Tassi *et al.*[83] on the basis of their surgical and neuropathological experience proposed a three subgroups: unilateral, bilateral symmetric and bilateral asymmetric. Battaglia *et al.*[85] further refined the classification recognizing two main groups: the bilateral and unilateral. Three subgroups have been distinguished in the bilateral form and two in the unilateral.

In familial bilateral PNH an X-linked dominant inheritage has been established also characterized by a high incidence of spontaneous miscarriage in male foetuses; linkage analysis mapped this disorder to Xq28. Sporadic cases of bilateral PNH both in female and male have also been described. Nodular heterotopia may also been observed in other conditions for with multiple causative genes and environmental aetiologies are suggested.[86] As noted before, neuropathological studies on tissue from epileptic patients with nodular heterotopia are rare and an autoptic study of a patient with genetically proven FLN1 mutation has been recently published.[87] In all cases the nodules consist of masses of neurons, without laminar organization, with well defined boundaries, surrounded by white matter

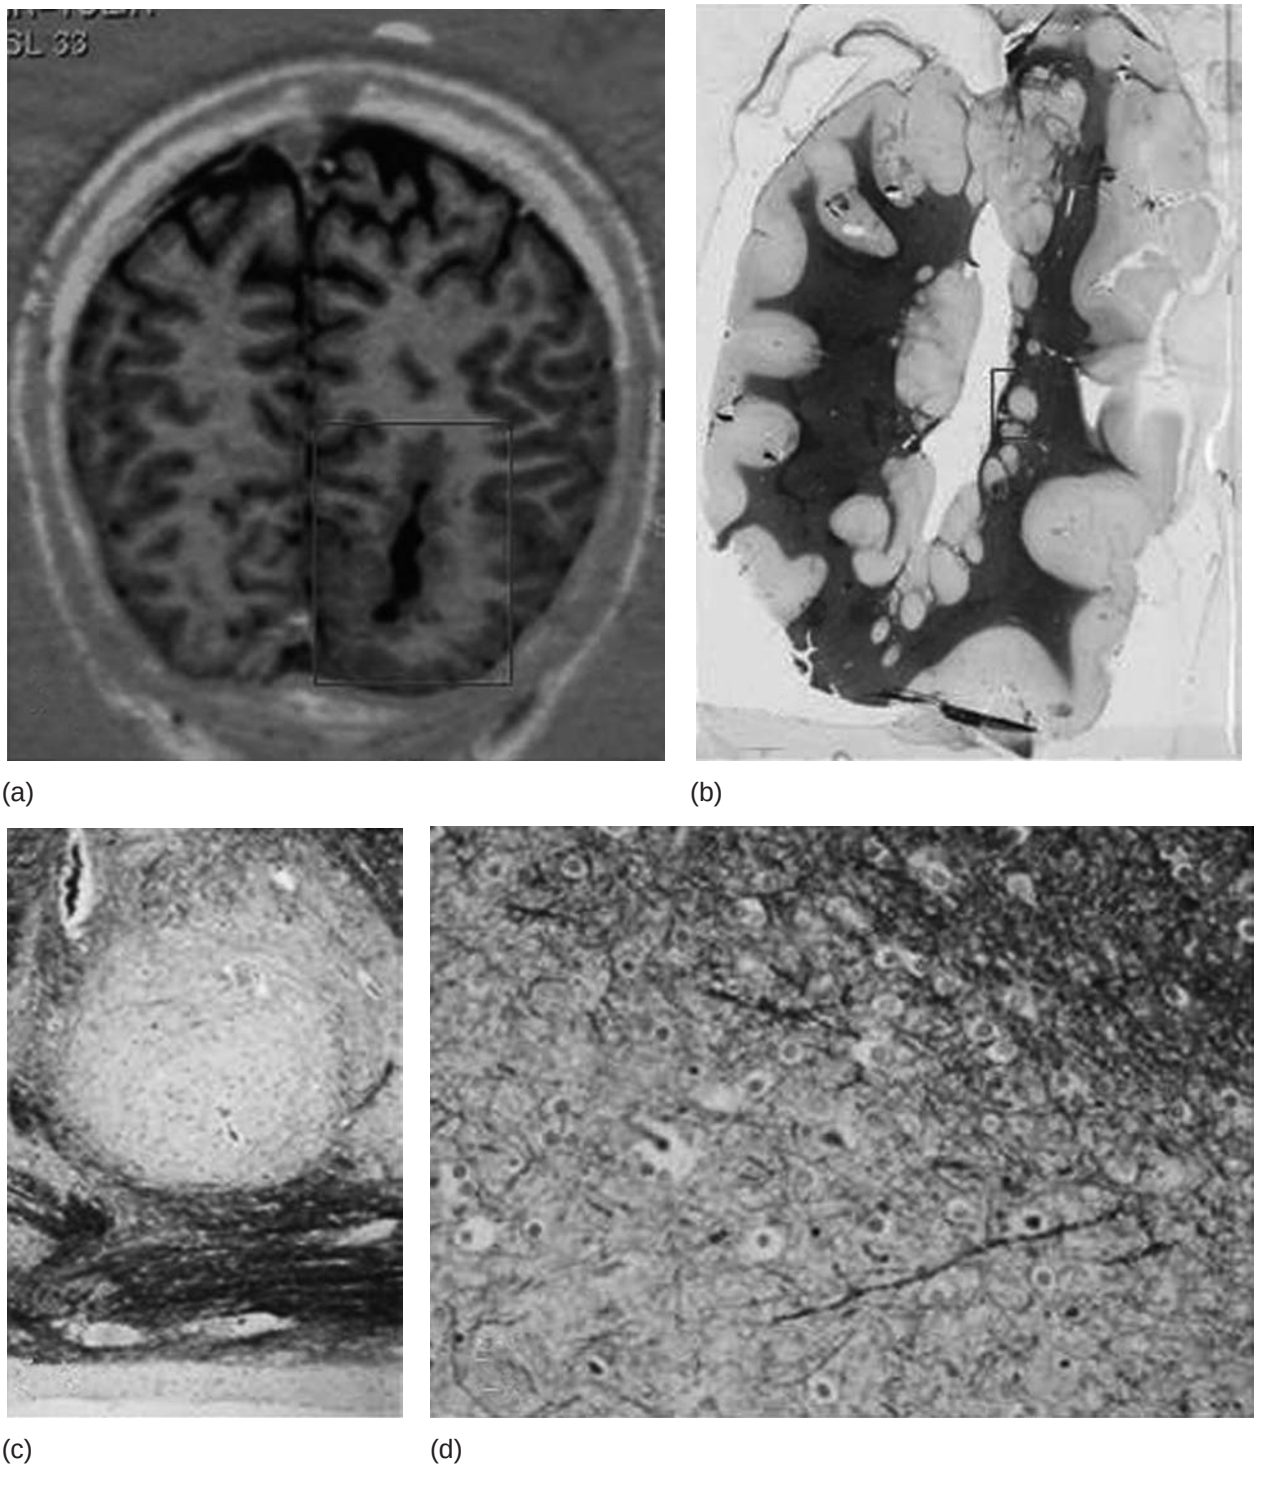

Figure 143.4 Periventricular nodular heterotopia. a. MRI showing large asymmetrical nodular heterotopia. b. Luxol Fast Blue stained section from specimen obtained after surgical resection. Note the large number of irregular nodules one of which (boxed area) can be observed at higher magnification in c. and showing aggregates of neurons with different size and morphology surrounded by white matter fibres. Some fibers penetrate within the nodule (d).

fibres some of which infiltrate the nodules (Figures 143.4b–d). Within the nodules aggregate of small pyramidal neurons, with some immature features and with haphazardly oriented dendrites, appear intermingled with neurons positive for calcium binding proteins suggesting the presence of different subpopulations of GABAergic interneurons.[83,87,88] Taken together these data suggest that the final structure of nodules seems to be independent from their etiology and unrelated to whether the heterotopia is unilateral or bilateral, subependymal or subcortical.

With regard to the neocortex overlying the nodular heterotopia, although MRI frequently suggests polymicrogyria, recent neuropathological data reported abnormal gyration but without histological abnormalities consistent with the typical four-layered or unlayered polymicrogyria.[83] In most, although not in all, of the reported neuropathological studies various degrees of cortical dysplasia are described with reduced expression of calcium binding proteins suggesting an impairment of GABAergic system. In other cases a normally layered cortex can be found although cortical disruption can

be noted in areas where nodules impinge on the cortex. In cases when nodular heterotopia involve the temporal lobe hippocampal sclerosis can also be present.[13,89]

Band heterotopia

This malformation is classified by Barkovich *et al.*[15] among those due to abnormal neuronal migration and included in the subgroup called lissencephalies/subcortical band heterotopia spectrum. However from the neuropathological aspect laminar heterotopia, also defined as band heterotopia or double cortex, is frequently included within the broad group of 'heterotopia'. The genetic aspects of this malformation has been reviewed in the 'lissencephalies' paragraph.

Being a diffuse cortical malformation, frequently genetically determined, only few neuropathological reports are available mainly on sporadic autoptic cases.[65] Although laminar heterotopia can be associated to intractable epilepsy, focal surgical resections have been reported to yield inadequate results.[90] However case reports on surgically treated patients with satisfactory postsurgical outcome have been published.[91,92] Despite the reduced number of neuropathological specimens an increasing number of evidences and careful anatomical descriptions are available thanks to the high resolution imaging also providing genotype/phenotype correlations of this malformation.[50,51,93]

The gross anatomical aspect observed on both MRI and neuropathological specimens is characterized by a continuous bilateral, roughly symmetrical, band of gray matter located between the cortical mantle and the ventricles. The thickness of the band varies among patients and seems to be correlated with the degree of associated mental retardation. The outer cortex may be normal although a slight reduction in number of gyri and pachygyria can be observed. The histological aspect of the cortex is generally normal with a regular six layers (Figures 143.5a and b) and normal distribution of neuronal elements with no cytological alterations.[91,94] Beneath the outer cortex a zone of white matter of variable thickness is present containing abundant heterotopic neurons frequently arranged in columns (Figure 143.5b).

The heterotopic band consists of unlayered small and medium sized rounded or pyramidal neurons (Figure 143.5b). Although macroscopical (as also observed at MRI) the heterotopic band appears as a continuous aggregate of neurons. At microscopic level it appears discontinuous and interrupted by radially oriented fibers. Within the white matter and in the heterotopic band the pyramidal neurons appear haphazardly oriented and nonpyramidal neurons express different calcium binding proteins suggesting the presence of different subpopulations of GABAergic interneurons.

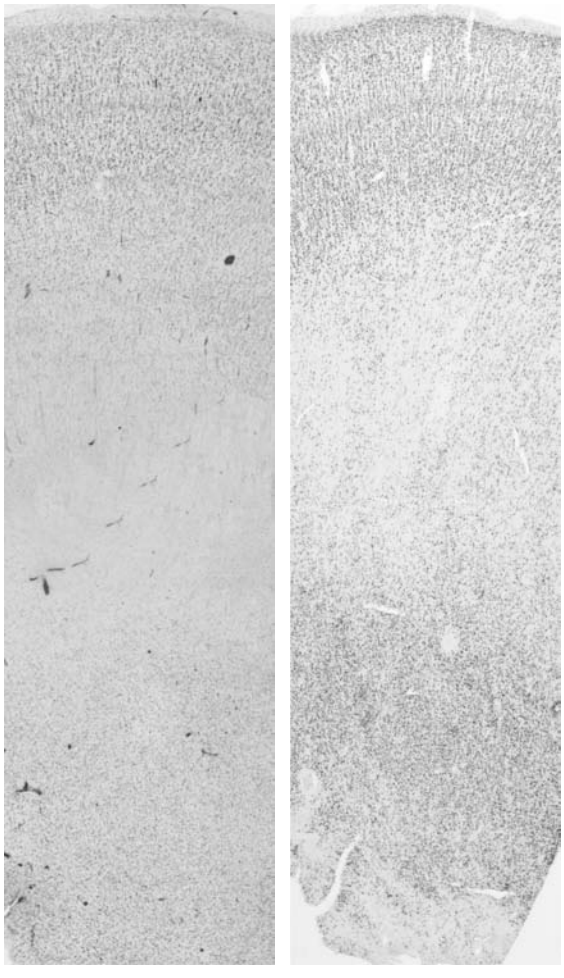

Figure 143.5 Laminar (band) heterotopia. Low power photomicrographs showing two adjacent sections from specimen obtained after surgical resection. a. Nisll stained section showing a regularly layered outer cortex and the heterotopic unlayered bend. In the white matter between the two cortices aggregates of heterotopic neurons arranged in columns are evident b. with NeuN immunostaining. (modified by Mai *et al*. Neurology 2003;60:1834–8).

144 Pathology of neurocutaneous abnormalities, vascular abnormalities: post-infectious and post-traumatic pathologies associated with epilepsy

I Blümcke and M Hildebrandt

Introduction

With recent advances in high-resolution brain imaging, focal lesions became increasingly detectable in patients suffering from chronic, intractable epilepsies. Tailored resection strategies emerged as a beneficial therapeutic option in many of these patients. Increasing access to lesional brain tissue allows systematic neuropathological investigation as well as molecular-biological and genetic studies. This comprehensive approach will further improve our understanding of specific pathomechanisms as well as enhanced seizure susceptibility of focal lesions. In this chapter, the spectrum of neoplasms and malformations associated with neurocutaneous syndromes as well as epilepsy-associated vascular, post-infectious or post-traumatic lesions will be discussed. Genetically determined neurocutaneous syndromes are particularly challenging. Often, multiple lesions are identified, i.e., cortical tubera, subependymal nodules, or subependymal giant cell astrocytomas in patients suffering from tuberous sclerosis complex (TSC). Sturge-Weber syndrome, another phakomatosis frequently associated with focal epilepsies, manifest with proliferation of leptomeningeal veins (meningoangiomatosis) of the subarachnoidal space and/or superficial neocortex. Progress in molecular-genetic analysis highlighted compromized developmental signaling pathways as underlying pathogenic mechanism whereas enhanced seizure susceptibility appears to result from axonal and molecular reorganization of adjacent brain tissue. Besides genetically determined pathology, post-traumatic and post-infectious lesions are other frequent findings in focal epilepsies. Astroglial cell populations transform into scarring tissue and altered molecular expression patterns, i.e., glutamate transporter versus receptors or other molecules associated with ion homeostasis may contribute to the generation of spontaneous seizure activity. In addition, axonal reorganization in brain tissue adjacent to a specific lesion as well as immunogenic mechanisms tackling affected neurons appear to play a major role. During postnatal development, progressive cortical dysplasia in the vicinity of affected brain regions also contribute to enhanced epileptogenesis. Vascular malformations will also be covered in this chapter. Cavernomas, arterio-venous malformations as well as rare hamartomatous lesions with a prominent vascular component can be histologically identified as underlying morphological substrate, whereas molecular pathomechanisms and enhanced epileptogenicity remain to be determined.

Neurocutaneous syndromes

Two distinct neurocutaneous syndromes typically associate with severe seizures, i.e., tuberous sclerosis complex (TSC) and Sturge-Weber syndrome (SWS). TSC manifests clinically with a triad of seizures, mental retardation, and facial angiofibroma (adenoma sebaceum).[1] However, presence of hamartomatous lesions in the brain, i.e., multiple cortical tubera, periventricular nodules, and subependymal giant cell astrocytomas (SEGA) or other organs, e.g., periungual angiofibromas, retinal tumors, angiolipomas in the kidneys or rhabdomyoma in the heart as well as dermal depigmentation ('white spots' as identified during Wood-light inspection) are hallmarks of the clinical diagnosis.[2]

Sturge-Weber syndrome usually presents with facial 'port wine haemangioma' (flame naevus) associated with the ophthalmic division of the trigeminal nerve, ipsilateral leptangiomatosis and glaucoma. Typical clinical manifestations are intractable seizures, stroke-like episodes, headaches, cognitive impairment, hemiparesis, and homonymus hemianopsia. Often mental retardation occurs. Other frequent findings include glaucoma, which affects nearly half of these patients. Brain manifestation usually shows unilateral venous angiomas, preferential within the occipital and parietal lobes. However, all lobes could be affected, occasionally both hemispheres are involved.

Macroscopic and microscopic findings in tuberous sclerosis complex (TSC)

Brain manifestations of TSC include cortical tubera, presenting as round hyperdense lesions in cortical gyri.[3] They occur

multifocal, are firm to palpation and extend into the white matter. The most characteristic feature of cortical tubera is the presence of giant cells (Figure 144.1). They are five to ten times larger than cortical pyramidal cells, present with an opaque cytoplasm and are often multinucleated. Distinct features of neuronal and/or astrocytic differentiation can only rarely be identified.[4] However, some giant cells express immunohistochemically either neuronal or glial antigens, occasionally coexpression occurs. More importantly, expression of immature markers can be observed in the majority of surgical

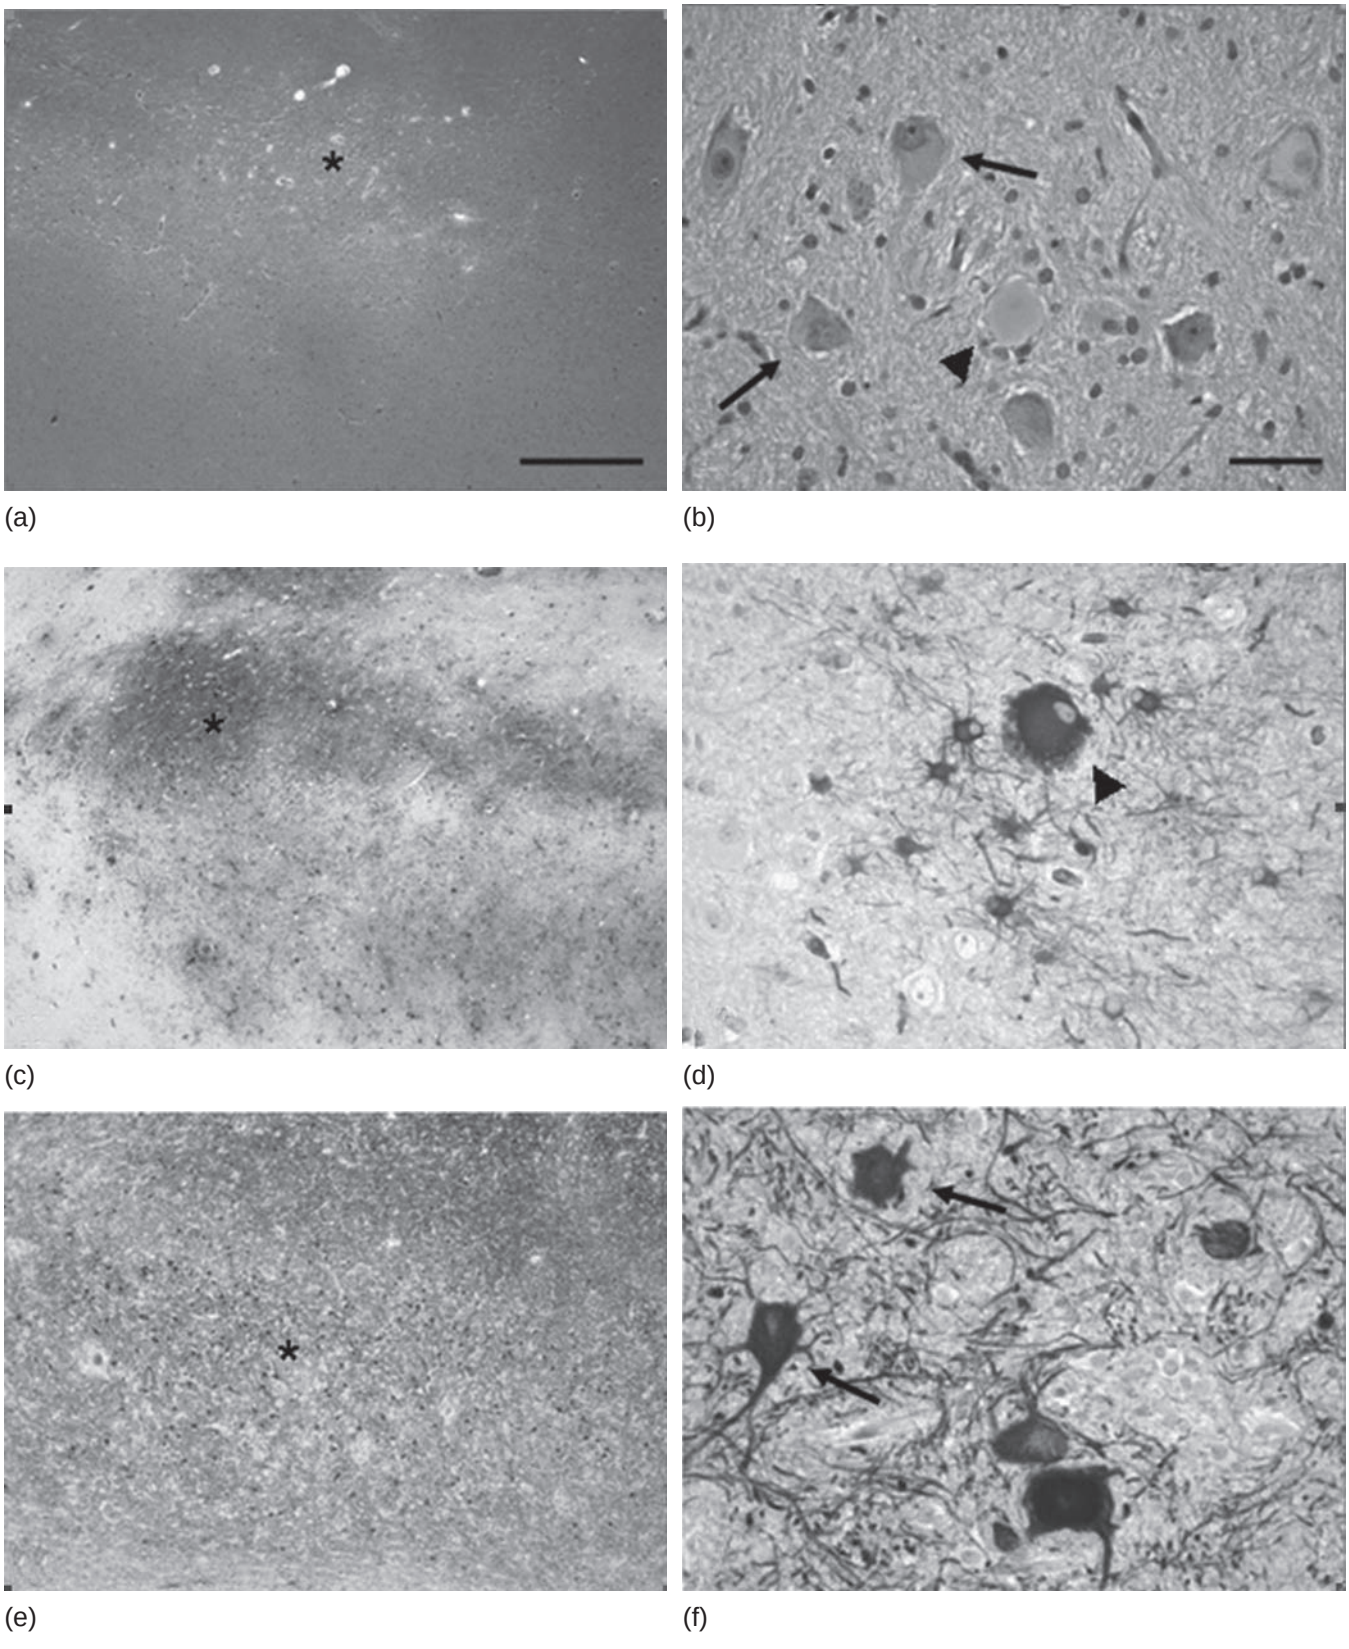

Figure 144.1 A cortical tuber (indexed by asterisk in a) was identified in this epilepsy patient suffering from tuberous sclerosis (serial sections in a = HE, c = Vimentin and e = Neurofilament; 12.5×, scale bar = 1000 µm). Higher magnification in b (HE), d (Vimentin) and F (Neurofilament) demonstrated a biphasic composition with dysplastic neurons (arrows in b and f) and opaque giant cells (arrowhead in b; scale bar = 50 µm) immunoreactive for vimentin (d).

specimens, including vimentin, nestin or the stem cell epitope CD34, which is compatible with an arrested differentiation of compromized progenitor cells.[4,5] Although the surrounding non-affected neocortex demonstrates usually with a normal cytoarchitecture, calcifications, either within or adjacent to the lesion, are frequently encountered in TSC patients.

Other typical features occurring in TSC are periventricular nodules, well-circumscribed masses containing giant cells as described above and subependymal giant cell astrocytomas (SEGA; Figure 144.2). The latter occur in 6–16% of patients with TSC and can occur at various localizations. SEGA is a benign, slowly growing tumor typically arising in the wall of the lateral ventricles corresponding to WHO Grade I. Histopathologically SEGA presents as a well circumscribed, often calcified tumor, mainly composed of large, plump cells resembling astrocytes. Perivascular pseudopalisading (Figure 144.2B) and clustering of tumor cells are common features. Cellular pleomorphism and occasional mitosis are common and do not indicate a malignant behavior. Anaplastic tumor progression has never been reported in TSC patients, although exophytic growth may reach extensive masses associated with severe clinical symptoms.[6] Recent microarray analysis identified similar expression profiles between cortical tubers, SEGA and conditional *Tsc1* knock-out mice, indicating pathogenic origin from related defects in progenitor cell differentiation during brain development.[7]

Molecular-genetic findings and enhanced epileptogenesis

TSC is a autosomal dominant inherited genetic disorder with a prevalence of approx. 9/100 000.[8] Despite its high penetrance considerable phenotypic variability can be observed, even within affected family members. The mechanisms remain, however, to be specified. Sixty percent of patients suffer from spontaneous de novo mutations. Two genetic loci are characterized. TSC1 is mapped on 9.q34, includes 23 exons, and encodes for the protein hamartin, which is strongly expressed in brain, heart, and kidney.[9] The transcript contains 8.6 kb. Hamartin consists of 1164 amino acids and has a molecular weight of 130 kDa. It inhibits tumor formation possibly by regulating cellular adhesion through ezrin-radixin-moiesin family proteins and the small GTP-binding protein Rho.[10]

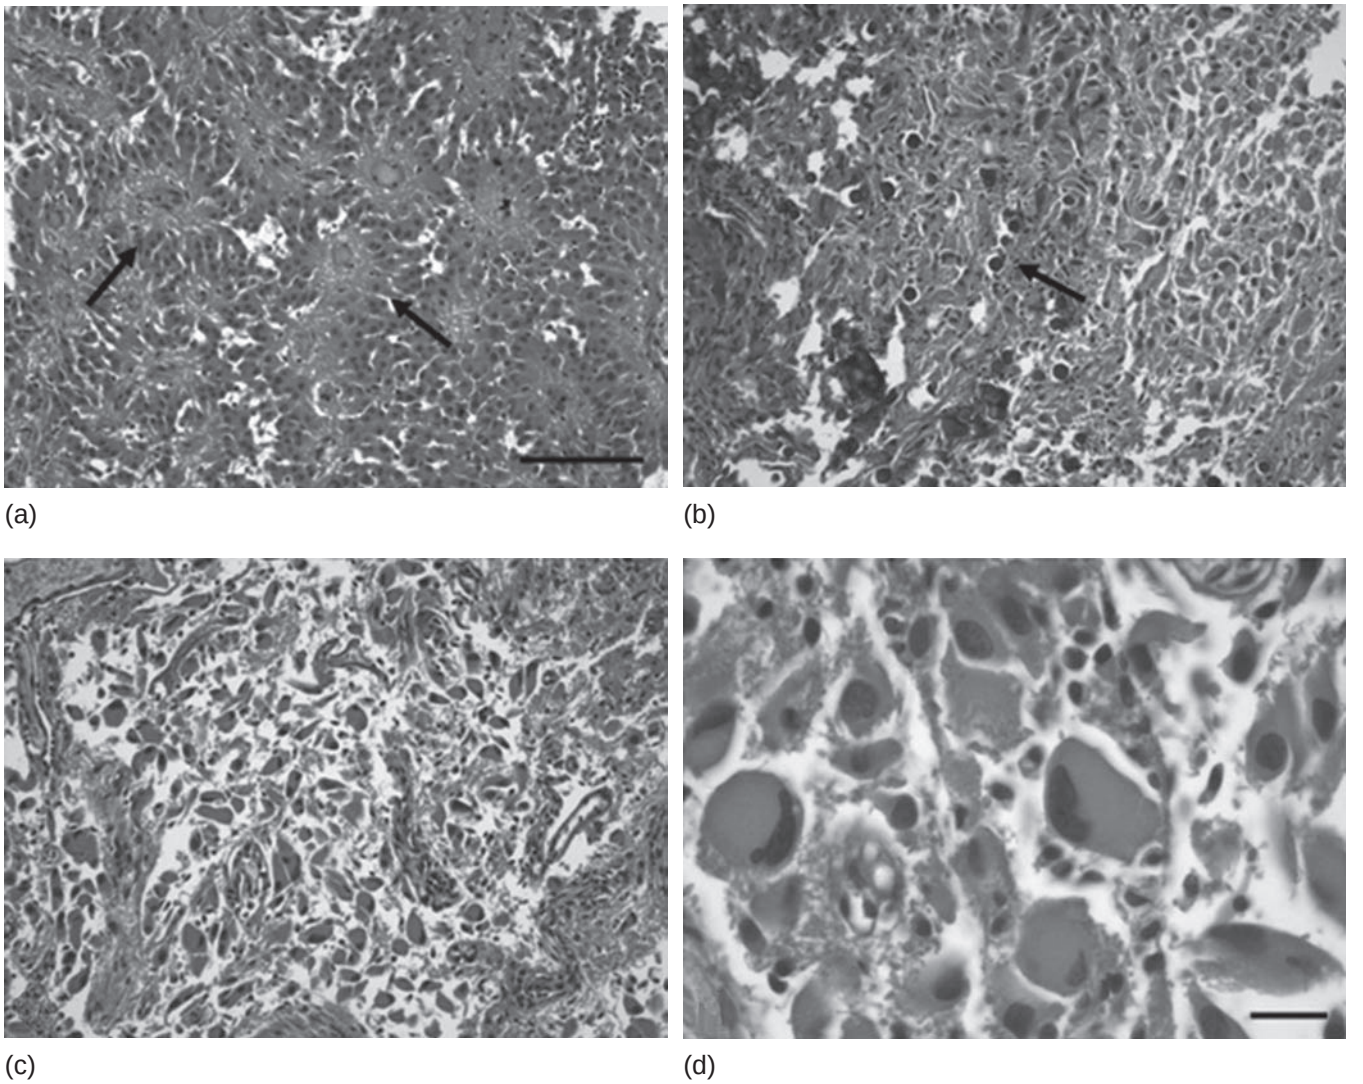

Figure 144.2 Subependymal giant cell astrocytoma (SEGA) in a patient with tuberous sclerosis. Tumor cells formed perivascular pseudopalisading (arrows, HE, scale bar = 1000 µm). Microcalcification can be frequently encountered (arrow in b, HE). Higher magnification characterize pleomorphic and multinucleated eosinophilic tumor cells (c and d, scale bar = 20 µm), frequently expressing vimentin (e) or neuronal marker proteins (arrowheads in f Microtubule associated protein MAP2).

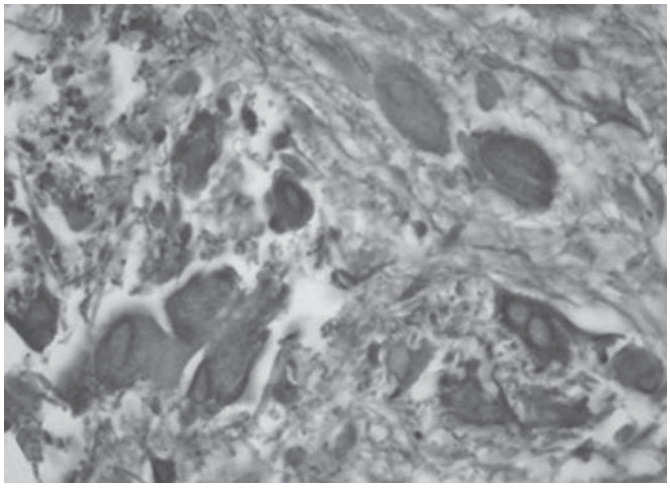
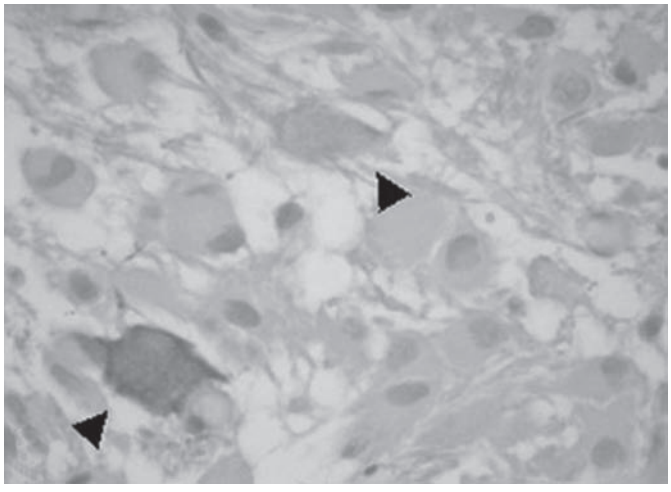
(Continued)



(e)



(f)

Figure 144.2—cont'd

The immunohistochemical pattern overlaps with tuberin, the gene product of TSC2, which is mapped to chromosomal region 16p13.3 and includes 41 exons.[11] The transcript contains 5.5 kb. Alternative splice variations are common. Tuberin contains 1807 amino acids with a molecular weight of 180 kDa. It bears significant homology with the catalytic domain of the GTPase-activating protein Rap1-GAP, a member of the ras family. It regulates cell cycle by inhibiting the G1/S transition and promoting entry to the G0 phase.[12]

A two-hit model is assumed for the clinical manifestation of TSC. Inactivating germline mutations of TSC1 or TSC2 is followed by a later somatic mutation in hamartomatous cells, explaining the clinical variability in an autosomal dominant inheritance. Loss of second TSC1- or TSC2-allels, i.e., loss of heterozygosity (LOH) leads to a homozygote negative state. LOH of TSC1 or TSC2 also occurs in sporadic tumors, e.g., carcinomas of mamma or bladder. Therefore both genes are likely to represent tumor suppressor genes. The recent finding that the TSC1/TSC2 complex is involved in the insulin growth factor receptor signaling pathway[13] is compatible with variable histomorphological phenotypes including defects in proliferation (SEGA), differentiation (occurrence of giant cells) and migration (missing lamination and heterotopic immature cells in the white matter).

The Eker rat with hereditary kidney cancer presents with germline mutations of the TSC2 homologue and functions as an animal model of human TSC. In Eker rat brains, lesions occur as cortical tubers, subcortical hamartomas, subependymal hamartomas, and anaplastic gangliogliomas.[14] Even though anaplastic gangliogliomas are not part of human TSC, the animal model demonstrates the similarity of glioneuronal lesions suggesting a comparable origin. Furthermore, TSC in humans shares histopathological features of glioneuronal tumors, especially gangliogliomas and dysembryoplastic neuroepithelial tumors (DNT) and tuberous form of focal cortical dysplasia (FCD) type IIb providing the hypothesis of a common origin.[15] The epileptogenicity of TSC associated brain lesions have been addressed in various clinical and molecular studies. Cortical localization, disrupted lamination, cytoarchitectural disturbances and possible altered synaptic connectivity of dysplastic neurons may account for intrinsic epileptogenicity of tubers, whereas giant cells are likely to be physiologically inert (Cepeda *et al.*, 2003).[16]

Sturge-Weber syndrome (SWS; macroscopic and microscopic findings)

Imaging and gross examination reveals widespread, usually unilateral leptomeningeal angiomatosis, cortical calcifications in a 'railroad track' pattern and less frequently atrophy of the underlying neocortex (Figure 144.3). White matter abnormalities are common and may be linked to chronic ischemia and reactive gliosis. Angiography demonstrates an overall lack of superficial cortical veins, non-filling of the dural sinuses and tortuous course of veins towards the vein of Galen.[17] Functional brain imaging has demonstrated decreased glucose metabolism and hypoperfusion of the affected neocortex.[18] Focal epilepsies are frequent clinical symptoms observed in almost 80% of SWS patients.[19]

Microscopically, leptomeningeal angioma in SWS presents with large tortuous and abnormal venous structures in thickened leptomeninges (Figure 144.3). The underlying brain tissue may be atrophic and displays neuronal loss, reactive astrogliosis, and microcalcifications. Laminar cortical necrosis may occur, suggesting ischemic damage secondary to venous stasis in leptomeninges and cerebral vessels. The underlying cortical vessels are increased in number, typically thin-walled and narrowed by hyalinization and subendothelial proliferation. Repeated stroke-like episodes and thrombosis may result in disease progression and neurological deterioration.

Molecular findings and enhanced epileptogenesis in Sturge-Weber syndrome

SWS occurs sporadically with a frequency of approximately 1/50 000. Inheritance is so far not established. Non-Mendelian genetic hypotheses, including chromosomal instability have been suggested. Spontaneous somatic mutations in a common progenitor cell line of dermal, neuronal and ocular tissue in the first trimester of development may lead to genetic mosaicism of the affected areas.[20] A case report about one of two monozygotic twins presenting with SWS supports this hypothesis.[21]

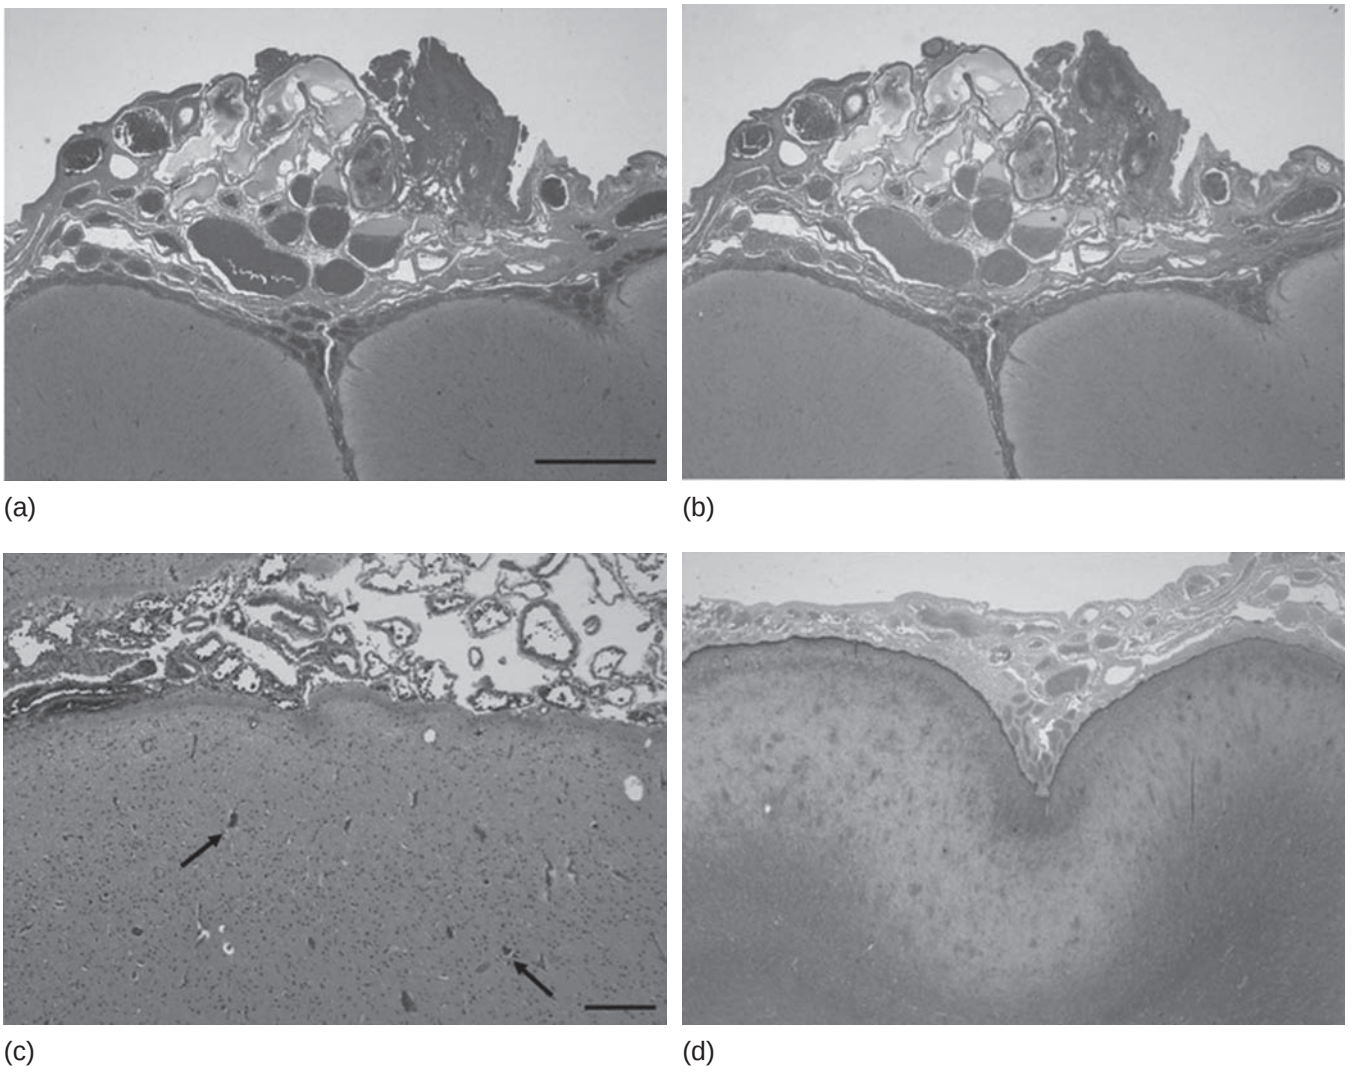


Figure 144.3 Leptomeningeal angiomatosis in a Sturge-Weber patient presenting with focal seizures (a HE, b Elastica van Gieson; 12.5×, scale bar in a = 1000 µm, applies also to b and d). The underlying neocortex demonstrates cortical atrophy with microcalcifications (arrows in c; HE 40×, scale bar = 200 µm) and reactive astrogliosis (d; GFAP).

Another possibility refers to a two-hit model combining hereditary and spontaneous factors. Excessive vascular proliferation of the angioma diverts blood flow from parenchyma and creates an anoxic environment in the surrounding brain, leading to cellular damage. As a result, the underlying cortex becomes atrophied, calcified, and eventually dysfunctional,[22] leading to seizures. The endothelial basal lamina contains an extracellular matrix composed of glycoproteins and proteoglycans including laminin, fibronectin, and tenascin. Fibronectin has been identified as a key regulator in angiogenesis and vasculogenesis and plays a crucial role in brain tissue response to ischemia and maybe to seizures.[23] Increased fibronectin gene expression levels were indeed observed in fibroblasts obtained from port-wine hemangiomas compared to normal skin samples. Moreover, there was a trend towards increased fibronectin protein expression in SWS brain samples compared to postmortem controls. Therefore, fibronectin is supposed to be a likely candidate for SWS.

Furthermore, analysis of families with hereditary port-wine stain identified RAS1 mutation on chromosome 5q.[24] The RAS1 gene product is p120-RasGAP, a negative regulator of the Ras-mitogen-activated protein kinase signaling pathway. It may also be a candidate for involvement in vascular abnormalities of SWS.

Vascular malformations associated with focal epilepsies

Vascular malformations are classified with regard to caliber and configuration of the blood vessels, their continuity with the normal cerebral vasculature and the amount of intervening brain parenchyma. They are assumed to represent congenital lesions as a result of disturbed mesodermal differentiation between the third and eighth week of gestation. Vascular malformations may be part of a distinct syndrome but also occur in combination.

Cavernomas

Cavernous hemangiomas (cavernomas) occur within the brain parenchyma or the leptomeninges. MRI usually reveals a well circumscribed superficial lesion with surrounding hemosiderine deposit. The lumen is occasionally occluded; therefore they

did not fill on angiography. Histologically, they are composed of closely apposed dilated vascular channels without intervening brain parenchyma (Figure 144.4). Elastica van Gieson (EvG) staining discovers thin blood vessel walls, containing endothelium and a collageneous adventitia. Calcification or even ossification can be microscopically detected. A peripheral rim of hemosiderin-storing macrophages may be identified in the surrounding tissue.

Molecular findings and enhanced epileptogenesis associated with cerebral cavernous malformations (CCM)

The prevalence of cavernomas is 0.02 up to 0.5%. Approximately 4–6% of pharmacoresistant epilepsies are caused by cerebral cavernous malformations (Table 144.1). There is no evidence that space occupying mass effect leads to epileptogesis. Rather repeated microhemorrhages and hemosiderin deposits in the surrounding cortical tissue may cause hyperexcitability by iron ions, providing free radicals and lipid peroxides. Furthermore, reactive glial proliferation may be epileptogenic. In some cases, dual pathology with Ammon's horn sclerosis occurs.[25]

Cerebral cavernous malformations (CCM) can occur in a sporadic form as well as a familial form. Familial CCM are inherited in the autosomal dominant mode, and three genes have been localized to chromosome 7q11.2-21 (CCM1), 7p15-13 (CCM2) and 3q25.2-27 (CCM3).[26] KRIT1 (Krev interaction trapped 1) is likely to represent the disease causing gene in CCM1.[27] Approximately 40% of families with cerebral cavernous malformations carry KRIT1-mutations. KRIT1 encodes a protein with a four ankyrin repeat domain at the N-terminus and C-terminal domain for interaction with Krev-1 (Rap1a, ras-related protein 1A). Most KRIT1 mutations are loss of function mutations leading to increased interaction between ICAP1α and β1 integrin, which influences integrin β1-dependent cell adhesion, migration and angiogenesis. Mutation of CCM2 gene occurs in 20% of patients with familial CCM. It contains a phosphotyrosine-binding domain (PTB), but its function is unknown.[28,29] Approximately 40% of CCM families are linked to the CCM3 locus, so-called PDCD10 (programmed cell death 10). Its role in vascular morphogenesis remains to be investigated.[30]

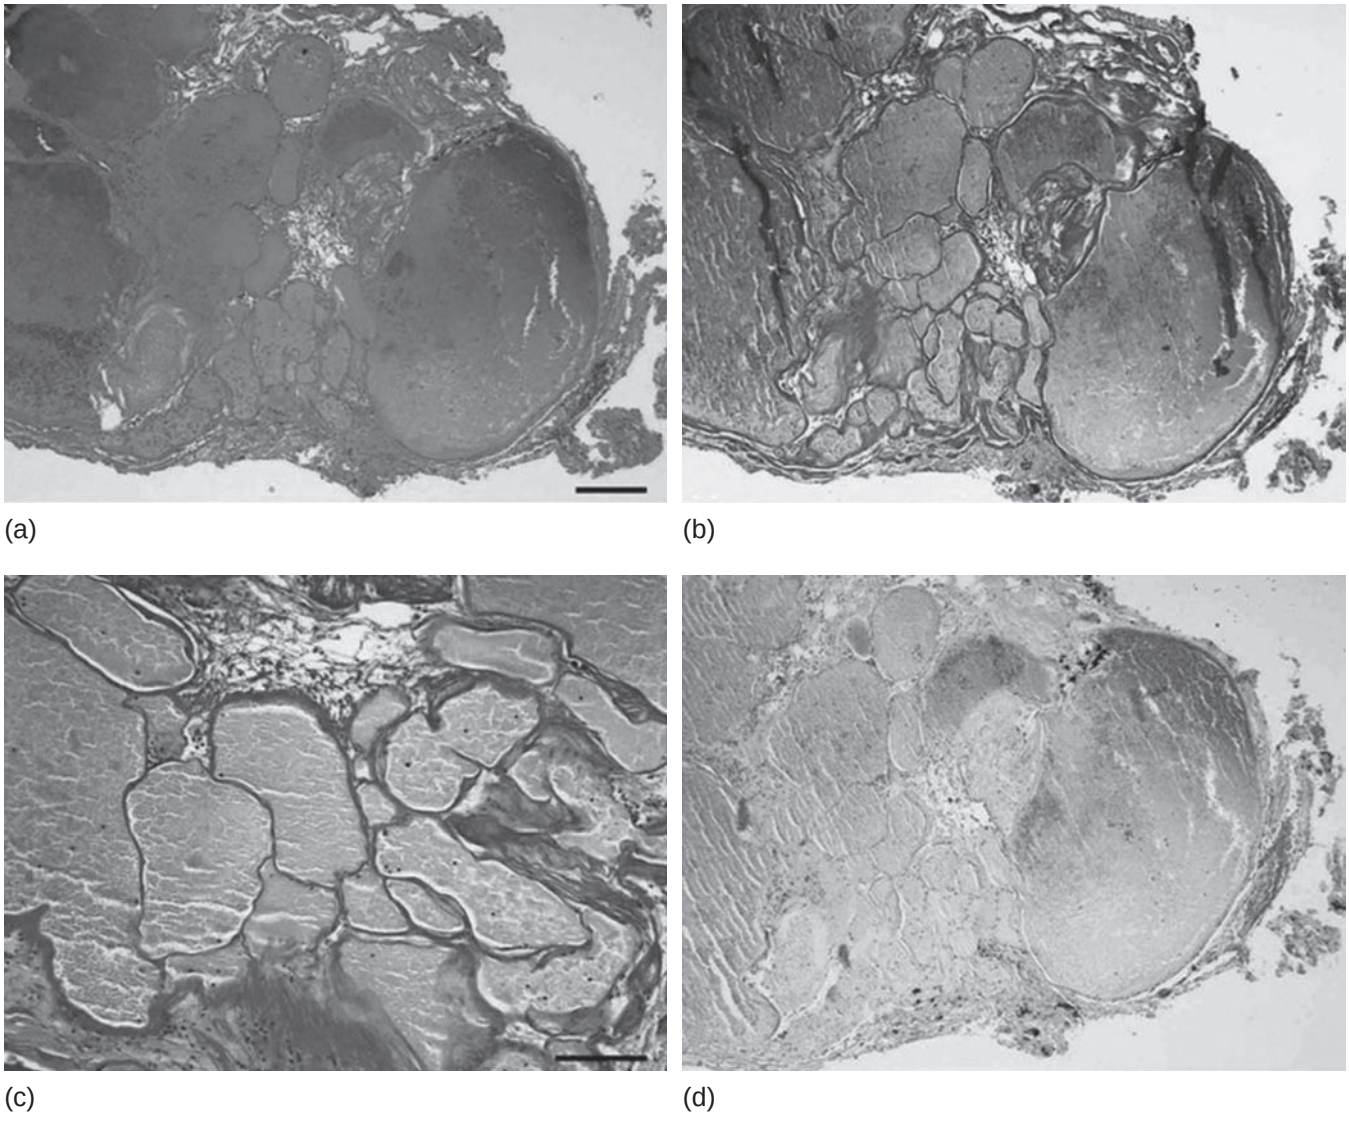

Figure 144.4 A cavernoma showing thin-walled vessels without intervening brain parenchyma is depicted in a (HE, scale bar = 200 µm, applies also to b, d). b: Elastica van Gieson staining (EvG) of a serial section to a; c: EvG staining at higher magnification fail to show regular lamination of vessel walls; scale bar = 100 µm. d: Hemosiderin storing macrophages are recognized using Berliner-blue reaction.

Table 144.1 Summary of 2386 epilepsy associated focal lesions (German neuropathological data base for epilepsy surgery)

	DIAGNOSIS	NUMBER	AGE	DURATION
MTS	AHS	902	33,9	22,8
	DUAL	137	22,8	12,6

NUMBER of patients included in the neuropathological database; AGE at operation (years); DURATION of epilepsy (years); MTS: mesial temporal lobe sclerosis; AHS: Ammon's horn sclerosis; DUAL: dual pathology presenting with AHS and another distinct histomorphological lesion (i.e., tumor, vascular lesion); GG: ganglioglioma (WHO grade I–III); DNT: dysembryoplastic neuroepithelial tumor (WHO grade I); ASTRO: astrocytoma (WHO grade I–III); OLIGO: oligodendroglioma or mixed glioma (WHO grade II–III); PXA: pleomorphic xanthoastrocytoma (WHO grade II); SEGA: subependymal giant cell astrocytoma (WHO grade I); FCD: focal cortical dysplasia (Type I or Type II according to Palmini *et al.*, 2004); HETEROTOPIA: ectopic neurons in white matter (single or neuropil islands) or nodular heterotopias; HAMARTOMA: glio-neuronal hamartomas or hamartias; PMG: Polymicrogyria; HEMI: Hemimegalencephaly; ENCEPHALITIS, VARIOUS: summary of lesions associated with bacterial, viral or parasitic infections.

Arterio-venous malformation (AVM)

AVMs may occur in all parts of the CNS but most commonly in the territory of the middle cerebral artery. AVMs range in size from grossly invisible to those which involve a large part of the entire hemisphere. They may enlarge over time by recruitment of contiguous blood vessels.

MRI shows vascular lesions with abnormal vessels and surrounding hemosiderine deposits. Angiography reveals arterio-venous shunting. Histological examination discovers vessels of irregular size, shape, and degree of muscularization. Besides venous appearing vessels with thin amuscular walls, arteries with intact media and lamina elastica could be observed (Figure 144.5). Arterio-venous shunts with disruption of arterial vessel wall architecture are visible using Elastica-van-Gieson staining. Interposed brain parenchyma is usually gliotic and frequently contains hemosiderin storing macrophages after recurrent bleedings. Remnants of preoperative embolisation may be incorporated into vessels.

Molecular findings and enhanced epileptogenesis associated with arteriovenous malformation (AVM)

AVMs arise congenital during embryogenesis and account for 70% of all cerebral vascular malformations in children. Immature developing veins and arteries contact with each other before development of capillaries. Lack of development of a capillary bed leads arterio-venous shunts and consecutive dilatation of the receptive venous system. AVM become symptomatic at any age but most commonly present in the second to forth decade with recurrent subarachnoidal bleeding. Seizures may be related to brain ischemia caused by 'stealing' of blood from surrounding brain parenchyma into the malformation.[31,32] As well as in cavernomas iron deposits after bleeding or reactive gliosis could also cause seizures.

AVMs seem to be sporadic lesions, and familial intracranial AVMs are rare.[33] However, recent studies identified possible candidate genes related to angiogenesis. Microarray analysis revealed increased mRNA of vascular endothelial growth factor A (VEGF A) and its protein product as well as increased expression of integrin $\alpha v\beta 3$ protein, leading to a possible role of integrins in AVMs.[34] An earlier study demonstrated a markedly decreased Tie-2 and also VEGF-R2 expression in AVM vessels, which may contribute to the pathogenesis of AVMs. Some arteriovenous malformations (AVMs) are associated with hereditary hemorrhagic telangiectasia type 1. Endoglin, the gene mutated in this disorder, is expressed at reduced levels on blood vessels of these patients. Endoglin is a component of the transforming growth factor-beta receptor complex critical for vascular development and homeostasis. Even though it seems not to be involved in the generation of AVMs, the presence of endoglin on fibroblasts in the perivascular stroma suggests an active role for this protein in vascular remodeling in response to increased blood flow and shear stress.[35]

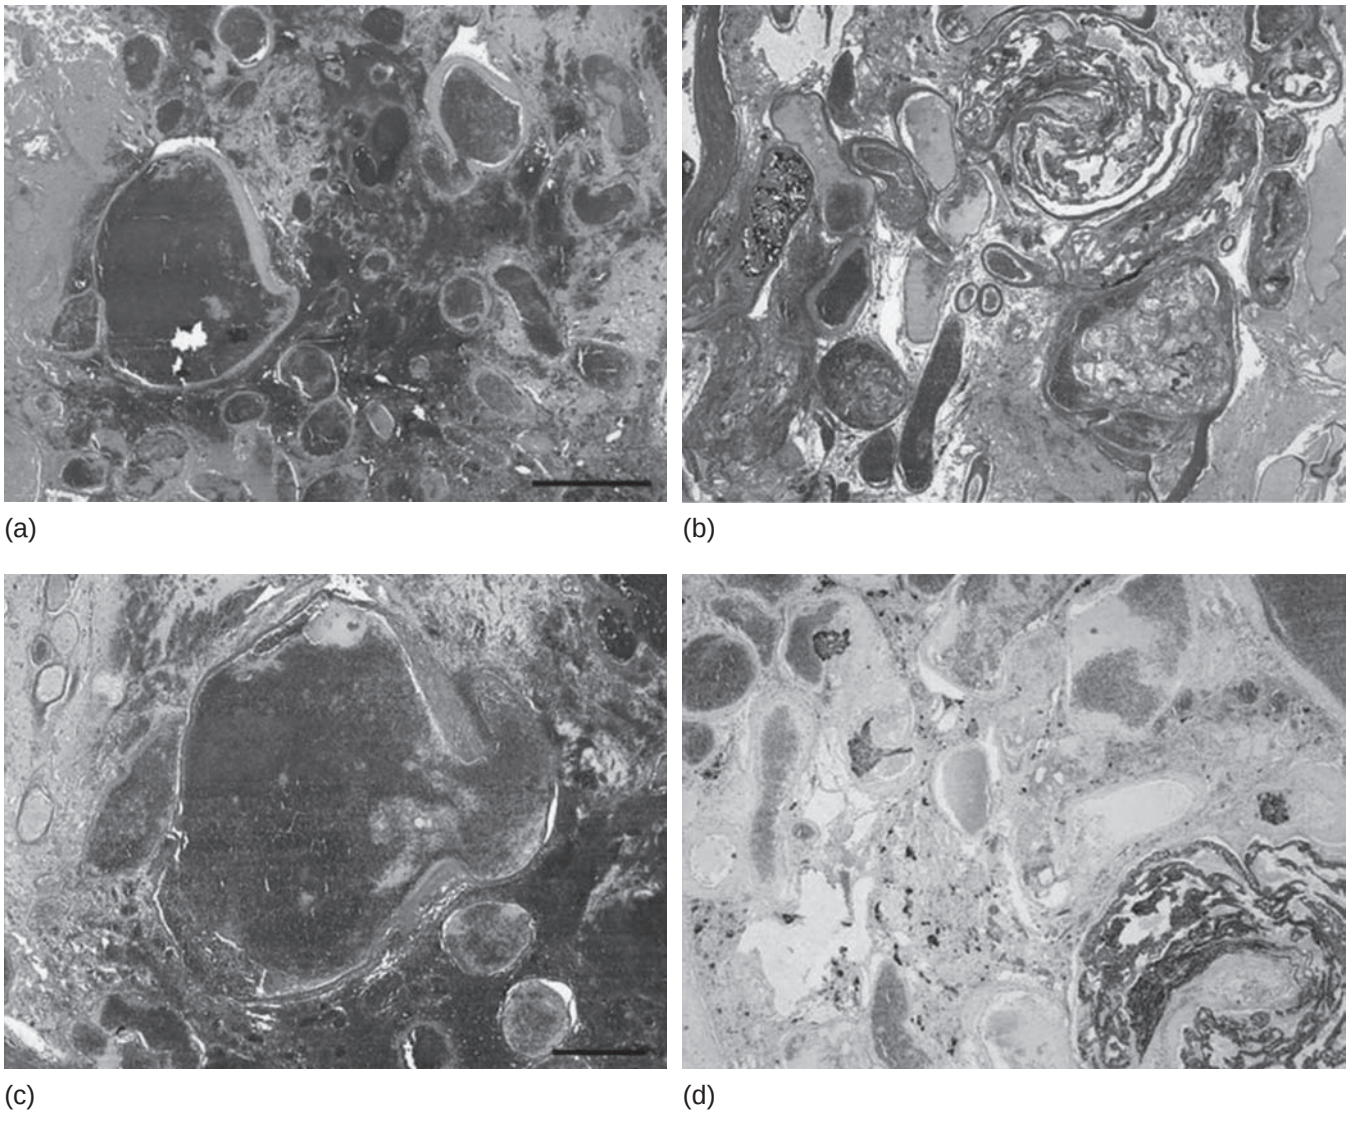

Figure 144.5 a: Arterio-venous malformation with vessels of irregular size (HE, scale bar = 1 mm, refers also to b). b: Occurrence of preoperative embolisation (EvG). c: Arterio-venous shunt vessel (EvG, scale bar = 500 µm, refers also to d). d: Hemosiderin saving macrophages, Berliner-blue reaction.

Capillary teleangiectasia

Capillary teleangiectasias are often an incidental finding during brain autopsy and cannot be detected by imaging unless the lesions are confluent or hemorrhagic. They are composed of dilated blood vessels separated by relatively normal brain parenchyma, which often shows reactive astrogliosis (Figure 144.6).

Molecular findings and enhanced epileptogenesis associated with capillary teleangiectasia

Capillary teleangiectasia have a high prevalence and are usually asymptomatic. Beeding is rare. If capillary teleangiectasias occur in distinct brain regions, e.g., within the hippocampus, or in association with other vascular malformations, seizures may occur. However, hereditary hemorrhagic teleangiectasias (HHT), an autosomal dominant vascular malformation of skin, mucosa and viscera can also manifest in brain vessels. Three gene loci are known: HHT1 on chromosome 9q34.1, HHT2 on chromosome 12q11-14 and HHT3 on chromosome 5q31.5-32.[26] HHT1 is caused by mutations in endoglin which encodes a TGFβ binding protein expressed predominantly in endothelial cells and lays an important role in vascular remodeling and the maintenance of vessel wall integrity.[36] HHT2 results from mutations in the ALK1 gene which encodes a type1 serine-threonine kinase receptor in endothelial cells. Alk1 binds to TGFβ1 and activin-A, and signal through phosphorylation of SMAD1 and SMAD5.[37] A third genetic locus, HHT3 was recently identified in a family without linkage to endoglin, ALK1 or SMAD4 on chromosome 5. However, the specific gene of HHT3 has not been identified yet.[38] There exists also an association with juvenile polyposis (JP), caused by mutations in the MADH4 gene on chromosome 18q21.1 which encodes SMAD4. SMAD4 is an integral downstream effector on the TGFβ signal transduction pathway.

Inflammatory lesions

Bacterial infections

The risk to develop epilepsy after cerebral infection is likely to dependent on the type of infection rather than on age. No obvious increase in risk to develop epilepsy is seen after

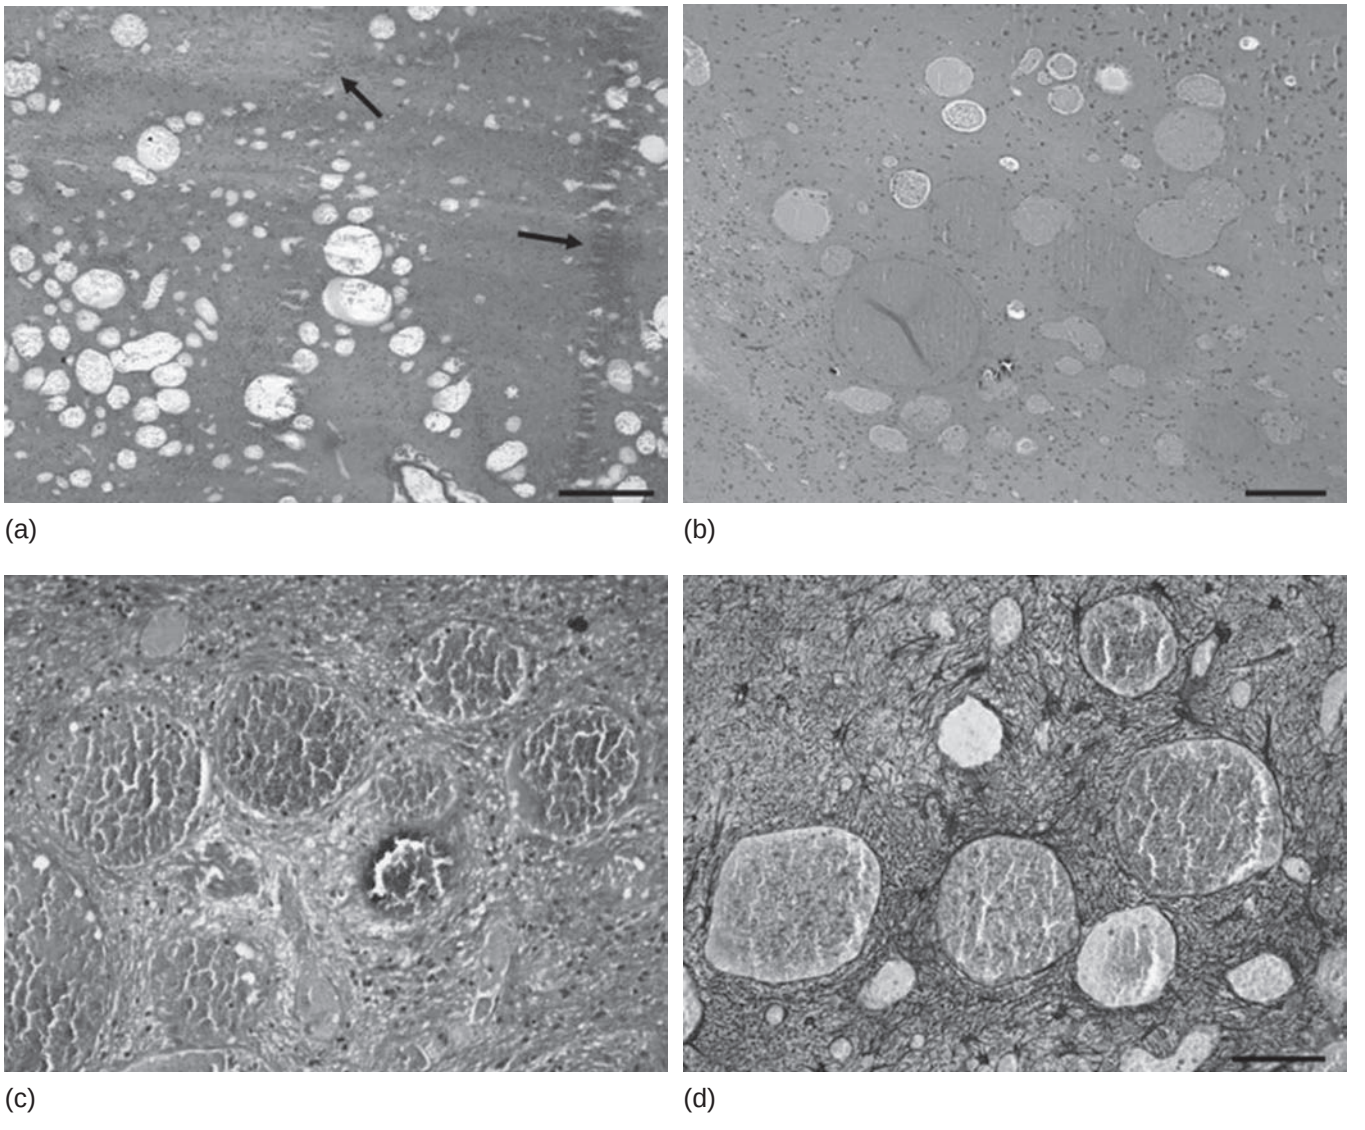

Figure 144.6 a: Ectatic vessels within the hippocampal hilus are identified in this epilepsy patient, the arrows indicate the dentate gyrus, frozen section (HE, scale bar = 500 µm). b: Ectatic vessels in the same specimen following paraffin embedding (HE, scale bar = 200 µm), c: Elastica van Gieson (EVG). d: Gliotic intervening brain parenchyma (GFAP), scale bar =100 µm, refers also to c).

aseptic meningitis. However, likelihood is fivefold increased in patients with bacterial meningitis. The highest risk comes along with viral encephalitis, especially if viral encephalitis is associated with early seizures.

Brain abscess

Brain abscesses may occur per continuitatem from neighboring foci in the paranasal sinus, middle ear or mastoid sinus or via hematogenous dissemination in the context of sepsis. The latter is advantaged by congenital heart disease with septal defect. Most common organisms are *Staphylococcus aureus*, hemolytic streptococci, *Streptococcus viridans*, and various aerobic gram negative rods.

MRI usually reveals a round lesion presenting with a thin capsule and a circumscribed contrast enhancing ring. Due to collagen the abscess capsule is characteristically dark on T_2-weighted MRI scans. A broad perilesional edema reflects the suppurative nature of the lesion. Histologically early stages present with granulocyte infiltrates, necrotic blood vessels, extravasated erythrocytes, and numerous bacteria. Subsequently microvascular proliferates and fibroblast migration from the blood vessel walls occurs as a response to hemorrhage and local infarction. With advanced abscess formation a firm fibrous, partly collagenous capsule encloses a saccular mass filled with purulent material surrounded by lipid-laden macrophages and aggregates of inflammatory cells (neutrophilic granulocytes).

Meningoencephalitis

The agent of bacterial meningitis varies with age. In newborns, *Escherichia coli* and group B streptococcus are the most frequent causes of bacterial meningitis. In children up to 12 years *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitides* are most common. The latter two are also frequent in adults, whereas older age comes along with a higher incidence of *Haemophilus influenzae*.[32]

Acute bacterial meningitis proceeds in two phases. The inital phase is characterized by bacterial proliferation from the primary respiratory focus, leading to bacteraemia. It is assumed that release of toxic molecules by bacterial lysis leads to disruption of the blood brain barrier. CSF has only a slight possibility to counteract infection. Meningeal inflammation is caused

by bacterial cell-wall components, activation of alternative complement pathway, and induction of inflammatory cytokines such as IL-1, IL-6, IL-8, and TNFα. Brain edema is a complication caused by disturbed blood-brain barrier, inflammatory mediators, and vascular changes. Edema and cerebral hypoxemia may lead to tissue damage and consecutive seizures. Moreover, neutrophilic granulocytes and bacterial products may exert a direct cytopathic effect on neurons or glia.[39]

In the early stages of purulent meningitis, neuroimaging often fails to identify the inflammatory foci. In later stages, contrast enhancing of meninges may occur. However, radiology is useful to detect complications such as edema, hemorrhages, or intracerebral abscesses. Histologically, acute phase is characterized by sparse exudation with numerous bacteria and margination of polymorphs in the leptomeningeal arterioles. If the patient survives for more than 2 days, migration of leucocytes leads to development of pus. At this stage cellular exudat composed of polymorphonuclear neutrophilic granulocytes is visible in the subarachnoidal space. Wisps of fibrin and bacteria occur intra- and extracellularly. Underlying cortex is not infiltrated, but it shows edema and beginning ischemic neuronal damage.

Parasitic infections

Within parasitic infections of the brain, neurocysticercosis is the most commonly associated with epilepsy. The cerebral lesion is caused by larvae of the pork tapeworm Taenia solium. Under physiological conditions, humans harboring the intestinal tapeworm are the definitive hosts, whereas pigs infected by eggs from the human stool are the intermediate hosts. The pig contains disseminated larvae. Ingestion of larvae due to inadequately cooked pork infects the human gastrointestinal tract to form mature worms. In contrast, in cysticercosis eggs are ingested by humans, and larvae infect primarily skeletal muscle and the brain. Here the organisms grow within the parenchyma, usually confined to the gray matter or within meninges. Solid or multiple lesions may occur. MRI shows solid, often calcified cystic lesions with a contrast enhancing rim and an internal point of enhancement that represents the scolex. After en bloc resection the organism presents with a surrounded rim of gliotic indurated parenchyma. Microscopically, cysts are composed of an outer eosinophilic lamina and a marginal cell layer containing scant nuclei. Internal parts contain loose connective tissue. The organism is armed with suckers and intimidating hooklets. The surrounding brain shows acute and chronic inflammation. Necrosis with peripheral palisading of monocytes may be seen, but giant cells are not common. Degeneration of the cysts leads to calcification and fibrosis of the lesion, often resulting into chronic seizures.

CNS infections with Taenia echinococcus or Schistosomas rarely cause epilepsy. Protozoa producing cerebral lesions may come along with seizures, namely Toxoplasma gondii and Plasmodium falciparum. In malaria, seizures are major clinical findings.[32]

Viral infections and immunological findings associated with enhanced epileptogenesis

Rasmussen's encephalitis

Rasmussen encephalitis (RE) was first described in 1958 in three patients with focal seizures due to chronic and focally localized encephalitis.[40] RE occurs sporadic, since there is no evidence for a genetic component.[41] A viral etiology was already suggested by Rasmussen due to immune reaction in the brain with lymphocyte infiltration and microglial nodules. The similarities of RE and Russian spring summer meningoencephalitis, caused by flavi virus support this hypothesis.[42] However, a viral agent has not been identified so far. Recent data suggest an immune basis to the pathogenesis of RE, including humoral factors, i.e., autoantibodies as well as cytotoxic T cells.[41] There exist two different hypotheses how autoantibodies lead to brain tissue destruction and seizure activity. First GluR3 autoantibodies have been identified, mediating a cytotoxic activation of the glutamate receptor.[42] Other investigators found signs of induced complement activation by GluR3 autoantibodies, primarily affecting glial cells.[43] However, GluR3 autoantibodies are not present in all RE patients. Moreover, GluR3 autoantibodies were found in other forms of epilepsy and may result rather from neuronal cell degeneration.

In RE the majority of inflammatory round cells are T lymphocytes.[44] Immunohistochemical studies provide evidence for Granzyme B (GrB) mediated cytotoxic T lymphocyte attack against neurons.[41] RE usually occurs unilateral in a progressive way. It is assumed, that seizures disturb the blood-brain barrier (BBB) allowing autoantibodies which in contrast to activated T cells cannot cross an intact BBB to reach the brain tissue. The interplay between immunopathology and seizures seems to provide progressive course of RE. However, the precise nature and sequence of the pathogenetically relevant processes is not clear.

At disease onset, RE becomes manifest with unilateral enlargement of inner and outer CSF compartments which are accompanied by an increased cortical or subcortical T_2 or FLAIR signal. Transient focal swelling may occur. Subsequently, a spread of signal changes and atrophy arises within the affected hemisphere.[45] Usually the uppermost amount of tissue loss happens during the first 12 months after onset of the acute disease state.[46] The histopathological changes in RE are those of a chronic inflammatory process with subsequent neuronal loss and gliosis. Pathological changes have been classified in four stages.[47] The active phase is characterized by numerous microglial nodules with facultative neuronophagia, perivascular cuffing, and reactive gliosis (Figure 144.7). During the active and remote state, these changes are accompanied by necrosis and cavitation of the cortex. Within the remote state neuronal loss and gliosis becomes prominent whereas microglial nodules occur to a lesser extent. At least inflammatory changes run short leading to a residual state with outstanding neuronal cell loss and gliosis. Inflammatory changes are confirmed by immunohistochemistry, indicating activated T lymphocytes with CD3 (Figure 144.7) and macrophages by CD68. Gliosis can be demonstrated by antibodies against glial fibrillary acidic protein (GFAP).

Limbic encephalitis

Patients suffering from tumors can develop an encephalopathy due to limbic encephalitis. Most common neoplasms associated with limbic encephalitis are small cell carcinomas of the lung, ovarian and breast cancers, seminomas, or Morbus Hodgkin.[32] However, limbic encephalitis is not necessarily associated with tumors. Recently, cases with spontaneously occuring non-paraneoplastic limbic encephalitis (NPLE) have

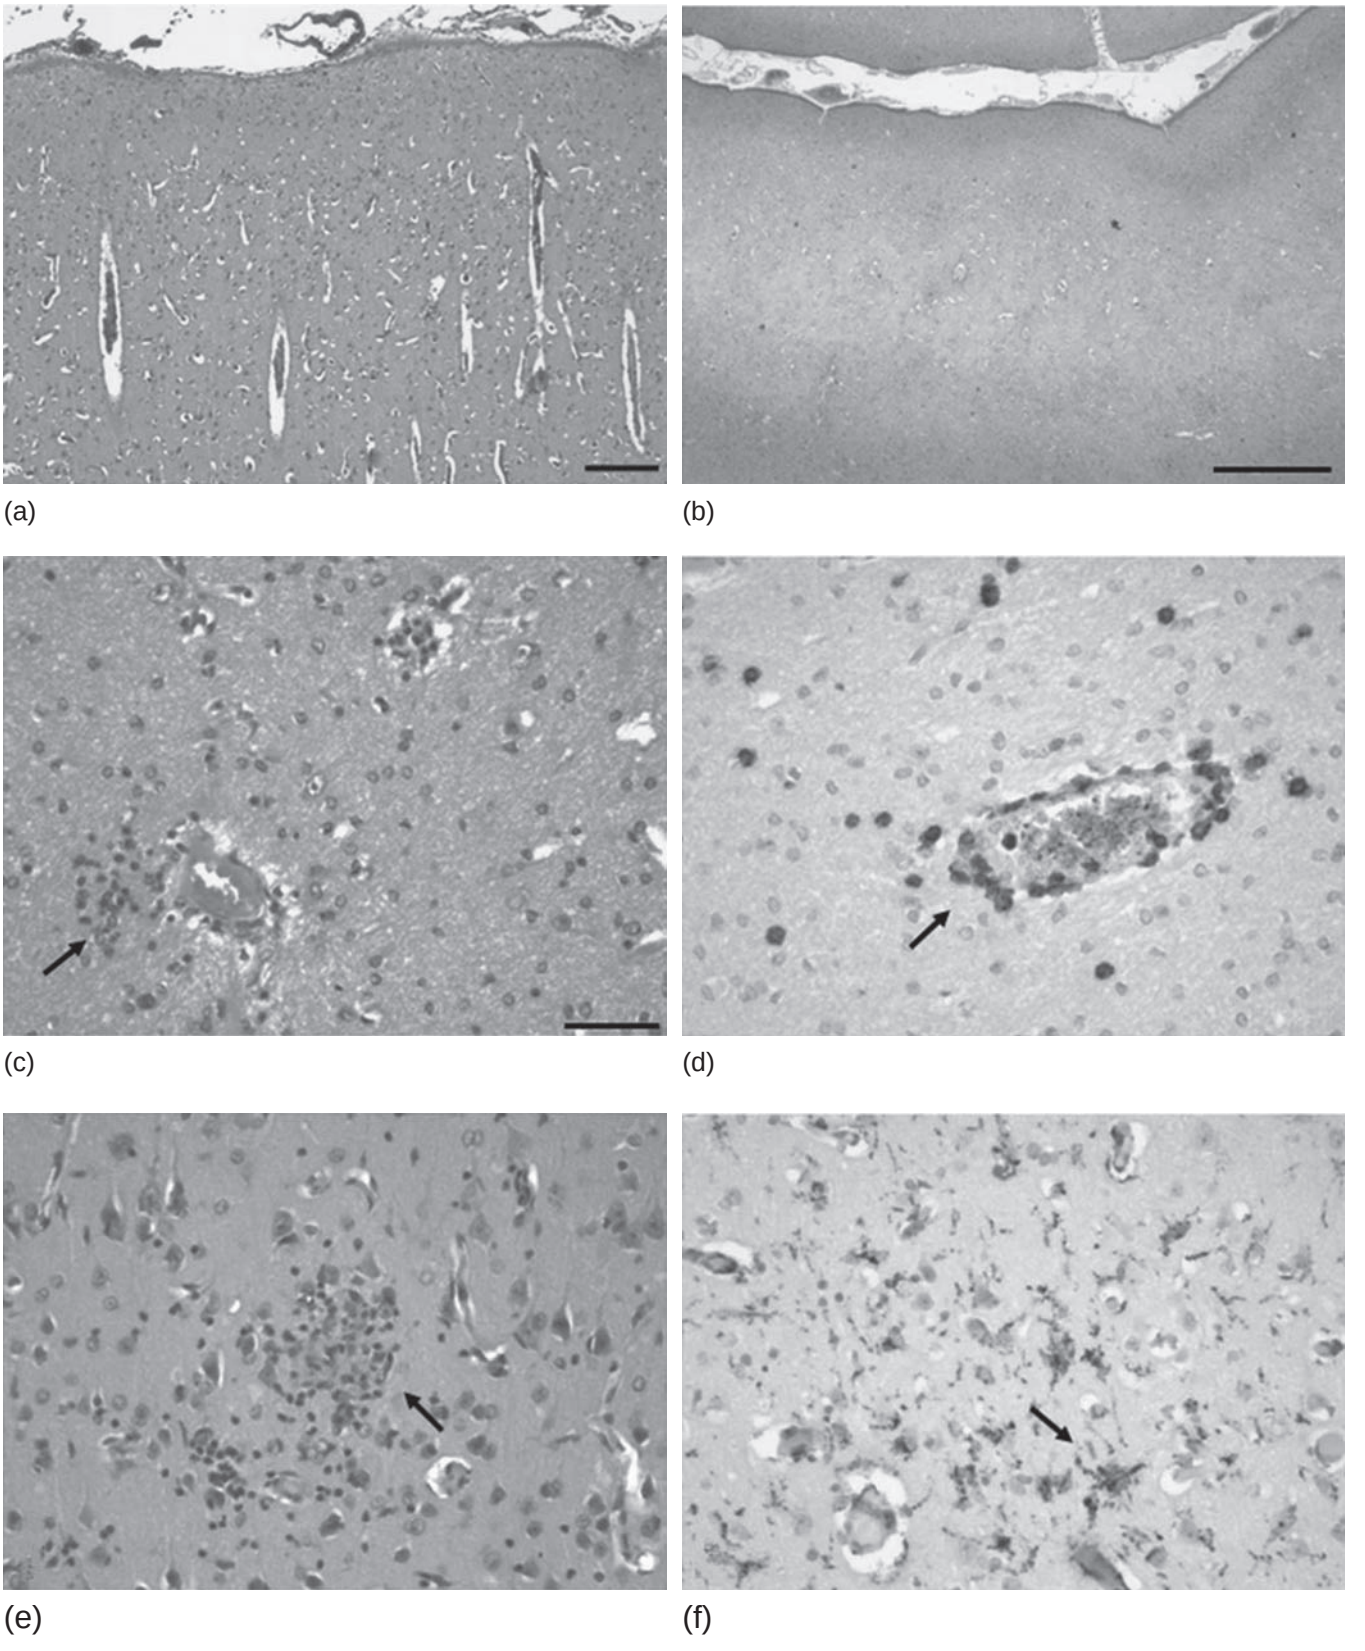

Figure 144.7 Rasmussen encephalitis presenting with cortical edema and atrophy (a). HE staining, scale bar = 500 μm). Cortical gliosis is visualized by GFAP immunohistochemistry (b). Scale bar = 1000 μm. Additional hallmarks of RE include perivascular T lymphocytes (arrows in c) and d (CD3), microglial nodules (arrow in e) and neuronophagia (arrow in f, CD68).

been described.[48] Both entities come along with similar MRI and histological findings. The course of the disease is characterised by subacute development. MRI shows increased T_2 signal in variable areas, mainly confined to limbic structures. It may occur unilateral or bilateral. Different stages may be present in the same image: Acute lesions with cortical swelling and increased signal besides recovering lesions with decreased signal intensity. There is no evidence for local tumor growth or viral infection. Histopathologically, NPLE is characterised by parenchymal and perivascular lymphocytic infiltration and microglial activation, partly in the forms of microglial nodules. Separation from Rasmussen's encephalitis (RE) is not always easy. However, whereas Rasmussen's encephalitis usually occurs within early childhood, NPLE starts rather in adulthood. Moreover, RE is usually restricted to one hemisphere and leads to progressive atrophy, while NPLE may affect both hemispheres with the capability to recover.

Herpes simplex encephalitis (HSE)

Among viral encephalitides herpes simplex is the most common cause of chronic epilepsy. In virus encephalitis, most infectious agents reach the brain by the blood stream, while herpes simplex virus reaches the brain by traversing peripheral nerve axons. HSE is the most common form of severe endemic encephalitis. Initial seizures occur in 60% of patients. Despite antiviral treatment mortality is still high. Most survivors present with severe neurological deficits and therapy refractory epilepsy.[49] Polymerase chain reaction amplification of viral DNA in the cerebrospinal fluid confirms the diagnosis. Almost all cases are caused by HSV-1 virus. Infection with HSV-2 virus is rare. The disease principally occurs at any age with a highest incidence in adolescence and in an immune-suppressive state. Radiologically, HSE presents as a unilateral or often bilateral temporal, insular and frontal lobe process with widespread increased T_2 signal. Contrast enhancement is possible.[50] By macroscopic inspection, the acute lesion consists of an expanding mass of necrotic, often hemorrhagic parenchyma. Microscopic findings include large necrotic areas with macrophage infiltration. Inflammation is characterized by lymphocyte perivascular cuffing and focal aggregates of microglial nodules. Appearance of viral intranuclear inclusion bodies, so-called Cowdry A inclusions within neurons or glia confirms the diagnosis. They typically appear as round or irregular, eosinophilic, intranuclear masses surrounded by a chromatine-free zone. Additional findings are homogenous red-wine nuclei.

Subacute sclerosing panencephalitis (SSPE)

SSPE is a rare but severe complication occurring in 1–22/100 000 patients after measles infection. It manifests months up to 10 years after primary infection. Pathogenetically, SSPE is caused by a genome mutation of intracellularly persisting measles virus (MV), causing viral nucleocapsides to accumulate in the brain cells. MV is not present in cerebrospinal fluid (CFS), therefore a negative PCR for measles in CSF does not exclude SSPE. Oligoclonal bands in the CSF and MV-specific IgG support the diagnosis. Rare SSPE manifestation after measles infection and occurrence of SSPE in siblings leads to a predisposing immune defect.[51] However, a specific predisposing immune defect is not known. Recent studies lead to a decreased cytotoxic T1 helper cell immune response or a defect in virus-specific production of interferonγ.[52,53]

Pathognomic EEG features are so-called Radermecker complexes, indicating fundamentally disrupted brain function. MRI findings are unspecific. Depending on the stage of the disease localized and diffuse T_2 hyperintensities may occur, indicating inflammatory and gliotic lesions followed by regional or global brain atrophy in later stages. Histological investigation reveals common findings in viral encephalitis with perivascular inflammatory cells, necrosis and nuclear inclusion bodies. The latter are large eosinophilic haloed intranuclear masses occurring within ganglion cells. Subtle intracytoplasmatic inclusions may also occur. Immunohistochemistry identifies measles virus antigen. Ultrastructurally nucleocapsids of SSPE are occasionally seen in neuronal processes.

Head injuries

Pathological findings

Head injuries can be separated in perforating and non-perforating lesions. The former are characterized by impressive skull fractures and bare the risk of severe complications by invasion of bone fragments, contamination with debris and pathogen organisms.

The pathology of non-perforating head injury includes two types, focal and diffuse lesions. Contusions and lacerations are the hallmarks of focal lesions differing in intact or torn pia mater. The latter condition is more likely to be found in fronto-temporal localization as well as in superficial gyri. Head trauma usually results a wedge-shaped defect with hemorrhage and edema, complicated by subdural hematoma due to laceration. At later stages, a V-shaped scar develops at apical gyri which carry yellow-to-brown hemosiderin pigment deposition (to be histologically verified using Berliner-blue reaction). The defect zone is surrounded by gliotic tissue and occasionally focal white matter demyelination. As in hemorrhagic infarction macrophage invasion and microvascular proliferates are common findings.

Contusions are frequently accompanied by contre-coup lesions opposite to the initial trauma. The most precarious complication after head trauma is intracranial hemorrhage. Hematoma and contusion lead to brain swelling which results in secondary brain damage. Imaging and macroscopic investigation reveal flattening of the gyri and, in severe cases, shift of the midline structures towards herniation. Diffuse lesions include ischemic brain damage predominantly involving the hippocampus, brain swelling secondary to vasogenic edema, diffuse vascular injury appearing as multiple petechiae, particularly evident in the white matter of the fronto-temporal lobes and diffuse axonal injury.[32] Hippocampal damage frequently occurs bilaterally and predominantly affects the hippocampal subfield CA1, whereas CA4, CA3, and CA2 are involved during disease progression.

Molecular findings and enhanced epileptogenesis associated with head injuries

Head injuries responsible for post-traumatic epilepsy can be divided into penetrating brain trauma with focal damage and

closed brain trauma due to a generalized insult. Incidence of post-traumatic epilepsy was found to be 7%–39% in patients with undamaged dura, whereas in patients with lacerated dura incidence rose from 20% to 57%. Post-traumatic epilepsy is predicted by the age of affected patients, with a higher incidence in children under 5 years, severity of the injury, localization, especially parietal lesions, duration of post-traumatic amnesia, and presence of intracranial hematoma.[32]

Blood-brain barrier dysfunction, vasogenic oedema, anoxic-ischemic neuronal damage, axonal sprouting, altered excitatory synapses, and synaptic disassembly are assumed to play a pivotal role in post-traumatic epileptogenesis.[54] Earlier studies found evidence for the hypothesis that post-traumatic epilepsy may result from blood extraversion and subsequent iron-mediated peroxidation of brain cell membranes.[55] However, recent findings point to a major impact of BBB disruption. As shown in animal studies, cortical exposure of low levels of serum albumin led to extravasion of serum proteins into the extracellular space and early activation of astrocytes followed by a lasting neuronal hypersynchronization.[56] Albumin may also play a role in microglial activation which is implicated in the neurotoxicity of neurodegenerative diseases.[57] Furthermore, intracerebral bleeding followed by activation of the coagulation cascade triggers brain edema. In addition, thrombin produces brain injury via direct brain cell toxicity.[58] There is further evidence that proinflammatory and anti-inflammatory molecules are synthesized during epileptic activity in glial cells. Various cytokines have been shown to affect neuronal excitability, leading to the hypothesis that they may play a role in altering synaptic transmission in epileptic conditions. Numerous studies indicate a central role of IL-1β for the exacerbation of brain damage after ischemic, traumatic or excitotoxic insults, suggesting that it may also contribute to neuronal cell injury associated with seizures.[59]

Besides reactive astrogliosis there seems to be evidence for disturbed astrocyte function following head trauma. The extracellular homeostasis of glutamate in the brain is maintained by the efficient uptake into astroglial cells. High extracellular glutamate levels seen during seizures probably result from an increased synaptic release and a deranged glutamate uptake. A prior study demonstrated decreased cortical levels of astrocytic glutamate transport protein GLT-1 in a rat model of post-traumatic epilepsy.[60]

145 Pathology of epileptogenic neoplasms

RA Prayson

Summary

This chapter focuses on the pathology of tumors associated with chronic epilepsy. Topics that will be discussed include:

- The prevalence of various tumor types as reported in the literature.
- Issues and pitfalls that may complicate the diagnosis of tumors in this clinical setting.
- Details regarding specific tumor types including gangliogliomas, dysembryoplastic neuroepithelial tumor, astrocytomas and oligodendrogliomas.

Introduction

Neoplasms have been long recognized as a cause of medically intractable epilepsy. Several series in the literature have reviewed large numbers of patients which have undergone surgical excision of lesions for chronic epilepsy. The frequency of various pathologies are a bit different if one examines temporal lobe epilepsy versus extratemporal lobe epilepsy. Table 145.1 summarizes the pathologic findings in four large series of temporal lobe resections, all of which had greater than 200 cases evaluated. The prevalence of tumors in this setting ranged from 12.6–56.3%.[1–4] In the temporal lobe epilepsy literature, summarized in Table 145.2, the prevalence of tumors is generally less; malformations of cortical development (cortical dysplasia) account for a significantly higher percentage of identified lesions.[5,6] In a subset of tumors arising in this setting, the tumor represents part of a dual pathology, where another lesion is pathologically identified which may itself be epileptogenic.[7–11] Most commonly, this second pathology is a form of cortical dysplasia. Several of the tumors which will be later discussed in this chapter are well known to be associated with cortical dysplasia.

Tumors that are associated with chronic, medically intractable epilepsy, tend to present earlier in life, frequently in childhood, and are generally low-grade lesions. Table 145.3 summarizes the prevalence of tumors in various reported series arising in the setting of medically intractable, chronic epilepsy.[12–17] In most series, either low grade glioneuronal tumors, such as gangliogliomas or dysembryoplastic neuroepithelial tumors, or low-grade gliomas, most commonly diffuse or fibrillary type astrocytomas, are the most commonly encountered tumors.

There are obviously a number of differences between results observed in various surgical series and there are several explanations for why these differences exist. The most recent version of the World Health Organization (WHO) Classification of *Tumours of the Nervous System* includes definitions of many of the lesions that will be subsequently discussed in this chapter.[18] Despite this, there are unavoidable differences between pathologists with regard to interpretation of these definitions. For example, exactly how much atypia one needs to see in a lesion to determine that it represents a low grade astrocytoma as opposed to gliosis or hamartomatous lesion can be difficult to decide, and to some degree be in the eye of the beholder. Other lesions, such as the dysembryoplastic neuroepithelial tumor, although fairly strictly defined by the WHO, has been variously interpreted by different pathologists. In contast, the WHO definition of oligoastrocytoma

(mixed glioma) is somewhat more vague; precise guidelines as to what percent of a minor component needs to be present in a given lesion in order to make the diagnosis has not been agreed upon. Although most pathologists would agree that tumors with geographically distinct areas of oligodendroglioma and astrocytoma qualify as a mixed glioma, lesions in which the two patterns are intermixed are more problematic, and subsequently, the reproducibility of diagnosis is less than optimal. Some series reported in the literature have not separated out or enumerated various subtypes of astrocytoma e.g., pilocytic astrocytoma, from the larger diffuse fibrillary astrocytoma group. There are also differences in terms of how one defines medically intractable or chronic epilepsy that has allowed for the inclusion of certain high grade tumors such as glioblastoma multiforme in some series. However, it is hard to conceive of a glioblastoma multiforme, which has such a poor prognosis, being a cause of 'chronic epilepsy', unless it is the end point of a malignant progression or degeneration from a prior low-grade astrocytoma that has been around for a long period of time.

Tissue sampling is an important consideration in rendering an accurate diagnosis in many of these cases. Gangliogliomas, for example, are tumors marked by an atypical ganglion cell component and a glioma component. Both components of the tumor are generally not evenly distributed throughout the entire neoplasm. In fact, in some gangliogliomas, the ganglion cell component may be present in only a small part of the tumor; obviously, if this region of the tumor is not sampled, a correct diagnosis will not be made. The classic dysembryoplastic neuroepithelial tumor is a multinodular, cortical based microcystic tumor. Small biopsies make it quite difficult or impossible to recognize the architectural pattern which is a salient and useful diagnostic feature of this tumor. In such cases, the differential diagnosis expands to include other low-grade tumors which can have a microcystic appearance and are comprised primarily of cells with rounded nuclei (such as microcystic oligodendroglioma and protoplasmic astrocytoma). Pilocytic astrocytomas classically have a biphasic appearance, which may not be readily apparent if a limited tissue sampling is obtained. Rosenthal fibers and granular bodies, which are useful diagnostic clues to a diagnosis of pilocytic astrocytoma, are not present in all cases, and their absence may also cause diagnostic confusion. To further complicate matters, occasional pilocytic astrocytomas can contain areas with small rounded cells marked by pericellular clearing, mimicking an oligodendroglioma.

More recently, many have come to recognize that there are certain lesions that are not easily classifiable. Over the last several years, there has also been a slowly growing literature describing lesions that seem to have mixed features of more than one tumor type.

The rest of this chapter will address specific details on the pathology of some of the more commonly encountered tumors associated with chronic epilepsy.

Ganglioglioma

Gangliogliomas are tumors which are defined as well differentiated, slow growing, neuroepithelial neoplasms comprised of an atypical ganglion cell component in combination with a glioma component.[19–24] The majority of gangliogliomas are designated as grade I or II tumors in the WHO classification.[18]

*Designated as 'astrocytoma' without any further specification.

Rare anaplastic gangliogliomas (grade III tumors) are recognized as well.[19,25–27] Gangliogliomas may present at any age, but are most commonly encountered in the first two decades of life. They arise anywhere throughout the neuroaxis, but are most commonly observed in the temporal lobe.

Grossly, the tumor may be solid or cystic and is generally not marked by mass effect. Calcification may be present. Necrosis and hemorrhage are unusual findings, the former being observed more commonly in anaplastic forms.

Microscopically, gangliogliomas are marked by an atypical ganglion cell or neuronal cell component (Figure 145.1). This component is not necessarily distributed evenly throughout the neoplasm, and therefore, sampling is sometimes required to discover it. A neuronal cell component may be marked by increased numbers of abnormally distributed or clustered ganglion cells. Many times, there are morphologic alterations to these cells including binucleation, abnormal distribution of Nissl substance, and rarely the presence of neurofibrillary tangles. Binucleate neuronal forms may be observed in up to 60% of these tumors. Immunohistochemical staining with markers of neuronal differentiation, such as synaptophysin, may be helpful in highlighting this component of the tumor. The typical neuronal cell component is often intermixed with a gliomatous component. The glioma component most commonly resembles a low-grade astrocytoma (Figure 145.2). The degree of cellularity may be focally prominent. Mild vascular proliferative changes may also be evident. Prominent mitotic activity and necrosis are generally not features of lower grade tumors and are used to differentiate the rare anaplastic variant. Occasionally, the glioma component may show features resembling a pilocytic astrocytoma or oligodendroglioma. Focal extension to involve the leptomeninges may be evident (Figure 145.3) Perivascular chronic inflammation, consisting primarily of lymphocytes, is not commonly encountered. Eosinophilic granular bodies and microcalcifications may also be focally present (Figure 145.4). Microcystic degenerative changes are also a feature of a subset of these tumors. Care should be taken not to overinterpret synaptophysin positive staining in normal resident neurons as the ganglion cell component of a tumor.[28]

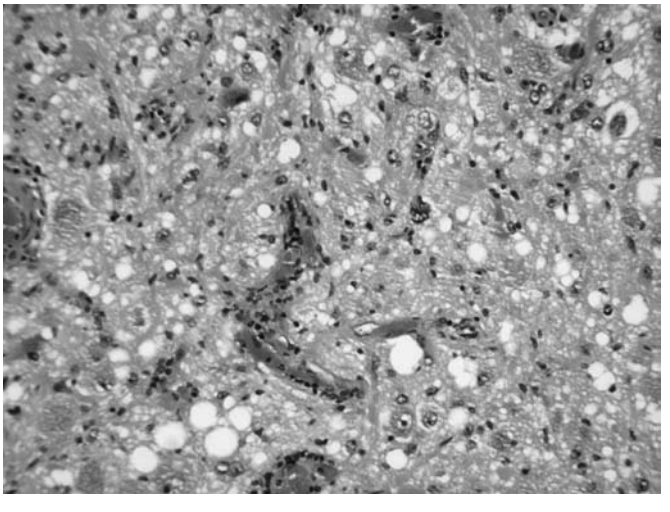

Figure 145.1 A ganglioglioma marked by predominantly ganglionic cells and blood vessels with mild perivascular chronic inflammation.

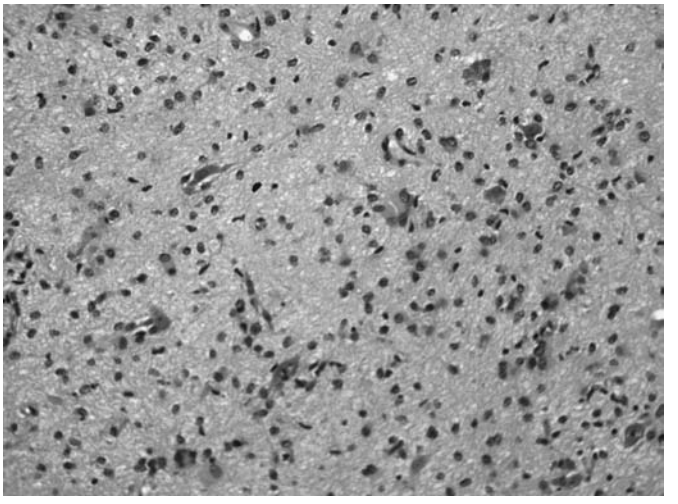

Figure 145.2 A ganglioglioma with intermixed large ganglionic cells and smaller glial cells.

Studies which have examined cell proliferation markers in these tumors found low rates of proliferation in the majority of neoplasms.[19,20] The two largest series to date that have examined this issue have observed Ki-67 or MIB-1 labeling indices of approximately 1%.[19,20] The rare anaplastic variant shows high rates of cell proliferation.

Information regarding genetics on these tumors is limited. These tumors demonstrate multiple chromosomal abnormalities.[29] P53 expression by immunohistochemistry has not been observed; however, increased immunoexpression in a subset of tumors with antiapoptotic proteins bcl-2 and bcl-X_L have been reported.[20,30] Fairly recent work has noted a splice-type-associated polymorphism in the tuberous sclerosis 2 gene that may predispose one to the development of sporadic ganglioglioma.[31]. Polymorphisms have also been noted in the tuberous sclerosis 1 gene.[32]

Gangliogliomas generally have an excellent prognosis and are quite amenable to surgical resection. There is little role for the use of adjuvant radiation therapy or chemotherapy in the routine management of these tumors. Such adjuvant therapies may be utilized in the management of the rare anaplastic variant.

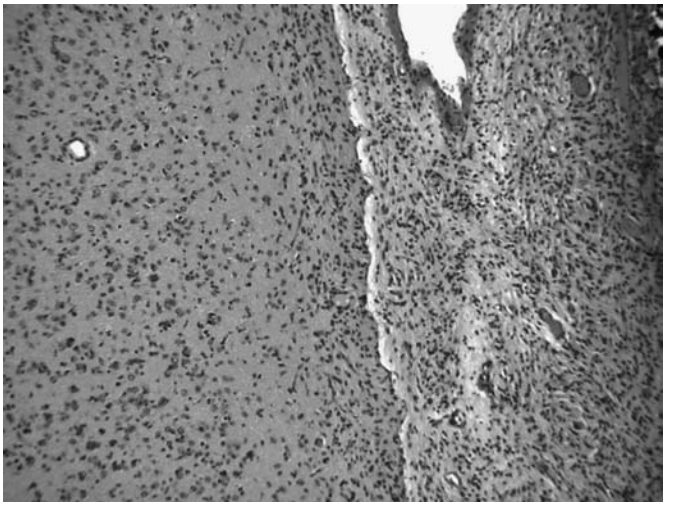

Figure 145.3 Extension of a ganglioglioma to involve the leptomeninges (right).

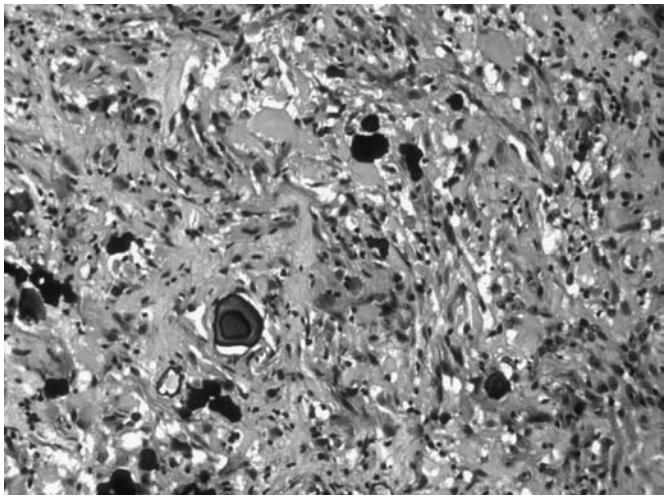

Figure 145.4 Foci of dystrophic calcification in a ganglioglioma.

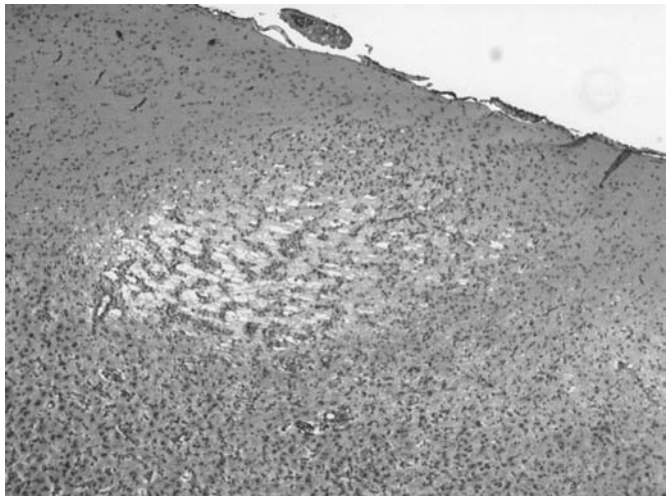

Figure 145.5 Low magnification appearance of a portion of a dysembryoplastic neuroepithelial tumor depicting the superficial, cortical basal location of the tumor.

The origin of ganglioglioma is still not known. As previously discussed, there may be a genetic component to the development of a subset of these tumors. A number of studies have also established an association of ganglioglioma with malformations of cortical development (cortical dysplasia).[19,20,33,34] The coincidence of cortical dysplasia with ganglioglioma appears to be more than just chance. Similar to cortical dysplasia, gangliogliomas may have a maldevelopmental basis to their origin. Some forms of cortical dysplasia are morphologically quite similar to ganglioglioma and distinction of one from the other may be difficult without the proper clinical or radiographic context.

Dysembryoplastic neuroepithelial tumor

Dysembryoplastic neuroepithelial tumors were first recognized as a distinct pathologic entity in 1988 by Daumas-Duport *et al.*[35] Prior to this time, many of these lesions were likely diagnosed as oligodendroglioma or perhaps even ganglioglioma. Subsequent literature on the entity has established it as a distinct lesion, which is commonly encountered in the setting of chronic epilepsy.[36–41] These tumors are generally thought of as glioneuronal neoplasms, marked by a multinodular architectural pattern and predominant cortical location. They are regarded by the WHO as grade I. Similar to gangliogliomas, they may arise at any age; however, they show a predominance in the pediatric population. Origin of these tumors in a variety of locations throughout the central nervous system have been reported, although the majority of them arise in the temporal or frontal lobes.

Grossly and on imaging studies, they are predominantly intracortical in location and multinodular (Figure 145.5). Peritumoral edema is usually absent. Foci of microcystic change are frequently present. The involved surface cortex may show a bubble-like or blustered appearance, secondary to this microcystic change.

Microscopically, the tumor is marked by a proliferation of cells with generally rounded nuclei, scant cytoplasm, and frequent pericellular clearing, very similar to oligodendroglial cells (Figures 145.6 and 145.7). These cells are often arranged against a microcystic background. Floating in the cystic pools are benign, normal appearing neuronal cells. Small numbers of astrocytic cells are interspersed among the other cells present. The tumor demonstrates minimal cytologic atypia. A chickenwire or arcuate capillary vascular pattern is often prominently noted. Mitotic activity is frequently absent. Necrosis and vascular proliferative changes are not seen. Occasional tumors may demonstrate evidence of focal calcification. By immunohistochemistry and ultrastructural studies, a subpopulation of the oligodendroglial-like cells may also demonstrate evidence of neuronal differentiation, but the majority of cells do not.[40,42]

Similar to ganglioglioma, an association of the dysembryoplastic neuroepithelial tumor with adjacent malformations of cortical development has also been described.[34–39,43] It has been suggested that these tumors might arise from subpial granular cells layer, their specific derivation has not been universally

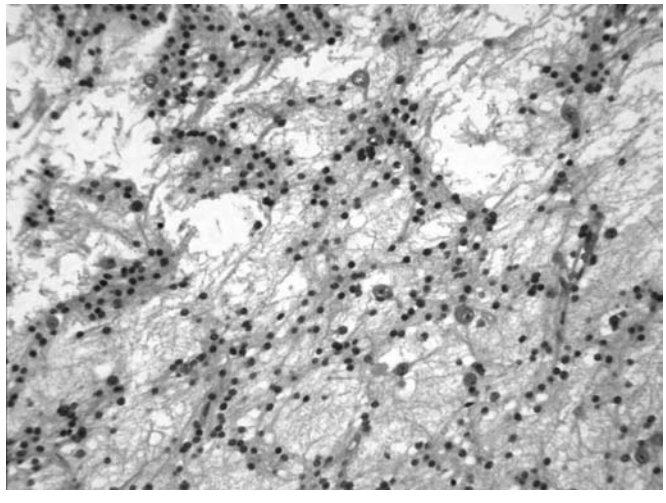

Figure 145.6 Typical microcystic appearance of a dysembryoplastic neuroepithelial tumor. Most of the tumor's cells resemble rounded oligodendroglial cells with an occasonal normal appearing neuron.

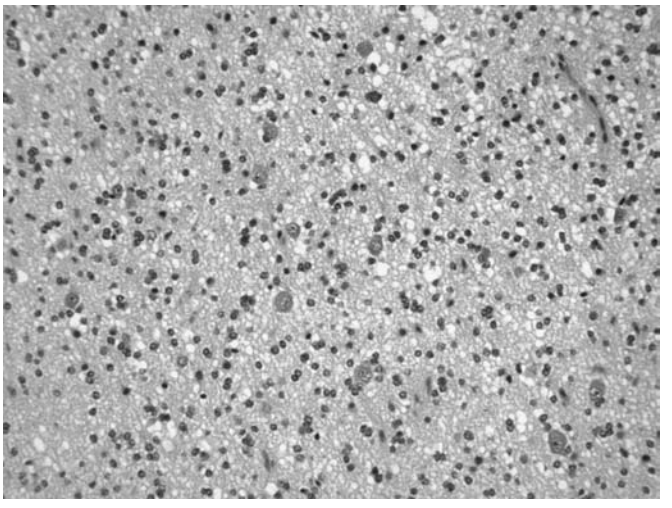

Figure 145.7 A more solid region of a dysembryoplastic neuroepithelial tumor showing both oligodendroglial-like cells and neuronal cells.

agreed upon. Again, the coexistence of this lesion with cortical dysplasia suggests a malformative basis for the tumor.

Studies which have examined cell proliferation markers in these tumors have demonstrated low labeling indices, typically on the order of 1% or less.[38,39,43,44] Because of the morphologic resemblance to neurocytomas and oligodendrogliomas, a few studies have explored genetic markers that are more commonly associated with these tumor types. Allelic loss on chromosomes 1p and 19q have not been observed in dysembryoplastic neuroepithelial tumors, in contrast to oligodendrogliomas, where approximately 60% of tumors demonstrate these allelic losses.[45,46]

Similar to gangliogliomas, dysembryoplastic neuroepithelial tumors are amenable to surgical resection and are potentially curable with a gross total resection. There is currently no role for adjuvant chemotherapy or radiation therapy in the management of these tumors. Rarely, cases of supposed malignant transformation or progression of these tumors to high-grade lesions have been reported; however, careful examination of these cases often shows atypical features making the diagnosis suspect. If one maintains strict criteria for the diagnosis, these tumors almost invariably have a benign clinical course.

Because the diagnosis requires assessment of architectural pattern, small biopsies may be inadequate and inappropriate for purposes of definitive diagnosis. The strong resemblance of this tumor to a low-grade microcystic oligodendroglioma or protoplasmic astrocytoma may cause differential diagnostic problems in the setting of a limited biopsy, where the location of the tumor, multinodularity of the lesion, or adjacent cortical dysplasia may not be appreciated.

Diffuse or fibrillary astrocytomas

Diffuse or fibrillary astrocytomas comprise the most common primary neoplasms of the central nervous system.[18] They arise anywhere in the neuroaxis and have peak incidence in young adults between the ages of 30–40 years; although, they may arise at any age. Seizures are a fairly common presentation for these tumors. The clinical course of higher-grade lesions (glioblastoma multiforme) often culminates in the death of the patient within a relatively short period of time. Therefore, these patients typically do not present with a medically intractable epilepsy. The World Health Organization stratifies the fibrillary astrocytomas into three grades. The low-grade lesions are generally designated as grade II neoplasms and are the lesion of primary interest in the chronic epilepsy venue. Higher-grade tumors are designated as anaplastic astrocytoma (grade III) and glioblastoma multiforme (grade IV).

Typically, the low-grade astrocytomas arise in the white matter and have an infiltrative growth pattern. As tumor cells infiltrate into the overlying cortex, they frequently obscure the gray-white interface. Microcystic or grossly cystic areas may be evident. Microcalcifications may be observed in approximately 15% of tumors.

Histologically, low-grade fibrillary astrocytomas are marked by increased cellularity due to a proliferation of atypical appearing astrocytes (Figure 145.8). The atypia is marked by nuclear enlargement, nuclear hyperchromasia associated with a coarse chromatin pattern, and nuclear irregularity or pleomorphism. Rarely, mitotic figures may be observed; they are more readily discernible in the higher-grade tumors. Vascular proliferative changes and necrosis, which are features more commonly associated with glioblastoma multiforme, are absent in low-grade tumors. Occasional tumors may show a prominent gemistocytic component. These gemistocytic cells are characterized by prominent eosinophilic cytoplasm and a laterally displaced, slightly enlarged nucleus with small nucleolus.[47,48] Tumors with a significant gemistocytic component tend to behave in a more aggressive fashion.

Rates of cell proliferation utilizing cell proliferation markers are generally low in the grade II fibrillary astrocytomas.[49–51] In general, the mean labeling index of the low grade fibrillary astrocytoma group is a bit higher than the gangliogliomas and dysembryoplastic neuroepithelial tumors. Tumor cells are generally (GFAP) positive. As previously mentioned, distinction of this lesion from ganglioglioma may sometimes be dependent on the extent of sampling of the

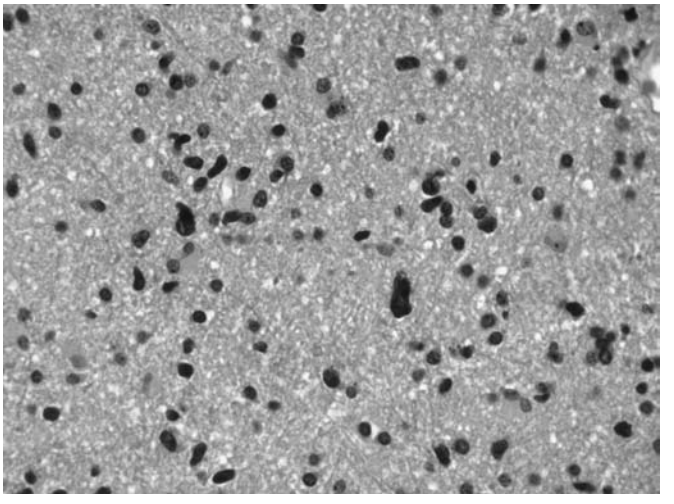

Figure 145.8 A low-grade fibrillary astrocytoma marked by atypical astrocytic cells with enlarged nuclei and irregular nuclear contours.

lesion in that the gliomatous component of ganglioglioma may resemble a diffuse or fibrillary type astrocytoma.

In contrast to most gangliogliomas and dysembryoplastic neuroepithelial tumors, fibrillary astrocytomas are well known to evolve over time into higher-grade lesions. This underscores the importance of distinguishing this entity from ganglioglioma. There is some recent suggestion in the literature that among the grade II fibrillary astrocytomas, a subgroup of these tumors arising in patients with long term epilepsy may have a more benign clinical course with a lower rate of occurrence and higher percentage of survival at 10 years.[50] Although differences were observed in this study based on clinical parameters, the morphologic distinction of this subset of tumors from other fibrillary astrocytomas is not possible. In contrast to gangliogliomas and dysembryoplastic neuroepithelial tumors, it appears that a significant subset of low-grade fibrillary astrocytomas demonstrate p53 mutations or alterations.[18] Treatment is generally determined by a variety of parameters including grade of tumor at time of presentation, location, age, and time course of the neoplasm. Low-grade lesions may be amenable to surgical excision and followed by observation. Adjuvant therapies are often reserved for tumors which demonstrate progression or are higher-grade lesions.

Protoplasmic astrocytoma

The protoplasmic astrocytoma is a rare low-grade astrocytic neoplasm (WHO grade II) that also has been linked to chronic epilepsy.[18] Many of these tumors arise in the first few decades of life and present with a long history of epilepsy. Temporal and frontal lobes are the most common sites of origin.[52] Many of these tumors appear to be cortical based.

Microscopically, these tumors are marked by a proliferation of astrocytic cells with round or slightly oval nuclear contours and scant amount of cytoplasm (Figure 145.9). Cells are arranged against a microcystic background. Prominent mitotic activity, vascular proliferative changes, and necrosis are not seen. Eosinophilic granular bodies or Rosenthal fibers, features that are fairly typical of pilocytic astrocytoma, are not observed in these tumors. In contrast to dysembryoplastic neuroepithelial tumors, which protoplasmic astrocytomas may also resemble, the protoplasmic astrocytoma lacks adjacent cortical dysplasia and usually presents as a unifocal mass.

The rate of cell proliferation in these tumors is rather low, with a mean MIB1 labeling index in one series of 0.7.[53] P53 immunoreactivity is present in a minority of tumors.[53] In contrast to oligodendrogliomas, 1p chromosomal deletions are not observed in these tumors.[54]

Clinically, most of these tumors behave like low-grade lesions. Their superficial location may make them somewhat more amenable to surgical excision.

Pilocytic astrocytoma

Pilocytic astrocytomas are the most common of the astrocytoma variant tumors. These neoplasms most commonly arise in the cerebellum, region adjacent to the third ventricle, brainstem, and optic nerve/chiasm. A subset of these tumors may present in the clinical setting of medically intractable epilepsy. Recognized by the World Health Organization as a grade I lesion, these tumors have a much better prognosis than the fibrillary type astrocytomas, and are important to distinguish from these tumors for that reason.[18] The majority of pilocytic astrocytomas arise in the pediatric age group.

Grossly, the classic pilocytic astrocytoma is a cystic tumor that has a mural nodule or nodules. Radiographically, these nodules enhance because of the increased vascularity of these neoplasms.

Microscopically, the classic pilocytic astrocytomas are biphasic neoplasms (Figure 145.10). Areas of the tumor consist of a dense fibrillary background and spindled cells. Often in these more compact areas, brightly eosinophilic Rosenthal fibers may be evident (Figure 145.11). These dense fibrillary areas are frequently juxtaposed to other regions of the tumor which may have a looser, more microcystic appearance. Often in these more microcystic areas, eosinophilic granular bodies may be evident. Foci of perivascular chronic inflammation

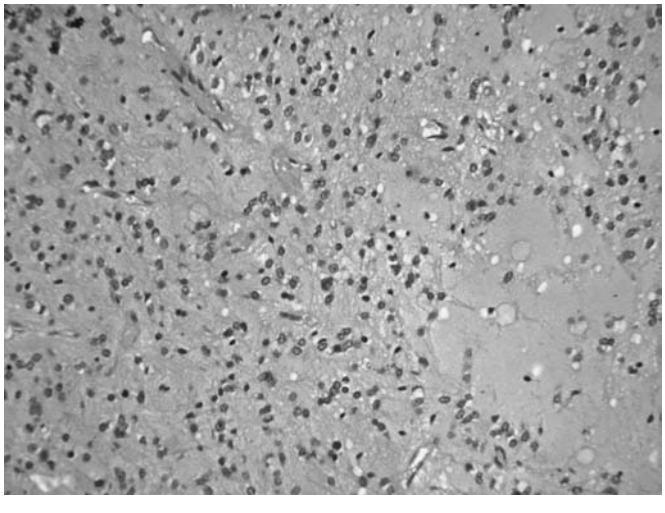

Figure 145.9 A protoplasmic astrocytoma composed of astrocytic cells with generally rounded nuclei arranged against a cystic or loose background.

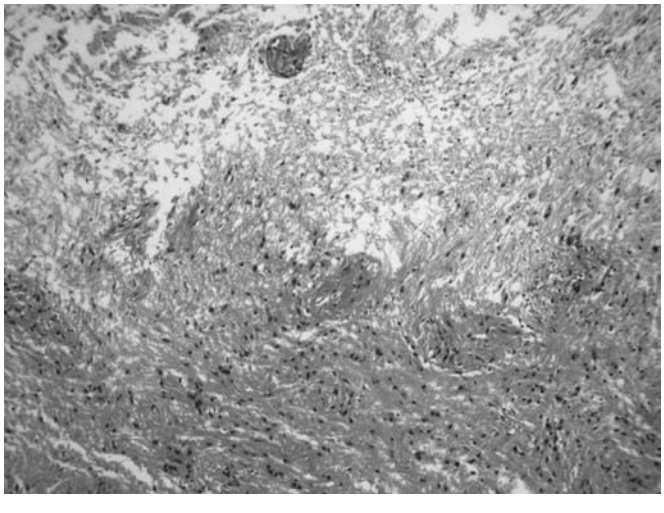

Figure 145.10 Compact fibrillary and loose patterns characterize the biphasic appearing pilocytic astrocytoma.

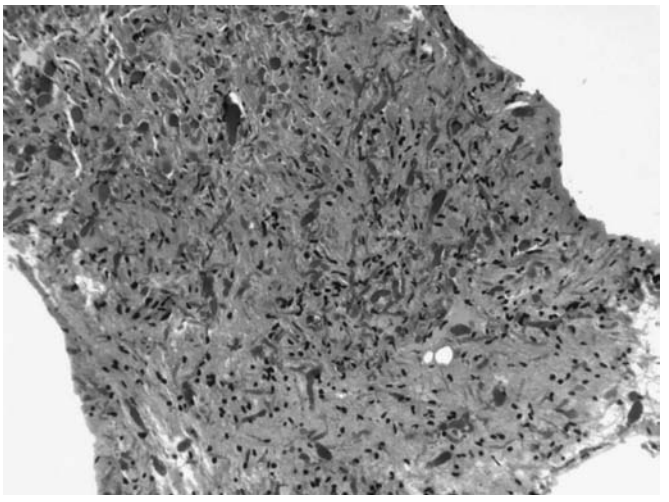

Figure 145.11 Numerous eosinophilic Rosenthal fibers in a compact area of a pilocytic astrocytoma.

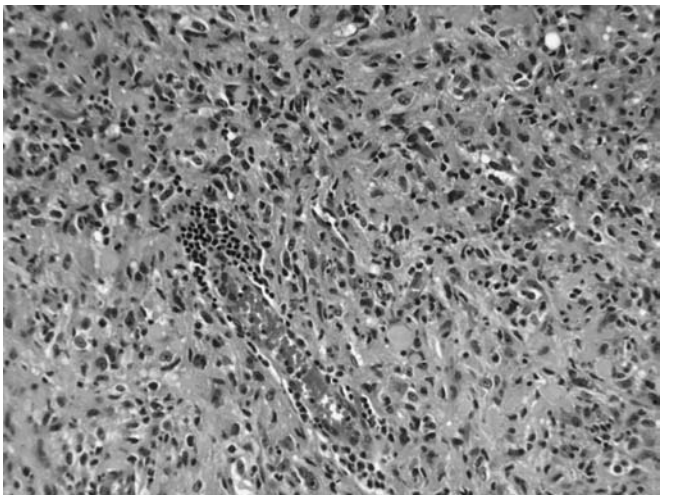

Figure 145.12 A markedly cellular pleomorphic xanthoastrocytoma with perivascular chronic inflammation.

consisting primarily of lymphocytes are frequently present. Vascular sclerotic changes may also be evident. Nuclear pleomorphism may prominent. Misinterpretation of the vascular proliferative changes and pleomorphism as representing features of a fibrillary type astrocytoma may result in an erroneous diagnosis of anaplastic astrocytoma or glioblastoma multiforme. Prominent mitotic activity and necrosis are generally not viewed as features of the pilocytic astrocytoma.

Being astrocytic in derivation, these tumors demonstrate GFAP immunoreactivity. Distinction of these tumors from ganglioglioma must be considered, given that the gliomatous component of the ganglioglioma may on occasion resemble a pilocytic astrocytoma. Rates of cell proliferation are generally low in keeping with the low grade of these neoplasms.[55–58] Many of the genetic alterations that have been previously attributed to diffuse or fibrillary type astrocytomas are generally not observed in pilocytic astrocytomas. The literature seems divided over the frequency of p53 mutations in these tumors.[59–61]

The vast majority of these tumors behave in a benign fashion and are amenable to surgical excision. Only rare cases of malignant degeneration or progression have been documented.[62] There is generally no role for adjuvant therapy in the treatment of most pilocytic astrocytomas.

Pleomorphic xanthoastrocytoma

Pleomorphic xanthoastrocytomas are low-grade tumors (WHO grade II) that account for less than 1% of all astrocytic neoplasms.[18,63–65] The majority of patients are in the pediatric age group. Tumors are typically located in the temporal or parietal lobes. On imaging studies, these tumors often have a cystic component with enhancing mural nodule or nodules. Focal areas of dystrophic mineralization may be evident. They are usually superficial and often attached to the meninges. Leptomeningeal spread of tumor may occasionally be observed.

The neoplasm is marked by prominent hypercellularity, comprised of cells which demonstrate considerable nuclear pleomorphism (Figure 145.12). In some cases, vacuolated or xanthomatous changes in the cytoplasm of astrocytic cells may evident (Figure 145.13). Multinucleated, giant astrocytes may also be present. On casual inspection, these tumors resemble high-grade fibrillary astrocytoma in terms of cellularity and pleomorphism. Vascular proliferative changes, which may be quite prominent in these tumors and account for the enhancement seen radiographically, may cause further confusion with high grade fibrillary astrocytoma. In contrast to high grade fibrillary astrocytomas, however, pleomorphic xanthoastrocytomas generally lack significant mitotic activity or evidence of necrosis. Eosinophilic granular bodies are frequently present as are perivascular collars of lymphocytes. In contrast to the usual fibrillary type astrocytoma, pleomorphic xanthoastrocytoma shows increased reticulin deposition between individual cells and small groups of tumor cells. In the usual fibrillary astrocytoma, reticulin deposition is confined to blood vessels and vascular proliferative changes. Rare examples of more aggressive pleomorphic xanthoastrocytomas, so-called anaplastic pleomorphic xanthoastrocytoma

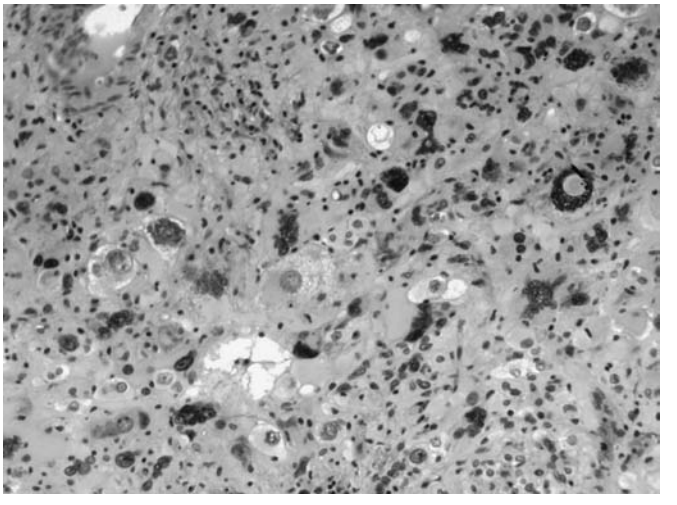

Figure 145.13 Scattered pleomorphic tumor cells and occasional vacuolated or lipidized appearing tumor cells in a pleomorphic xanthoastrocytoma.

(WHO grade III), have been recognized and are marked by increased mitotic activity and/or necrosis.[66–68]

GFAP immunoreactivity in these tumors is evidence for their astrocytic differentiation. Of interest in pleomorphic xanthoastrocytomas is that a small subpopulation of cells demonstrate evidence of neuronal differentiation by immunostaining, suggesting that perhaps these tumors may be glioneuronal in nature rather than purely astrocytic.[69] Furthermore, the presence of associated cortical dysplasia in a subset of these tumors and existence of cases of ganglioglioma/pleomorphic xanthoastrocytoma mixed tumors raise further questions with regard to the exact nature of this neoplasm.[70–72] In one series in which 29 tumors were evaluated with MIB1 antibody, a mean labeling index of 1.9 ± –3.1% was observed.[65]

As a group, pleomorphic xanthoastrocytomas generally do well with surgical excision. As previously indicated, a subset of tumors have demonstrated more aggressive behavior and may require additional adjuvant therapy

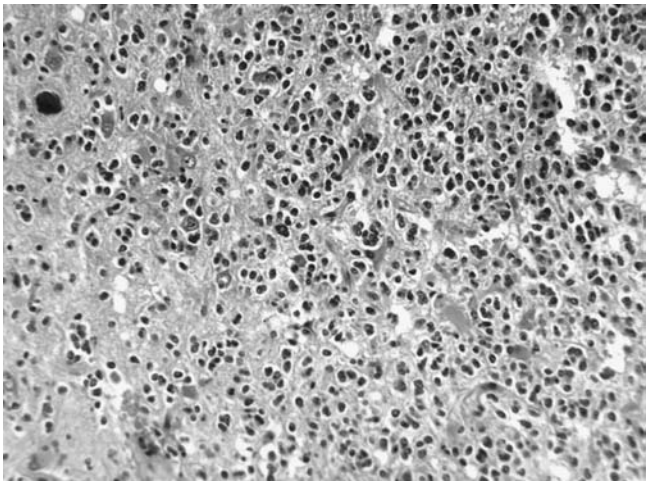

Figure 145.14 A low grade oligodendroglioma characterized by a proliferation of rounded cells with pericellular clearing or halos (fried egg appearance) and focal calcification.

Oligodendrogliomas and mixed gliomas (oligoastrocytomas)

Oligodendrogliomas comprise between 5–18% of intracranial gliomas.[18] Similar to astrocytomas, the majority of cases arise in adults, with the peak incidence in the 5th and 6th decades of life. They are relatively uncommon in the pediatric population. Many pediatric lesions, which were historically diagnosed as oligodendrogliomas, have turned out to be dysembryoplastic neuroepithelial tumors. Several large series that have been published on these tumors show that oligodendrogliomas arise in the white matter, with frontal lobe being the most common location, and often present with a long preoperative history of neurologic signs and symptoms.[73–78]

Like their fibrillary astrocytoma counterparts, these tumors frequently are infiltrative and cause obscuring of the gray matter/white matter interface. The majority of tumors demonstrate calcification. Cystic degenerative changes and evidence of hemorrhage may be seen.

Microscopically, these tumors are marked by a proliferation of cells with rounded nuclei and scant cytoplasm (Figure 145.14). An artefact of delayed formalin fixation results in the classic 'fried egg' or perinuclear halo that may be seen morphologically. A delicate capillary vascular pattern is evident in these tumors. Microcalcifications are also fairly frequent findings (in up to 80% of tumors). Occasional tumors may be marked by a population of cells with increased eosinophilic cytoplasm, so-called mini gemistocytes; there is no prognostic significance attached to these cytologic changes. The WHO recognizes two grades of oligodendroglioma (grades II and III).[18] Grade III or anaplastic oligodendrogliomas are marked by increased cellularity and nuclear pleomorphism, readily identifiable mitotic activity, vascular proliferative changes, and/or necrosis.

To date, there are no reliable immunohistochemical markers for the identification of oligodendroglial cells. Studies looking at cell proliferation indices in these tumors have shown correlation of grade with labeling indices. Of particular note is the presence of deletions on chromosome 1p and 19q in the majority of these tumors.[78–82] Interestingly, these deletions have been associated with better prognosis and chemoresponsiveness in the anaplastic oligodendroglioma group.[78–82] This has prompted some institutions to routinely screen their oligodendrogliomas for these molecular markers. In addition, the markers may also be useful in selected situations from a diagnostic standpoint. A limited biopsy of a microcystic tumor in the temporal lobe consisting of rounded cells with interspersed neurons raises a differential diagnosis of infiltrating oligodendroglioma involving gray matter versus dysembryoplastic neuroepithelial tumor. Evidence of deletions on chromosomes 1p and 19q in this setting would favor oligodendroglioma.[46] In a tumor that does not demonstrate deletions on these chromosomes, the differentiation between the two entities may still be uncertain.

In contrast to diffuse fibrillary astrocytomas, oligodendrogliomas are often (although not invariably) chemoresponsive. As previously noted, chemoresponsiveness appears to be associated with certain chromosomal deletions. High-grade tumors may also be treated with adjuvant radiation therapy.

There clearly are a subset of low-grade gliomas that appear to demonstrate mixed features of oligodendroglioma and fibrillary astrocytoma. In some cases, these two patterns of cell types are intermixed, and in other instances, there appears to be geographically distinct areas of each tumor type. The designations of mixed glioma or oligoastrocytoma have been used in reference to this subset of gliomas.[83–85] A universally agreed upon precise definition as to what constitutes a mixed glioma has not been well defined in the literature. Arbitrary cutoff points between 20–35% of a minor component have been variously used. Due to the lack of uniformity with regard to definition and diagnosis of this entity, it has been difficult to come to an understanding of the significance or the characteristics of this group of tumors. Similar to oligodendrogliomas, the World Health Organization stratifies these lesions into low grade (grade II) and high grade anaplastic (grade III) lesions.[18] There is some data to suggest that a subset of mixed gliomas demonstrates deletions on chromosomes 1p and 19q, and this subset may be more amenable to chemotherapy.[80]

Composite lesions

A number of cases reports and small series have been published describing tumors which demonstrate features of more than one tumor type, i.e., composite tumors. Cases of composite pleomorphic xanthoastrocytoma and ganglioglioma[70,71,86,87] as well as reports of tumors demonstrating areas of dysembryoplastic neuroepithelial tumor and ganglioglioma,[88–90] have been reported. Coexistence of these lesions raises interesting questions regarding the pathogenesis of these entities and possible malformative nature of this group of tumors. Interestingly, these are also tumors that have been described arising in association with cortical dysplasia.

Hamartoma

Hamartomatous lesions may rarely account for chronic epilepsy. Hamartomas in this context are defined as tumoral lesions composed of disorganized, but mature cellular elements.[91] These lesions may consist of admixtures of both glioneuronal elements, but in contrast to gangliogliomas, they lack appreciable cytologic atypia (Figure 145.15). Occasional granular bodies and microcalcifications may be present. Adjacent cortical dysplasia may also be noted. Cell proliferation markers show negligible evidence of cell proliferation. Because of the benignity of these lesions and their circumscribed nature, they are amenable to surgical excision and have a good postoperative outcome.

Meningioangiomatosis

Meningioangiomatosis is a rare benign lesion that probably has a maldevelopmental basis to its origin that may arise as a mass lesion in the setting of chronic epilepsy.[92–95] This lesion has been variously associated with a neurofibromatosis. The entity is marked by a benign proliferation of blood vessels collared by meningothelial cells which extends into the cortex and white matter (Figure 145.16). The intervening neural parenchyma shows gliosis and may show dystrophic mineralization. Gross total resection of the lesion appears to be curative.

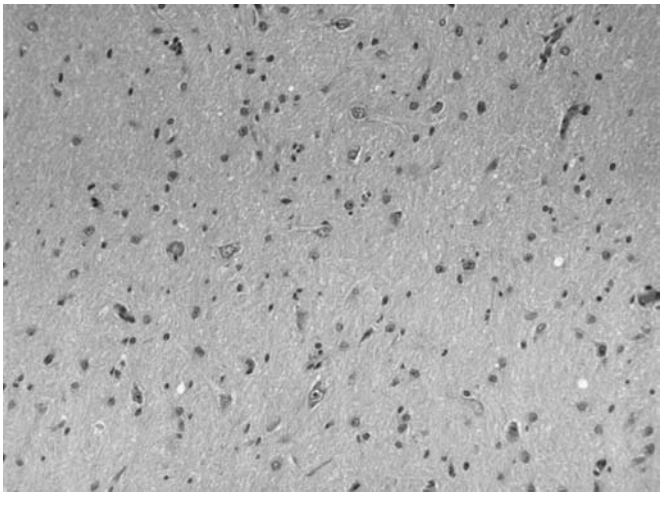

Figure 145.15 Glioneuronal hamartoma characterized by a disordered admixture of relatively benign appearing glial and neuronal cells.

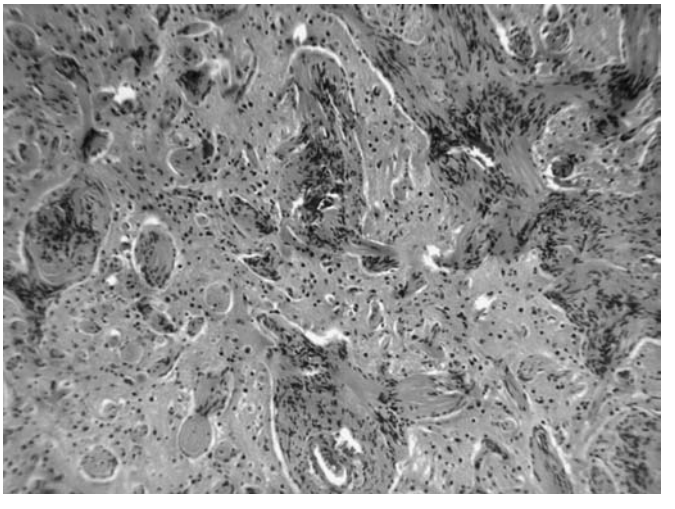

Figure 145.16 Meningoangiomatosis marked by a prolifertion of blood vessels collared by benign meningothelial cells.

146 In vitro neurophysiological studies

GL Möddel and IM Najm

Introduction

For the past 50 years researchers have developed powerful methods in order to study the mechanisms which are involved in the generation of epileptic activity in neuronal tissues. In general, experiments can be performed using either living laboratory animals ('in vivo'), or tissue preparations (e.g., brain slices or separated single neurons) derived from such subjects ('in vitro'). In vivo experiments enable the researcher to study epileptic phenomena in an intact brain with all its neuronal structures and white matter connections preserved. Accordingly, those experiments constitute a rather valid model mimicking the processes that generate seizures in an epilepsy patient. However, many questions arising in regard to the basic mechanisms of epileptogenesis require more reduced, simplified models that enable the researcher to control for as many experimental parameters as possible and to manipulate others.

In vitro neurophysiological methods in experimental epilepsy research – an overview

The 'brain slice in vitro' preparation constitutes such a powerful experimental model. In short, axial sections of the hippocampus or neocortex of about 400–500 μm thickness are prepared from the brains of experimental animals (i.e., mostly, rats, mice, or guinea pigs). Additionally, human brain tissue samples resected from epilepsy patients for the treatment of intractable epilepsy have been studied using the in vitro slice model since resective surgery became a widely accepted treatment for intractable focal epilepsy in the late 1970s.[1–4]

Brain slices contain a limited, relatively simple, virtually two-dimensional neuronal network that is anatomically and physiologically well-described.[5] Following preparation, brain slices are incubated and stored in artificial cerebrospinal fluid (ACSF, i.e., saline mimicking the ional and glucose concetrations of CSF).[6] For electrophysiological recordings, individual brain slices are placed in a recording chamber and constantly superfused with oxygenated ACSF. Flow velocity, temperature, and pH are monitored and held constant throughout the experiment (Figure 146.1). This setup allows experimental manipulations such as changing the ionic composition of the extracellular medium, application of convulsant or anticonvulsant substances in exact, graded concentrations and without interference by the blood–brain barrier, transsection of defined axonal connections, or electrical stimulation of gray or white matter structures. Extracellular recording electrodes ('field potential electrodes') can be used to assess spontaneous or electrically induced synchronized discharges of the surrounding neuronal population ('epileptiform field potentials', EFP) or the extracellular correlate of synchronized action potential generation ('population spike'). Positioned within the dendritic layers of the neocortex or hippocampus, the extracellular correlate of excitatory or inhibitory synaptic potentials (eEPSPs, eIPSPs) can be recorded. Sharp electrodes which penetrate neuronal membranes are used to record membrane potential fluctuations of individual neurons as well as to inject positive or negative current pulses into neurons. These intracellular recordings can be maintained for many hours, and the effects of changes in the perfusion medium can be assessed. Parameters of interest are, for example,

- the resting membrane potential,
- input resistance (i.e., change of membrane potential in relation to amplitude of injected current),
- EPSPs and IPSPs (spontaneous, electrically induced, pharmacologically induced),
- spontaneous and electrically induced firing pattern (i.e., regular action potential firing with slow adaptation, fast adaptation, or intrinsically bursting firing mode; see Figure 146.2).

The patch-clamp technique[7] allows single-cell recordings using low-resistance electrodes in conjuction with special software to keep either the membrane potential or the current across a membrane patch constant over time (i.e., 'voltage-clamp' or 'current-clamp') while measuring the respective other parameter. By using suitable ion channel agonists and antagonists, the voltage-clamp technique can be employed to 'filter out' individual channel species and thus assess, for example, the time course of fast sodium currents or slow calcium currents directly. Besides, patch-clamp electrodes in situ can be used to inject neurons with dyes, so that individual recorded neurons can later be identified in histologically or immunocytochemically stained sections. Ion-selective electrodes are sensitive to concentration changes of defined ion species in the extracellular medium, so that localized activity-dependent changes in extracellular ion concentrations (e.g., potassium or chloride) can be assessed. Comb-like arrays of up to eight or ten extracellular electrodes provide field potential profiles, e.g., across neocortical layers. Recently, optical imaging techniques

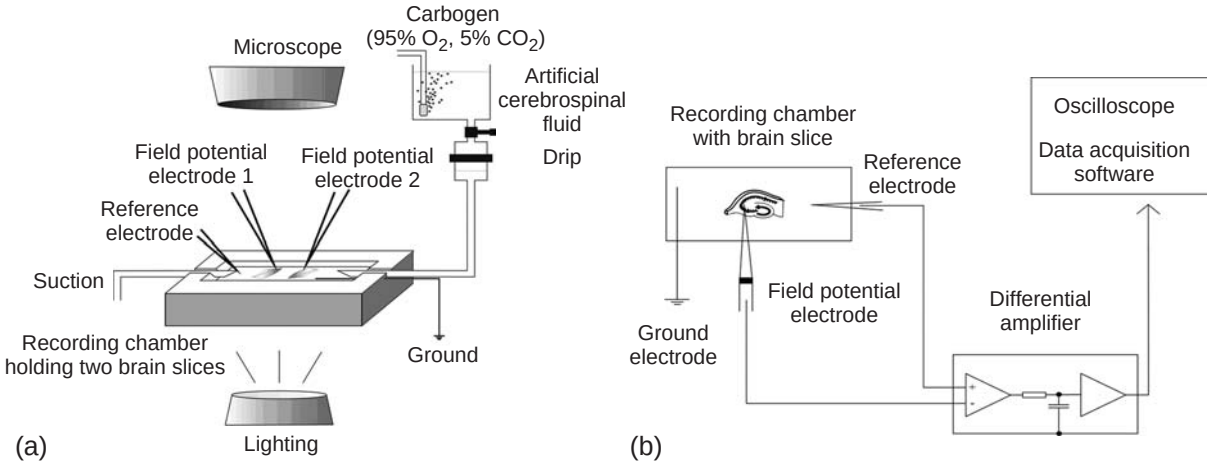

Figure 146.1 Experimental setup used for in vitro neurophysiological experiments. a, Mechanical setup; b, electrical setup.

have been developed which employ voltage-sensitive dyes and two-dimensional diode arrays instead of electrodes in order to assess the spread of neuronal activity across a brain slice and along pathways with high time and space resolution.[8]

When recording from a brain slice bathed in normal ACSF, spontaneous synchronized network activity is only rarely present. This is the case, for example, in cortical samples derived from surgically excised seizure foci of patients with medically intractable epilepsy,[9] or in slices prepared from animals with exprerimentally induced epileptogenic lesion or a genetic epileptic predisposition. In most cases, however, additional manipulations are necessary to induce epileptiform activity in brain slices. These 'in vitro seizure models' include:

- Electrical stimulation of afferent or efferent axonal pathways
- Application of substances which block GABAergic inhibition, such as penicillin,[10–12] bicucullin or picrotoxin.[13,14]
- Application of agents which block repolarizing voltage-gated potassium channels, such as 4-aminopyridine or barium.[15]
- Changes of the ionic composition of the bathing medium, such as
  – lowering of $[Cl^-]_o$, $[Ca^{2+}]_o$, $[Mg^{2+}]_o$, or $[K^+]_o$
  – elevating $[K^+]_o$.

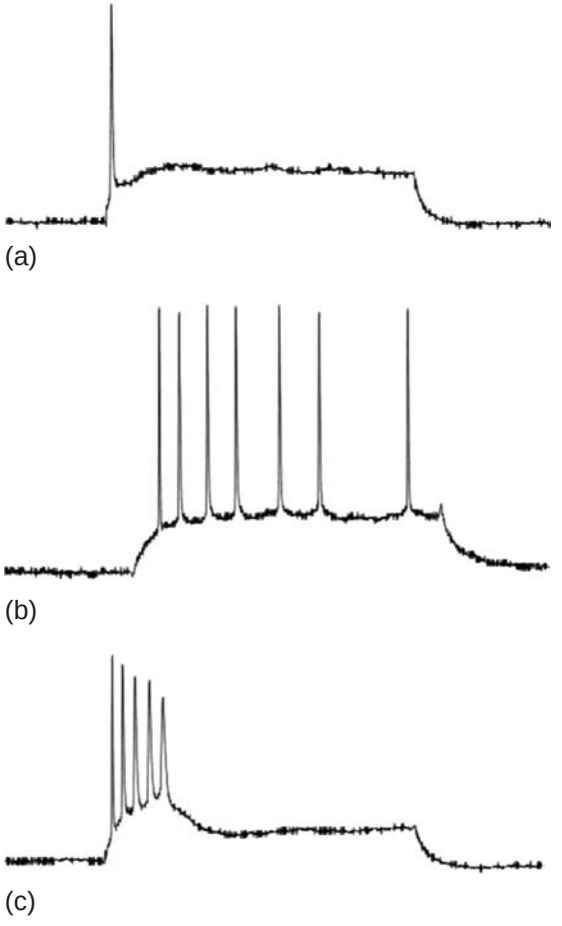

Figure 146.2 Typical neuronal discharge patterns, elicited by intracellular injection of positive current pulses (400 nA, 200 msec). a: Fast adaptation. b: Regular spiking with slow adaptation. c: Intrinsically bursting neuron. (guinea pig, hippocampus, CA3 pyramidal cells).

Among these models, the lowering of $[Mg^{2+}]_o$ ('low-magnesium model' or 'zero-magnesium model') has been proven to be especially useful because it reliably induces robust periodic spontaneous network bursts in both hippocampal and neocortical slices without requiring external stimulation. These 'epileptiform field potentials' (EFP) of 10–200 ms duration resemble interictal spikes in the EEG and were therefore termed 'interical bursts'. The epileptogenic effect of low $[Mg^{2+}]_o$ is mainly mediated by increasing sodium and calcium influx through N-methyl-D-aspartate (NMDA)-receptor associated ion channels.[16–21] At normal resting membrane potential of around –60 mV, magnesium ions block the NMDA-receptor channel pore, so that the channel remains inactive despite binding of the agonist glutamate to the receptor. Depolarization of the postsynaptic membrane (e.g., by concomitant activation via AMPA receptors) reduces the electrochemical gradient and causes magnesium ions to exit the channel pore, thereby removing the block. (Figure 146.3) Calcium ions entering the neuron cause further depolarization and serve as second messengers, inducing processes that are the basis for activity-dependent neuronal plasticity, such as induction of long-term potentiation (LTP),[22,23] or changes in

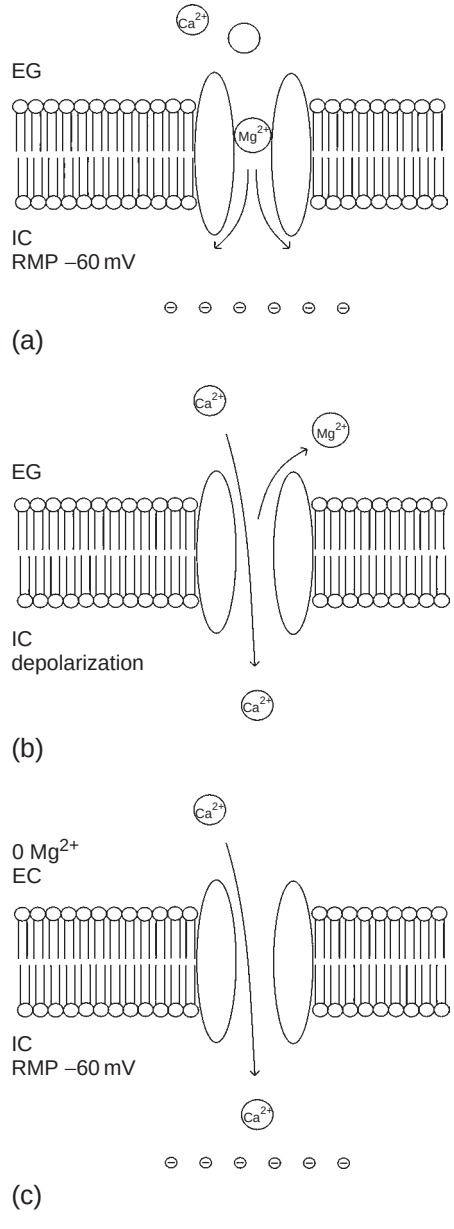

Figure 146.3 Gating of the NMDA receptor associated channel by extracellular magnesium ions. a: At normal resting membrane potential (–60 mV), the NMDA receptor channel pore is blocked by a magnesium ion, preventing cation influx into the postsynaptic neuron despite NMDA binding. b: Depolarization of the postsynaptic membrane releases the magnesium block. NMDA binding consecutively leads to sodium and calcium influx. c: When extracelluar magnesium concentration is markedly reduced, NMDA receptor activation leads to cation influx into the postsynaptic neuron without previous depolarization of the postsynaptic neuron. (0 Mg^{2+}: virtually magnesium-free extracellular solution; RMP: resting membrane potential; EC: extracellular; IC: intracellular).

gene expression patterns. When $[Mg^{2+}]_o$ is reduced by using nominally magnesium-free ACSF, NMDA-receptor associated ion channels can be activated at resting membrane potential without requiring prior depolarization, resulting in increased glutamatergic excitation. Secondarily, increased intracellular calcium, via calcium-calmodulin dependent enzymes, induces dephosphorylation of GABA-A receptors[24] which impairs GABA-ergic inhibition by reducing the receptor affinity for GABA.[25–27] NMDA-receptor independent effects of low-$[Mg^{2+}]_o$ include: direct membrane depolarization, as the 'screening' of negative phospholipid surface charges by the divalent cations magnesium and calcium is impaired,[28] and reduced presynaptic adenosin-receptor mediated inhibition.[29]

In vitro correlates of epileptiform activity

Simultaneous extracellular and intracellular recordings in the hippocampus demonstrated that synchronized epileptiform field potentials are correlated intracellularly by bursts of action potentials riding on a slow depolarizing wave-like potential fluctuation see Figure 146.4a).[21,30] Similar bursts had first been recorded by Spencer and Kandel[31] from the CA3-region of the hippocampus in cats in vivo. Plateau-like epileptiform bursts beginning with a steep initial depolarization are also termed 'parosysmal depolarizing shifts' (PDS).[32,33] Alongside epileptiform bursts resembling interictal spikes, prolonged seizure-like discharges have been described in brain slices in vitro.[4,6,9,15,34–36] Intracellular recordings show a steep initial depolarization with occasional superimposed action potentials, followed by a plateau and prolonged, slow repolarization with multiple superimposed after discharges (Figure 146.4b).

'Interictal-like' epileptiform bursts and epileptiform field potentials (EFP)

The majority of hippocampal pyramidal cells respond to supra-threshold depolarizing stimulation (i.e., injection of square current pulses via intracellular electrodes) with trains of action potentials showing slow or fast frequency adaptation. A subpopulation, however, generates intrinsic bursts of action potentials riding on a slow wave-like depolarizing envelope ('intrinsically bursting neurons', Figure 146.2). Intrinsic bursters serve as putative amplifying elements within neuronal networks and are thought to initiate synchronous activity in the hippocampus.[31,37,38] Dichter and Spencer[39] and Ayala *et al.*[40] have postulated that the process of synchronization is mainly facilitated by recurrent excitatory synaptic connections. Using computer simulations of hippocampal networks, Traub and Wong[41–43] and Traub and Dingledine[44] developed the following model scenario for the generation and spread of synchronous burst activity in the CA3 region of the hippocampus: postsynaptic membranes generate occasional 'spontaneous excitatory postsynaptic potentials' (EPSPs), e.g., by 'random' transmitter release from presynaptic terminals. If two or more of these spontaneous EPSPs occur virtually simultanously in an 'intrinsically bursting' neuron, the cell will generate an epileptiform burst. Given that (a) the excitatory interconnectivity is strong enough and (b) recurrent and lateral inhibition are weak enough to evoke consecutive epileptiform bursts in more than one neighboring neuron, a chain reaction will result: as soon as the number of simultaneously bursting neurons within the population exceeds a critical value, the number of firing cells will first rise explosively and then suddenly drop as the majority of neurons will almost simultaneously be hyperpolarized by recurrent inhibitory interneurons. The electrical correlates of this event as recorded by extracellular electrodes will be an 'epileptiform

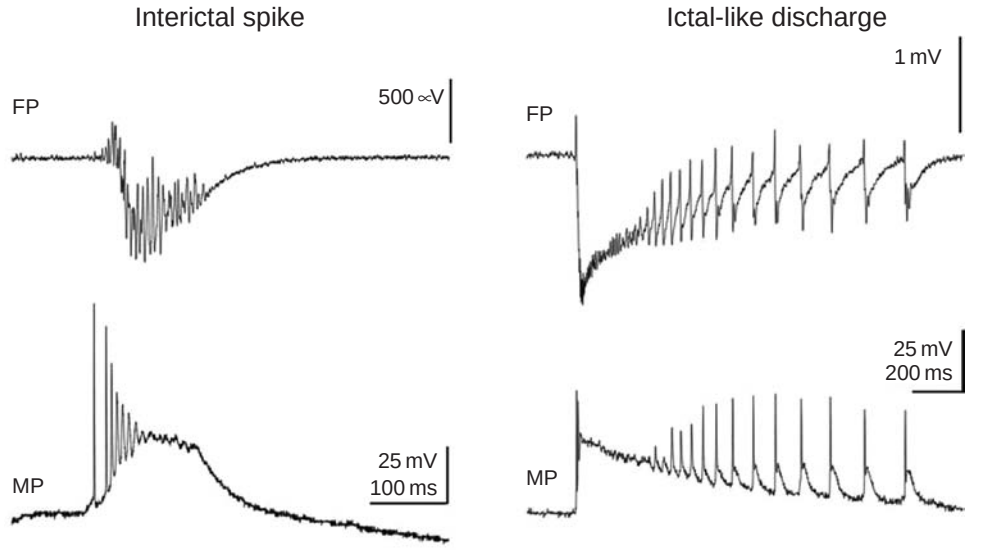

Figure 146.4 Spontaneous interictal and ictal-like epileptiform discharges recorded in vitro. Simultaneous extracellular field potential (FP) and intracellular membrane potential (MP) recordings, guinea pig, hippocampus, CA 3 region, pyramidal cell layer. Epileptiform activity was induced by reduction of the extracellular magnesium concentration (0 Mg^{2+}).

field potential' (EFP) in vitro, or an epileptiform spike or sharp wave in vivo. According to this model, the propensity of a neuronal network to generate EFPs is directly dependent on the proportion of intrinsic bursters within the neuron population, the degree of excitatory connectivity, and on active inhibition.

Seizure-like discharges

Alongside epileptiform bursts resembling interictal spikes, prolonged seizure-like discharges have been described in brain slices in vitro. Intracellular reocordings show a steep initial depolarization with occasional superimposed action potentials, followed by a plateau and prolonged, slow repolarization with multiple superimposed after discharges (Figure 146.4b). Extracellularly, an initial negative spike is followed by a sustained negative potential shift and multiple afterdischarges towards the end of the event. The occurrence of seizure-like discharges suggests that the mechanisms involved in epileptiform burst repolarization are impaired. This includes increased excitatory neurotransmission, reduced inhibition, or impaired intrinsic membrane repolarizing mechanisms:

- low $[Cl^-]_o$ which reduces GABA-A-mediated chloride currents[6,34]
- penicillin and bicuculline that block GABA-A-ergic inhibition[35]
- 4-aminopyridine which blocks repolarizing K^+ channels[15]
- low $[Mg^{2+}]_o$ which leads to increased NMDA-receptor activation,[4,9]
- low $[K^+]_o$ (unknown mechanism, probably increased AMPA/kainate receptor activation[36]

As the transition of epileptiform bursts into prolonged seizure-like discharges serves as a model for interictal to ictal transition in vivo, the involved mechanisms are of special clinical relevance.

Mechanisms of epileptogenesis revealed by in vitro neurophysiological studies

The following processes have been postulated to underly the generation of synchronized network dicharges:

- Intrinsic burst activity. Membrane excitability is regulated by
  – 'active membrane properties' such as voltage-gated ion channels or ligand-gated ion channels, and
  – 'passive membrane properties' such as the resting membrane potential, membrane resistance and capacitance, neuron geometry, leak channels, etc.
- Excitatory coupling between neurons, which can hypothetically be mediated by
  – excitatory synaptic connections,
  – electrical coupling via gap junctions,
  – direct electrical ('ephaptic') interactions between neighbouring neurons, and
  – changes in the concentrations of extracellular K^+ concentration.
- Reduced or impaired inhibition.
- Membrane properties, excitatory neurotransmission, and inhibition are further regulated by
  – Extra- and intracellular ion concentrations,
  – Neuromodulators, and
  – Second-messenger mechanisms.

Mechanisms regulating neuronal membrane excitability

Active membrane properties: voltage gated channels, ion-gated channels

The wave-like depolarization underlying an epileptiform burst has been shown to be caused by a slow cation influx. For hippocampal CA3 pyramidal cells and dentate gyrus granule

cells, slow voltage-activated sodium *and* calcium currents have been identified.[45–48] In CA1-neurons, a persistent sodium current ($I_{Na,p}$) is of major relevance.[49,50] Superimposed somatic action potentials are generated by an interplay between fast voltage-activated sodium currents and subsequent 'delayed rectifying' potassium efflux. Pyramidal cell dendrites generate slow calcium-dependent action potentials ('calcium spikes') which may coincide with somatic sodium spikes, producing the after-depolarization (ADP) that is often seen following action potentials recorded from the cell soma. The epileptiform burst ends with a repolarization, followed by an after-hyperpolarization (AHP) of up to 2 seconds duration. The initial burst repolarization is mainly facilitated by slow voltage-activated potassium channels and GABA-A-receptor mediated recurrent inhibition leading to chloride influx.[51] The same GABA-A-induced chloride influx contributes to the early phase of the AHP. The late phase of the AHP, which also determines the duration of the AHP, is generated by two potassium-dependent mechanisms: GABA-B mediated inhibition and slow Ca^{2+}-acitvated potassium currents.[14,52–54] Chamberlin and Dingledine[55] found that the duration of the AHP correlates positively with the inverval between two subsequent epileptiform bursts ('inter-burst interval') and negatively with the repeptition rate of EFP. Therefore, burst repetition rate in the hippocampus is regulated by GABA-B mediated inhibition and by the extracellular potassium concentration.

These data on burst generation mechanisms have facilitated research investigating the efficacy of voltage-gated ion channel blockers as anticonvulsant drugs. Blockade of slow voltage-activated calcium channels by application of the organic calcium antagonist verapamil exerts strong suppressant effect on bicuculline-induced and low-Mg^{2+}-induced epileptiform burst dicharges in the hippcampus and in the neocortex.[56–58] Similar results have demonstrated the efficacy of flunarizine in vitro. Severe cardiac side-effects in vivo have so far precluded these drugs from clinical use as anticonvulsants. Inhibitors of voltage-gated sodium channels, such as lidocaine, are widely used clinically as local anesthetics and antiarrhythmic drugs. However, their anticonvulsant properties are also well described (e.g., Schurr *et al.* 1986).[59] Lidocaine has been proposed as a drug of third choice for the treatment of refractory status epilepticus. Moreover, blockade of sodium channels is thought to be the major mechanisms of action of the anticonvulsant drug phenytoin.

Passive membrane properties

The excitability of neurons is crucially dependent on intrinsic properties of neuronal membranes. The resting membrane potential (RMP), described mathematically by the Goldman equation,[60] is determined by concentration gradients of ions in the extra- and intracellular compartments and by the membrane permeabilities of the respective ions. At resting conditions, the membrane permeability for potassium ions by far exceeds the permeability for all other ions, so that the RMP is basically a function of the relation between intracellular and extracellular potassium concentration. Potassium permeability is mainly dependent on potassium leak channels ($I_{K,leak}$), whereas ion concentration gradients are maintained by active transport through ATP-dependent pumps (e.g., Na-K-ATPase). Although, to the authors' knowledge, no experimental data exists so far that links changes of $I_{K,leak}$ to epileptogenesis, the block of this current can result in sustained changes in RMP and thereby change the probability of action potential generation. Inhibition of the Na-K-ATPase by the cardiac glycoside dihydroouabaine (DHO) has been shown to induce synchronized burst discharges in the CA1 area of rat hippocampus.[61] Hypoxia-induced epileptiform discharges[62] are, at least in part, mediated by ATP depletion and resulting impairment of ion pumps. Neuronal geometry is another, commonly underestimated determinant of excitability: The capacitance of neuronal membranes, i.e., the amount of electrical charge (e.g., number of ions) necessary to produce a given change in membrane potential, is a function of membrane surface area. The length constant of dendritic processes determines the probability of distal dendritic input to depolarize the soma and is the greater the larger the diameter of the dendrite. Cepeda *et al.*[63] have shown that these passive membrane properties are altered in dysmorphic neurons in cortical dysplastic lesions resected from pediatric epilepsy patients. Dysplastic neurons are characterized by thickened dendritic shafts and a loss or enlargement of dendritic spines.[64] Dendritic spines control excitability by compartmentalization of postsynaptic calcium influx, by enlarging total membrane area, and by attenuating electrotonic propagation of EPSPs: The spine neck accounts for approximately one half of the electric resistance between a given synapse and the cell soma. Hence, loss of spines in cortical dysplasia may be one factor responsible for hyperexcitability.

Mechanisms regulating network connectivity

Excitatory synaptic neurotransmission

Induction of epileptiform activity in hippopcampal slices by disinhibition (bicuculline, penicillin) or reduction of extracellular magnesium concentration gives rise to paroxysmal depolarization shifts (PDS), which behave like giant synaptic potentials: Their amplitude is dependent on the membrane potential, with hyperpolarization increasing and depolarization decreasing PDS amplitude.[36,65] Therefore, excitatory synaptic transmission plays an important role in synchronization of neuronal networks, at least during 'interictal' conditions. Excitatory neurotransmission in the mammalian brain mainly depends on the amino acid transmitter glutamate. Two classes of ionotropic glutamate receptors have been described: (1) those that respond to alpha-amino-3-hydroxyl-5-methyl-4-isoxazole propionic acid (AMPA) or kainic acid, and (2) those that respond to N-methyl-D-aspartate (NMDA).

AMPA/kainate receptors

AMPA/kainate receptors are tetramers or pentamers of subunits (termed GluR1-GluR7, KA-1, and KA-2) derived from three gene families and constitute the major vehicles for fast excitatory synaptic transmission. Their activation gives rise to excitatory post-synaptic potentials (EPSPs) which are mainly mediated by sodium influx and characterized by a short latency, rapid rise time, and short duration of several milliseconds. A subgroup of AMPA/kainate receptors that lack the GluR2 subunit are also permeable to Ca^{2+} ions.[66,67] In most in vitro preparations, interictal epileptiform burst discharges are dependent on AMPA/Kainate receptor activation: Sponaneous,[9] electrically induced,[68] and low-Mg^{2+}-induced[69] epileptiform burst discharges in human neocortical neurons are completely abolished by the AMPA/Kainate-receptor

specific antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). In contrast, blocking AMPA receptors with 1-(aminophenyl)-4-methyl-7,8-methylenedioxy-5H-2,3-benzodiazepine (GYKI 52466) in rat neocortex only gradually reduces low-Mg^{2+} and 4-aminopyridine (4-AP) induced epileptiform discharges, while still abolishing spontaneous discharges induced by bicuculline.[70] This might reflect species differences between rodent and human neocortex. The horizontal propagagion of epileptiform discharges in normal rat somatosensory cortex[71] as well as in an animal model of focal cortical dysplasia induced by cortical freeze lesions[72] is dependent on AMPA-repeptor activation.

In the hippocampus (CA1) of rats, the ampltitude of epileptiform discharges is reduced by application of CNQX, but block of both AMPA/kainate and NMDA receptors is necessary to completely abolish spontaneous bursts in the bicuculline model.[73] Excessive hippocampal activation by repetitive seizures has been shown to increase the number of functional AMPA receptors at Schaffer collateral synapses, indicating their potential role in activity-dependent plasticity and kindling-induced epileptogenesis.[74] In rat hippocampal slices made chronically epileptic by perinatal hypoxia, the expression of GluR2 subunits is markedly reduced, resulting in increased calcium influx through AMPA receptors.[75] Hence, intracellular calcium is likely to play an important role in the development of chronic epileptogenesis.

NMDA-receptors

Numerous studies, using different in vitro seizure models, demonstrate the blocking effect of NMDA receptor antagonists on epileptiform activity, implying that NMDA receptors play a pivotal role in the generation of synchronized discharges. Avoli and Olivier[4] showed that the the nonspecific NMDA receptor antagonist D-2-amino-5-phosphonovalerate (APV) blocks electrically-induced epileptiform bursts in human neocortical slices resected from epilepsy patients. In rodent hippocampus, the durations of bicuculline- or pentylenetetrazol-induced epileptiform depolarizations is reduced by APV.[76] Several features make NMDA receptors particularly interesting for the pathophysiology of epilepsy: (a) the NMDA receptor is activated in a voltage-dependent manner, i.e., depolarization of the membrane is necessary for relieving the block by Mg^{2+} of the ion channel pore; (b) the NMDA receptor interacts with numerous intracellular scaffolding, anchoring and signalling molecules associated with the postsynaptic density, such as the tyrosine kinase Fyn or neuronal nitric oxide synthase (nNOS);[77–79] (c) Ca^{2+}-permeability of NMDA receptor associated channel by one to two orders of magnitude larger than Ca^{2+}-permeability of AMPA/kainate receptors, depending on the subunit composition of receptors.[66,67,80–83] Intracellular calcium acts as a second messenger with short-term (e.g., activation of protein kinases and nNOS) and long-term (alteration of the gene expression pattern) effects, thus NMDA receptors constitute an important substrate for synaptic plasticity;[84–86] (d) NMDA receptors display slow kinetics with an inactivation time constant one to two orders of magnitude longer than that of AMPA receptor channels. NMDA receptors are likely to play an important role in the generation of seizure-like discharges. Upon activation, NMDA receptors generate prolonged excitatory postsynaptic currents (EPSCs). These prolonged NMDA-receptor mediated depolarizations are normally masked by recurrent inhibition via GABAergig interneurons. Luhmann and Prince[87] showed that minimal disinhibition by application of low doses of bicuculline in adult rat neocortex can 'unmask' the NMDA receptor mediated depolarizations and give rise to synchronized afterdischarges which are senstitive to APV. In juvenile rat neocortex, the same investigators demonstrated long-lasting oscillatory NMDA-dependent field potential responses upon layer VI electrical stimulation without experimental disinhibition, indicating an imbalance between NMDA-mediated excitation and GABA-mediated inhibition in immature cortex. Additionnally, excessive NMDA receptor activation is known to reduce GABA efficacy by Ca^{2+}-mediated dephosphorylation of the $GABA_A$ receptor.[24,87,88] Repetitive tetanic electrical stimulation of hippocampal stratum radiatum induces increased NMDA-receptor activity. Hence, changes in NMDA and, consecutively, GABA receptor efficacy are probably the molecular basis for kindling-induced hyperexcitability.[87]

Three families of NMDA receptor subunits have been identified, termed NR1, NR2, and NR3. The NR 1 subunit is a single-gene product with eight different mRNA splice variants.[89] The four different NR2 subunits (termed NR2A-D) and two NR3 subunits (NR3A-B) are encoded by separate genes. Native NMDA receptors are heterotetramers or pentamers[90,91,92] consisting of multiple NR1 subunits and at least one NR2 subunit. NR2 subunits alone cannot form functional receptors, but have to co-assemble with NR1. Heteromeric NR1-NR2A NMDA receptors dominate in the mature neocortex. In contrast, NR1-NR2B receptors are physiologically expressed during fetal and early postnatal development and display higher peak ionic currents and a six times slower inactivation time constant,[93–95] resulting in an increased Ca^{2+} influx upon activation. Several reports have demonstrated the association of increased NR2B expression with human epilepsy.[69,96–98] Crino *et al.*[96] reported increased NR2B and NR2C, along with decreased NR2A mRNA levels in dysplastic compared with pyramidal neocortical neurons in surgical specimen from epilepsy patients with focal cortical dysplasia. Ying *et al.*[97] and Najm *et al.*[98] have demonstrated differential NR2B expression in areas of cortical dysplasia resected from patients with intractable epilepsy and correlated the density of immunocytochemical staining for NR2B with in situ epileptic activity assessed by subdural grid recordings. Epileptiform field potentials recorded from NR2B-overxpressing dysplastic human neocortex are differentially blocked by the NR2B-specific NMDA receptor antagonist ifenprodil.[69]

Electrical synapses: gap junctions and the influence of pH

Gap junctions are connections between neighbouring neurons made up by large transmembranous proteins that extend through the membranes of both cells, forming ion permeable pores that result in direct electrical coupling of neurons. At least in some brain regions, the conducting properties of gap juctions can additionally be altered by neurotransmitters or modulators. Traditionally, gap junctions have been thought to be of minor importance for neurotransmission in the mammalian brain. However, Somjen *et al.*[99] found that action potentials in dentate gyrus granule cells and CA3 pyramidal cells of the rat hippocampus are highly synchronized without detectable preceding synaptic potential, indicating that direct

electric interactions exist between these neurons. Some recent publications suggest that gap junctions might be involved in the pathophysiology of epilepsy. Naus *et al.*[100] and Elisevich *et al.*[101] found that mRNA and protein levels of the heart-type gap junction protein connexin 43 are increased in temporal lobe neocortex and hippocampus, respectively, of patients with intractable seizures. The patency of gap junctions is regulated by intracellular pH, with intracellular acidosis reducing, and intracellular alkalinization increasing their ion permeability. Additionally, gap junctions are blocked by heptanol, octanol, or carbenoxolone. Intracellular acidification or addition of octanol, heptanol, or carbenoxolone has been shown to reduce epileptiform activity in rat hippocampus,[102–105] whereas alkaline perfusion with ammonium chloride induced spontaneous ictal-like epileptiform discharges in piriform cortex,[106] suggesting that gap junctions indeed play a role in epileptic synchronization. Köhling *et al.*[107] demonstrated that hippocampal gap junctions are involved in the transition from interictal to ictal-like activity in the low-Mg^{2+} model. Gap junction blockers reversibly block low-Mg^{2+}-induced ictal-like activity without abolishing interictal bursts. Intrinsic membrane properties and chemical synaptic transmission are not altered by gap junction blockers.[107] As spontaneous and evoked epileptiform discharges in hippocampal slice cultures chronically exposed to bicuculline are correlated with an increased expression of connexin 43 and connexin 32,[108] activity dependent gap junction protein upregulation may be involved in the epileptogenic process. Finally, besides neuronal electrical coupling, gap junctions connecting glial cells may play a role in hypersynchronously active cortex. Lee *et al.*[109] found increased gap junctional coupling between astrocytes in human epileptic cortex specimen, compared to extrafocal cortex. As glial cells are involved in clearing and buffering extracellular potassium following intense neuronal activity, syncytial coupling of glia may facilitate the spread of 'potassium waves' that lead to increased neuronal synchronization.[110]

Ephaptic interactions and the role of extracellular osmolarity

Ephaptic interactions refer to interaction between neighboring neurons caused by direct electrical field effects. Neuronal activation induces extracellular electrical potential and ion concentration gradients. These result in extracellular currents which direcly influence surrounding cells. The degree of ephaptic electrical interactions between neurons is dependent on the spacial proximity of the cells and is therefore increased when the extracellular space shrinks. Ephaptic interactions are involved in synchronizing neuronal networks and can also influence firing patterns of single neurons.[111] Ephaptic coupling is increased by conditions that induce cell swelling, such as intense neuronal activity, or hypoosmolar extracellular medium: high-$[K^+]_o$-induced seizure-like events in the hippocampal CA1-subfield increase the electrical resistance of the tissue by 10–20%, indicating a reduction of extracellular volume.[112] Hypoosmotic bath solutions increase synchronized burst firing in hippocampal slices. Conversely, media made hyperosmotic by addition of agents that remain restriced to the extracellular space (such as mannitol, sucrose, or dextran) abolish high-$[K^+]_o$-induced seizure-like events in the hippocampal CA1-region and reduce the duration of interictal bursts in CA3, while simultaneously decreasing the electrical resistance of the tissue.[112] The epileptogenic effect of hypoosmolarity (e.g., hyponatremia-induced seizures) and the depressant effect of extracellular hyperosmolarity on neuronal excitability (e.g., hyperosmolar coma diabeticum) are in line with common clinical observations.

The role of extracellular potassium in network synchronization

Increased extracellular potassium concentration. There is good evidence for the crucial involvement of synaptic transmission in interictal burst discharges. However, seizure-like events in vitro are seen under experimental conditions that preclude neuronal communication via chemical synapses, suggesting that interictal spikes and focal seizures are triggered by different mechanisms. Blockers of synaptic transmission abolish high-$[K^+]_o$-induced interictal-like bursts in hippocampal slices, but do not inhibit the initiation of seizure-like events in the CA1-subfield.[113] Lowering of extracellular calcium concentration ($[Ca^{2+}]_o$) to values less than 0.2 mM blocks synaptic transmission, because calcium influx into the presynaptic terminal is the triggering stimulus for the release of synaptic vesicles. Despite this block, low-$[Ca^{2+}]_o$ induces spontaneous seizure-like events in CA1, suggesting that mechanisms other than synaptic transmission are sufficient to synchronize a neuronal network.[114] Yaari *et al.*[115] showed that washout of $[Ca^{2+}]_o$, as well as transient hypoxia, are accompanied by a rise in extracellular potassium concentration ($[K^+]_o$) that precedes the onset of seizure-like events. Lian *et al.*,[116] using the same model, demonstrated that this nonsynaptic synchronization between CA3 and CA1 region, mediated by a slowly diffusing 'wave' of increased extracellular potassium, persists even when the axonal connections between CA3 and CA1 subfields are physically transected. Insertion of a thin water-impermeable film into the transsection site abolished synchronization. In another study, Voskuyl *et al.*[117] demonstrated that one type of 4-aminopyridine-induced spontaneous discharges in hippocampal slices slowly propagates from CA3 to CA1 and cannot be suppressed by blockade of synaptic transmission. Even transsection of the Schaffer axon collaterals that connnect CA3 and CA1 pyramidal neurons, does not block propagation of these discharges as long as stratum moleculare is preserved.[117] These data indicate that potassium homeostatis is likely to play a crucial role in seizure initiation. The amplitude of a potassium current with given membrane potential and membrane conductance is dependent on the potassium equilibrium potential ('Nernst potential'), which is determined by the relation between extracellular ($[K^+]_o$) and intracellular potassium concentration ($[K^+]_i$). The electrochemical gradient for repolarizing potassium currents is increased by low $[K^+]_o$ and decreased by high $[K^+]_o$. Accordingly, changes of $[K^+]_o$ effectively change both the excitability of single cells and the behaviour of neuronal networks. There is extensive evidence that elevated $[K^+]_o$ induces epileptiform activity[118–120] and increases the repetition rate of EFP.[121,122] Jensen *et al.*[123] found an increased proportion of intrinsically bursting neurons in the hippocampal CA1-region with elevated $[K^+]_o$. Besides reducing the amplitude of repolarizing potassium currents, elevated $[K^+]_o$ leads to direct neuron depolarization.[124] Korn *et al.*[118] showed that increased $[K^+]_o$ is accompanied by increased intracellular

chloride concentration ($[Cl^-]_i$), probably by activation of a K-Cl co-transporter, with consecutive reduction in the amplitude of inhibitory GABA-A mediated chloride currents. Extracellular potassium ions released from the intracellular compartment during neuronal activity are normally cleared by neuronal and glial K^+ reuptake. Excessive elevation of $[K^+]_o$ leads to osmotic glial swelling[119,120] with reduction of the extracellular volume and increased ephaptic interactions between neighbouring neurons (see above). These findings have major implications for the pathophysiology of epileptic seizures: during excessive neuronal activity, $[Ca^{2+}]_o$ decreases to values incompatible with synaptic transmission.[110] Maintenance of long-lasting epilepitc acitvity as it occurs, for example, during status epilepticus, is therefore very unlikely to be dependent on synaptic mechanisms. As extracellular potassium concentration increases to values above 10 mM during seizures, impaired potassium homeostasis may be one of the key mechanisms leading to prolonged ictal discharges.

Reduced extracellular potassium concentration

Elevation of $[K^+]_o$ during neuronal activity is normally followed by a transient reduction of $[K^+]_o$ below the physiological baseline ('K^+ undershoot',[121,122] possibly by excessive Na^+-K^+-ATPase activation. The effect of reduced $[K^+]_o$ on epilptiform activity is not yet well characterized, but several studies report an epileptogenic effect of low extracellular potassium.[36,123] The epileptogenic effect of low $[K^+]_o$ may be related to increased GABA-B mediated potassium outward currents leading to recruitment of low-threshold calcium channels which are inactivated at normal resting potential.

Inhibition

Gamma-amino butyric acid (GABA) is the major inhibitory neurotransmitter in the mammalian brain. Two major types of GABA receptors play a role in the neocortex and hippocampus, termed GABA-A and GABA-B receptors. (GABA-C receptors are encountered in the retina and are not further discussed here).

GABA-A mediated inhibition

The cortical glutamatergic principal neurons innervate GABA-ergic interneurons, which in turn inhibit the original pyramidal cell ('recurrent inhibition'), and surrounding excitatory neurons ('lateral inhibition'), thus restricting neuronal activity temporally and spacially. GABA binding to postsynaptic GABA-A receptors opens chloride (Cl^-) selective ion channels. As the chloride equilibrium potential ('Nernst potential') at baseline conditions is negative to the resting membrane potential (RMP), chloride ions will enter the cell and cause a hyperpolarizing, inhibitory postsynaptic potential (IPSP). In rodent hippocampus, as well as in human and rodent neocortex, application of substances that block GABA-A-ergic inhibition, such as bicuculline or penicillin, leads to synchronized epileptiform bursts driven by large and long-lasting inhibitory synaptic conductances.[10–13,35,124–126] In the neocortex, these bursts are initiated within small, spatially discrete subpopulations of cells[127] and then spread to the disinhibited surrounding cortex. The role of lateral inhibition in confining neuronal activity to a limited portion of cortex has been demonstrated by Chagnac-Amitai and Connors:[128] using horizontal arrays of extracellular electrodes, they showed that neuronal activity evoked by focal electrical stimulation remained restriced to a narrow strip of cortex at control conditions, whereas disinhibition by application of graded concentrations of bicuculline first increases the spatial spread of acitvity and finally gives rise to synchronized evoked epileptiform activity. Interestingly, epileptiform activity occurred at bicuculline concentrations that were still insufficient to completely abolish IPSPs. This finding suggests that minimal disinhibition can already induce epileptiform activity. Although these findings derived from in vitro models are dependent on pharmacological manipulations, they are of major relevance for the initiation and spread of epileptic acitivity under clinical conditions: Strowbridge *et al.*[129] showed that inhibitory synaptic potentials are reduced in the vicinity of cortical lesions resected from patients for treatment of intractable epilepsy, indicating that loss of inhibition is involved in the pathophysiology of epileptogenic foci. It remains unclear, however, whether disinhibition constitutes an underlying cause for epileptiform activity, or merely one step in a pathophysiological sequence that finally leads to seizures: repetitive GABA-A-receptor activation during long-lasting neuronal firing is associated with chloride influx into neurons. As extracellular chloride concentration is reduced, the chloride equilibrium potential ('Nernst potential') is shifted to more positive values, with IPSPs decreasing in amplitude. As soon as the chloride equilibrium potential becomes more positive than the resting membrane potential, GABA-activated chloride currents become excitatory, leading to a breakdown of GABA-A-receptor mediated inhibition. Impaired recurrent inhibition interferes with the termination of burst discharges, facilitating ictal transition, whereas impaired lateral inhibition allows spread of seizure activity. The epileptogenic effect of reduced extracellular chloride concentration ($[Cl^-]_o$) has been demonstrated by Chamberlin and Dingledine:[130] reduction of $[Cl^-]_o$ from the physiological 136 mM to 53 mM induced spontaneous interical bursts in hippocampal slices, which was associated with a +10 mV positive shift in the chloride reversal potential. Recent experiments using intraoperative microdialysis in epileptogenic foci of patients undergoing epilepsy surgery have indeed demonstrated extracellular chloride concentrations which are incompatible with intact inhibition (Speckmann, unpublished observations).

GABA-A mediated inhibition is also related to the anticonvulsant action of benzodiazepines. Benzodiazepine binding to its binding site on the extracellular domain of GABA-A receptors facilitates GABA-ergic inhibition by increasing chloride influx. Long-term exposure to benzodiazepines, however, induces secondary changes in the efficacy of the GABAergic system that have epileptogenic effects. Davies *et al.*,[131] for example, showed that long-term incubation of rat hippocampal slices with clonazepam induces spontaneous epileptiform bursts, which are associated with a reduced duration of the post-spike-train afterhyperpolarization. This is the putative basis for benzodiazepine withdrawal seizures.

GABA-B mediated inhibition

GABA-B receptors are located pre- and postsynaptically and induce G-protein mediated opening of potassium channels.[132,133] The hyperpolarization caused by GABA-B receptor activation has a slower onset and longer duration than the 'fast' GABA-A inhibition. GABA-B mediated IPSPs therefore contribute to the late phase of the afterhyperpolarization (AHP)

following epileptiform bursts and determine its duration. Presynaptic GABA-B receptors inhibit synaptic neurotransmitter release.

Data about the involvement of GABA-B receptors in epileptogenesis are ambiguous: Asprodini *et al.*[134] report that in vivo kindling of rats reduces the sensitivity of presynaptic GABA-B receptors as assessed by the EC50 of the GABA-B receptor agonist baclofen needed to depress EPSPs, suggesting a protective role of GABA-B receptors against excessive excitatory activity. On the other hand, presynaptic GABA-B receptors can enhance epileptiform activity by reducing synaptic GABA release by interneurons.[135] Sutor *et al.*[136] report a concentration-dependent differential effect of GABA-B receptor antagonists on bicuculline-induced epileptiform activity in rat neocortex, with low concentrations enhancing, but higher concentrations suppressing stimulus-evoked epileptiform discharges. GABA-B receptor activation by baclofen has been shown to induce a long-lasting potentiation of evoked population spikes and spontaneous epilepitform discharges.[137] Low-Mg^{2+} and 4-aminopyridine induced interictal-like epileptiform activity in the hippocampus is reversibly transformed to ictal activity by application of baclofen.[138,39] These findings suggest that interictal discharges may be to some degree protective against ictal transition. Reducing the repetition rate of interictal discharges by enhancing the GABA-B-mediated late phase of the burst afterhyperpolarization might be a mechanism involved in seizure generation, possibly by synchronizing large cell populations and/or by recruiting cation conductances that are otherwise incativated at resting membrane potential, such as the hyperpolarization-activated inward current (I_h) or low-threshold Ca^{2+} channels.[140] A similar interaction between GABA mediated inhibition and slow conductances activated by hyperpolarization has been proposed as the underlying mechanism for the generation of generalized spike-wave seizures through thalamocortical loops.[141]

Neuromodulators and second messenger mechanisms

Metabotropic glutamate receptors

Metabotropic glutamate receptors (mGLU) are second-messenger coupled receptors that have diverse effect on neuronal excitability and are likely to be involved in neuronal plasticity. Some evidence suggests a role of mGLU receptors in epileptogenesis.[142,143] Pasti *et al.*[144] have demonstrated that mGLU receptors mediate glutamate release from astrocytes, which might play a role in seizure propagation. However, several studies have shown that some mGLU subtypes have anticonvulsant effects as well. For example, mGLU types I and II reduce the ampltidute of AMPA- and NMDA-receptor mediated EPSPs by a presynaptic mechanism.[145,146] This may be a means of regulating excitatory transmission during massive excitation. The relevance of these various data for human epilepsy is still unknown and requires further investigation.

Adenosine receptors

Adenosine is an endogenous neuromodulator that is released following excessive metabolic activity and exerts inhibitory effects on neurons. As extracellular adenosine concentration rises markedly during seizures, its depressant effects on excitability and extitatory transmission may be involved in seizure termination. Adenosine and other purinoreceptor agonists suppress epileptiform activity in the CA3 region of the hippocampus by a presynaptic mechanism.[147] Blockers of the adenosine receptor, such as caffeine and other methylxanthines, have well-known stimulating effects on cortical activity. In the guinea pig hippocampus in vitro, caffeine induces epileptiform discarges.[148] Moreover, blocking effects on adenosine receptors have been shown to be involved in the epileptogenic effect of reduced extracellular magnesium concentration.[29]

Acetylcholine (ACh) receptors

Muscarinic ACh receptors

Slow excitatory postsynaptic potentials (EPSPs) have been identified in rat neocortical slices which are antagonized by muscarinic acetylcholine receptor antagonists and enhanced by cholinesterase inhibitor,[149] suggesting a role of muscarinic acetylcholine receptors in regulating excitability. In cat visual cortex, acetylcholine induces depolarization by reducing the conductance of potassium channels.[150] Application of muscarinergic substances such as pilocarpin causes severe seizures in rodents.

Nicotinic ACh receptors

Activation of the nicotinic ACh receptor–ion channel complex by ACh leads to fast unspecific ion influx through a nonselective cation channel. The pharmacological properties of nicotinic ACh receptors are dependent on their subunit composition which is differentially distributed throughout the brain. The role for the pathophysiology of epilepsy is still unclear from a mechanistic standpoint. Genetic studies, however, revealed that a missense mutation in one nicotinic ACh receptor subunit is associated with nocturnal frontal lobe epilepsy in an Australian family.[151]

Noradrenergic receptors

Noradrenaline (norepinephrine) (NA) exhibits differential modulatory effects on epileptiform activity. Via alpha-1 receptors, NA blocks low-Mg^{2+}-induced epileptiform activity in the entorhinal cortex.[152] In rodent dentate gyrus and neocortex, in contrast, NA exerts proconvulsant effects mediated by beta receptors.[149,152] Beta receptor activation induces prolongation of low-Mg^{2+}-induced ictal discharges, probably by activation of a slow synaptic cation current.

Dopamine receptors

Co-application of dopamine (DA) and NMDA enhances NMDA-induced membrane depolarization and action potential firing. Co-application of DA and glutamate, however, decreases fast synaptic potentials mediated by non-NMDA glutamate receptors.[153] From a neurocognitive perspective, this might represent the underlying mechanism of dopamine as regulator of the 'signal-to-noise ratio' in the neocortex. The proconvulsant properties of dopamine antagonists, such as neuroleptic drugs, may be related to enhancement of AMPA/kainate receptor mediated lateral spread of epileptiform activity.

Neuropeptide Y

Neuropeptide Y (NPY) and two neuropeptide Y agonists ((P)YY(3-36) and 1-4-(6-aminohexanoic acid)-25-36-([ahx(5-24)])-NPY) inhibit low-$Mg2^{+}$- and picrotoxin-induced interictal epileptiform discharges in rat hippocampal slices in vitro by inhibiting glutamatergic synaptic transmission, suggesting a protective role of NPY against epileptogenic hyperactivity.[154]

Nitric oxide

Nitric oxide (NO) is synthetized by nitric oxide synthase (NOS) from L-arginine.[155] The neuronal form of NOS (nNOS) is linked to the postsynaptic density protein complex[156] and is activated by increase of intracellular free Ca^{2+}, mediated by Ca^{2+}-calmodulin, which enters the cell through NMDA-receptor channels and voltage-gated Ca^{2+}-channels.[157–160] NO affects neuronal excitability via a multitude of actions that are mediated by guanylate cyclase activation[161–163] and S-nitrosylation of target proteins.[164,165] Most effects of NO are excitatory: As a 'retrograde transmitter', NO increases presynaptic glutamate release after crossing the synaptic cleft by diffusion.[157,167] Besides, it facilitates voltage-gated Na^{+} channels,[168] and decreases $GABA_A$ repeptor mediated currents.[169] On the other hand, NO also exerts some depressant actions on excitability: it dampens excitatory post-synaptic potentials (EPSPs) by decreasing AMPA-receptor[170,171] and NMDA-receptor[172–174] mediated currents, thus providing a 'negative feedback' following synaptic activation. It may also decrease membrane excitability by inducing tonic activation of K^{+} channels.[175]

Other neuromodulatory effects on epielptiform activity

Activation of mu opioid receptors in the ventral, but not in the dorsal hippocampus induces triggered and spontaneous epileptiform bursting.[176] Pregnanolone, a metabolite of progesterone, depresses the amplitude of population spikes in the CA1 region of the hippocampus, probably by enhancing GABA-A receptor function.[177] This might have implications in regard to catamenial epilepsy. Ethanol reversibly suppresses the duration of NMDA-receptor mediated synaptic responses, implying that it exerts anticonvulsant properties when acutely applied.[178] Long-term exposure to ethanol, in contrast, leads to up-regulation of NMDA-receptor NR2B subunits, thereby increasing the potency of NMDA receptors.[179] This may be the mechanism underlying epilepsy induced by chronic alcohol intake.

147 In vitro cytochemical studies in epilepsy

JA González-Martínez, CQ Tilelli, and IM Najm

Introduction

Initially, data about the histology of epileptic tissue started with histochemical descriptions in tissue processed by relatively simple techniques such as cresyl-violet, Nissl, hematoxylin-eosin and Golgi stainings.[1–3] The current epileptic tissue research includes not only these studies, but also single-cell injection of markers that fill all the projections of the cell,[4,5] immunohistochemistry of many proteins[6–8] and *in situ* hybridization that shows expression of mRNA.[9,10] Those techniques provide not only morphological data, but also elucidate cell morphology, type, functionality, chemistry and role in the epileptic brain.[11]

In this chapter, we will review the general findings in cytochemical studies in epilepsy research and their contribution in the understanding of pathophysiological mechanisms of epileptogenicity.

In vitro cytochemical studies in temporal lobe epilepsy

More than a century after the first histological description of sclerotic hippocampus associated with temporal lobe epilepsy (TLE),[3] much has been added to the description of the tissue, but the mechanisms by which hippocampal sclerosis (HS) occurs and its specific role in seizure initiation and propagation is still uncertain.

Hippocampal sclerosis

Hippocampal sclerosis (HS) is characterized by extensive loss of pyramidal neurons from areas 1, 3, and 4 of the Ammon's horn (CA1, CA3, and CA4, respectively), as well as neurons in granular, polymorphic and molecular layers of dentate gyrus (DG).[3,12] Granular cells of DG suffer dispersion and marked plasticity, which includes primarily a simplification of its dendritic arbor, loss of dendritic spines and nodulation of dendrites.[2,13,14] Cytochemical studies showed the loss of dentate gyrus (DG) interneurons, supposedly GABAergic, with plasticity of the remaining ones.[15–17] In addition, synaptic terminals coming from granular cells of DG and probably also from the supramammilary tract sprout their connections through the inner third of DG molecular layer.[18]

Hippocampal-related areas such as amygdala and temporal lobe cortices can also have cell loss in different magnitudes, and although this is frequently found in association with HS, it can also be independent.[19] Indeed, amygdala damage may contribute to seizure propagation, as this structure receives monosynaptic inputs from large areas (frontal and temporal cortices), and spreads the signals to its outputs by activating dense intradivisional connections (extrapyramidal system, cortex and hippocampal formation).[18] Hystological studies revealed that the volume of amygdala reduces as a function of lifetime seizure number, and also argue that the presence of fear in seizures may be an indication of amygdala participation.[18]

Hippocampal sclerosis and mossy fiber sprouting

One of the most striking findings from cytochemical studies in HS tissue is the mossy fiber sprouting (MFS), which was first described in animal models of epilepsy and later confirmed in human specimens by in vitro cytochemical studies.[7,20] This intense reorganization of excitatory connections in the hippocampal circuitry can be easily visualized by TIMM's staining, a cytochemical technique that enhances zinc-containing synaptic terminals,[21] which are supposedly linked to excitatory neurotransmission. The dentate gyrus (DG) of sclerotic hippocampus presents a zinc-positive region in the inner third of molecular layer, which is completely absent in the normal hippocampus.[20]

Hippocampal neuroanatomy is very well characterized, and the MFS findings with HS attracted so much attention to hippocampus as a probable seizure-causative structure in epilepsy that for decades the study of other related structures was put aside. Interestingly, the first theories that considered MFS in HS and its relation to seizure initiation and propagation claimed that loss of inhibitory interneurons and/or the recurrent excitatory pathway in the DG would contribute to the hyperexcitation of the hippocampus.[22,23] Later, evidence both in animal models and human studies showed that the DG, in spite of hyperexcitation, presented a tonic hyperinhibition, and that the collapse of such inhibition would be responsible for seizure initiation.[19]

Much work remains to further illustrate how such circuitry alterations contribute to seizures in epileptic patients. There is evidence suggesting that modifications occurring in HS are an acute process, and seizures do not contribute to damage of remaining neurons.[24,25] Mathern *et al.*[24] based this assumption on results from children's HS compared to autopsy cases, where they confirmed hippocampal sclerosis and found no evidence of increased dead neurons (using TUNEL staining, a technique that marks neuronal apoptosis). Additionally, some studies utilizing immunocytochemistry to PSA-NCAM and GAP-43 (developmental related molecules) suggested that

sprouting is an ongoing event in sclerotic hippocampus from TLE patients, as both molecules are increased in the molecular layer of the DG in this tissue.[26,27]

Neurotransmitters and receptors

Characterization of neurotransmitters and receptors in the epileptic area can indicate the relation between excitation and inhibition in the tissue. The differential expression of many excitatory receptors is already described in HS.[9] Ying *et al.* found NMDA-R1 receptor (NR1) upregulated in both granular cells and molecular layer of DG in sclerotic hippocampus as compared to nonsclerotic hippocampus of epileptic patients with TLE.[28] In contrast, Mathern *et al.* did not find NR1 protein expression increased in HS, but its mRNA. In addition, they also found that other subunits of glutamate receptors of AMPA and NMDA families were increased, both mRNA and proteins (GluR1-3 and NR2b).[9] They discuss the fact that other works found decreased expression in the same proteins/mRNAs, and point to the possibility that these differences can be a result of presence or absence of correction of the quantification per neuron in HS, as there are much less neurons in sclerotic hippocampus that survive and are able to express proteins as compared to a normal, nonsclerotic hippocampus.

Different receptor compositions can result in different patterns of channel activation and inactivation, what could directly impact on neurotransmitter-mediated neuronal response. Indeed, heteromeric combinations of NMDA receptors (NR1 plus NR2B) result in higher and slower decay currents when compared to a channel composed exclusively by NR1.[29,30]

There is a 100% increase in AMPA receptors binding and a 50% decrease in NMDA receptors binding in DG of human HS.[31] This could indicate a differential expression of receptors or a different affinity of the receptors to its binding molecules. In contrast, studies in a rat model of TLE show a reduction of AMPA binding in hippocampus.[31] In a study of MTLE granular cells of DG, glutamate currents were found prolonged and this phenomenon would be related to NMDA receptors activation.[5] They suggest that the dendritic alterations usually seem in DG granular cells may have a role in this excitatory facilitation, based on the fact that cells growing in a medium containing bicuculline develop epileptic tissue-like characteristics.[5]

According to in vitro cytochemical studies, inhibitory neurons can be extensively affected and modified in epileptic tissue. Parvalbumin (PV)-positive cells are reduced in MTLE patients, compared to autopsy hippocampi.[15] The surviving cells in HS receive the majority of inputs probably excitatory (asymmetric synapses as seen by electron microscopy) and send inhibitory (symmetric synapses) connections to pyramidal neurons of the Hippocampus.[15] In addition to PV-positive, the number of calbindin (CB)-positive neurons is also reduced in HS.[16] These interneurons are dispersed in the DG granular layer and this dispersion is accompanied by proliferation of PV- and CB-positive terminals, as well as in GABA transporter 1-positive terminals, mainly in hippocampi presenting stronger sclerosis.[16] Additionally, there are chandelier terminals in the granular cells layer of DG, which are absent or less complex in nonsclerotic hippocampi. Chandelier terminals are synaptic buttons complexes localized in the axon of pyramidal cells, proximal to cell body, and have strong inhibitory action.[17] The same increased complexity of synaptic terminals is found in PV-positive basket formations around surviving neurons at the border between CA1 and subicullum areas.[16] Interestingly, cytochemical studies revealed that microregions of the DG maintained cellular density but lacked inhibitory terminals, maybe resulting in hyperexcitatory microregions. Additionally, there are evidence that $GABA_B$ receptor histology in non-sclerotic hippocampi closely matches hippocampal cytoarchitecture, but it is down regulated in HS.[32]

Maglóczky *et al.* also report loss of CB-positive neurons in TLE, but additionally describe that the remaining cells have larger soma, acquire somatic spines and present invaginated nuclei (indicative of been metabolically very active). On the other hand, those cells are extensively surrounded by glia, what can bock the formation of synapses.[33] In the same work, they report that calretinin (CR)-positive neurons are also lost, and the remaining ones also present nucleus invagination and are surrounded by glial processes.[33] CR-positive terminals distribution is expanded in the DG, and the authors suggested that these terminals are probably coming from the supramammillary tract, indicating a second source of excess excitation of DG cells in addition to de MFS.[33] Maybe even more interestingly then the compensatory sprouting described above, substance P receptor (SPR)-positive neurons change their position, migrating from inside the hilus of DG to the molecular layer.[33] These neurons also present a deeply invaginated nucleus and a cell body partially covered by glial processes.[33] Substance P containing neurons in MTLE have also been described by de Lanerolle *et al.* (2003),[34] with concomitant sprouting of substance P-containing fibers to the DG.

In vitro studies in neocortical epilepsy and malformations of cortical development

Malformations of cortical development (MCD) are one of the main causes of epilepsy in humans.[35–37] They include many pathologies, among them polymicrogyria, paquigyria, hemimegalencephaly, tuberous sclerosis, and focal cortical dysplasia (FCD).[38,39] In this review, we will focus our discussion in in vitro cytochemical findings in human FCD.

FCD are characterized by a disruption of the normal lamination of the cortex that can vary in intensity, ranging from a light disruption of lamination with normal-appearing neurons to a strong loss of lamination, usually accompanied by the appearance of dysmorphic and misoriented neurons, neuronal clustering, giant neurons and balloon cells (BC).[1,40,41] In addition, heterotopic neurons and gliosis are observed in the white matter,[1,40,41] sometimes concomitant with a lack of myelin in that region.[42] Giant neurons in FCD apparently have a normal content of cytoplasmatic organelles[43] and, as normal pyramidal cells, receive numerous symmetric synapses in cell body and proximal dendrites.[43] There is evidence for morphological alteration of both excitatory and inhibitory neurons in FCD.[6,44,45]

FCD may be a consequence of erroneous migration of stem cells, or their maturation, programmed cell death that also

occurs in ontogenesis, or maybe even a combination of various factors.[46–48] Based on morphological studies using antibodies against NeuN, a specific marker for neurons, Andres *et al.*[40] suggested that some characteristics of the dysplastic cortex resemble prenatal cortex of primates and humans and propose that FCD would be a defect occurred in late phases of development. This data is partially in agreement with Mischel *et al.*[49] who proposed a classification of the MCD with a grading system, based on the probable time-frame when the abnormality of development takes place, suggesting that mild FCD (or FCD type I) would be in late development and FCD with BCs would be severe (or FCD type IIb), happening in early developmental phases.[36]

The study of protein expression in FCD is very useful in order to help to highlight dysmorphisms in the disrupted cortex.[6] Using immunocytochemical studies (with primary antibodies for MAP2, neurofilaments, GFAP, PV, CB, and CR), Spreafico *et al.*[48] suggested that the lesion observed in MRI does not correspond exactly to the area of dysplasia, but is included in it. Additionally, an abnormally increased expression of neurofilaments can be observed in the areas where FCD is more evident on MRI. MAP1B is increased in dysmorphic neurons from FCD, and it is abundant in immature brain, declining with maturation in the normal brain, thus indicating that morphological remodeling may be an ongoing process in FCD.[6,50] Other proteins that are usually expressed during brain development and are downregulated in mature neurons such as vimentin, nestin, and SMI311 (marker for nonphosphorilated filaments), are expressed in BCs from FCD, tuberous sclerosis and hemimegalencephaly.[6,47] mRNA of vimentin, nestin, neurofilament, peripherin, and α-internexin are also suggestive of neuron immaturity and are detected in a subset of neurons in FCD tissue.[37]

In malformations of cortical development, the histological appearance and the location of balloon cells suggest that they are developmentally immature. By using silver impregnation technique, Derosa *et al.*[51] had shown the presence of nucleolar organizer regions that were believed to be involved in cell proliferation. Additionally, transcription of genes for nestin and vimentin were enhanced in the balloon cells.[37] Over the past several years, much more attention has been focused on nestin, a marker for neuronal progenitor cells.[52–55] Recently, human hematopoietic stem cell antigen AC133, also called CD133, was shown to be expressed in both hematopoietic and neuropoietic cells.[56] CD133 positive cells are capable of neurosphere initiation, self renewal, and multilineage differentiation at the single cell level.[56] Therefore, CD133 has been used to identify neural stem cells in the human brain.[56–58]

Balloon cells were found to be immunoreactive to CD133, nestin, Bcl-2, Tuj1, vimentin, and GFAP. Confocal double labeling analyses also showed that balloon cells were dual immunopositive for CD133/nestin; CD133/GFAP; CD133/Bcl-2, and nestin/GFAP (Figure 147.1).

The expression of CD133 protein in BCs may suggest that these cells fail to mature fully and therefore continue to express embryonic genes. Subsequently, these immature cells may lack some of the cellular machinery for migration. This may explain at least in part the localization of the BC in the white matter and gray/white matter junction.

Using organotypic slice preparation, our group identified the presence of BrdU uptake in neocortex of patients with epileptic cortical dysplasia, suggesting increase cell proliferation in epileptic cortical dysplastic samples. It is unknown if the increment in BrdU uptake observed in the epileptic samples corresponded to neurogenesis (Figure 147.2).

We also found the presence of Tuj1 expressing cells (a marker for immature neurons) in the subventicular zone of dysplastic epileptic patients (Figure 147.3a). The immature neurons were organized in chains, suggesting the presence of migration. Additionally, in the same tissue samples, BrdU positive cells double-labeled with nestin were presented, suggesting stem cell proliferation and probably differentiation (Figure 147.3b).

There is an extensive modification of neurotransmitters receptors in FCD.[28,59] For example, NR2A/B and NR1-1a, 1b, 2a, and 2b are over-expressed in FCD tissue, more specifically in dysplastic neurons.[60] Other glutamate receptor subunits are distributed equally in both FCD and normal cortex, such as NR1-3a, 3b, and 4a.[28] This abnormal expression of glutamate receptors in FCD may be part of the mechanism of epileptogenesis in this tissue. In microdissected cells of FCD tissue, where RT-PCR was used in order to identify mRNA differential expression, there is a reduction in glutamate receptors subunits Glu R1 and NMDA-R2A, and GABA receptor subunits GABA α1, α2, β1, and β2.[59] Increased expression was described for Glu R4, NR2B, and NR2C glutamate subunit receptors.[59]

In vitro cytochemical studies also indicated differential expression and interaction between glutamate receptor subunits and related proteins. Ying *et al.*[61,62] found an increased expression and co-assembly of NR1, NR2B, and PSD-95 in epileptic versus nonepileptic cortical samples from patients with cortical dysplasia and epilepsy who underwent resective surgery. Interestingly, in another set of experiments using ICC, the same group found no change in NR1 quantity in epileptic cortex from FCD, but increased expression of NR2A/B in dysplastic area.[44,63] These results suggested that these alterations and apparent differential interaction between NR1 and NR2A/B may be an important mechanism of epileptogenesis in FCD.[61] Electrophysiology of FCD tissue showed that normal appearing neurons have characteristics of neurons from control cortex, but dysmorphic neurons have lower capacitance, increased resistance and decreased time constant.[64] On the other hand, giant neurons are more excitable, as they present increased capacitance, decreased resistance and longer time constant,[4,8] and need prolonged time to recovery from desensitization to NMDA.[8] Cepeda *et al.*[8] found that BCs are not excitable at all, and suggested that their presence could lead to modification of the structure of surrounding cortex, thus collaborating to the net excitability of the tissue.

Advanced molecular techniques such as proteomics and cDNA arrays are becoming important tools in the investigation of FCD and other types of epilepsy. Nonetheless, although some first works in this area have been successful in finding variation in various molecules in FCD as compared to normal cortex, they are not able to discuss in details their findings, probably because of the quantity of molecules with altered expression as well as the fact that many of those molecules have their role in nervous system poorly understood or apparently not related to mechanisms that could lead to epileptogenicity. Kim *et al.*[65] found seven genes that had modified regulation in FCD compared to normal cortex, three of them up-regulated and 4 down-regulated, showing that those

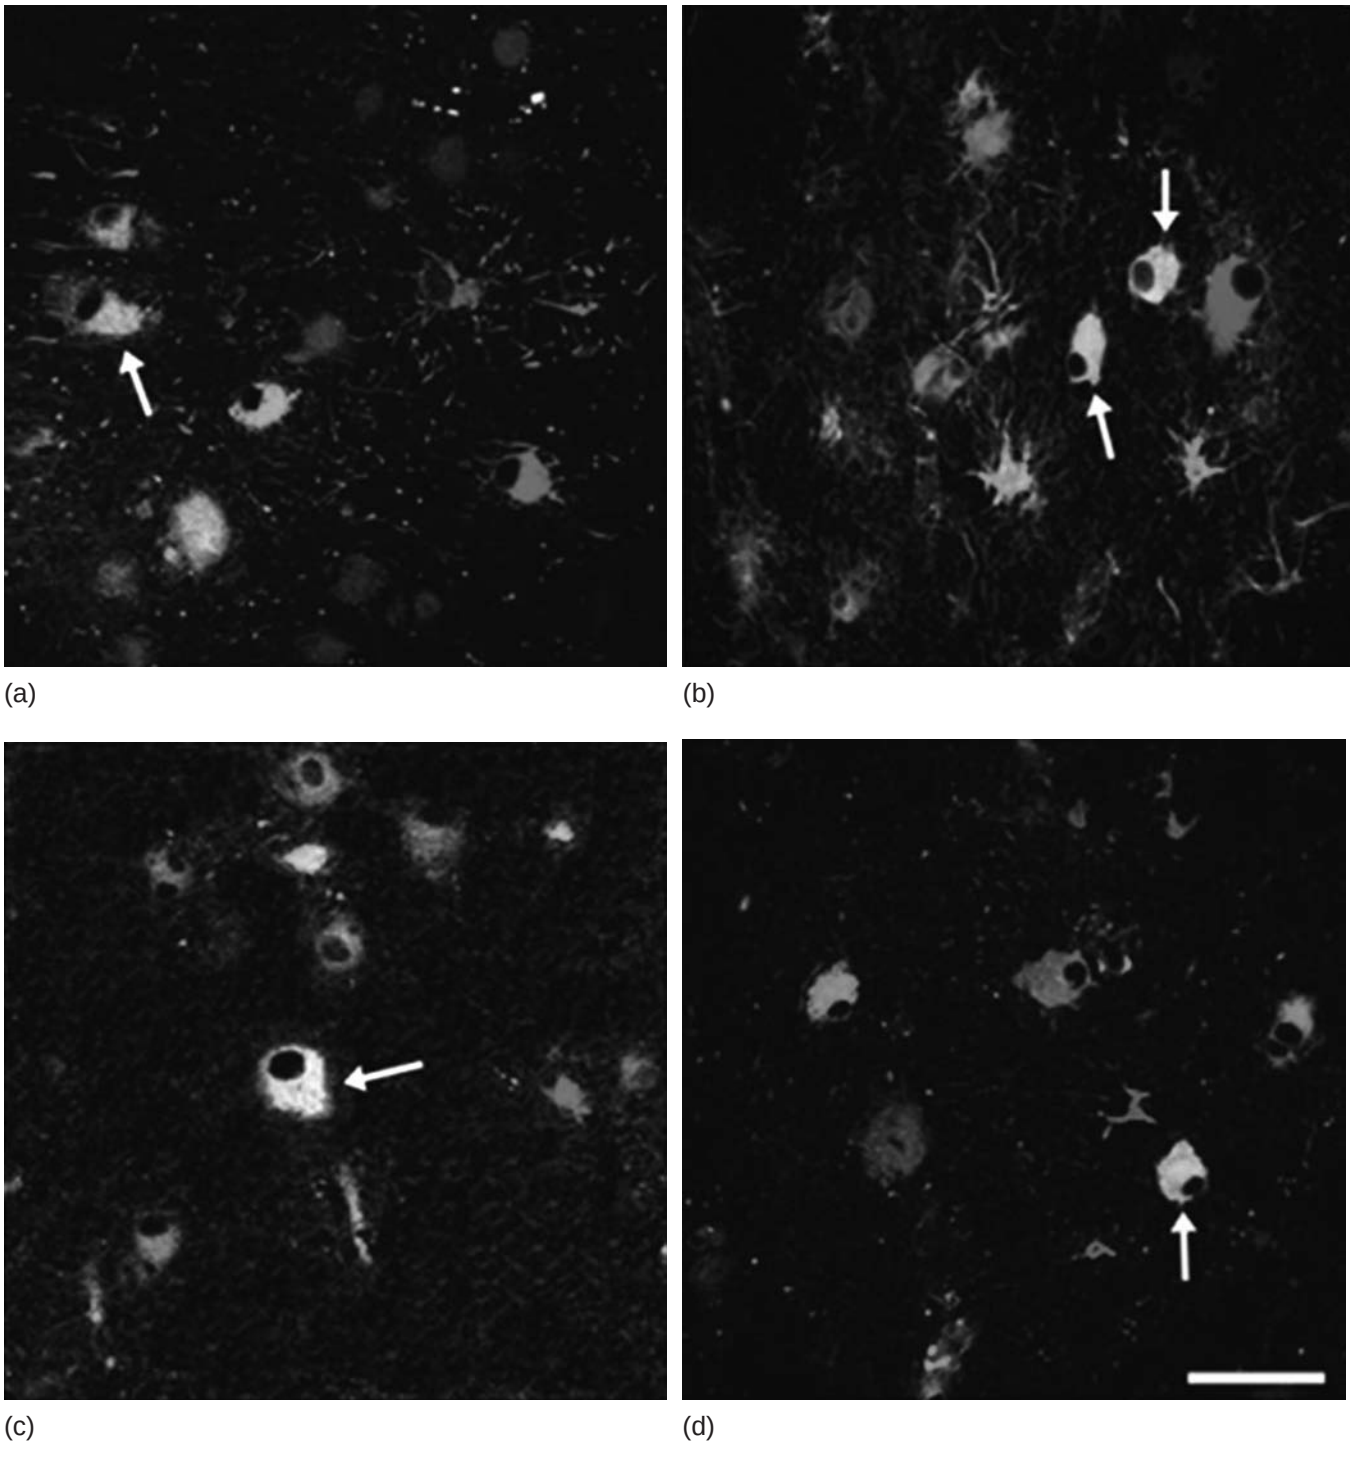

Figure 147.1 Colocalization of antibodies against CD133 with antibodies to intermediate filament proteins (nestin and GFAP) in balloon cells by confocal microscopy. Co-expression of CD133 with either nestin or GFAP was clearly detected in the balloon cells (a and d). The presence of singly-labeled CD133, nestin, or GFAP were also observed. Co-expression CD133 and Bcl-2 in a subset of balloon cells is shown in c. A population of balloon cells is shown to be immunoreative to both nestin (red) and GFAP (green) (b). Double staining for CD133 and MAP2 failed to reveal any co-locolization of these proteins in the balloon cells. (See Color plates.)

molecules may have a potential role in cascades that are related to epileptogenesis, as they participate in neurogenesis, apoptosis and migration-regulation processes. Another study using proteomics showed nine molecules differentially regulated in dysplasic temporal lobe neocortex.[66] Among them, the authors selected two to be discussed, the mitochondrial type Mn-superoxide dismutase, that takes place in antioxidant processes, and the glycerol phosphate dehydrogenase, which is a multifunctional protein involved in triglycerides metabolism.[66]

The comparison between FCD with other types of MCD may give hints of the underlying mechanisms of epileptogenicity in those pathologies. For example, hamartin- and tuberin-expressing genes TSC1 and TSC2, respectively, are found altered in tuberous sclerosis pathology.[67] These proteins are part of a tumor-suppression mechanism, related to cell

growth and proliferation regulation.[68,69] Both TSC1 and TSC2 genes role were investigated in FCD, and indicate that FCD with BCs is characterized by a high incidence of TSC1, but not TSC2.[68,69] Interestingly, TSC2 is more frequently found altered in familial tuberous sclerosis pathology, while TSC1 alterations are found related to sporadic incidence.[69] When comparing immunocytochemistry in FCD type IIb, hemimegalencephaly and tuberous sclerosis tissue, Fauser *et al*. described similarities in CD34 (neural development marker), GFAP (glia marker), and neurofilament (neural marker) expressions in all groups.[70] Based on similarities between TS and FCD, Mackay *et al*.[71] suggested genetic counseling to patients presenting FCD with balloon cells. Crino *et al*.[6] suggested that extensive histological similarities can be found when comparing hemimegalencephay and FCD, with disorganized cortical lamination and presence of white matter heterotopias and BCs, the main difference been the area committed in the pathology.

Glia in epilepsy

Studies that analyzed the role of glial cells in epileptic tissue point to an important role of those cells in seizure initiation and maintenance.[72–74] Gliosis is frequently found in epileptic tissue.[2,11,73] There is evidence that glia in epileptic tissue is not able to maintain K^+ and Ca^{++} homeostasis.[72,75,76] In MTLE tissue, glial cells from DG hilus have a reduction in the number of K^+ channels, what could contribute for the decreased K^+ conductance in specific regions in the epileptic brain.[76–78] Glial cells from FCD may also have their electrophysiological characteristics modified, suggesting inability to maintain ionic balance in epileptic tissue, thus maybe contributing to its hyperexcitability.[76] Potassium homeostasis may be important in neurons excitability, as its increased concentration in the extracellular medium may result in cell depolarization.[72–74] There is an upregulation of Na^+ channels inHS astrocytes, possibly leading to an enhancement of intracellular sodium, and consequently increasing glial intracellular calcium. Increased intracellular calcium would promote the release of transmitters, cytokines and growth factor in the epileptic tissue.[72]

Conclusions

The availability of resected focal epileptic tissue from patients with medically intractable focal epilepsy and the development and characterization of animal models for various types of epilepsies have provided a better understanding of some of the cellular and electrophysiologic mechanisms of epileptogenesis. At the single-cell or local circuitry level, in vitro models of hyperexcitability or synchronization have provided additional insights about the various mechanisms of epileptogenicity. Synaptic and nonsynaptic mechanisms have been proposed as having critical role in seizure generation and spread. Using in vitro cytochemical studies, changes in excitatory and inhibitory receptors, imbalance between excitation and inhibition and the evidence for plasticity and neurogenesis are being investigated, constituting important mechanisms involved in the generation and maintenance of intrinsic epileptogenicity.

148 Animal models of epilepsy with special reference to models relevant for transitional research

S Chabardès, I Najm, and HO Lüders

Animals models of epilepsy have been used extensively for the study of mechanisms underlying the epilepsies in general, but also to test new antiepileptic drugs and clarify their mode of action. To face the diversity of epilepsies encountered in human pathology, a large variety of animal epilepsy models have been developed and characterised at a behavioral, electrical, histopathological, and sometimes genetic level. Development of neurosurgical strategies will require also the development of relevant animal models mimicking intractable epilepsies in humans. Epilepsy models in animals are frequently severe, leading to the death of the animal. This is not what is usually seen in humans. New treatment strategies such as electrical brain stimulation (DBS, VNS, cortical stimulation) or local drug delivery, require chronic models to assess the efficacy of the procedures. Besides, excessive severity of seizures may obscure potential efficacy of these therapies.

This chapter will review the main characteristics of animal models of epilepsy and the possible usefulness of these models to evaluate clinical problems.

In this review, we have classified the animal models in a clinical way trying to mimic as much as possible the clinical situations usually encountered in humans.

Focal or regional seizures

Focal epilepsy is the most common type of human intractable epilepsy. The most frequent involves the temporal lobe but can also involve extratemporal cortex.

Limbic seizures

Acute

In rats, limbic status is easily produced by a single intraperitoneal (ip) injection of KA (10 mg/kg). Hippocampal seizures usually occur 5–10 minutes after KA injection and last 50–100 sec. These seizures eventually spread to the neocortex within minutes and sometimes generalise (See Figure 148.1–2). The status usually last 8–12 h. Clinical behaviour is generally well stereotyped with arrest phases, wiping nose, head nodding, and motor manifestation. Histopathological findings show neuronal loss in the amygdala, the hippocampus (mainly CA1, subiculum, and CA1), the entorhinal, and piriform cortex, and also widespread cortical lesions.[1,2] This model is very easy to use, reproducible, with limited interindividual variability, and the seizures tend to be pharmacoresistant. The disadvantage of this model is that usually even the first injection produces inner cell bodies damage created by the KA itself. These structural lesions together with the severity of the seizures do not allow chronic experiments and introduce some bias in case-control studies.

Chronic

Chronic models of limbic seizures can be produced by local injection of small amounts of drugs like KA in the hippocampus and the amygdala, or by single/repetitive (kindling) stimulation of these structures.

Small doses of KA (0.8–2.0 μg) injected in the hippocampus or the amygdala create limbic status[1,3] followed by intermittent limbic seizure 2–4 weeks later. Electrical and clinical manifestations of these seizures have been classified by Racine *et al.*[4–6] into five reproducible steps which allow comparison of the severity of seizure from one situation to another.

Repetitive electrical stimulation of the hippocampus or the amygdala (kindling) in cats has been described by Alonso-De Florida and Delgado in 1958[7] and has since been applied in most species used in experimental conditions. In rats, this technique has been described in details.[8–13] Briefly, the amygdala or the ventral hippocampus is stimulated through bipolar electrodes using trains of 400 μA in intensity, 50 Hz in frequency, and 2–5 sec in duration, for a period of 90 min. The first seizure appears after 8–38 days in 70% of the stimulated rats.[12]

Recently, Nissinen *et al.*[14] have proposed a new kindling paradigm that shortens the stimulation period and produces a temporal seizure that closely mimics temporal lobe epilepsy (TLE) encountered in human pathology. The parameters used are as following: 60 hz bipolar pulse, pulse width 1 ms, 400 μA applied in trains of 100 ms every 0.5 ms for 20–30 min. Using these parameters, 85% of rats developed limbic seizures 6–85 days after the stimulation. Histopathologically, observation indicated neuronal loss in the hippocampus, the amygdala, and surrounding cortex with mossy fiber sprouting in the dentate gyrus. Interestingly, these rats eventually developed memory impairment as assessed in the Morris water-maze. This model is very useful in preclinical studies as it is well characterized, standardized, easy to produce in the lab, and lesions appear to be the result of the seizures and not the result of KA damage.

Figure 148.1 Example of seizures recorded in rats after ip injection of kainic acid. aLH, aRH: left, right hippocampus electrode; RF,LF: right, left frontal electrode. Status involves both hippocampi while bilateral seizures are also recorded at the frontal neocortical level and occur chronically every 10 to 20 seconds.

Neocortical / motor seizures

Focal neocortical seizures are difficult to produce in rats or mice but can be produced more easily in bigger mammals such as cats or monkeys. In rats, partial seizures tend to involve extensive areas of the brain rather than strictly focal areas.

Acute

After discharge model

Acute focal seizures (see Figure 148.3, personal observations) can be obtained using electrical bipolar stimulation of the surface of the cortex.[15] In this model recently revisited by Shigeto *et al.*[16] at the CCF, focal seizure lasting 5–30 sec can be elicited by electrical stimulation. In this model, seizures are obtained using a bipolar, biphasic square pulse of current with pulse width set at 1 ms, frequency at 50 Hz, duration at 5 sec, and intensity varying from 0.5–2 mA. This model, could be relevant for testing the epileptogenicity threshold. However, the electrical stimulation creates an artefact electrical noise which can hide the beginning of seizures.

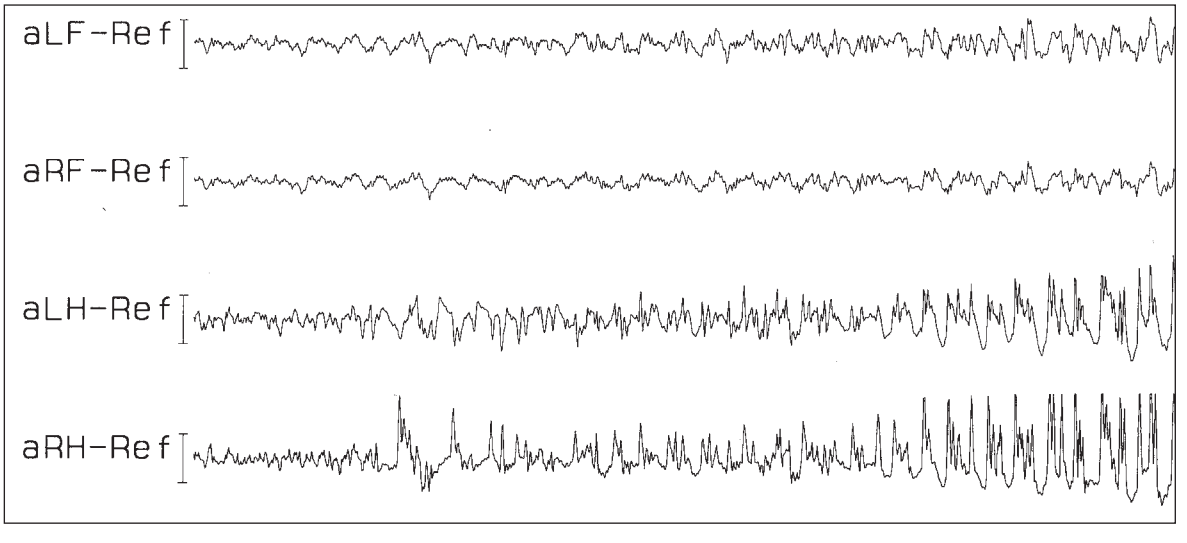

Figure 148.2 Example of seizures recorded in rats after intraperitoneal injection of kainic acid. aLH, aRH: left, right hippocampus electrode; RF,LF: right, left frontal electrode. Referential montage. Seizures start in the hippocampus bilaterally. Seizure activity secondary spreads to the frontal neocortex.

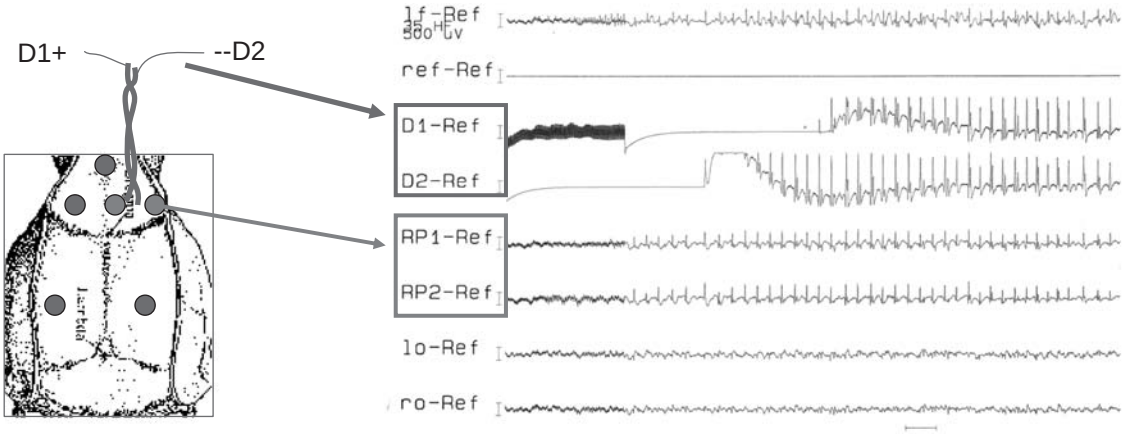

Figure 148.3 After discharges elicited by bipolar stimulation of the neocortex in rats. The seizure is mainly observed in the stimulating electrodes (D1 and D2) and on recording electrodes (RP1 and RP2) located at the vicinity of vicinity of the stimulating contacts (D1 and D2).

Focal chemical agents: penicillin model

Topical application of GABA antagonists agents can produce acute focal or regional spikes. This includes penicillin (PG),[17–24] bicuculline[25–28] and 4-aminopyridine (4AP).[29,30] Topical use of other agents such as KA (glutamatergic agonist) can also produce focal spikes.[31,32] However, seizures produced by topical applications of convulsivant agents (unpublished data) are more difficult to standardize and are less reproducible, leading to frequent rapid generalisation. GABA withdrawal has also been used to elicit focal seizure which starts immediately after having injected GABA in the cortex.

In our experience,[33] intra cortical injection of small amounts of Penicillin G produces very focal, long lasting, reproducible seizures. For preclinical studies, we developed an acute model of focal neocortical status epilepticus, using intracortical injection of PG in the motor cortex of rats. This model of motor seizure mimics seizures that are usually seen in patients suffering from epilepsia partialis continua. Briefly, the right motor cortex was implanted with an intracortical injection-recording cannula, and epidural screws were used for EEG recordings. PG was injected through the cannula using a Hamilton syringe at a dose of 1125–2250 IU per min for 5 min. All the rats developed focal epileptic status (see Figure 148.4 a,b,c,d) in the ipsilateral frontal cortex that lasted up to 36 hours and was always associated with contralateral forelimb clonic movements. Secondary generalisation was very rare and only occurred once when a higher amount of PG was used. In this model, EEG and behavioral patterns are both reproducible in their occurrence and predictable in their evolution. An in-house program for offline analysis was developed in order to automatically detect and characterize the number and amplitude of all spikes (Figures 148.5a and 148.5b). Histopathological examination of the focus revealed no lesions. This model has the advantage to be simple to produce; it is reproducible, well standardized and can be quantified because of the properties of spikes which are well identified. PG injections can be repeated several times in a single animal without any damage.

Chronic/semi chronic

Metal deposits at the surface of the cortex

Different metals introduced in the cortex produce neocortical, focal or regional seizures. One of the most convenient models for transitional research is probably the one obtained after local insertion of cobalt. This model originally developed in the 1970th[34–37] has been recently revisited by Chan *et al.*[38] It consists in inserting a small piece of cobalt wire in the cortex and, approximately 10 days later, focal seizures can be recorded in electrodes surrounding the placement of the cobalt (see Figure 148.6a; 148.6b, personal observations). Seizures are usually stereotyped, focal or regional. The number of seizures increases progressively for 2 or 3 weeks and then stops.

Iron, zinc, and aluminum were also used to create focal neocortical seizures.[39–43] In big mammals like rabbits, cats, dogs, and monkeys, the alumina cream model of focal neocortical seizures has been described extensively.[44–51] Focal neocortical seizures are produced by subpial injection of 0.2–0.4 ml of alumina. Two to four months later, focal seizures can usually be recorded, and these can continue for several years. This model has the advantage of producing neocortical seizures that mimic those usually seen in humans for whom the seizures persist for several years. On the other hand, the seizure focus requires several weeks or months to be established and the severity of the focus tends to vary between animals.

dysplasic related seizures

Models of epilepsy related to cortical dysplasia are of major importance since cortical dysplasia is a frequent cause of intractable epilepsy affecting children and adolescents. Unfortunately, models of epilepsy produced by cortical dysplasia are very rare.[52,53]

Cortical malformations can be obtained by utero insults produced by X irradiation or by exposure to methyl-azoxymethanol (MAM) which is a DNA alkylating agent. To be effective, the exposure must occur between embryonic days 14–17. These methods create a neuronal migration disorder. Experiments conducted at CCF recently showed that low (100 cGy) or mild irradiation (145 cGy), were more effective to create seizures

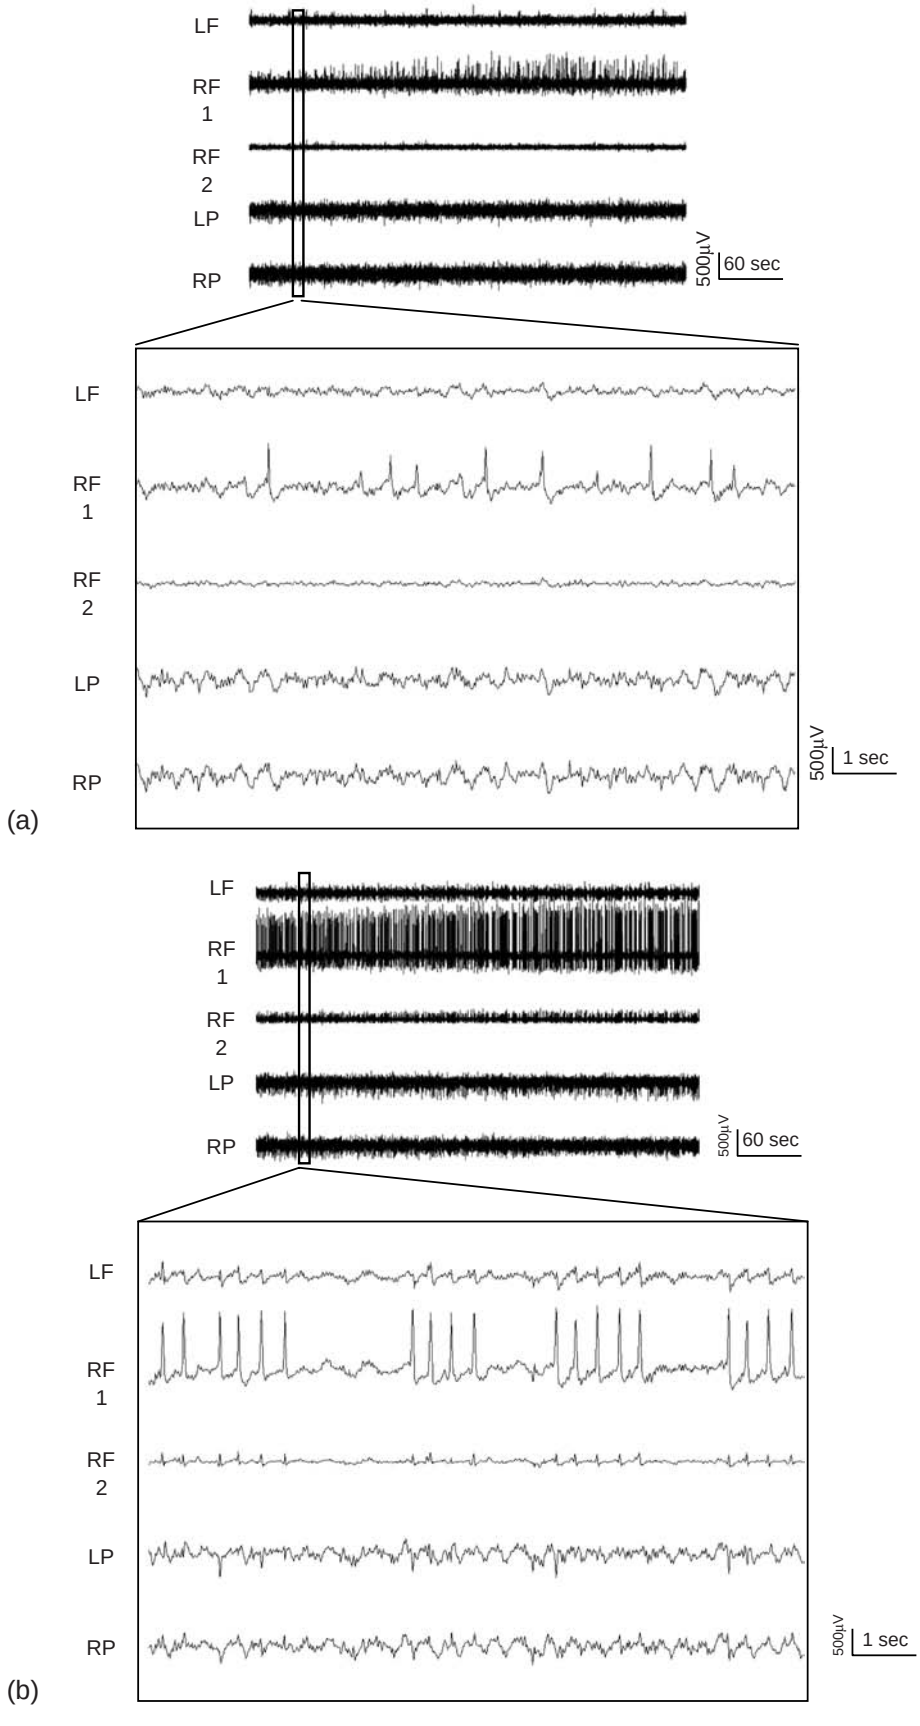

Figure 148.4 a. EEG pattern of a focal neocortical seizure occurring 3 to 8 minutes after penicillin injection in the right motor cortex in rat. For a duration of 1 to 3 min, irregular low amplitude spikes (200–800 V) are restricted to the right frontal electrode (RF1) located at the side of the PG injection. b. EEG pattern of a focal neocortical seizure occurring 4 to 11 min after penicillin injection in the right motor cortex in rats. Bursts of rhythmic focal spiking (800 to 1200 µV in amplitude, 2 to 4 Hz in frequency), are recorded for a duration of 3 to 20 min. These focal spikes are mainly recorded from the right frontal (RF1, RF2) and at times from the right parietal (RP) electrodes. They are always associated with contralateral forelimb clonic movements.

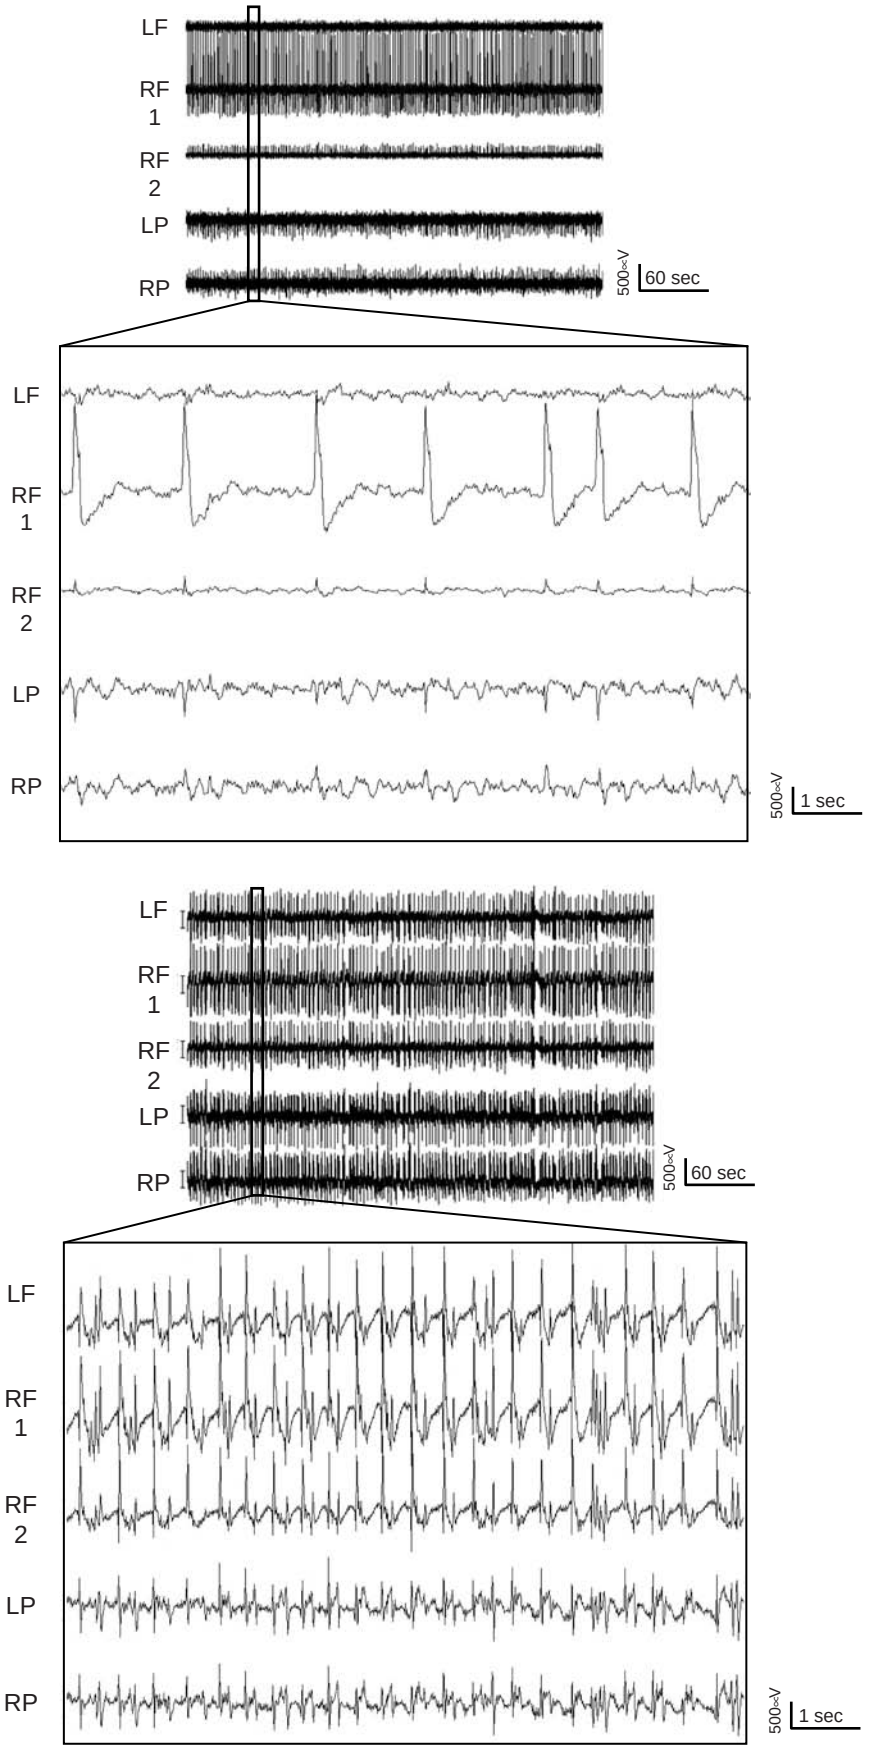

Figure 148.4 c. EEG pattern of a focal neocortical seizure occurring 7 to 31 min after penicillin injection in the right motor cortex in rats. It consists of continuous rhythmic focal (frontal electrodes) or lateralized (ipsilateral parietal area) high amplitude spikes or polyspikes (1200 to 3000 μV in amplitude, 0.5 to 2 hz in frequency) that last between 2 and 8 hours. Each spike is associated with contralateral forelimb and or facial clonic movement. d. EEG pattern of generalised seizure occurring after penicillin injection in the right motor cortex in rats. This is a late seizure evolution pattern consisting of generalized spiking intermixed with low amplitude fast spiking (10–20 Hz). This pattern occurred only once in one rat and apparently is produced by injecting a higher dose of PNG relatively fast.

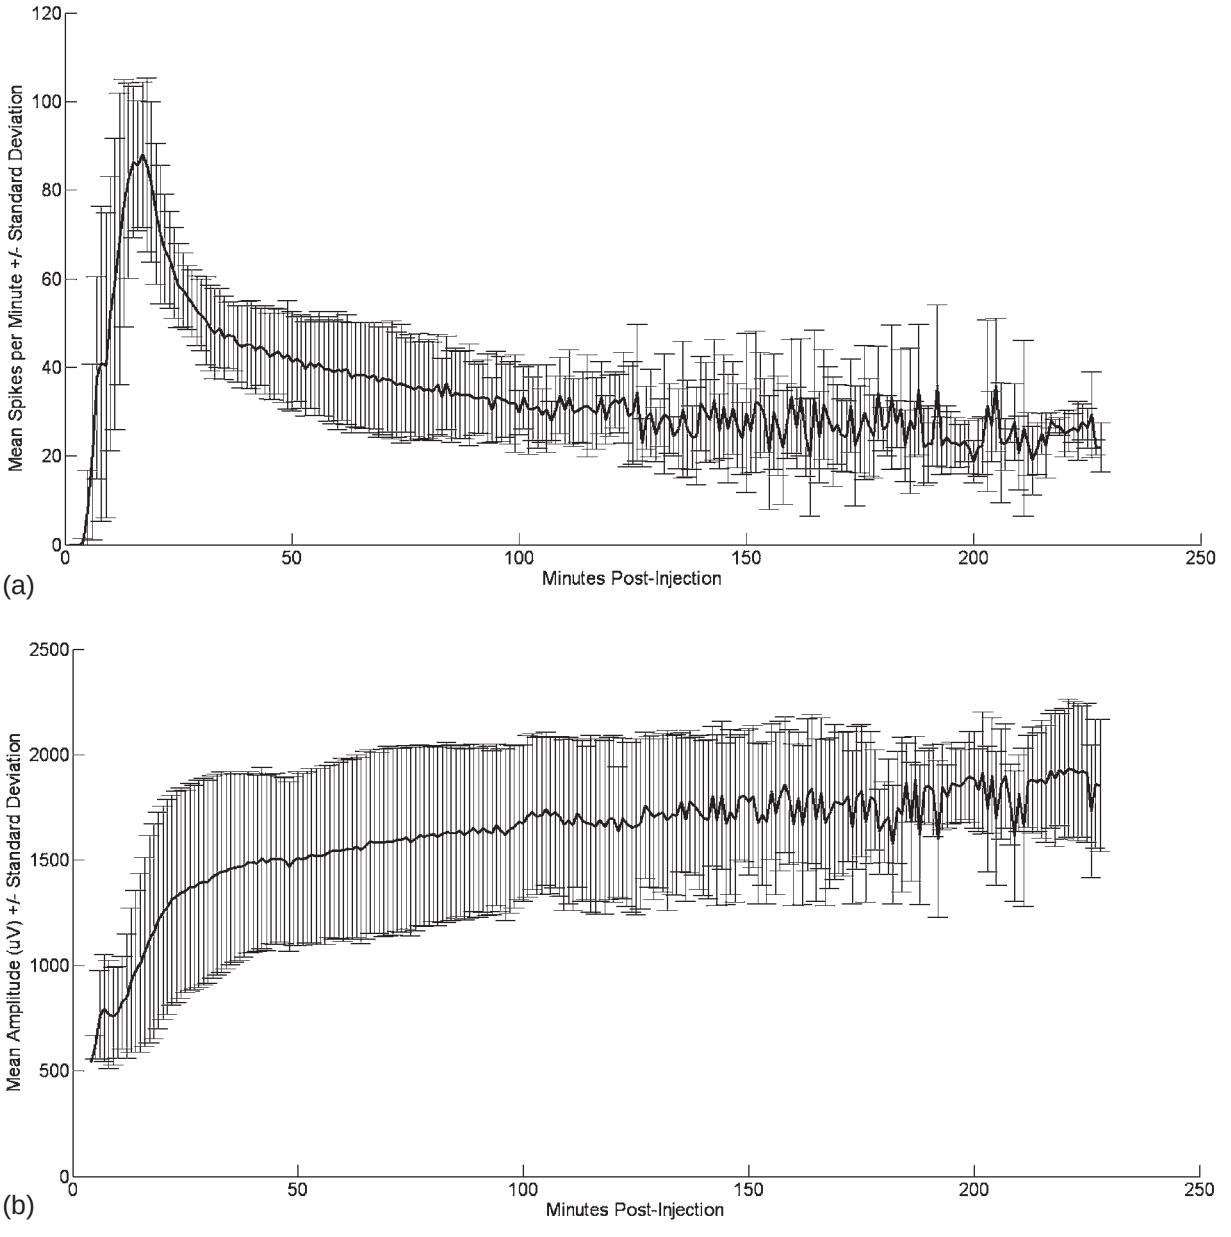

Figure 148.5 a.Time course (± SD) of spikes after one single injection of penicillin in the right motor cortex in rats (*n*=7). Each point represents the mean number of spikes ± SD occurring during 1 mn. Spikes started within 5 min of PG injection, increased rapidly to reach a aximum of 88 spikes/min at an average of 11 min after PG injection. Then, the spike numbers decreased progressively for 2–5 hour. b. Time course of spike amplitudes following a single injection of penicillin in the right motor cortex in rat (*n*=7). Each point represents the mean amplitude of spikes (± SD) occurring in one minute. Threshold of spikes detection was set at 500 ∝V. The amplitude increased dramatically within the first 20 min after penicillin injection and reached a plateau that lasted for several hours. A maximum amplitude of 1934 µV (± 327.1) was achieved 223 min after the penicillin injection.

compared to high dose (175 cGy) of irradiation.[54,55] The EEG characteristics of these models have also been recently described by the same group.[56]

Freeze lesions have also been used to induce focal cortical malformations. They usually create microgyri with hyper excitable cortical tissue because of an excess of excitatory glutamatergic neurons projecting to the affected gyrus.[57–61]

Generalized seizures

Absence-like seizures

Acute models

Various chemical agents have been used to create absence-like seizures. Penicillin injected intraperitoneally in cats and Gamma OH injected intraveinously in monkeys are examples of such models. Snead *et al.*[62] described that in monkeys

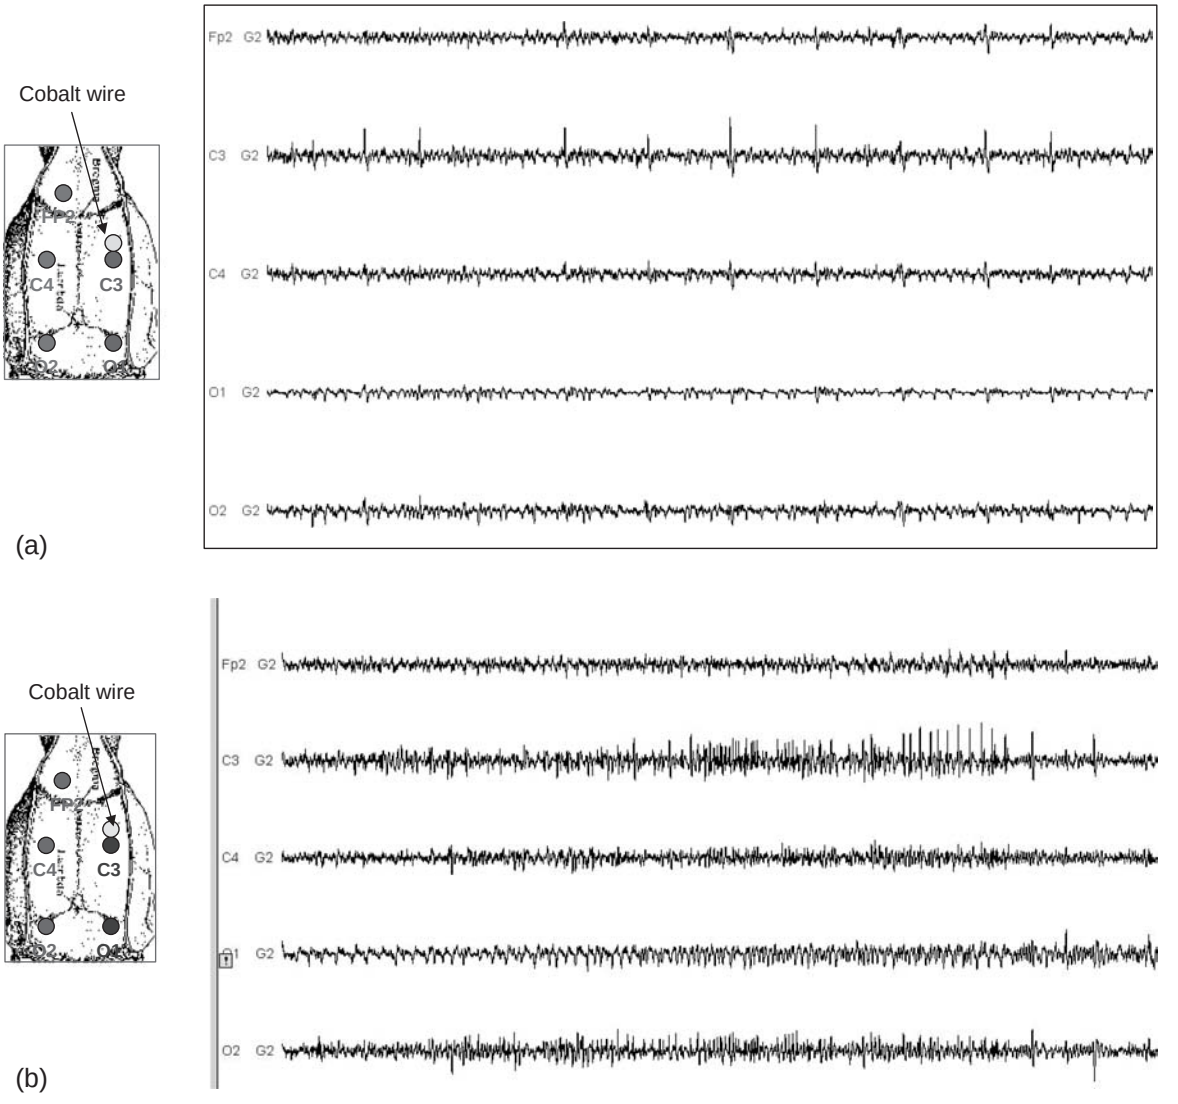

Figure 148.6 (a) Example of interictal spikes recorded on the electrode 'C3' located at the vicinity of the site of the cobalt insertion at the surface of the neocortex. (b) Example of focal seizure recorded 15 to 20 days after the insertion of a small piece of Cobalt at the surface of the motor cortex in a rat. Usually, these seizures can be recorded 2 to 4 weeks after the cobalt insertion at the surface of the cortex and then stopped spontaneously after several weeks.

treated with IV injections of Gamma Hydroxybutirate (200–400 mg/Kg), continuous and hypersynchronous spike-and-wave discharges (SWD) at a frequency of 1–3 Hz occurred 5 min after the injection. Usually, during SWD, the monkeys stared and were immobile, with the eyes closed and without any response stimuli.[65] After injection of ethosuximide (150 mg/Kg), SWD stopped. Snead *et al.* concluded that this was a good model of '*petit mal absence*'. Intraperitoneal injection of pentylenetetrazol (PTZ)[64,65] in rats also induces acute '*petit mal absence*'.

Chronic/genetic

The Genetic Absence Epileptic Rats of Strasbourg (GAERS) and the WAG/Rij strain of rats mimic absence seizures.

GAERS are a strain of Wistar rats in which all animals show spike and wave discharges (SWD) in the cortical electroencephalogram. The seizures occur very often (One up to three per minute) and usually last approximately 20 minutes. They are characterized by generalized spike-and-wave discharges (SWD), and are associated with behavioral arrest. They share many features with human absence epilepsy and generalized epilepsy in human, and the seizure can be suppressed by all antiabsence drugs. These discharges are facilitated by reduction of noradrenergic and dopaminergic neurotransmitters, and increments of Gabaergic transmitters. They are suppressed by ethosuximide and other antiabsence drugs, but are exacerbated by phenytoin and other anticonvulsant drugs. Progress in the understanding of the role of basal ganglia in the control of seizures has strongly benefited from the use of this genetic model of generalized non-convulsive seizures.[66,67] Studies in this model suggest that the cortex, the reticular nucleus, and the ventrobasal relay nuclei of the thalamus play a predominant role in the development of SWD. However, recent evidence[68] seems to indicate a seizure

initiation site within the perioral region of the primary somatosensory cortex (S1po) in the Wag/Rij stain of rats, as another well characterised genetic model of absence seizures.[69–72]

The tottering mouse also, exhibits features of generalized epilepsy (generalized spike-waves on EEG and absence-like clinical seizures).

'EL mice' are the only genetic animal models that express seizure-associated damage to the hippocampus, a region of the brain commonly damaged by epilepsy in humans.

In the past 5 years, the genetic mutations responsible for epilepsy in several different mouse models were identified. Unlike GAERS, the tottering and the stargazer mice have a known genetic mechanism. The stargazer mutation (21), which occurred in a newly discovered calcium channel gamma subunit, interferes with proper functioning of calcium channels, allowing overexcitation of neurons that leads to seizures. A second form of seizure, known as 'slow-wave epilepsy' because of its characteristic pattern of electrical recordings from the brain, is caused by a mutation that inactivates the sodium–hydrogen transporter.

Tonic-clonic seizures

Acute

The Maximal electroshock model (MES) has been extensively used in particular in pharmacological studies to screen AED. Stimulation parameters used are usually as follows: 150 mA, 60 Hz for 0.2 sec delivered via corneal electrodes. Seizures are 'Maximal' when animals show tonic hind-limb extension and flexion followed by clonus.[42]

Chronic /genetic

The genetically epilepsy-prone rats GEPRs have three types of convulsive epilepsy: generalized tonic-clonic seizures, partial seizures, and partial seizures with secondary generalized tonic-clonic seizures. GEPRs have a predisposition to sound-induced seizure assessed by an audiogenic response score (ARS), (0: no response to 9: severe seizure). GEPR rats exhibit a characteristic convulsive response to each ARS. (GEPR 3s: moderate seizures exhibiting clonic convulsions. GEPR 9s: complete tonic extensions). Anticonvulsant treatment can lower the ARS score. GEPRs respond to broad spectrum drugs, and also to those useful in generalized tonic-clonic seizures and partial seizures, but not to baclofen and chlorpromazine.

Conclusions

The existence of many models of epilepsy reflect the vast spectrum of epilepsies that clinicians have to face daily. However, on the other hand, it also reflects the fact that these models have a lot of limitations and unfortunately do not fitful all the clinical, electrical and genetic characteristics of human epilepsies. One must be cognizant of these limitations especially when new preclinical therapeutic strategies are tested in these models.

SECTION 20

Surgical failures: reoperation

149 Surgical failures: pre-surgical evaluation

CT Skidmore and MR Sperling

Introduction

Epilepsy surgery has been shown to be a reasonably safe and effective therapy for medically refractory localization-related epilepsy. The success of surgery at 1 year ranges from approximately 50–80% depending on the location of the surgery and the underlying pathology.[1–3] However, long-term follow-up reports demonstrate that a substantial proportion of patients, approximately 50%, relapse within 5–10 years of temporal lobectomy.[3–4] Relapse rates are even higher for extratemporal epilepsy, with 70% of patients experiencing a relapse within 5 years of frontal lobe surgery.[1] Therefore, recurrent seizures are a common problem after epilepsy surgery.[1,3,5,6]

It is common practice to consider performing a second operation in selected patients to see if seizures can be stopped, thereby obtaining maximum surgical benefit. This practice is supported by literature reports demonstrating that 48–81% of reoperated patients achieve seizure control or have rare seizures.[5–12] This chapter will focus on the repeat pre-surgical evaluation which needs to be performed prior to subsequent operations.

Before addressing the evaluation process, we should first review which patients are suitable candidates to consider for reoperation. In brief, if the goal of surgery was to abolish seizures, then any patient with persistent seizures after surgery might be a candidate for reoperation. However, deciding to offer additional surgery is not always straightforward. Some patients who relapse after surgery later enter remission, experiencing the 'running down' phenomenon.[13] This observation leads many physicians to adopt a conservative posture, and wait at least a few months, perhaps more, before considering further surgery. Some patients recur after surgery but their seizures are quite rare, so the value of surgery may be uncertain. Lastly, should a physician try additional medications prior to considering reoperation? Whether new medication trials offer a realistic hope of alleviating seizures after unsuccessful epilepsy surgery is uncertain. It seems reasonable to try at least one new medication before proceeding to additional surgery, given the relative risks. Nonetheless, the decision to embark upon the path towards reoperation is a difficult one.

Ultimately, the patient must decide for himself whether he is satisfied with the surgical result, and if not, reoperation should be considered. In our experience, patients who have had as few as two seizures in the year after surgery have asked for additional surgery, since their goal of seizure freedom was not attained, and the secondary benefits of operating a motor vehicle and increased independence were not achieved. Others with more frequent seizures, or seizures that produced injury, have also been interested in reoperation, since the reasons to have surgery the first time remain. Others have elected not to have surgery, because of doubts as to efficacy, or because of satisfaction with the reduction in seizure frequency or severity that might have occurred.

Review of data from the first operation

The first question to be answered is why the initial surgery failed. Possible reasons for surgical failure include inappropriate interpretation of the initial pre-surgical data, incomplete resection of an epileptogenic zone, or the presence of a de novo epileptogenic zone. Unfortunately, there is no single test or method to identify this region precisely prior to epilepsy surgery. One can only know the approximate location of the epileptogenic zone after surgery – if seizures persist, then it was not completely removed. Determining its boundaries relies on the accurate interpretation and application of the pre-operative testing. The surgical plan was employed to address the most logical hypothesis as to the location of the epileptogenic zone based upon this testing. In order to determine why the first surgery failed, a detailed analysis of the initial pre-surgical data and hypothesis needs to be repeated (Table 149.1). If it was known at the time of surgery that complete resection was not possible, then surgical failure might not be a surprise.

This should be easy to accomplish when the patient was operated in the same institution, but there are sometimes challenges in obtaining complete records from other institutions. This barrier is quickly being eliminated by the ability to share electronic records, which allows for the independent reinterpretation of the initial data. Reviewing the initial data and post-operative MRI allows a physician to determine if the initial hypothesis was correct and if the appropriate resection was performed. If it is determined that the localization was incorrect, then alternative hypotheses with regard to location of the epileptogenic zone might be generated to help guide a repeat surgical evaluation. One must reassess all aspects of the evaluation, to determine the concordance of the data and the accuracy of the interpretation.

Table 149.1 Analysis of evaluation prior to first operation

Initial surgery	Questions to consider
Ictal behavior	Was the history correct?
	Was there more then one type of seizure?
	Were all types of seizures captured with video-EEG?
Scalp EEG	Was the interictal focus focal or not?
	In what state did the spikes occur?
	Was the ictal EEG interpreted correctly?
Intracranial EEG	Was the electrode placement adequate?
	Did the EEG onset precede behavioral onset?
	How rapidly did the seizure spread to additional regions or to the contralateral hemisphere?
	Were spread patterns consistent and logical?
	Was the localization concordant with the other information?
MEG	Is there a predominant focus?
	Was it concordant with the resection?
MRI	Were the proper sequences performed?
	Was the image interpreted correctly?
	Was a lesion identified?
	Was there a single lesion or multiple?
Functional imaging	Was focal hypometabolism identified?
	Was an ictal hyperperfusion identified with SPECT?
Data synthesis/Surgical plan	Was the hypothesis correct?
	How concordant was the pre-operative data?
	Was there evidence for multifocal disease?
	Was the localization clearcut?
	Was the surgical plan appropriate?
Surgery	Was the intended resection accomplished?
	Was the desired extent of resection limited by functional or anatomic barriers?

History and semiology

The first step to be performed is to review the epilepsy history and pre-operative seizure semiology. Does the history suggest a particular epilepsy syndrome? Is it consistent with the syndrome that was diagnosed? Is the patient's or family's description of the seizure consistent with the diagnosis? Did the patient have more then one seizure type, and were all types of seizures captured during the video-EEG monitoring session? The assessment of the history provides critical information that aids in identifying the location of the epileptogenic zone.

Neurophysiology

The pre-surgical scalp and intracranial EEG evaluations must be reviewed. If both evaluations were performed they should be reviewed independently to determine if the data are concordant. The EEG evaluation helps determine the irritative and ictal onset zones. Several questions must be addressed. First, were the EEGs correctly interpreted? What was the location of the interictal spikes, and was their more than one location? In what states did they occur? When examining the ictal EEG, were seizures localized and how many ictal patterns were seen? What was the relationship between the timing of the ictal onset, and clinical onset? Was the onset and spread pattern of the seizure consistent with the ultimate localization? If intracranial EEG was performed, did ictal onset precede the clinical onset? Also, if an invasive evaluation was performed, was cortical sampling adequate? Invasive EEG is highly susceptible to sampling error and occasionally too much weight is placed upon the value of intracranial recordings. Therefore, was the intracranial EEG consistent with the rest of the data, or did it contradict the other findings? Lastly, if magnetoencephalography (MEG) was performed, was it correctly interpreted, and where were the interictal spikes located?

Video

The video enables direct observation of the seizure and testing of the patient during seizures. Was the behavior suggestive of a particular type of seizure? Was the behavioral localization reliably seen with several seizures, and was more than one ictal behavior observed? Most importantly, was the behavioral localization consistent with the site of surgery?

Imaging

Perhaps the most important step in the re-evaluation is the review of the pre-operative and post-operative imaging studies, particularly the MRI. The presence of a structural lesion which colocalizes with the other data is perhaps the best prognostic sign for successful surgical treatment. The pre-operative MRI should be re-evaluated to determine if it was correctly interpreted. Was any structural lesions present, if so, how many, and were they within the proposed resection margins? If the extent of resection was limited by the relationship between the presumed epileptogenic zone and eloquent cortex, reassessment of the surgical extent can be performed, and perhaps sub-pial transection considered. Other imaging data, such as positron emission tomography (PET) and single photon emission computed tomography (SPECT), must also be reviewed, to ascertain whether they were correctly interpreted and whether relevant imaging abnormalities were included within the resection line.

Synthesis

Since the goal of reassessment is to review all of the available data, one must then determine whether a reasonable hypothesis was generated, and if the appropriate surgery was performed. This assessment requires intellectual honesty and rigor, and a willingness to take a fresh look at the data. After review of the data, one must consider alternative hypotheses, and these will help guide the repeat pre-surgical evaluation. The physician or treatment team may reinterpret the findings of the initial evaluation, perhaps formulating a different hypothesis regarding localization of the epileptogenic zone, or may draw the same conclusions as before. In either circumstance, a rigorous examination of the pre-operative data must be done before embarking on new investigations.

Re-evaluation

The second pre-surgical evaluation has exactly the same goals and objectives of the first, to define the boundaries of an epileptogenic structural lesion. The presence of a structural lesion must be determined, and the limits of the epileptogenic zone established. One must reassess and define the symptomatogenic zone (region producing symptoms), irritative zone (region of EEG or MEG interictal spikes), ictal onset zone (region of EEG ictal onset), and functional deficit zone (regions of abnormal function defined by examination, PET, SPECT and other testing methods) and the extent of an epileptogenic lesion (defined by MRI), though this task is made more complex by the presence of a skull defect and the prior cortical resection. The methods utilized in the repeat evaluation are the same as before the first operation, including performance of a detailed history, neurological examination, scalp video-EEG monitoring, MRI, and a neuropsychological evaluation at a minimum (Table 149.2). Additional tests which may be employed include PET scan with fluorodeoxyglucose (FDG), interictal and ictal SPECT scans, magnetoencephalography (MEG), and functional MRI (fMRI). A full discussion of these technologies is beyond the scope of this chapter and is reviewed elsewhere in this text.

History and semiology

The first order of business is to assess the neurological history, with particular attention to seizures and the psychiatric state of the patient. Have seizures changed in character compared with the pre-operative seizures? Does the patient experience the same aura, and exhibit the same behaviors during seizures? Do family members note a change in the behavior, either during or after a seizure? Is there more than one type of aura? These factors are all important to assess the effects of surgery and determine whence seizures might originate. A change in aura symptoms or behavior might suggest a modification to the pre-existing epileptogenic zone, the development of a new epileptogenic zone, or it might suggest a different ictal propagation pattern. Careful review of the signs and symptoms might lead one to favor one of these possibilities over the others. Do seizures have different implications with regard to risk of injury and ability to function compared with the pre-operative state? Have new psychiatric problems emerged, such as depression, anxiety, or psychosis? These first require treatment, and might affect patient ability to make an informed decision about additional surgery. Changes in the neurological or neuropsychological examination may suggest the existence of new lesions, and offer clues as to the location of these lesions. On the other hand, new deficits in neuropsychological functioning have impact regarding the risks of additional surgery. For example, development of even modest language problems after a first operation may lead a physician to counsel against extending the prior resection, whereas lack of post-operative deficit would not deter further surgery.

Table 149.2 Re-evaluation after failed surgery

Repeat surgical evaluation	Questions to consider
Ictal behavior	Has the seizure semiology changed? Is there more then one type of seizure? Were all types of seizures captured with video-EEG?
Scalp EEG	Is the interictal focus focal or not? Is the ictal EEG localizing? Are there multiple ictal onsets?
MEG	Is there a predominant focus? Does it support the other data?
Intracranial EEG	Is the electrode placement adequate? Does the EEG onset precede behavioral onset? What is the relationship between the prior resection and the ictal onset? Is the localization concordant with the other information?
MRI	Were the proper sequences performed? Was the initial surgery complete? Is there evidence of a new lesion or surgical complication?
Functional imaging	Was an ictal hyperperfusion identified with SPECT?
Data synthesis/Surgical plan	How concordant is the data? Is there evidence for multifocal disease? Is the localization clearcut? Is a safe surgical procedure technically feasible?

Neurophysiology

Next, video-EEG monitoring is usually done. The diagnosis of epileptic seizures should be confirmed, since some have found de novo psychogenic seizures after epilepsy surgery.[14] The seizure description should be confirmed by analyzing ictal behavior with video monitoring. Behavioral analysis may yield valuable clues as to location of the remaining epileptogenic tissue. The interictal and ictal EEG need to be assessed and compared with the pre-operative data. This analysis may help reveal the location of the diseased cortex, defining the relationship between the prior surgery and the current ictal onset zones, and assessing whether new areas may be involved in seizure generation. Hennessy *et al.* presented data on 282 consecutive temporal lobe resections with a failure rate of 18%. On analysis of 44 surgical failures, 70% of the post-operative seizures were noted from the ipsilateral hemisphere in patients with mesial temporal sclerosis and in 64% of patients with non-specific pathology.[15] In the remaining patients, findings suggested either a contralateral focus or were inconclusive. However, EEG analysis is influenced by several factors. First, skull defects have been created which alter the potential field of both interictal and ictal EEG discharges. Second, changes in cerebral anatomy occur as a consequence of surgery. These may alter the field distribution of EEG potentials, so that the source of the discharges might be incorrectly identified. Lastly, removal of a portion of a lobe of the brain often results both in different propagation patterns of seizures and loss in amplitude of the ictal discharge in the region of prior surgery. These can lead to false lateralization or localization of ictal discharges. However, the location of the interictal spike often provides a clue as to whether the seizure localization is genuine, for it is uncommon for seizures to arise from the hemisphere contralateral to a prominent unilateral interictal spike focus.

MEG may serve a useful role when evaluating patients for reoperation.[16,17] MEG can identify interictal spikes, providing further definition to the irritative zone and the source localization is not altered by skull defects. Since MEG detects dipoles that are tangential to the EEG, spikes that are invisible to EEG are readily detected with MEG. Also, MEG can be used to identify sensory and language cortex; knowledge of these regions are helpful when planning surgery.

Imaging

Imaging studies play an important role in the evaluation process. The post-operative MRI scan must be reviewed to determine if the initial surgical plan was carried out successfully (i.e., the entire lesion and perilesional tissue was removed), and to determine if a surgical complication such as an infarct or hemorrhage occurred, or if a previously unidentified epileptogenic lesion was missed. To our knowledge, there is no extant literature defining the expected findings at the resection margin after epilepsy surgery. Therefore, in the absence of new lesions, it is difficult to know whether a small gliotic lesion adjacent to the prior resection constitutes a new epileptogenic lesion, or is benign post-operative gliosis. This might only be defined with electrophysiological techniques at a later time. Functional MRI (fMRI) may at times aid in presurgical investigation. It may be used to identify eloquent cortex, thereby guiding the surgeon and perhaps reducing operative morbidity. While fMRI has been used to study interictal spikes, this use is still investigational and not suited for clinical use.[18] PET-FDG scans are generally not useful after epilepsy surgery, since the resection produces a metabolic defect in the region of resection, and distant areas of diaschisis appear as well.

Synthesis and completion of evaluation

Once the non-invasive evaluation is complete, the data can be synthesized (Figure 149.1). The principles that apply at the time of initial evaluation are still valid when contemplating reoperation. Successful surgery usually relies upon multiple lines of evidence converging on a single location. Hence, one hopes to find that the preponderance of data indicates a single location. Reoperation can be considered provided one can generate a clear hypothesis as to why the first surgery failed and determine where the epileptogenic zone now lies. Often, the non-invasive data does not provide information that is sufficiently precise. In these cases, it is advisable to record seizures with intracranial EEG before performing additional resection. This enables confirmation of the location of proposed area to be excised, and permits mapping of cortical function, so that critical areas can be spared. Both interictal and ictal data are obtained with intracranial video-EEG monitoring; these can help define the boundaries of the resection. However, using intracranial EEG does not guarantee success, since it is but one tool, subject to many limitations and biases.

What strategy should be employed when using intracranial electrodes? Electrodes should be placed in any area that is reasonably suspected to be the source of seizures. A sufficient number of electrodes should be used to accurately define the cortex in which seizures originate and the initial spread patterns. One cannot know where seizures begin unless they can be shown to start focally in one area. Thus, it is mandatory that some electrode contacts not show ictal onset but instead show later ictal spread, and that the observed spread pattern logically derives from known anatomic connections. If there is a suspicion that seizures arise from more than one region of the brain, electrodes should be placed in both regions (Figure 149.2). This aids the physician in establishing whether a single epileptogenic zone exists, or if there are multiple areas that trigger seizures. If surgery is contemplated near eloquent cortex, then electrodes should be placed over relevant areas, so that vital functions can be mapped and the boundaries of resection defined.

Factors affecting outcome

Many of the initial reports[6,11] identified the presence of residual epileptogenic tissue as a favorable prognostic factor with regards to reoperative success. However many of these patients were operated before the widespread availability of MRI and advanced intraoperative navigation. Siegel *et al.*[12] assessed seizure outcome in 64 patients who underwent at least one additional surgery and found duration of epilepsy less then 5 years and focal interictal epileptiform activity as positive predictors. Holmes *et al.*[9] reported that data concordant with the prior resection imparted a good prognosis, while no patient with a CNS infection was rendered seizure free. The location of surgery, whether temporal or extratemporal, did not influence outcome after a second procedure. Salanova *et al.*[10] reported

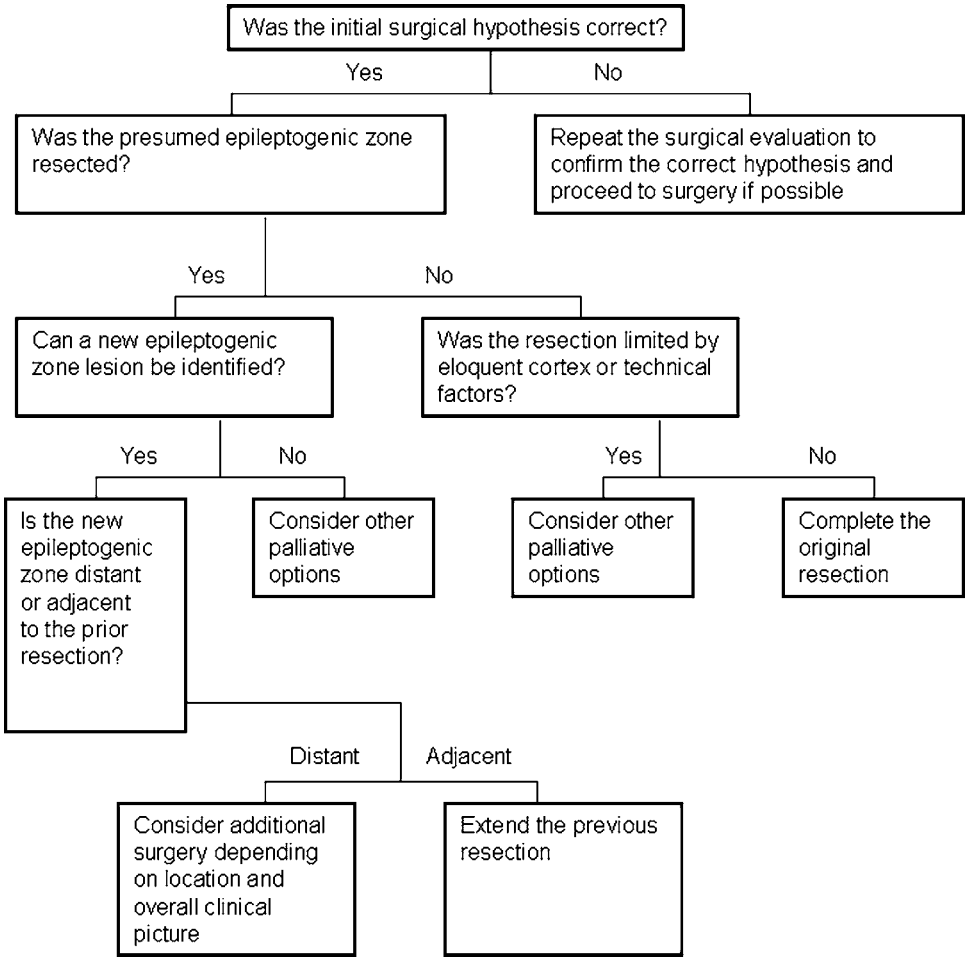

Figure 149.1 Flow chart demonstrating the typical decision algorithm when considering additional epilepsy surgery.

residual interictal epileptiform activity in the postresection electrocorticogram as a poor prognostic sign in patients with frontal lobe epilepsy. González-Martínez *et al.*[5] reported no relation between outcome and history of febrile seizures, CNS infections, seizure semiology, duration of epilepsy, or response to the first surgery. However, patients with tumors or dual pathology at the time of reoperation had a significantly better outcome compared with patients who had cortical dysplasia or mesial temporal sclerosis. Possible reasons for this include the inability to successfully image the entire extent of the cortical dysplasia and the possibility of the development of a contralateral mirror focus in the presumed normal temporal lobe. In an analysis of data from our center, we evaluated 30 patients who underwent reoperation in an attempt to determine if the response to the first surgery could predict the response to the second operation.[19] We found no relationship between response to the first surgery and the outcome of the second surgery. We also found no difference in outcome between temporal versus extratemporal resections or extension of a prior resection compared to resection within a different region.

Illustrative cases

Case 1

A 29-year-old right-handed woman developed complex partial seizures after the birth of her third child. The seizures were described as beginning with an ineffable feeling for several seconds followed by a loss of consciousness. She then had a look of terror on her face, afterward becoming unresponsive with late right-sided clonic activity. She had 4–5 seizures per month despite appropriate medical therapy. Four years after onset of her epilepsy, she had a left anterior temporal lobectomy based on a scalp evaluation. Seizures stopped, and her antiepileptic medication was discontinued 1 year after surgery. Her seizures recurred 6 years after the initial resection, coinciding with the birth of her sixth child. Despite medical therapy she remained refractory and experienced 3–4 complex partial seizures per month.

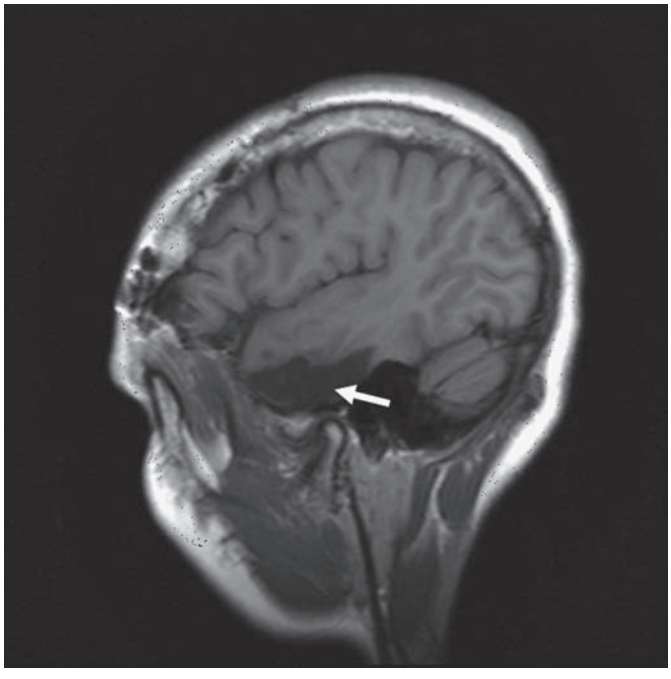
Repeat evaluation

Semiology: She had the same aura as before surgery and loss of consciousness, but the look of terror and right sided clonic activity late in the seizure were not present.

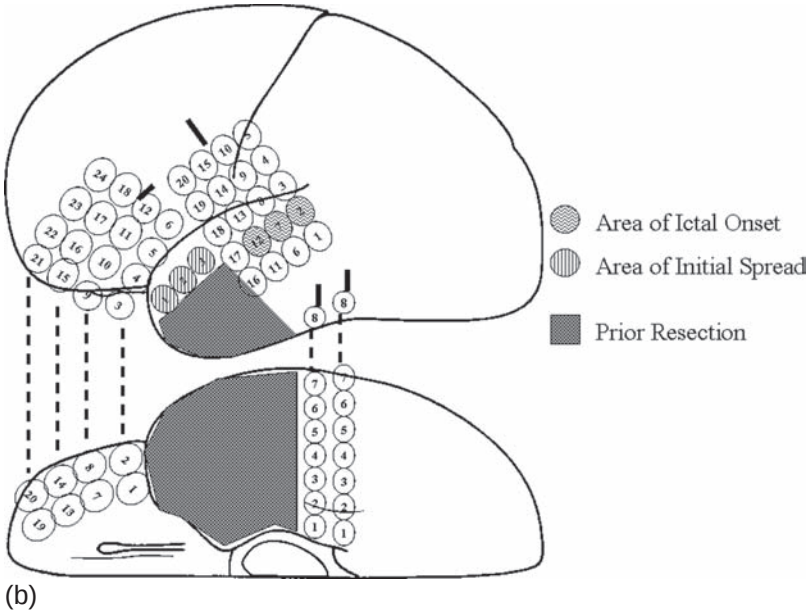
Scalp video-EEG: The interictal EEG showed left temporal continuous theta slowing and rare right sphenoidal sharp waves. The ictal EEG revealed a right sphenoidal ictal onset with rhythmic theta spiking. Semiology was consistent with an automotor seizure with loss of consciousness.

MRI: This showed the prior left temporal resection, with 1 cm hippocampal resection and 4.5 cm lateral temporal resection.

Neuropsychological testing: This showed average visuospatial memory and poor verbal memory.



(a)



(b)

Figure 149.2 (a) Saggital T1-weighted MRI revealing the prior area of resection (white arrow) in a patient with medically refractory aphasic seizures. Note the superior temporal gyrus was spared. (b) Representation of the intracranial implant with inferior frontal, orbitofrontal, lateral temporal and basal temporal subdural electrodes covering the possible epileptogenic regions. Ictal onset was noted behind the resection margin with rapid spread to the anterior superior temporal gyrus. No language function was identified within these regions with electrocortical stimulation. The patient had the superior temporal and middle temporal gyrus resected beyond the ictal onset.

Surgical plan

The patient initially had left temporal lobe epilepsy which had responded to a left temporal resection with a limited mesial resection. However, the re-evaluation EEG data suggested an irritative zone and ictal onset zone within the right anterior temporal lobe. There are two main possible explanations for this. Either she still had left mesial temporal lobe epilepsy with preferential spread to the right temporal lobe due to the prior resection, or developed a new epileptogenic zone in the right temporal lobe. Less likely, an orbitofrontal epileptogenic zone had developed. To address these possibilities the patient was implanted with depth electrodes in the hippocampus and subdural strip electrodes in both left and right temporal lobes. In addition, orbitofrontal subdural strip electrodes were placed bilaterally.

Results

With intracranial video-EEG monitoring, the patient had four complex partial seizures arising from the right anterior hippocampus and six subclinical seizures arising from the left

posterior hippocampus. Due to the bilateral nature of her disease and the predominance of clinical seizures now emanating from the right hippocampus, she was not offered further resection. This case illustrates the potential for progression of disease which can occur in epilepsy and the need to consider the development of de novo epileptogenic zones after failed epilepsy surgery.

Case 2

A 53-year-old right-handed woman developed epilepsy at age 12. She initially had nocturnal generalized tonic-clonic seizures occurring 1–2 times per year despite medical treatment. Then, at the age of 27, she was involved in a motor vehicle accident which resulted in abdominal trauma, but she denied CNS trauma. However, after this accident she developed complex partial (automotor) seizures. Observers now reported a sudden loss of awareness which occurred without a warning. She then looked fearful, having hand and verbal automatisms. Despite medical treatment, she continued to have 2–4 seizures per week while the generalized tonic-clonic seizures continued at 1–2 per year.

First evaluation

Video-EEG: The interictal EEG showed right and left sphenoidal sharp waves, with 10 right-sided sharp waves for every one on the left. The ictal semiology was as described above. Ictal EEG showed bilateral attenuation of background frequencies at onset and then either an independent right or left temporal seizure discharge.

MRI: This showed increased T2 signal in the left temporal-occipital gyrus, located 5 cm from the temporal tip.

Neuropsychological testing: This showed impaired naming and verbal memory.

Wada test: This showed left hemisphere dominance for language.

Initial surgery

The patient had intracranial video-EEG monitoring using bilateral mesial temporal depth electrodes and bilateral temporal lobe subdural strips. The interictal EEG data revealed bilateral hippocampal and amygdala epileptiform activity. Multiple complex partial seizures were recorded with left posterior hippocampal onset followed by spread to the right temporal lobe in 15–30 seconds. She then had a left anterior temporal lobectomy. After surgery, she continued to have 1–2 complex partial seizures per week and the frequency of generalized tonic-clonic seizures increased to once per month.

Repeat evaluation

Neuropsychological testing: This showed significant verbal memory decline and severe anomia compared to the pre-operative data.

MRI: This showed residual left basal temporal T2 signal hyperintensity within the temporo-occipital gyrus.

Video-EEG: This was not performed since the seizure semiology had not changed and the patient had a residual structural lesion.

Surgical plan

The patient was taken back to the operating room approximately 1 year after the first surgery with resection of the residual basal temporal lesion.

Results

The patient had three possible seizures several months after the second operation, and has been seizure free for the next 19 years. Her neuropsychological measures improved after her second surgery, with resolution of the anomia and improvement in verbal memory. Multiple follow-up EEGs have been devoid of epileptiform activity. This case illustrates the need to completely excise an epileptogenic lesion and that extensive basal temporal resection can be performed safely in the dominant hemisphere with improvement in neuropsychological functioning if seizures can be abolished.

Conclusion

Epilepsy surgery is an effective option for many patients with medical refractory epilepsy, but current techniques do not assure a successful outcome. Further surgery may be possible in individuals who fail to fully respond, and approximately half benefit from reoperation. However, better tools and prognostic indicators must be devised to help guide the reoperation and predict which patients are apt to benefit. Until then, an individualized approach must be employed. The evaluation should aim at developing a reasonable hypothesis regarding the location of the remaining epileptogenic cortex, devising a safe strategy for intracranial investigation should this be needed, and planning an effective operation that minimizes the chances of producing a neurological deficit.

150 Reoperation after failed epilepsy surgery

A Boongird, JA González-Martínez, and WE Bingaman

Introduction

Surgical failure is defined by the inability of surgical intervention to accomplish the surgical goals, whether they are diagnostic or therapeutic in nature. Diagnostic procedures include subdural and/or depth electrode implantations for identification of epileptic tissue, while therapeutic procedures can be subdivided into those which may improve seizures (palliative) and those intended to stop seizures (curative). The seizure freedom rate after a palliative procedure such as vagal nerve stimulator (VNS) implantation is considerably low.[1–3] Residual seizures after VNS implantation therefore would not necessarily be considered a 'surgical failure'. In contrast, resective surgery for a focal epilepsy carries a much greater chance for curing seizures, especially if there is an associated lesion on neuroimaging.[4]

The term 'surgical failure' in resective cases is defined in this chapter as persistent or recurrent seizures after resective epilepsy surgery. Surgical failure rates for common epilepsy surgery procedures such as selective amygdalohippocampectomy or standard anterior temporal lobectomy are well characterized in the literature, with many reports citing widely varying outcomes after resective surgery. These outcomes seem to differ widely from center to center based on underlying substrate, surgical experience and method, outcome grading scheme used, and volume of cases. It is not the aim of this chapter to validate surgical therapy for epilepsy, but rather to explore some common reasons for failure and the potential for improving seizure control with re-operation in selected patients.

Additionally, the time-period for diagnosis of surgical failure needs some consideration. Early versus late recurrenceof seizures is poorly understood. In general, surgical failure should be defined as identification of seizure(s) following the operation, with persistence of habitual seizures perhaps the most important criteria for clinical diagnosis of surgical failure.[5] Prediction of surgical failure differs from patient to patient and should be individualized to the clinical scenario. The 'running down phenomenon' should be kept in mind, especially in patients experiencing major effects on clinical seizures.[6–8] Siegel *et al.* reported 8 of 64 patients that were initially free of seizures after the first surgery for a mean of 4.6 years, followed by late recurrence and reoperation.[9] Other studies also confirm the decreasing success of epilepsy surgery over time.[10] These results underscore the necessity of long-term follow-up after surgery for epilepsy.

Frequency of surgical failure and reoperation

The incidence of surgical failure is different from center to center because of referral bias, criteria for defining surgical success, number of cases, and different surgical experiences and strategies. Munari *et al.* reported 131 of 344 (38%) patients having persistence of seizures immediately after operation. This number might be lower if using different criteria to define outcome.[11] The incidence of surgical failure was also reported in relation to specific locations of surgery. For example, Hennessy reported 51 of 282 patients (18.1%) experiencing persistent or recurrent seizures following temporal resections.[12]

The incidence of reoperation reported varies from 4.3–14%, depending on individual center practices.[9,13,14] Diagnostic procedures are also associated with a chance for failure. Experience at our center from January 1997 through June 2005 included approximately 1440 epilepsy operations, in which 250 procedures were diagnostic, 190 procedures palliative, and about 1000 procedures for curative aims. Among 234 cases of subdural electrode evaluation and 17 cases for bilateral temporal depth electrodes, 30 patients (12%) underwent subdural electrodes removal without surgical resection and ten cases underwent depth electrodes removal without resection.

Surgical failure after resective surgery remains challenging. At our institution, among 1000 resective operations within the same period of study, about 15% of patients still experience persistence of disabling seizures after the first surgery. Ninety-two patients underwent reoperation and within this group, 26 patients (28%) were referred from outside institutions for further evaluation and management. Although these numbers are in line with other published reports on reoperation after failed epilepsy surgery, the true frequency of failure and success after reoperation will remain unknown until the epilepsy community has a standardized method of defining and recording outcomes. In this regard, a national database specific to outcomes after epilepsy surgery is needed.

Possible causes of surgical failure and the surgical approaches for reoperation

For diagnostic procedures, the two main reasons for failure to localize the epileptogenic zone (EZ) are the diffuse nature of specific types of intractable epilepsy syndromes and the anatomical limitations of electrode implantation (insular cortex,

interhemispheric surfaces, posterior basal orbitofrontal region). The first may be considered a failure in the preoperative evaluation and most often occurs due to the clinician's inability to accurately localize the epileptogenic zone. The second is surgical technique related and potentially avoidable. The possibility of combined depth electrode and subdural electrode implantation may be a better method in approaching these difficult anatomical areas. Alternatively, stereoelectroencephalography may be a better method for accessing difficult to access or more widespread cortical regions.[15]

Incorrect localization of the epileptogenic zone

During the presurgical work-up, the epileptologist formulates a hypothesis of the epileptogenic zone by using clinical semiology, neurophysiology, and anatomical and functional neuroimaging. Non-lesional cases and those with discordant data require assumptions based on the interpretation of preoperative data. In most of these cases, further diagnostic invasive recording is necessary prior to establishing surgical resective candidacy. With these particular cases, surgical failure has been reported as higher compared to the more straightforward lesional case.[16] When the preoperative data is discordant and/or there is no lesion present to steer surgical resection, the chances of incorrect localization or perhaps better termed incomplete characterization of the epileptogenic zone is more likely.[16] Additional reasons for incorrect localization of the epileptogenic zone include misinterpretation of preoperative data and presence of dual pathology on imaging.

The following clinical example helps to demonstrate how incorrect characterization of the EZ might occur. In case 1, clinical semiology starts with an aura of 'a scary feeling in my chest' or a hard-to-describe sensation for seconds to a few minutes. This is followed by elevation of both arms and legs with tonic stiffening. Typical seizure duration is 20–30 seconds. Seizures occur mostly out of sleep, about 2–20 times per night. Neurophysiology revealed interictal sharp waves in the right frontotemporal region and non-localizable ictal onset. Magnetic resonance imaging (MRI) of the brain revealed a slightly hyperintense area on fluid-attenuated inversion recovery sequences at the depth of the right inferior frontal sulcus, most likely reflecting a malformation of cortical development. Because of the semiology, lack of electroencephalographic (EEG) ictal onset, and potential for a widespread malformative lesion, invasive mapping was recommended. Two 8×8 subdural electrodes (covering right fronto-parietal convexity area, including the abnormal area) were used for invasive monitoring. The mesial frontal regions were not covered. The EEG onset was characterized by diffuse attenuation of the background activity and was simultaneous to the clinical onset. Focal EEG changes were seen no earlier than 1–2 seconds after the clinical onset when beta-range rhythmic discharges arose from posterior fronto-temporal electrodes and evolved into repetitive spike waves over the adjacent area (Figure 150.1).

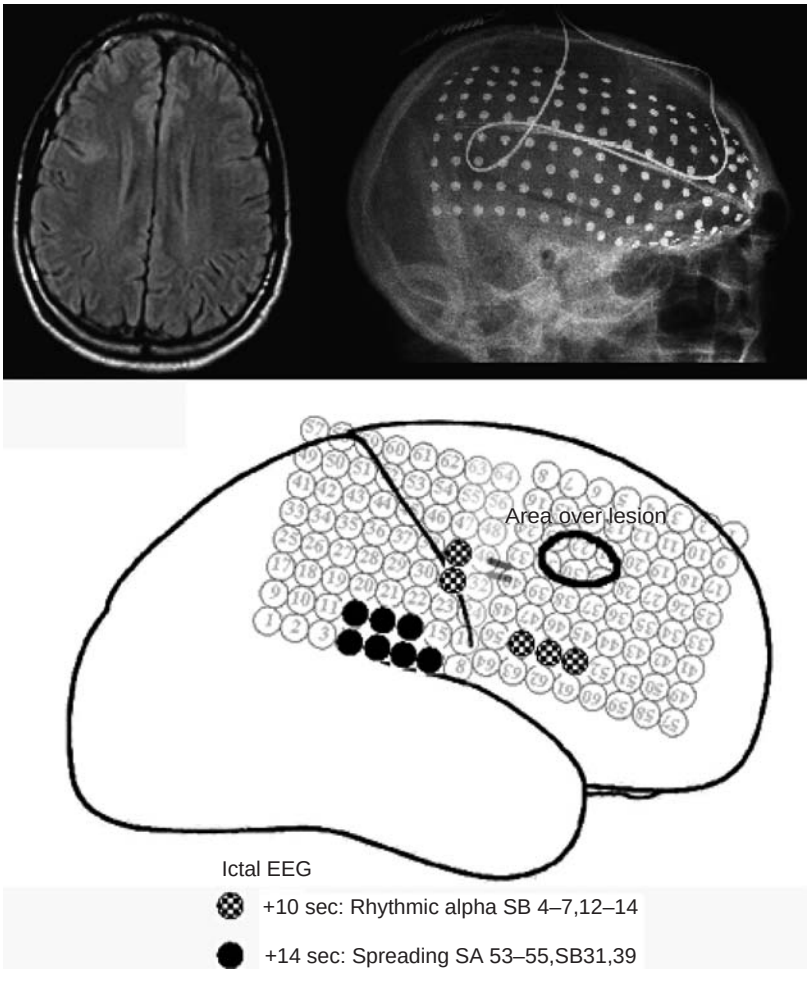

Figure 150.1 Demonstrating the lesional MRI and ictal EEG findings in relation to the area of the overlying lesion.

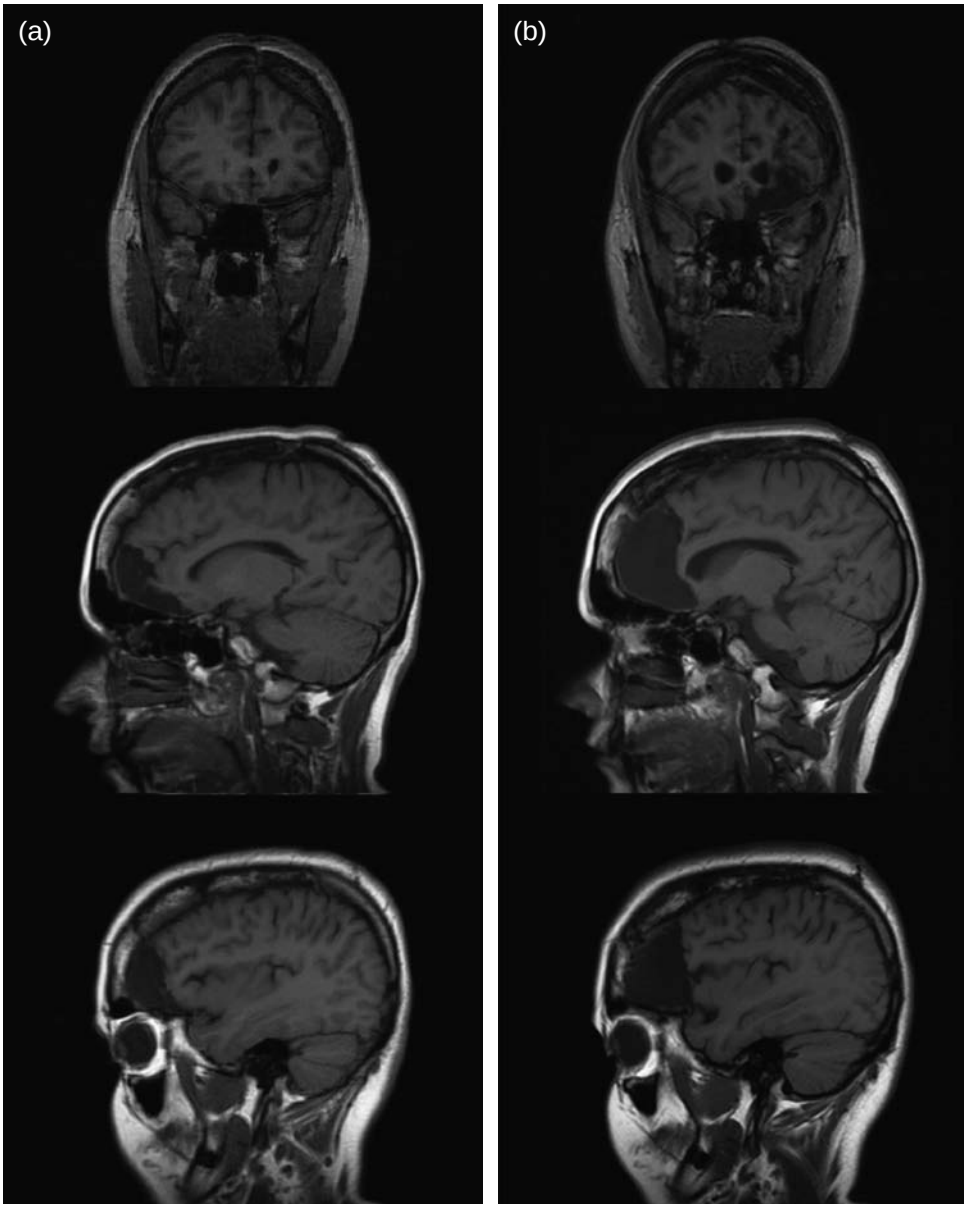

Figure 150.2 Comparison of extent of left orbito-frontal resection between two operations. a. Initial frontal resection based on invasive recording data, b. Second resection of additional cortical tissue in region of initial resection.

The case illustrated demonstrates several salient points that may lead to the incorrect localization of the EZ and thus reduce the chances of a seizure-free outcome. First, the EZ may be more widespread than the lesion, when present. Similarly, the EEG data gathered via scalp or invasive recording may also not correlate with the lesion and/or the EZ. Surgical limitations in the number and location of invasive electrodes implanted may influence the data gathered and the hypotheses from this data. Finally, when a lesion is present (especially cortical malformations) it may or may not coincide with the EZ. In the final synthesis of data and operative plan, the epileptologist and surgeon must decide on the extent of tissue that needs to be removed and it is this human factor where likely most incorrect localizations of the EZ occurs.

As mentioned earlier, surgical accessibility to some cortical regions is limited, especially for surface electrodes (subdural recordings). For example, the mesial frontal and parietal regions, cingulate gyri, orbital frontal, and mesial temporal areas are difficult to access in a comprehensive fashion because of the size and inability to directly visualize the areas of interest. Figure 150.2 is an example of left basal frontal lobe epilepsy with a seizure free outcome achieved after two resections in the same region. This patient experienced a recurrence of habitual hypermotor seizures 3 months after undergoing an initial resection of left orbito-frontal cortex identified by an invasive subdural electrode evaluation. Following seizure recurrence, more extensive resection of the same cortical area under awake conditions led to long-term seizure freedom. Pathology revealed malformation of cortical development from both specimens.

Due to the limitations of subdural electrode evaluation in specific areas of the brain as previously described above, the combination of subdural electrodes and depth electrodes may play a role for improved localization of the epileptogenic zone (Figure 150.3). In this example, the patient had a right posterior frontal seizure onset with a normal MRI. Implantation of

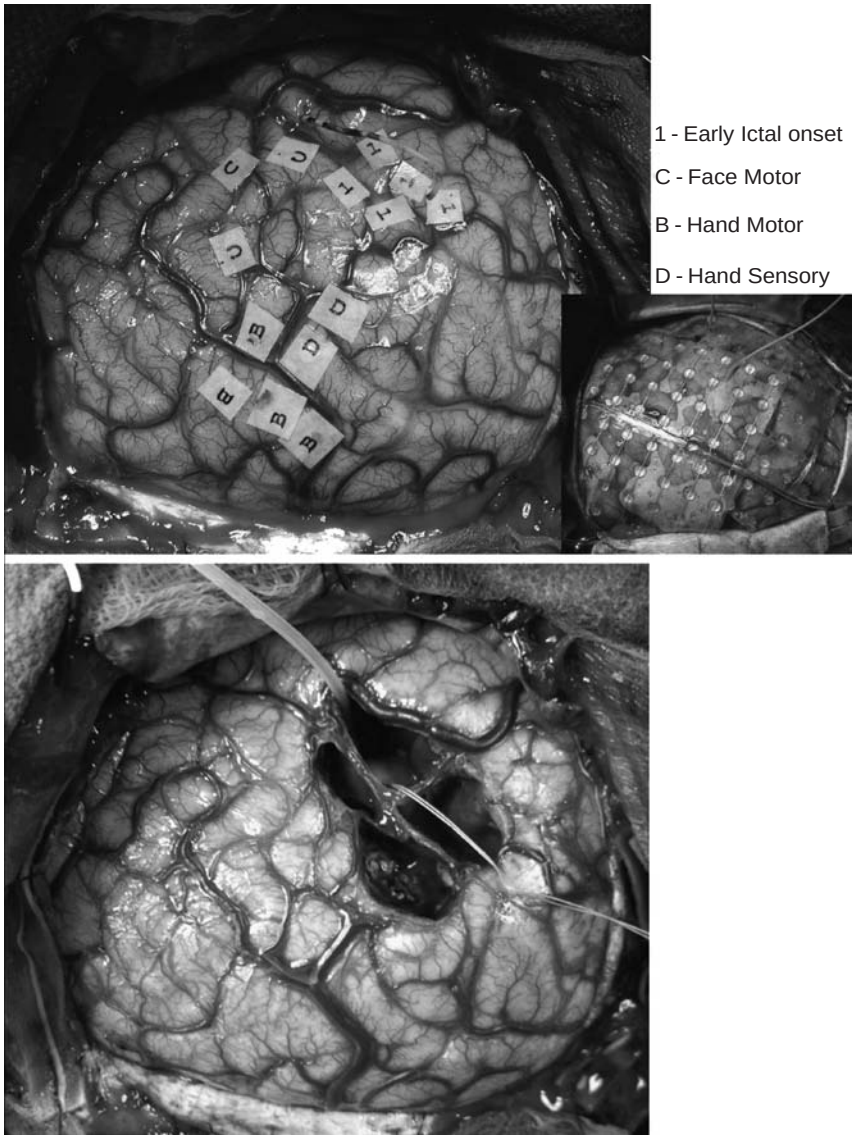

Figure 150.3 Demonstrates the combination of subdural and depth electrodes for an extraoperative brain mapping (upper photo) and intraoperative electrocorticography (ECoG) of the insular lobe (lower photo) during the resection.

a combination of surface electrodes and intra-cortical electrodes in the insular cortex were utilized to document an insular ictal onset with an early spreading pattern to the surface subdural electrodes. The pathology report showed malformation of cortical development (MCD). The patient experienced seizure freedom after surgery.

Limitations in the epileptogenic zone surgical resection

The epileptogenic zone may involve eloquent cortex and resection of such may possibly lead to a permanent neurologic deficit. Invasive monitoring with subdural electrodes can provide information defining epileptic cortex and functional cortex and may lead to potential surgical extirpation of the epileptogenic zone. Despite accurate functional mapping, surgery in and around eloquent cortex carries risks of neurologic decline and this must be adequately discussed with patients and families prior to surgical treatment. Despite these risks, surgery can be performed with minimal deficits in some areas of sensorimotor cortex. For example, if the seizure onset zone arose from the sensorimotor face area, surgery can be performed without significant permanent neurological deficit.[17] Multiple subpial transections (MST) can be performed on the eloquent cortex in selected cases. The Yale group reported a 42% seizure frequency reduction after MST.[18] Other surgical options including vagal nerve stimulation (VNS), responsive cortical stimulation, and deep brain stimulation (DBS) can be considered for palliative aims.

Example 2

Left central lobe intractable epilepsy arose from a malformation of cortical development (MCD) involving motor and language cortex Figure 150.4a. A partial lesionectomy with preservation of hand function after invasive monitoring did not alleviate seizure frequency or severity Figure 150.4b. Other options including vagal nerve stimulation and deep brain stimulation targeting the subthalamic nucleus were performed in an attempt to stop the epilepsia partialis continua that developed after the biopsy procedure. Eventually a

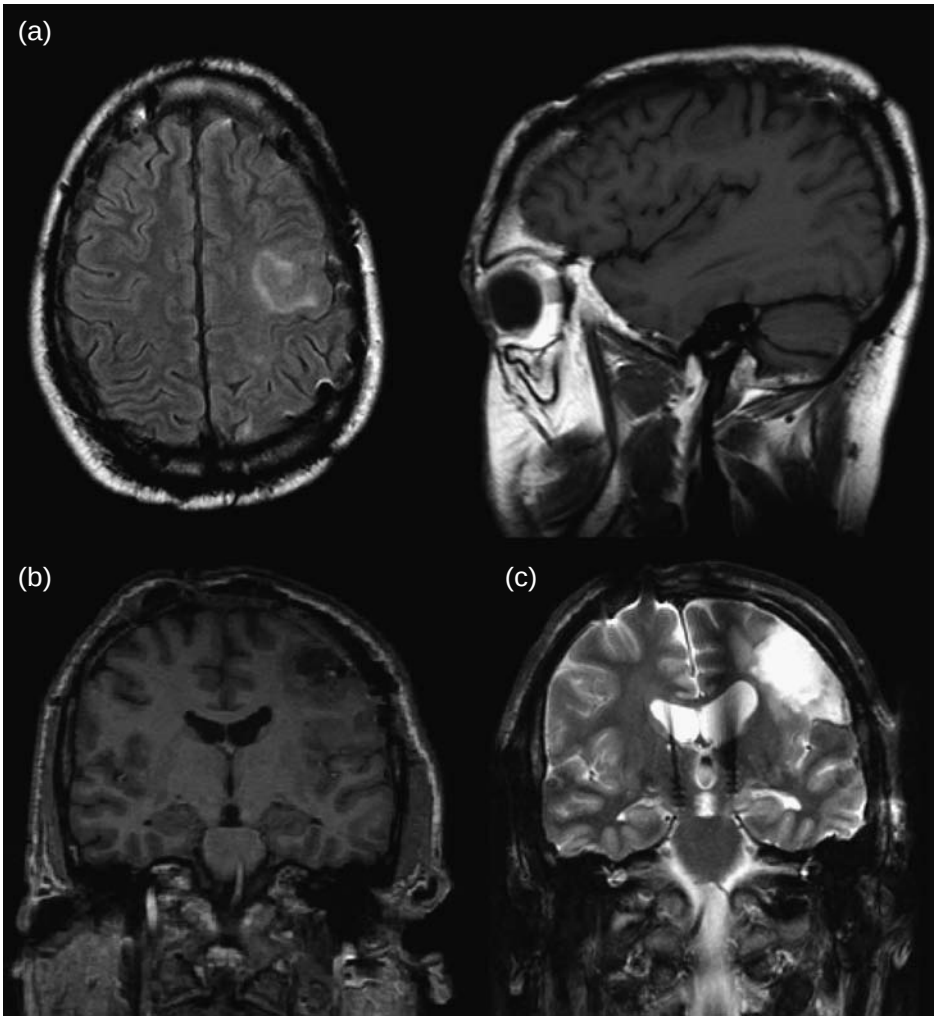

Figure 150.4 a Preoperative MRI of left frontal lobe malformation of cortical development. b. MRI after biopsy procedure, c. final postoperative resection.

lesionectomy completely removing the abnormal cortex was undertaken with successful cessation of the seizures Figure 150.4c. Postoperatively the patient had a significant right hemiplegia and motor aphasia. Recovery of ambulation and language occurred over 12 months. His hand function remains with poor fine motor control.

Postsurgical extension of the epileptogenic zone

Postsurgical processes in the epileptic brain are poorly understood. Cortical re-organization, kindling, and maturation or extension of the epileptogenic zone are processes potentially explaining seizure recurrence. Rasmussen reported the latent period between brain injury and onset of recurring seizures can vary from a few months up to decades.[8] The underlying mechanism of this latent period is still unknown.

Most of the epileptic processes occur in the region of the previous area of pathology such as tumor recurrence, signal changes in MCD, maturation of cortical scarring. However, secondary epileptogenicity can arise from remote areas within the network such as the contralateral hippocampus. For example, Hennessy reported 25% of surgical failures in mesial temporal sclerosis cases had seizure onsets exclusively in the contralateral temporal region.[12]

Weiser reported a patient seizure free for 11 years following stereotactic amygdalotomy who then experienced recurrent complex partial seizure arising from the residual hippocampus. Hippocampectomy regained seizure freedom for at least 9.5 years.[19] This example may indicate a new seizure type arising from a new epileptogenic zone or maturation of the previous epileptogenic zone.

Incomplete resection or disconnection of the epileptogenic zone

Penfield and Jasper first described the role of residual hippocampus resection for the treatment of surgical failure in temporal lobe epilepsy.[20] Rasmussen revealed 45% of 121 patients had remarkable seizure reduction after further cortical excision.[8] Many series confirmed the role of residual epileptogenic lesion removal and long term seizure freedom.[21–23] Surgical resection, if possible, for dual pathology with proof of independent foci should be recommended for long-term seizure freedom.[25] For curative or palliative aims following hemispherectomy, an incomplete disconnection can be the reason for persistence or recurrence of seizures. Postoperative MRI provides useful information for incomplete anatomical disconnection (Figure 150.5). Electroencephalography (EEG) can be difficult to interpret especially following functional

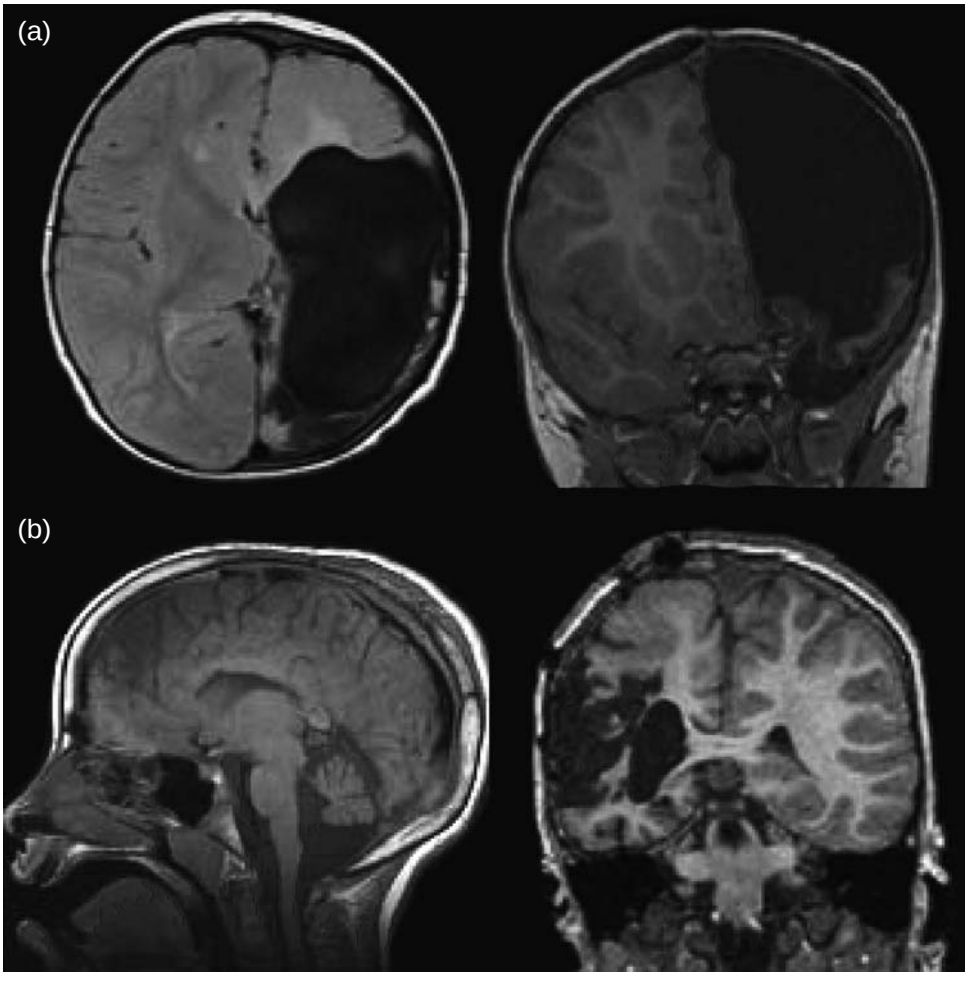

Figure 150.5 Demonstrates two cases of incomplete corpus callosum disconnection causing recurrence of disabling seizures at 6 months and 2 weeks respectively following the first surgery (a – Genu area, b – Splenium area).

hemispherectomy. Clinical semiology is very helpful to determine whether or not the seizure onset is arising from the previously resected hemisphere.

Technical difficulties and complications of using invasive electrodes in reoperation

Foramen ovale electrodes

The electrodes are placed at base of middle fossa (extracranial). Previous intracranial surgery should not be a contraindication for the placement of these electrodes.

Subdural electrodes

The main surgical difficulties for placement of subdural electrodes in previous surgery are dural adhesions with the cortical vessels and distortion of anatomical landmark structures. Careful sharp dissection is necessary, especially when opening adhered dura over major cortical vessels (sylvian fissure). The risk of bone flap infection is also higher in reoperated cases. Watertight dural closure should be accomplished in order to reduce the incidence of CSF leak and postoperative meningitis. Intensive care unit stays during the first 24 hours are routinely recommended for serial neurological examination.

Depth electrodes

Invasive depth electrodes in re-operation cases may carry higher risk of bleeding because of adhesions and anatomical distortion. Depth electrodes should be inserted utilizing stereotactic guidance while observing the precautions of any stereotactic procedure (minimizing crossing of pial planes, avoiding traversing CSF spaces, etc.).

Other technical difficulties

The key to reducing complications during redo-surgery is to find reliable anatomic landmarks in order to orient the surgeon, for example pericallosal artery and corpus callosum. Surgical navigation helps in areas where reliable landmarks are not readily identifiable such as identification of perirolandic cortex and anatomic language areas. Issues that affect stereotactic navigation such as brain shift should be kept in mind as possible technical limitations.

Re-operation in vagal nerve stimulation

The risk of vagal nerve injury may be higher for redo VNS surgery. The main reasons for reoperation are infection and lead failure identified by high lead impedance during device interrogation. Exploration and/or removal or revision of the electrode is often hampered by adhesions and scarring around the

vagus nerve. Redo VNS should be carefully performed under loupe magnification with normal nerve identified above or below the previous operative site. Macdonald recommended using microsurgical dissection for complete removal of the helical electrode from the vagus nerve without apparent physiological consequences.[26]

Outcome of re-operation and its complications

The overall seizure-free outcome for lesionectomy is reported as 70–80%.[23,27] Seizure-free rates after re-operation were described from 20–60%.[9,28–30] The surgical strategies of re-operation for surgical failure vary across individual patients and epilepsy centers. However, two aspects of surgical outcome after re-operation were reviewed. The first aspect is the location of reoperation, which is sub-classified into intralobar resection (same lobe as the first operation), multilobar resection, and distant resection. Shaver reported a 62% seizure-free rate for intralobar resection as compared to 44% seizure-free rate for distant resection or multilobar resection.[29] The second aspect is imaging, which is sub-classified into non-lesional, single lesion, and multiple lesions.

For temporal lobe surgery, residual mesial structures were commonly reported as a cause of surgical failure during the early 1990s. Intralobar resection for residual mesial structures may accomplish a 50–60% seizure-free rate.[21,22,31] Tailored resection based on neurophysiological data and/or functional mapping can be an ideal surgical option for re-operation especially in the dominant hemisphere.[32] Intraoperative hippocampal electrocorticography was also reported for tailored hippocampal resection to maximize seizure-free outcome while leaving a portion of the hippocampus insitu. Hennessy reported 70% of mesial temporal sclerosis had postoperative seizures arising in the same hemisphere of the resection with 85% of those arising from nearby temporal lobe regions. Interestingly, neocortical seizure onset was more frequently found than residual hippocampal seizure onset. Dual pathology was reported in up to 15%, especially in patients with congenital lesions.[33] As our technology improves, the causes of surgical failure may be shifting from technical operative failures to different causes such as large epileptogenic zones, dual pathology, recurrence of tumor, and limited ability for resection to preserve function.[28] Salanova reported the unfavorable factors after reoperation in temporal lobe surgery including a history of head injury or encephalitis and posterior temporal localization. Predictors for favorable outcome after re-operation included anterior temporal localization and abnormal imaging studies.[14]

For frontal lobe epilepsy, Salanova reported 39 of 284 (14%) patients underwent re-operation with a 20% seizure-free rate. The main cause of surgical failure was a large epileptogenic zone, which was demonstrated by residual postresection electrocorticographic spikes.[13]

Re-operation after hemispherectomy had been reported in a few series. Cortical dysplasia is the most common pathological substrate of surgical failure.[34,35] In these cases, a more complete tissue removal operation such as tailored anatomical hemispherectomy may be a better surgical option at the first surgery.[35] In cases of surgical failure after functional hemispherectomy, residual tissue was commonly found at the basal posterior frontal and insular regions. Surgical removal of the residual tissue, especially if it is dysplastic should be considered for maximal seizure-free outcome.[36] The risk of developing postoperative hydrocephalus should be considered for anatomical hemispherectomy.

Acknowledgment

The authors specially thank to Ann Warbel for a great support with the epilepsy patients' database.

Case presentations

151 Lesional mesial temporal epilepsy case discussions

J Mani and IM Najm

Introduction

Lesional mesial temporal epilepsy is by far, the commonest cause of medically intractable partial epilepsy. Mesial temporal sclerosis (MTS) has been identified as the most frequent pathological feature in surgically treatable mesial temporal lobe epilepsy. Mesial temporal epilepsy (mTLE) syndrome is also the epilepsy most frequently associated with drug resistance. It has very good surgical prognosis in suitable candidates.

The establishment of surgical candidacy requires the unambiguous demonstration of the mTLE syndrome associated with MTS, by comprehensive presurgical evaluation.

In this chapter we document the case stories of two patients with mesial temporal sclerosis who had presurgical evaluation followed by surgery, one of the non dominant temporal lobe and the second of the dominant temporal lobe.

Patient 1: clinical details

History

Seizure description and frequency

Ms LN, a 38-year-old, right-handed woman was evaluated for intractable seizures. Her seizure history goes back about 20 years when she developed auras, which she described as a déjà vu sensation occurring about once or twice per month, invariably around her menstrual period. These were brief sensations, lasting 10–15 seconds of familiarity in unfamiliar situations. She took no notice of these events until about a year ago.

Over the 18 months prior to her evaluation, the episodes changed in character. The more recent subjective sensations consisted of a hot flushed feeling in the head with a sensation of *déjà vu* that progressed to loss of awareness. Observers had noted reduced responsiveness with rolling movements of her finger tips, with drooling and chewing. Ms LN had no recollection of this however, and the last event that she remembered of her seizure was the *déjà vu* sensation.

Seizures clustered around her menstrual period, occurring about three to five times a month. There was no history suggestive of a generalized motor seizure, though she did lose control of her urine in one of the episodes.

Between events, Ms LN is in good health. Seizures continued despite two antiepileptic medications in therapeutic doses, Carbamazepine 1200 mg/day and Levetiracetam 2500 mg/day. LN complained of excessive sleepiness on these medications. She had previously been tried on Lamotrigine and Acetazolamide without success.

Medical history and epilepsy risk factors

Perinatal history was notable for neonatal blood transfusion due to Rhesus incompatibility. There was no report of febrile seizures, intracranial infection, or significant head injury. Family history was remarkable in that LN's brother had a single febrile seizure.

Social history

Ms LN had recently lost two jobs in quick succession and was unemployed. She lived with her husband and three children.

Clinical examination

The general physical and neurological examination were unremarkable

Brain imaging

Magnetic resonance imaging (Figure 151.1a, b)

Brain magnetic resonance imaging was performed on a 1.5 Tesla Siemens SP Scanner (Erlangen, Germany). T1-weighted coronal images showed bilaterally small hippocampi with increased signal in the right hippocampal body on FLAIR sequences.

Positron emission tomography (Figure 151.2)

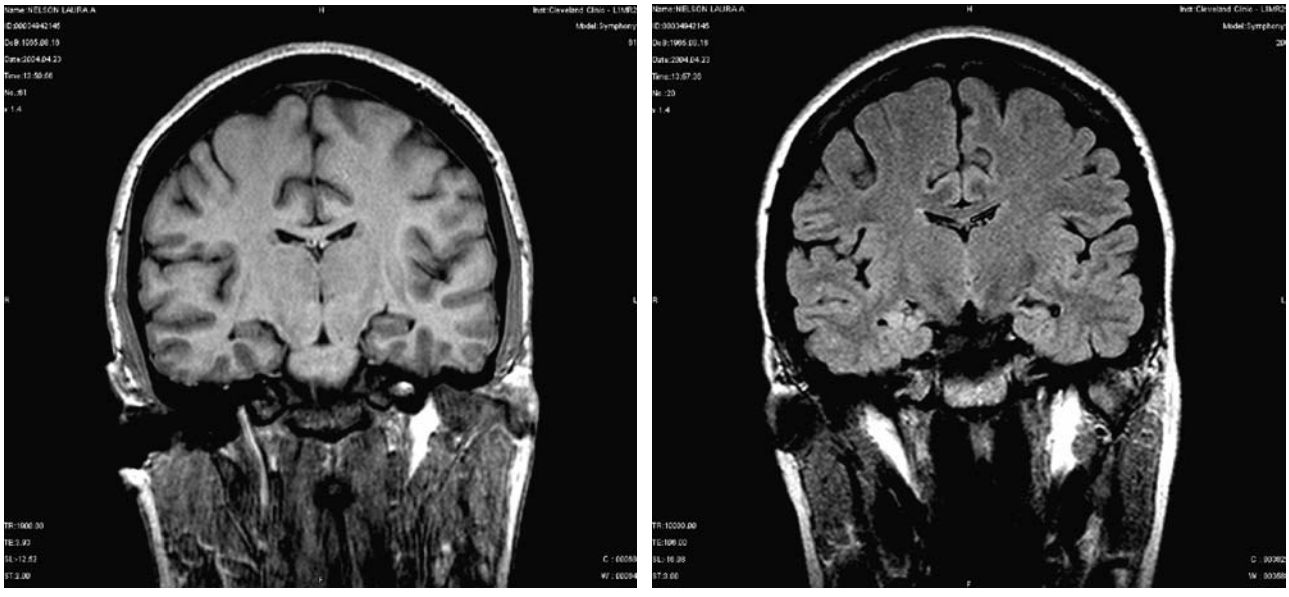
PET study showed reduced Fluorodeoxyglucose uptake in the right mesial temporal structures.

Electrophysiology

A 20 minute scalp EEG did not reveal any epileptiform activity.

Video EEG monitoring

Ms LN underwent video-EEG evaluation after withdrawal of antiepileptic drugs using the 10–20 system of scalp electrode placement with additional 10–10 coverage over the bitemporal regions and with sphenoidal electrodes.



(a) (b)

Figure 151.1 Coronal images through the body of the hippocampi showing biolaterally small hippocampi (T1) with increased signal (FLAIR) in the right hippocampus consistent with predominant right hippocampal sclerosis.

Interictal activity (Figure 151.3a, b)

Runs of intermittent slow activity at 3–4 Hz lasting 3–4 seconds were noted in the right temporal region. These runs were more frequent in drowsiness. Sharp waves were exclusively right temporal with maximum amplitude at the sphenoidal (SP2) electrode.

Ictal activity

Clinical seizure: aura- automotor seizure (loss of awareness)

Five typical seizures were recorded over a period of 24 hours. All the episodes were stereotyped. LN recognized an aura and pushed the button at seizure onset. She was able to declare verbally that she was 'having an aura'. She then had florid mouth and bilateral hand automatisms but continued to follow some verbal and nonverbal commands during the early phase. She was able to appropriately verbalize her name when asked, during the early phase despite the oral automatisms. She subsequently became confused and partially unresponsive during the late phase of the seizure. Immediately after the end of the seizure, LN was able to describe the aura which she called a 'hot flush that spread across her head' with increased salivation. However, she has no recollection of the events after the aura. No postictal tiredness or confusion was noted. The average duration of the clinical event was approximately 1 minute.

This type of seizure would be described under the ILAE system as a *simple partial seizure that evolved into a complex partial seizure*. Under the semiological classification system this would be described as *cephalic aura- automotor seizure*.

The seizure semiology is consistent with temporal lobe involvement, but has no clear lateralizing motor features. However, the preserved awareness and appropriate verbalization during the early phase are consistent with a nondominant temporal lobe origin.

EEG seizure (Figure 151.4a, b)

The ictal pattern on EEG began with rhythmic sharp waves at 1 Hz over the right temporal region, maximum at the sphenoidal electrode. These evolved into rhythmic spikes at 3–4 Hz that then evolved into a sharply contoured theta rhythm (6 Hz) that increased in amplitude but remained localized to the right anterior temporal region without contralateral spread. The clinical and EEG onsets were simultaneous. The duration of the seizure was approximately 60 seconds.

Neuropsychology

Preoperative neuropsychological assessment using the Wechsler Adult Intelligence and Memory Scales III edition revealed a full Scale IQ 118; 116 on the verbal measure, 117 on the visual measure. Verbal memory scores were 111 for the immediate and 99 for the delayed with a delayed recognition score of 90. Visual immediate and delayed scores were 106 and 97, respectively.

Analysis

In summary, data from presurgical evaluation was concordant for a right mesial temporal epileptogenic zone. Seizure semiology was consistent with nondominant temporal lobe origin. Déjà vu sensations that LN reported are commonly associated with epilepsies of the temporal lobes. Isolated auras are reported to be highly specific of mTLE,[1] and in general, are more common in right TLE.[2,3] Oroalimentary and hand automatisms are typical signs in TLE. Preserved ictal consciousness despite involuntary automatisms is a rare finding, but is strongly associated with the primary epileptogenic zone in the nondominant hemisphere.[4] Electrophysiology clearly demonstrated the irritative zone to be in the right temporal lobe, in view of the stable morphology and distribution of the right anterior

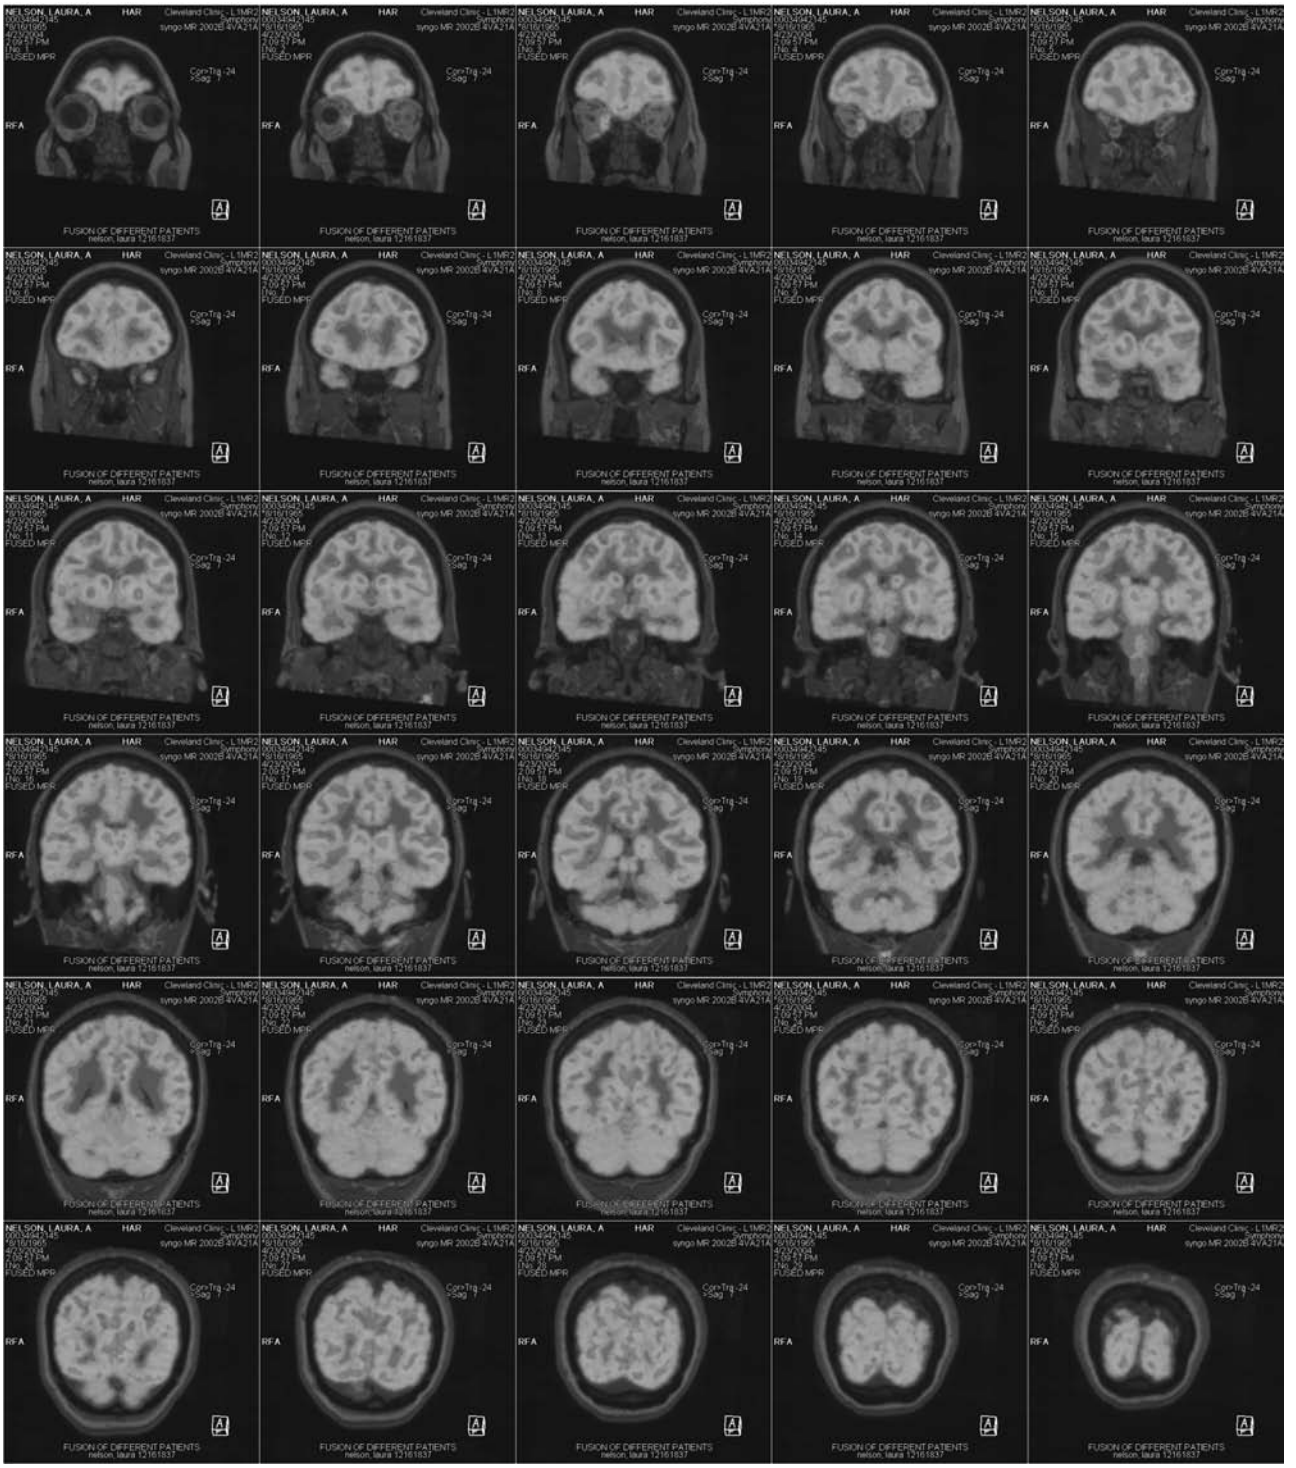


Figure 151.2 Fluorodeoxyglucose PET shows reduced radioactive tracer uptake in the right mesial and basal temporal regions.

temporal spikes. The temporal alpha pattern on the ictal EEG with a maximum in the anterior temporal electrodes confirmed that the seizures (ictal onset zone) were right mesial temporal in origin. This was corroborated by MRI, which revealed right mesial temporal sclerosis. Functional imaging also revealed hypometabolism in the same region. The neuropsychological scores were not strongly lateralized to the right side. Thus the presurgical evaluation was strongly indicative of right mesial temporal lobe epilepsy.

In view of the strong evidence for right mesial temporal lobe epilepsy, the presurgical team was unanimous in its recommendation for right temporal lobectomy. The high preoperative visual memory scores was not considered a deterrent for surgery of the nondominant temporal lobe.

Surgery

Ms LN underwent right temporal lobectomy that included a resection of the lateral temporal lobe extending 5 cm from the temporal pole with removal of the mesial structures. Histopathology was consistent with hippocampal sclerosis.

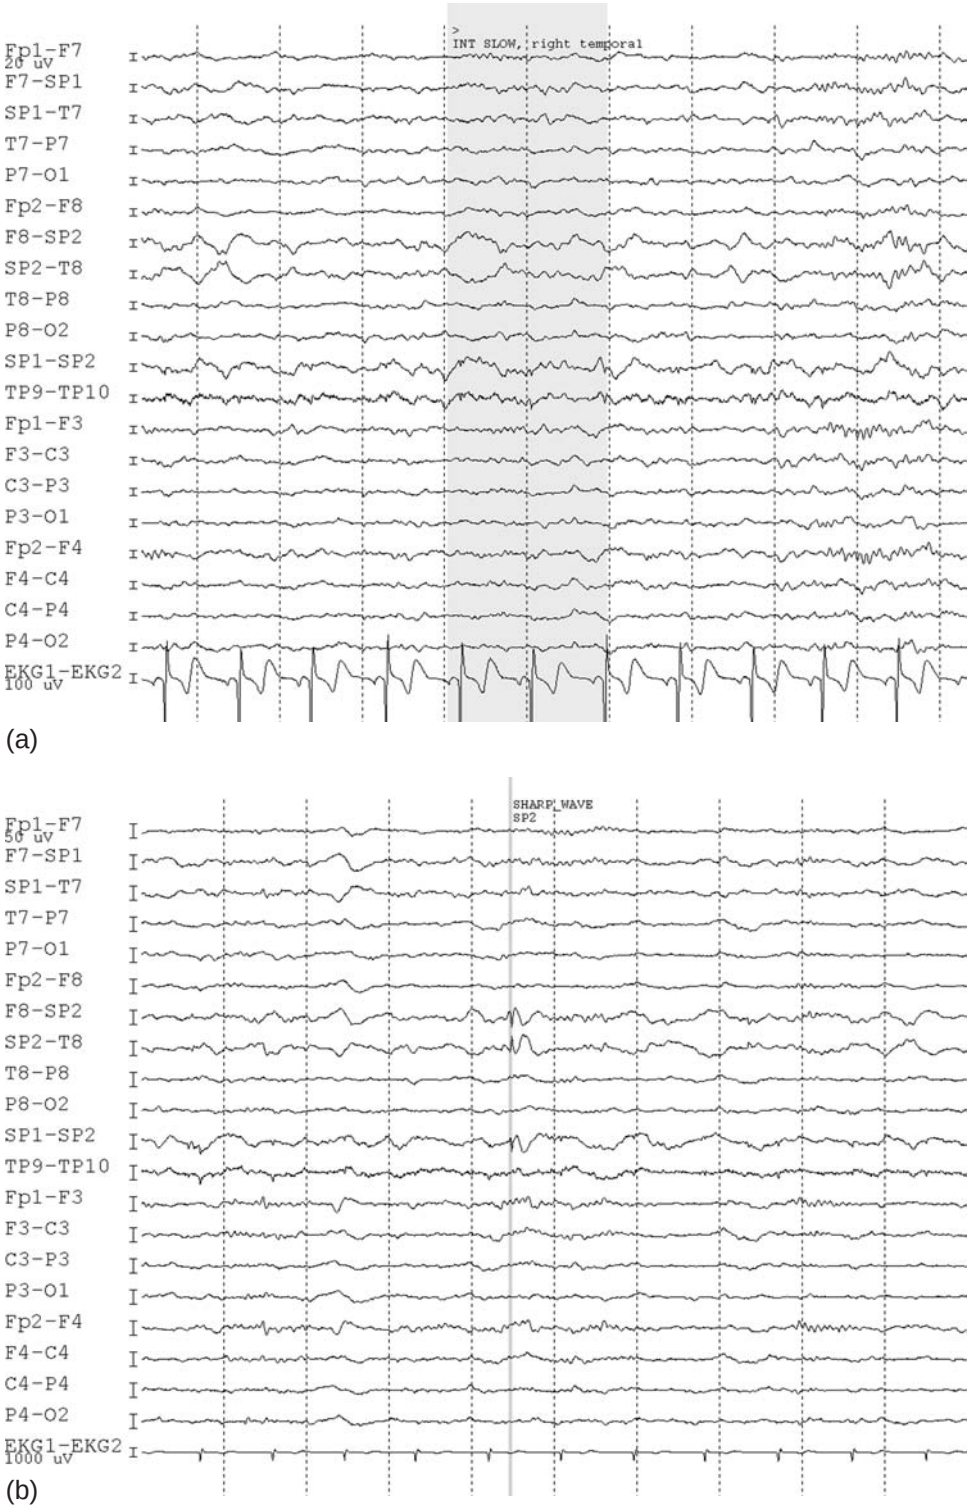

Figure 151.3 (a and b) Interictal scalp EEG tracing on a bipolar montage shows right temporal slowing with sharp waves in the same region having a maximum negativity as SP2.

Post-operative outcome

Ms LN was seizure and aura free at the 6-month follow-up visit. Postoperative MRI revealed resection of the temporal lobe including the mesial structures. Neuropsychological evaluation at 6 months revealed a Full Scale IQ of 121 (superior), a Verbal Comprehension Index of 105 (average), a Perceptual Organization Index of 128 (superior), and a Processing Speed Index of 120 (superior), Auditory Immediate Memory Index of 105, an Auditory Delayed Memory Index of 94, and an Auditory Delayed Recognition Index of 100, Visual Immediate Memory Index of 97 (average) and a Visual Delayed Memory Index of 75 (borderline). These scores were corrected for practice effect and a significant decline was noted in the visual delayed memory scores. In spite of this change, the patient denied having experienced a significant change in her cognitive status or memory as a consequence of her right temporal lobectomy.

Patient 2: clinical details

History:

Seizure description and frequency

Ms DN, a 49-year-old right-handed registered nurse had intractable epilepsy since childhood. Her first seizure occurred at the age of 1 year in the context of high-grade fever secondary to pneumonia. Rare seizures persisted until age 9. These were described as episodes of staring followed by generalized body shaking. She was seizure free on a combination of phenytoin and phenobarbital for many years. Antiepileptic medications were tapered and discontinued at age 28.

Seizures recurred at age 31 during the eighth month of DN's second pregnancy. The seizure frequency increased from one to two per year in the first 3 years of recurrence to two per month in the year prior to the presurgical evaluation.

DN reported an aura which she described as 'a sick feeling in my stomach' and 'a little light headedness,' which lasted for 1–2 min. This was usually followed by loss of awareness. 'All I know is that I do pass out'. Observers reported that she was unresponsive, and then had jerking of her limbs (more marked in the lower limbs) for seizures that lasted more than 30 seconds. She occasionally bit her tongue during seizures but had never been incontinent. There was no significant postictal confusion, but DN had language difficulties. 'When I'm starting to come out of it I know what is happening around me, but I cannot talk'. For example she was able to identify in her mind that she was looking at a computer, but could not 'get the thought related to my speech'. This difficulty in speaking lasted for 30–90 seconds.

There was no history of generalized motor seizures or status epilepticus.

Medical history and epilepsy risk factors

DN had hypertension, depression and chronic back pain. She worked as a part-time registered nurse and continued to drive. Seizures persisted despite a trial of three different antiepileptic drugs (Phenytoin, Phenobarbital, Oxcarbazepine) in the past and the present combination of Lamictal 900 mg/day and Phenytoin 500 mg/day.

Brain imaging

Magnetic resonance imaging (Figure 151.5a, b)

MR imaging of the brain in a 1.5 Tesla Siemens SP scanner (Erlangen, Germany) revealed left mesial temporal sclerosis in the form of a shrunken left hippocampus (head, body, and tail) in T1 coronal images and increased hyperintensity of the left mesial temporal structures on FLAIR imaging.

Positron emission tomography (Figure 151.6)

An interictal PET study of the brain showed reduced fluorodeoxyglucose uptake in the left mesial temporal structures and the anterior temporal neocortex.

Electrophysiology

Routine EEGs documented intermittent slowing and occasional sharp transients in the left temporal region.

Video EEG evaluation

Ms DN underwent video-EEG evaluation with discontinuation of antiepileptic medications over a period of 8 days using 10-10 system of scalp electrodes and additional sphenoidal electrodes.

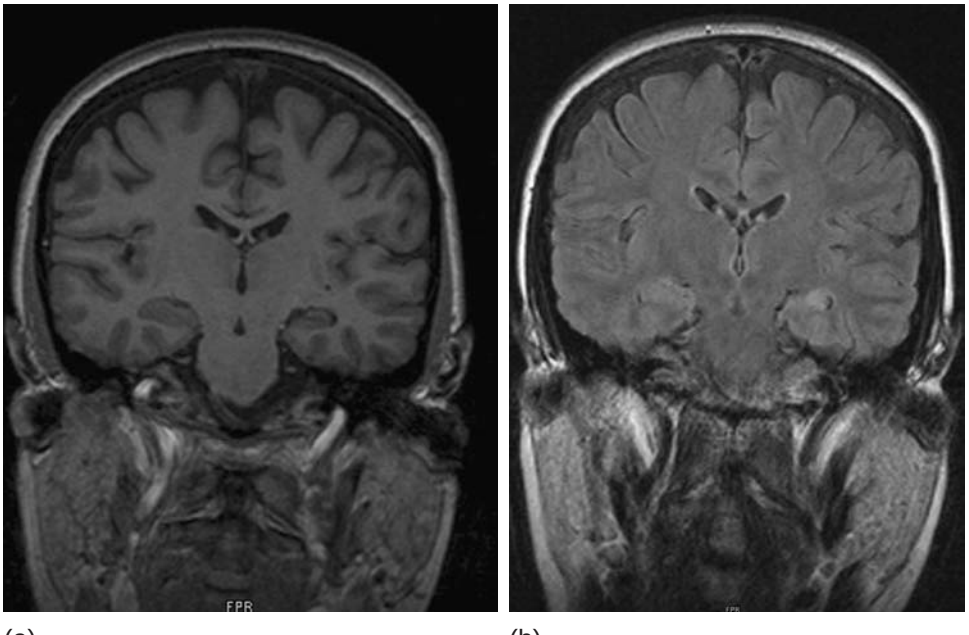
Interictal activity (Figure 151.7)

Interictal recording revealed intermittent left temporal slowing at 5–7 Hz lasting 2–3 seconds in sleep and wakefulness. Rare left temporal spikes were recorded which were maximum at the sphenoidal electrode.

Ictal activity (Figure 151.8a, b)

Clinical seizures: automotor seizure (loss of awareness)

Two of the three typical seizures recorded occurred out of wakefulness. DN did not recognize the onset of her seizures. The seizure began with a prolonged period of staring. She then had chewing and swallowing movements. She was tested towards the end of the clinical seizure and was partially attentive but had difficulty following commands. After the end of the EEG seizure, DN was fully attentive but had difficulty



(a) (b)

Figure 151.5 (a and b) Coronal images through the body of the hippocampi showing a smaller left hippocampal body (T1 image) with increased signal (FLAIR) consistent with left hippocampal sclerosis.

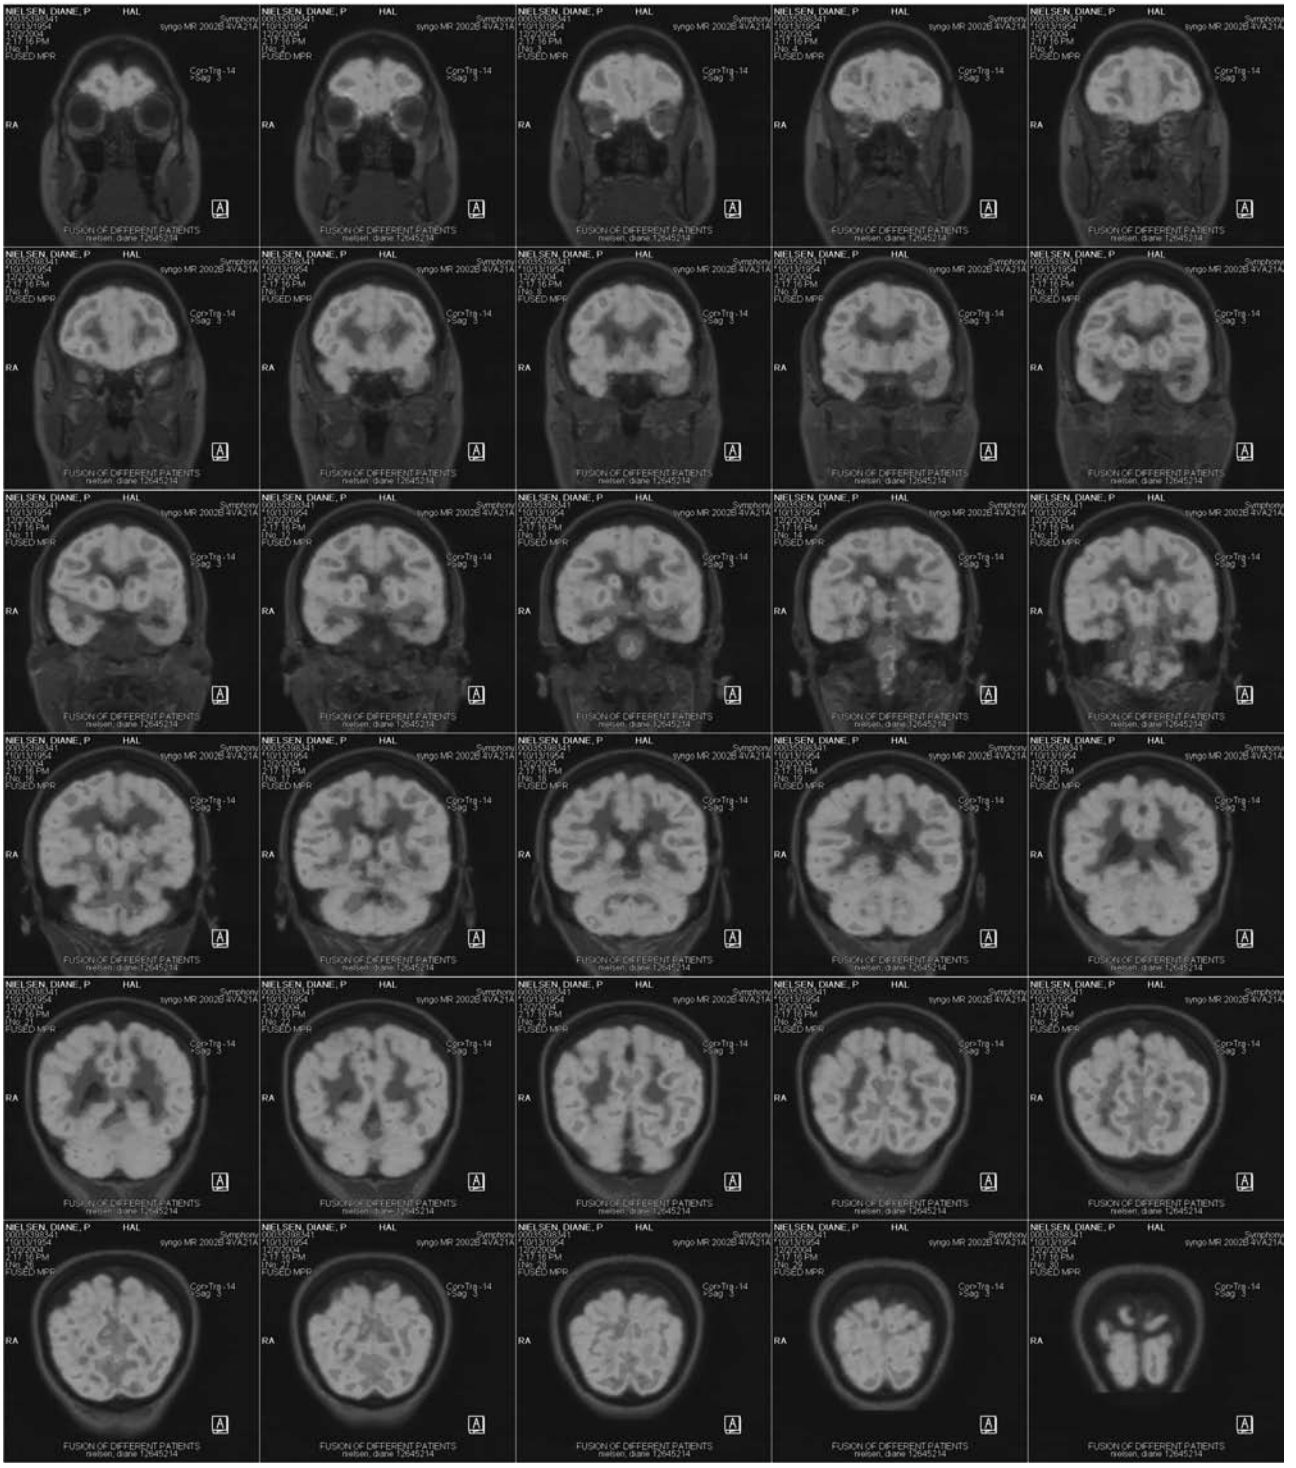


Figure 151.6 Fluorodeoxyglucose PET shows reduced radioactive tracer uptake in the left mesial and basal temporal regions.

saying her name, repeating words and naming a pen. She was however able to stick out her tongue and point to her nose when instructed. This phase lasted for 90 seconds. She later reported being aware of the testing but being unable to speak. This seizure would be labeled a complex partial seizure in the ILAE classification. In the semiological seizure classification this would be an *automotor seizure with loss of awareness*. LN had classical postictal aphasia which lateralized the seizure to the left hemisphere.

EEG seizures

Ictal EEG patterns were stereotyped in all the three seizures.

EEG onset was marked by a rhythmic theta frequency discharge over the left temporal chain, maximal at Sp1. This evolved over 15 seconds to rhythmic spiking over the left hemisphere, that continued for another 25 seconds before slowing to a delta frequency rhythm with sharp components. The delta slowed further, and became smoothly contoured before the end of the EEG seizure. There was no significant involvement of the opposite side in the initial and spiking phase, and modest involvement with a low-amplitude delta-frequency rhythm in the latter part of the seizure. Duration of EEG seizure was 1 min 28 sec.

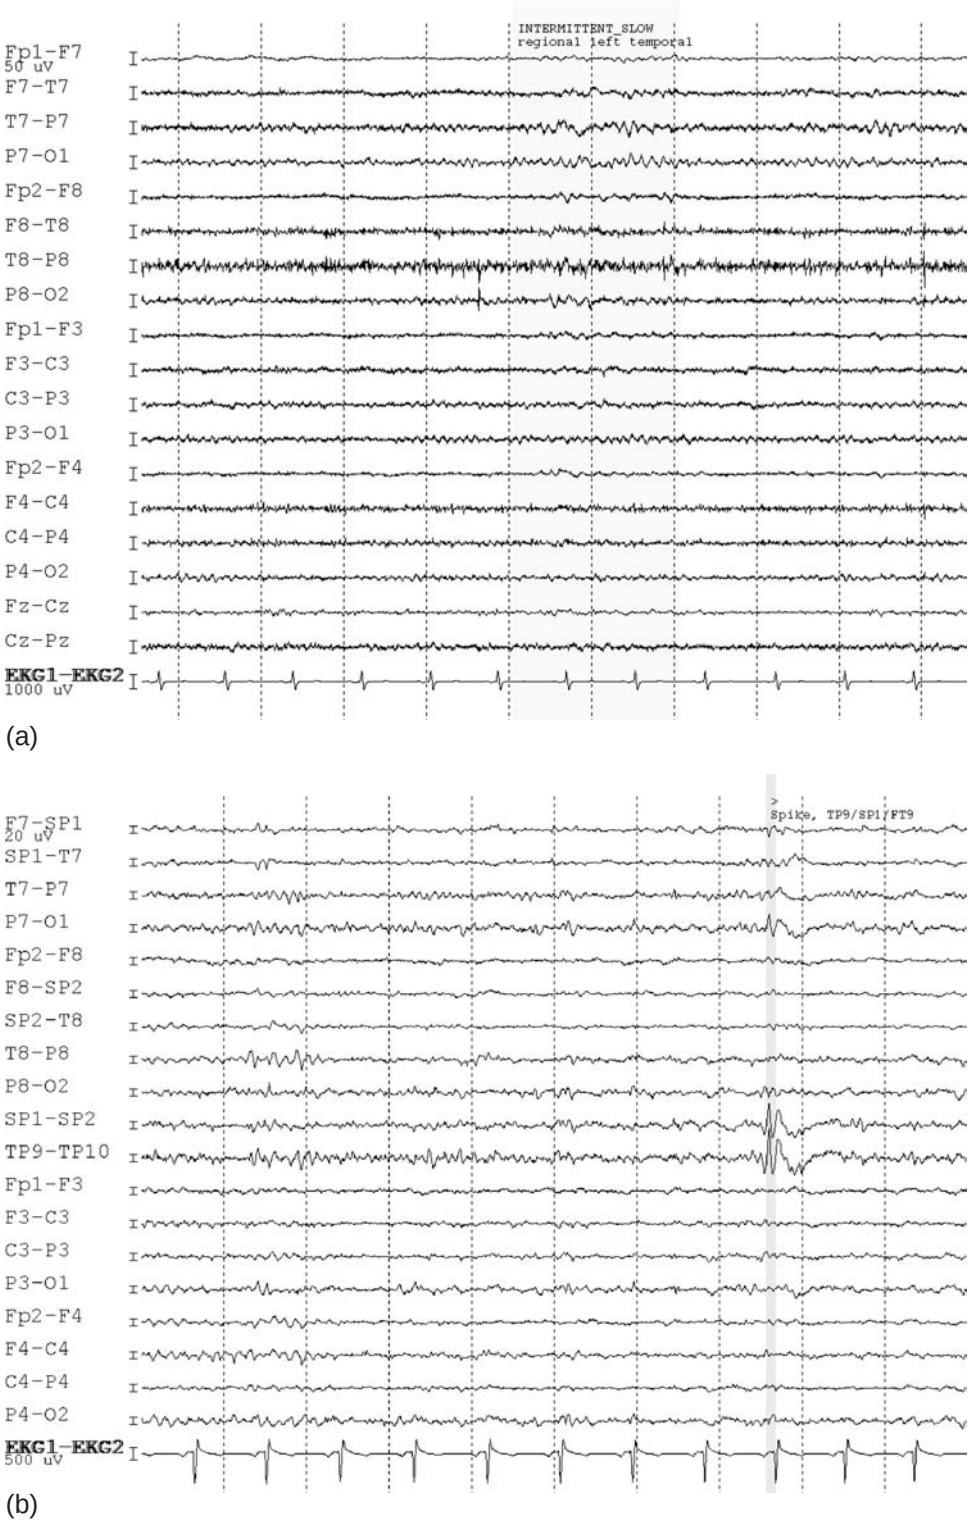

Figure 151.7 Interictal scalp EEG tracing on a bipolar montage shows left temporal slowing with sharp waves in the same region having a maximum negativity as left sphenoidal electrode SP1.

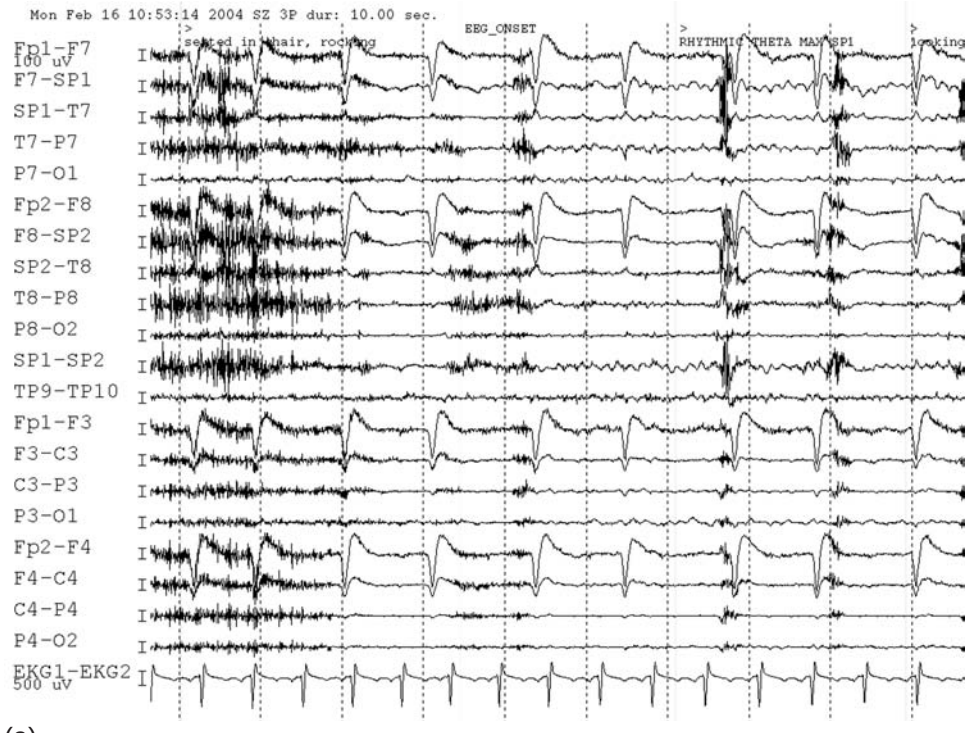
Neuropsychology

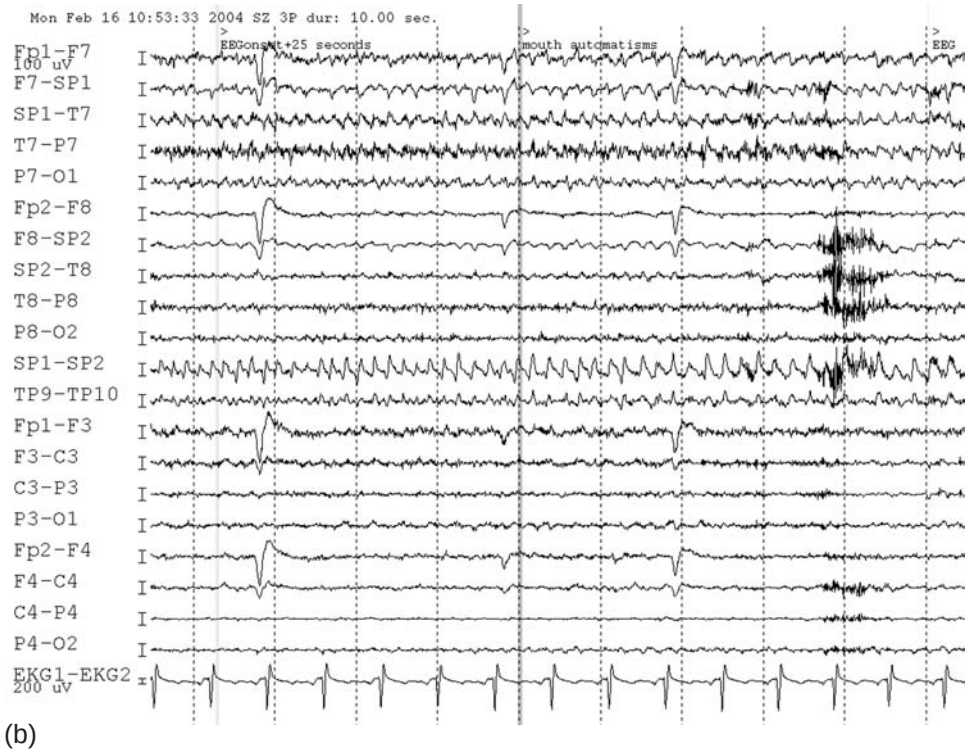
Neuropsychological examination using the Wechsler Adult Intelligence and Memory Scales Version III revealed an average level of preoperative functioning with no asymmetry of verbal and visual scores. The Full Scale Intelligence Quotient (IQ) was 97 with the Verbal IQ at 98 and Performance IQ at 94. Scores for Immediate Memory were 77 and 75 in the verbal and visual spheres, with delayed memory scores of 80 and 78 for verbal and visual material respectively.

Analysis

In summary, the preoperative evaluation provided evidence of left temporal lobe epilepsy, with complete concordance



(a)



(b)

Figure 151.8 (a and b) Ictal rhythms at seizure onset and after 25 seconds documenting the left temporal seizure rhythm with a left sphenoidal (SP1) maximum.

between seizure descriptions by history, interictal EEG, observed clinical semiology, ictal EEG and neuroimaging. Epigastic auras are very common in mTLE but are not specific for mesial temporal seizure origin.[5] Though the seizure semiology in itself was not lateralizing, LN had a striking postictal aphasia. Post ictal aphasia has been consistently associated with seizure onset in the language dominant hemisphere.[3,6–8] The neuropsychological scores did not lateralize memory deficits. In view of the average preoperative verbal memory scores and the presence of significant hippocampal sclerosis on MRI, it was predicted that Ms LN would have only a small risk for memory decline. It was concluded that no Wada test was necessary. DN was offered a left anterior temporal lobectomy.

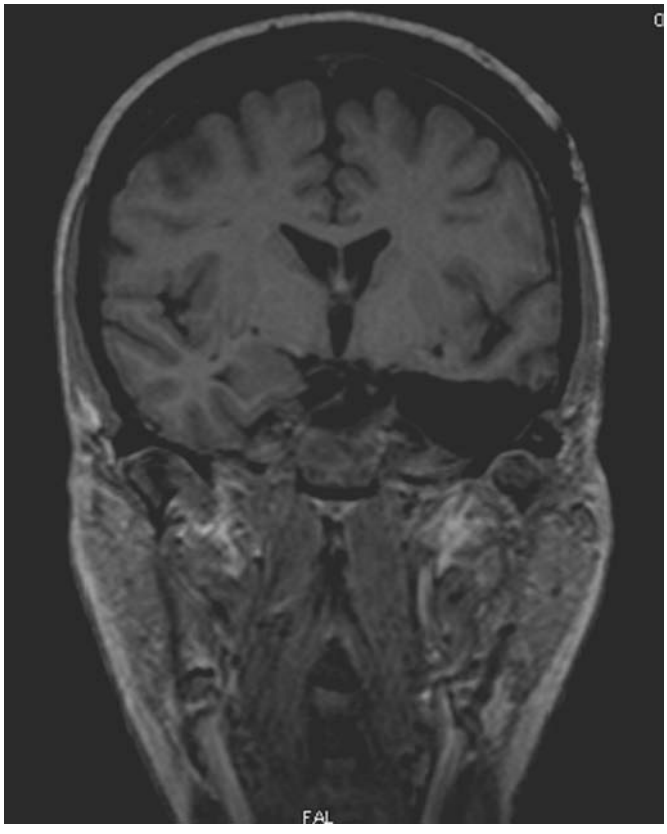


Figure 151.9 Postoperative coronal T1 image showing the resection of the lateral and mesial left temporal structures (6-month postoperative image).

Surgery

A left temporal lobectomy was performed under general anesthesia. Four and a half centimeters of the lateral temporal lobe were removed with resection of the amygdala and the hippocampus. The parahippocampal gyrus was also resected. DN had an uneventful postoperative course. Histopathology revealed hippocampal sclerosis.

Post-operative outcome

Ms DN was seizure free at the 6-month follow-up visit. Phenytoin was discontinued and she was maintained on Lamictal monotherapy. DN continued to do well at the 1-year follow-up visit. She had a single seizure in the 10th month after surgery. Follow-up neuropsychological assessment showed improvement in raw scores for all subsets of performance but these were not considered significant after correction for practice effects.

Discussion

The essential purpose of the presurgical evaluation in lesional mTLE surgery is to demonstrate the overlap between the epileptogenic lesion and the epileptogenic zone.

Seizure semiology in MTLE

Ictal semiology is a reflection of the activation of the symptomatogenic zone(s). The symptomatogenic zone is usually located in the proximity of the epileptogenic zone but very frequently it does not overlap with the epileptogenic zone. It is essential to remember that no single symptom or EEG feature in isolation is diagnostic of mesial temporal cortical activity. It is therefore crucial not to evaluate any symptom in isolation, but to consider the sequence and context of their occurrence.[5]

EEG in mTLE

Interictal discharges in hippocampal sclerosis have a very localized field which may be missed by scalp electrodes.[9] When recorded in the scalp-EEG, they are highly restricted to the anterior temporal electrodes. True anterior temporal electrodes help increase the likelihood of recording temporal interctal epileptiform discharges (IEDs). Sphenoidal electrodes and anterior temporal electrodes help in the differentiation between neocortical temporal epilepsy (spikes have higher amplitude in mid-temporal electrodes) and mesial/anterior temporal epilepsy (spikes have a relatively higher amplitude in sphenoidal and anterior temporal electrodes). Frequent posterior temporal or extratemporal sharp waves may decrease the certainty of the diagnosis of hippocampal sclerosis. *Ictal rhythms* in the form of rhythmic theta (Figure 151.4a) or alpha activity (Figure 151.8a) within the first 30 seconds of the electrographic or clinical seizure onset are observed in approximately 80% of patients with mTLE and have a high lateralizing value.[10,11] However these patterns are significantly more common in patients with moderate to marked hippocampal atrophy rather than those with mild hippocampal atrophy.[12] Neocortical ictal onset patterns may be indistinguishable from those of mesial temporal origin, but some authors have suggested that the 5–9 Hz inferotemporal rhythm is more specific for hippocampal onset seizures.[13]

In patients with history and ictal symptoms suggestive of mTLE, interictal discharges can reliably lateralize the seizure focus if they are consistently unilateral and concordant with the MRI identified unilateral hippocampal atrophy. Concordance of MRI and interictal EEG is more closely associated with good surgical outcome than concordance of MRI and ictal EEG findings with nonlateralized interictal EEG.[14] Studies indicate that noninvasive ictal EEG recordings do not improve seizure localization in patients with suspected TLE in whom MRI and interictal EEG are concordant.[15]

Neuropsychological outcome in mTLE

Cognitive outcome after temporal lobe surgery has been recently evaluated in multivariate analyses.[16,17] Dominant hemisphere surgery, extent of mesial temporal sclerosis on volumetric MRI and good baseline memory scores on neuropsychological testing were associated with a greater risk of memory decline following surgery. IAP memory scores did not contribute to the prediction of memory deficits in one study,[16] but ipsilateral IAP memory score was an independent predictor of outcome in another study.[17]

Conclusion

Lesional mesial temporal lobe epilepsy lends itself to a simple and fairly standardized presurgical work-up and promises an excellent surgical outcome. In patients with intractable focal epilepsy and MTS on MR imaging, it is tempting to assume that the MTS is identical to the epileptic region. However it has been shown that the positive predictive value of MTS alone is not satisfactory.[18] Hence it is essential to establish the overlap of the epileptogenic lesion with the irritative zone, the seizure onset zone and the functional deficit zones, by complementary multimodality testing. Such a demonstration of concordance may permit more selective surgery such as a selective amygdalohippocampectomy. The aim of a limited resection would be to limit postoperative functional deficits especially in cases with dominant temporal lobe epilepsy. The value of selective over more extensive temporal lobe resections in limiting deficits and in relative seizure outcome is still a matter of intense debate.[19,20]

152 A patient with nonlesional mesial temporal lobe epilepsy

A Ray, G Kalamangalam, and HO Lüders

Clinical history

The patient was a 14-year-old right-handed female whose seizures started at the age of 9 years. Seizures were characterized by a blank stare, followed by repetitive semi-purposeful movements of her hands and lip-smacking (manual and oral automatisms). No preictal aura was reported. Observers reported that she was unable to speak during the seizure; she was amnestic for the seizure afterwards. She would usually fall asleep in the postictal period, though on occasion she would be awake and combative. Seizures lasted approximately 1 minute; seizure frequency varied from weekly to as many as seven seizures per day. There was no history of generalized motor seizures.

There was no past history of febrile seizures, significant head trauma, or intracranial infection. Her health otherwise was excellent. There was no family history of epilepsy or other neurological disease.

The patient had failed combinations of multiple antiepileptic drugs (AEDs) including zonisamide, topiramate, levetiracetam, carbamazepine, and phenobarbital.

Previous EEGs had shown sharp waves at the left anterior temporal electrodes (F7, T7).

General physical, and complete neurologic, examination was normal.

Noninvasive video-EEG monitoring

Recordings were performed with the usual 10–20 scalp electrode coverage with additional sphenoidal electrodes.

Interictal EEG

Spikes, regional left temporal, maximum at the left sphenoidal (Sp1) electrode (Figure 152.1); 100% of discharges.

Ictal EEG

Four seizures were recorded.

Clinical seizures

These were characterized by blank staring, florid oral automatisms, and symmetric automatisms of the upper extremities. The patient could not speak or follow commands during seizures.

Figure 152.1 Left temporal spikes (location marked by grey dots) on scalp EEG, maximum at the left sphenoidal (Sp1) electrode.

In this phase progressed to clonic movements of the right side of the face. The patient was aphasic in the postictal period and wiped her nose with her left hand. In the ILAE classification system, the patient would be regarded as having complex partial seizures, as there appeared to be an 'alteration of consciousness' during the seizure. However under the semiological classification system[1] followed in the Cleveland Clinic, the patient would be classified as having automotor seizures progressing to right face clonic seizures, with lateralizing signs of postictal aphasia and postictal nose-wipe. The latter two features, and the right face clonic activity, suggested a dominant (left) hemisphere seizure onset.[2,3]

EEG seizures

Regional left temporal. Seizures began with brief electrodecrement over the left temporal region. This was followed (usually within approximately 10 seconds) by rhythmic theta activity over the left temporal region, maximal over the left sphenoidal (Sp1) electrode. Theta activity usually lasted between 30–40 seconds followed by postictal slowing, again maximal over the left temporal region (Figure 152.2).

High-resolution brain MRI

Normal T1-weighted and FLAIR coronal sequences. In particular, there was no evidence of shrinkage or asymmetry of hippocampal volumes, or hippocampal high signal (Figure 152.3).

PET (positron emission tomographic) scan

Left temporal hypometabolism (Figure 152.4).

Ictal SPECT (single photon emission computed tomographic) scan

Injection was performed at 35 seconds after EEG seizure onset. Intense ictal hyperperfusion (20–25%) was observed in the left temporal region (Figure 152.5).

Neuropsychological evaluation

This is detailed in Table 152.3 (left-hand columns). Memory was mildly impaired overall, with low-average impairment of verbal immediate memory (with delayed verbal recall relatively spared), and impairment of both immediate and delayed visual recall. Full-scale and verbal IQ were both in the normal range, with performance IQ scored in the low-average range. Overall, the patient was judged to function in the average range of intellectual ability, with an advantage for verbal, over nonverbal, material. Memory scores also reflected an advantage for verbal over visual tasks. This pattern was considered unusual in view of her right-handedness and putative left temporal lobe epilepsy. She was deemed to be at risk for decline in her verbal memory if subjected to left anterior temporal lobectomy.

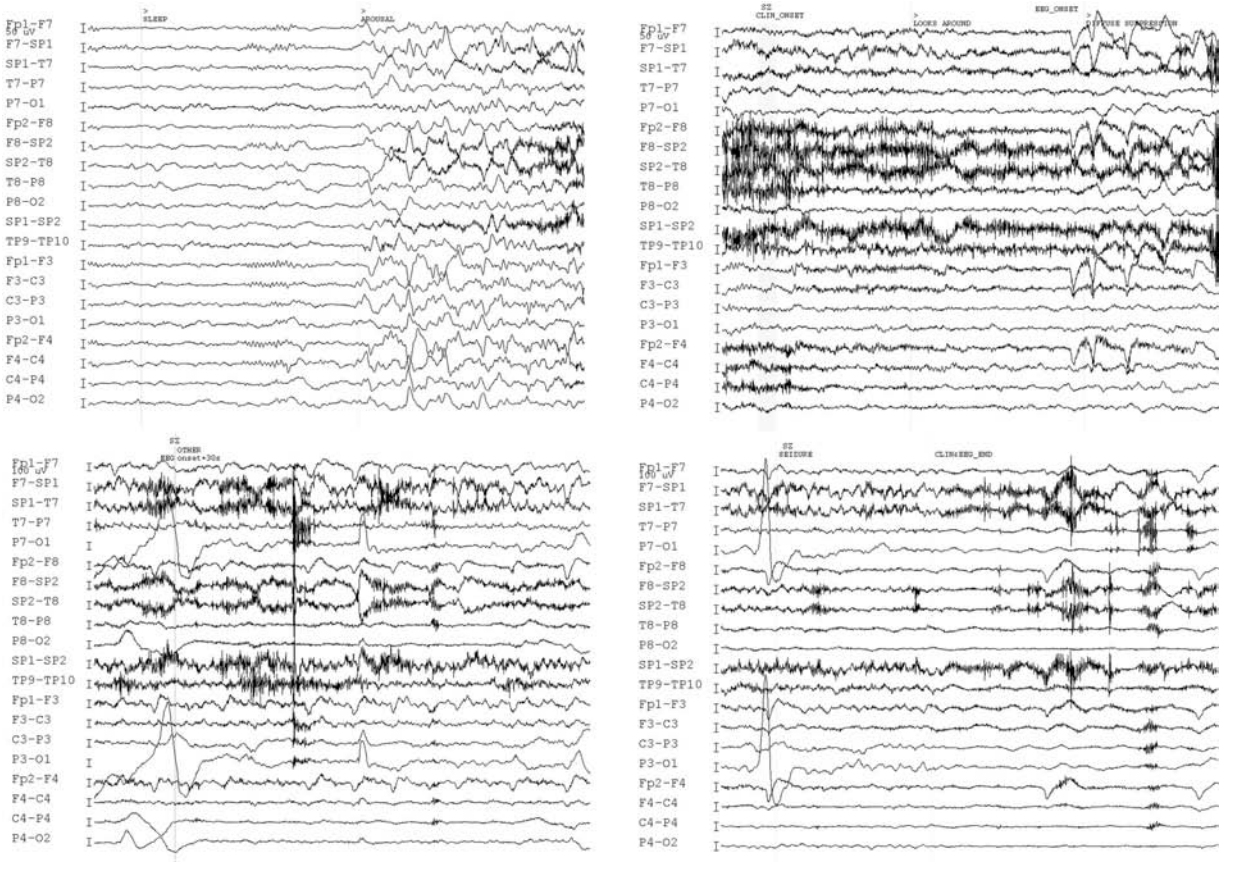

Figure 152.2 EEG seizure on scalp EEG. Top left: Baseline: sleep in the first half of the page followed by arousal. Top right: Clinical onset followed about 8 seconds later by EEG seizure onset characterized by brief electrodecrement. Bottom left: EEG Onset + 30 seconds: theta rhythms are seen over the left temporal region, maximum over the Sp1. Bottom right: Seizure rhythms continue in the first half of the page, terminating in the middle of the page. Postictal slowing follows, again maximal over the left temporal region.

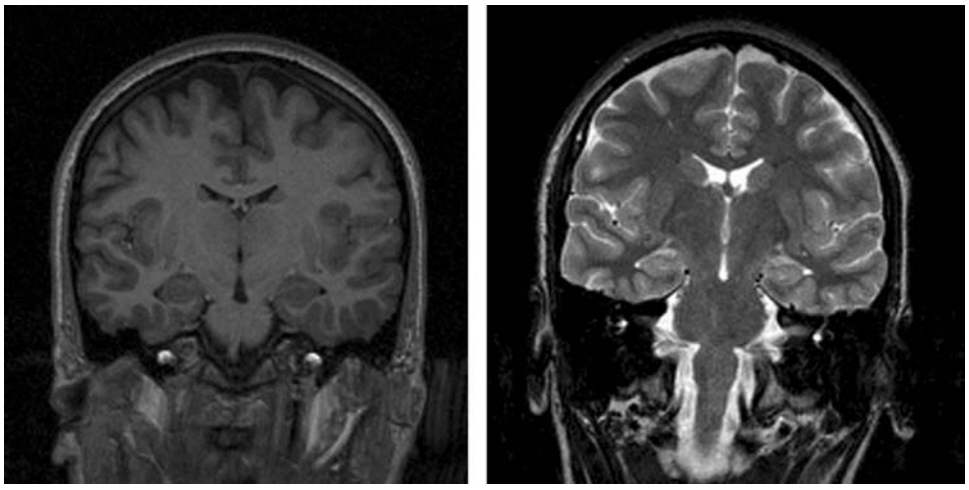

Figure 152.3 Brain MRI. Left image shows T1-weighted volumetric coronal sequences. Right image is a T2-weighted coronal study. Hippocampi are normal in volume and appearance.

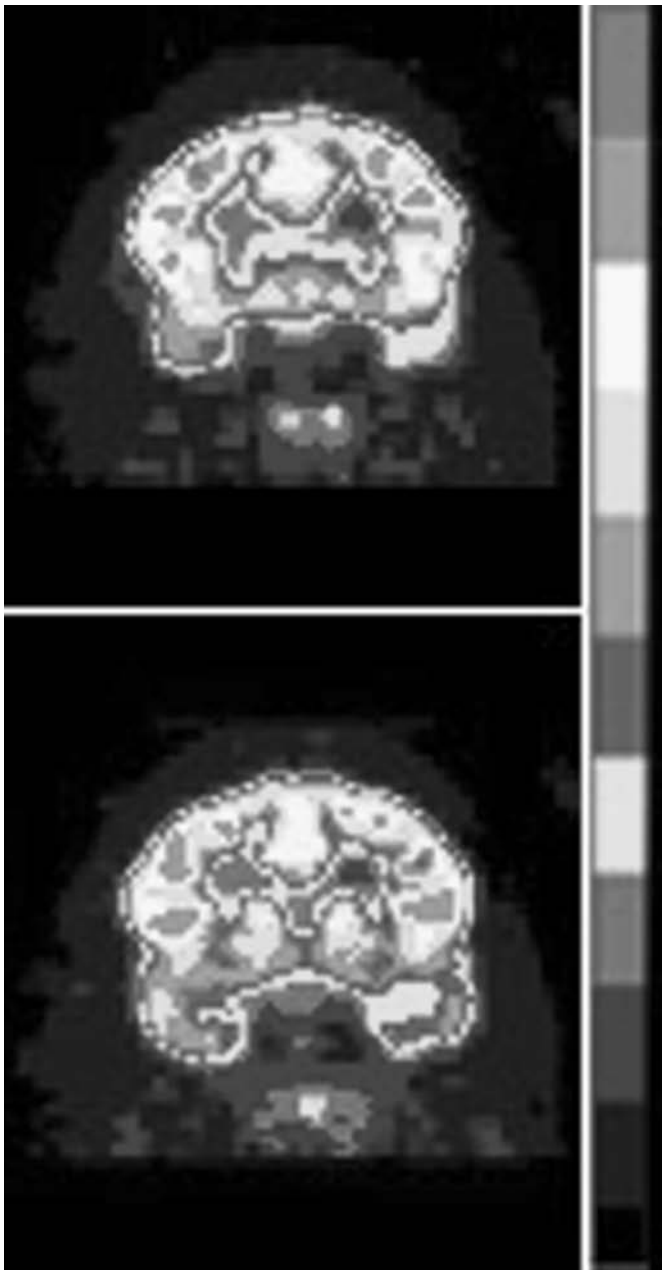

Figure 152.4 (Interictal) PET scan: left temporal hypometabolism.

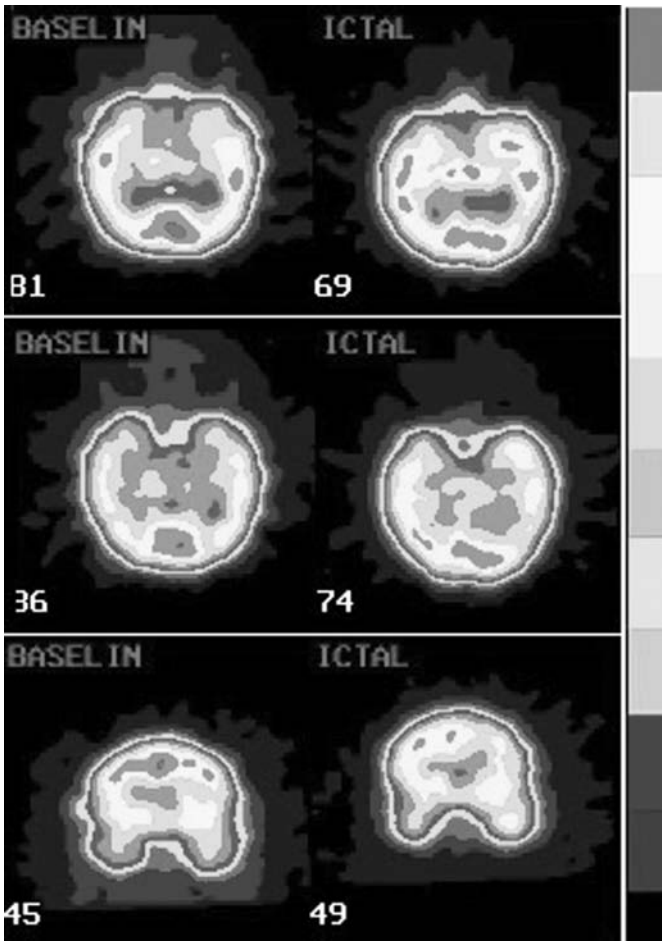

Figure 152.5 Ictal SPECT scan: left temporal ictal hyperperfusion. Axial (top two) and coronal (bottom) images.

Intracarotid amobarbital (Wada) testing

Results are summarized in Table 152.1. There was left hemispheric dominance for language, and bilaterally intact memory representation. Together with the preoperative neuropsychological evaluation, this emphasized the risk for some decline in verbal memory following left temporal lobe resection.

Summary of evaluation and further management

The patient's history and seizure semiology suggested left temporal lobe epilepsy. Interictal EEG showed a single population of epileptiform discharges, maximum over the left sphenoidal electrode; ictal EEG rhythms were best developed over the left sphenoidal electrode (with the earliest changes of electrodecrement also over the left temporal region). The electrographic findings were thus of left mesial temporal lobe epilepsy. Interictal PET and ictal SPECT were concordant. However, the lack of an MRI lesion, the relatively preserved verbal memory scores on the neuropsychological evaluation, and bilateral memory representation on Wada put her at risk for memory decline following a standard left anterior temporal lobectomy.

Following discussion at the epilepsy patient management conference, it was recommended that the patient undergo invasive evaluation with subdural grid electrodes prior to resective surgery. This would allow precise localization of the ictal onset zone, allowing a tailored resection sparing eloquent cortical areas identified by cortical stimulation mapping.

Invasive video-EEG monitoring

Four subdural grids were placed at craniotomy (Figure 152.6). The A-plate (8 × 8) covered the lateral aspect of the inferior left frontal lobe and the adjacent left temporal lobe. The posterior edge of this plate overlapped the central sulcus. The B-plate (4 × 4) covered the left orbitofrontal region as well as the anteroinferior aspect of the left frontal lobe. The C-plate (2 × 6) was placed over the left midbasal temporal region. The D-plate (1 × 6) covered the left basal temporooccipital region. The position of electrodes was confirmed by 3D reconstructed MRI (Figure 152.7).

Interictal EEG

Recordings were reviewed in a referential montage to an electrode on the A-plate (SA59), presumed distant from the irritative zone. Two populations of epileptiform activity were observed.

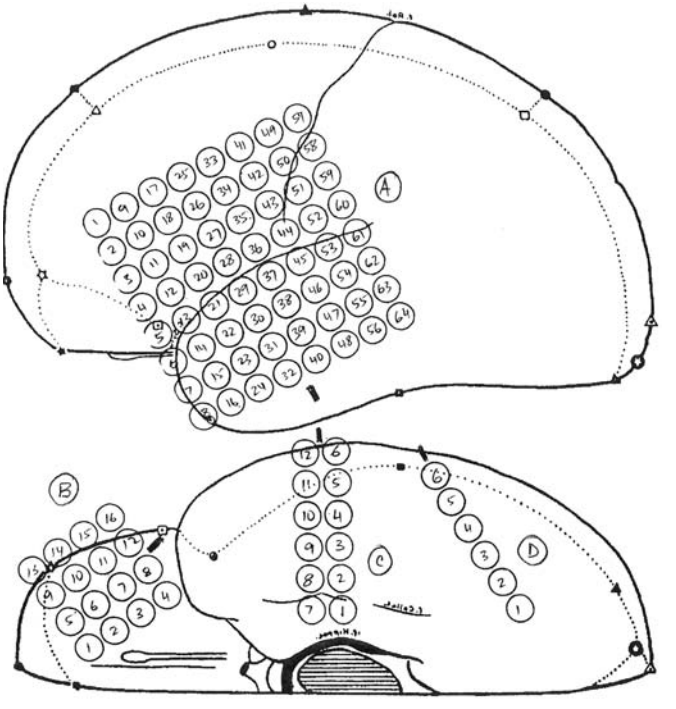

Figure 152.6 Schematic diagram showing A, B, C and D subdural electrode plate positions.

- *Spikes, left mesial temporal:* These were the most frequent (70% of discharges) and present over the C-plate. These were usually maximum over C1 and C7 (Figure 152.8), and occasionally over C10.
- *Spikes, left anterior temporal:* This independent population was present over the A-plate and comprised 30% of all discharges. Spikes were usually maximum over the A8, A16 or A23 electrodes (Figure 152.9).

Ictal EEG

Five seizures were recorded. Semiologically, these seizures were identical to those seen during the noninvasive evaluation, including one that progressed from an automotor phase involving oral and upper extremity automatisms to clonic activity of the right side of the face. Ictal EEG change preceded clinical symptoms by 7–8 seconds but on occasion by up to 30 seconds. The first EEG changes seen were poly-spikes (Figure 152.10) and paroxysmal fast activity over the left mesial temporal electrodes (C1>C2) followed by diffuse suppression over the left frontotemporal region (anteroinferior A-plate and entire C-plate) as well as the left orbitofrontal (B-plate) region. About 20 seconds after

Table 152.1 Wada test

	Left Injection	Right Injection
First verbal response	1 min 18 seconds after injection (followed by perseveration until 1 minute 37 seconds)	12 seconds after injection
Memory retention score	11/12 (92%)	12/12 (100%)

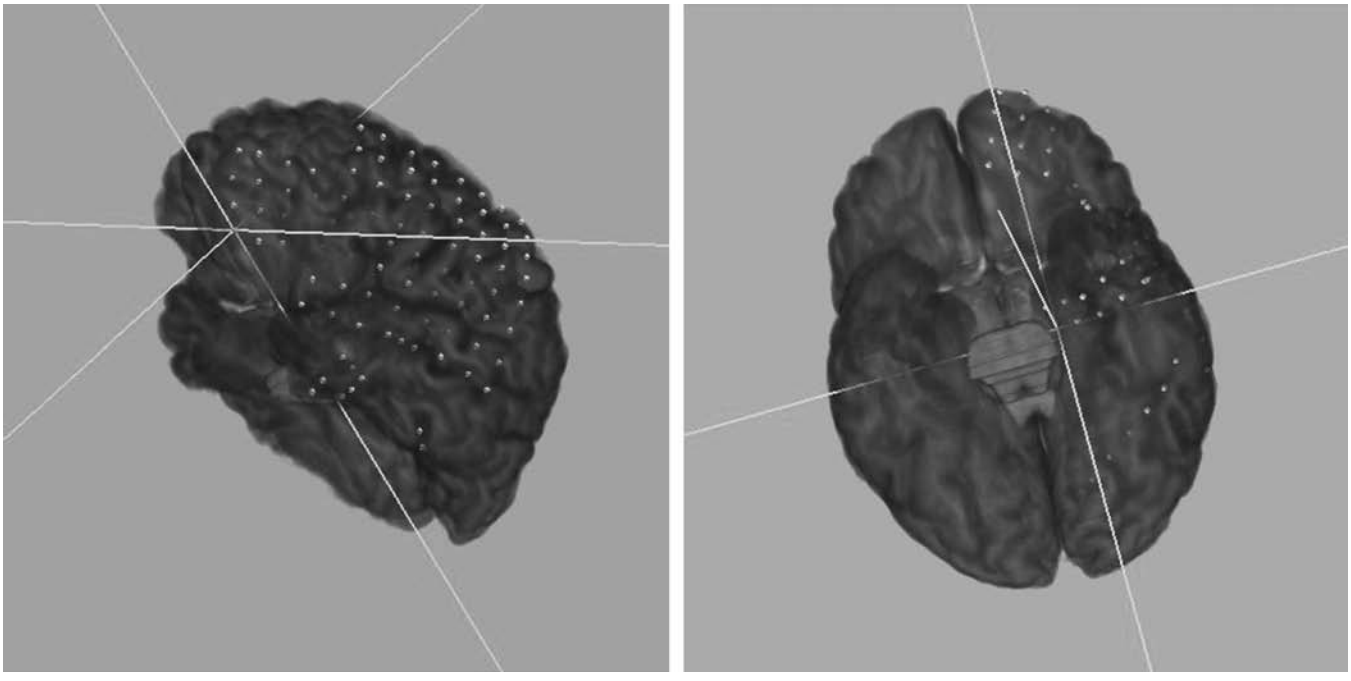

Figure 152.7 3D reconstructed images of electrode locations. These were obtained by superimposing the patient's preoperative brain MRI on a further MRI obtained after subdural electrode placement.

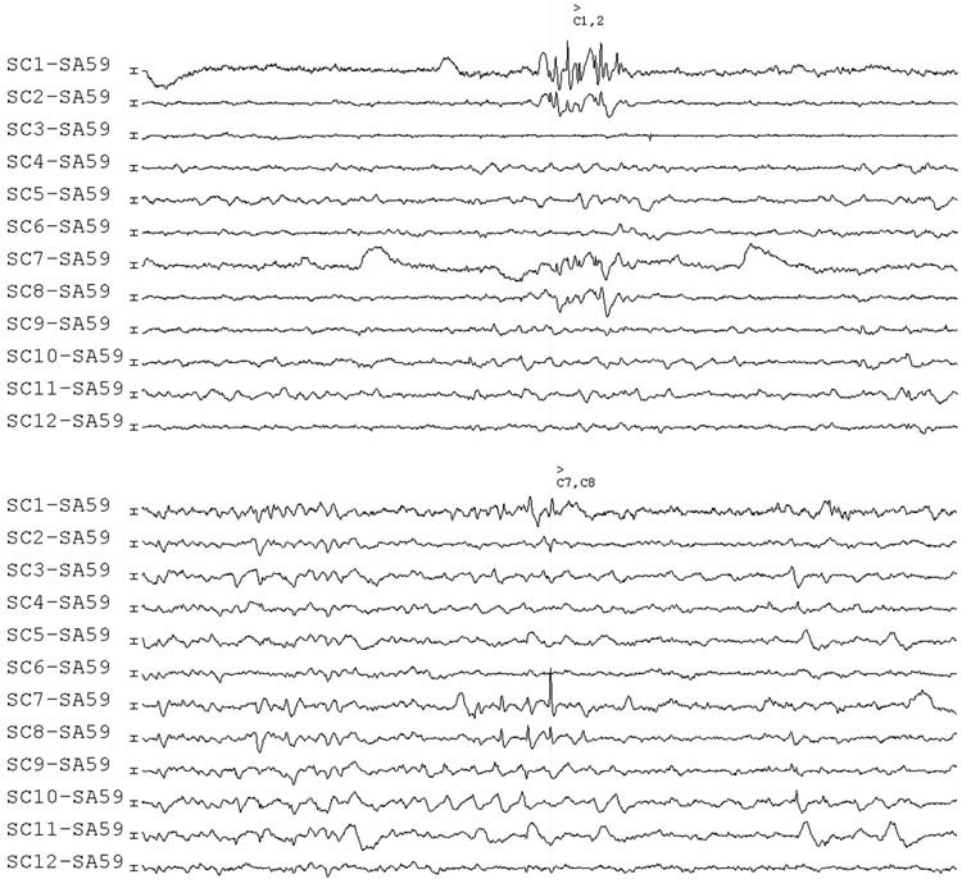

Figure 152.8 Intracranial EEG of spikes on the C-plate (the main spike population). The top figure shows spike-polyspike discharges with maxima over the C1–2 electrodes (also seen at C7–8). The bottom figure shows spikes with maxima over the C7–8 electrodes (also seen at C1–2).

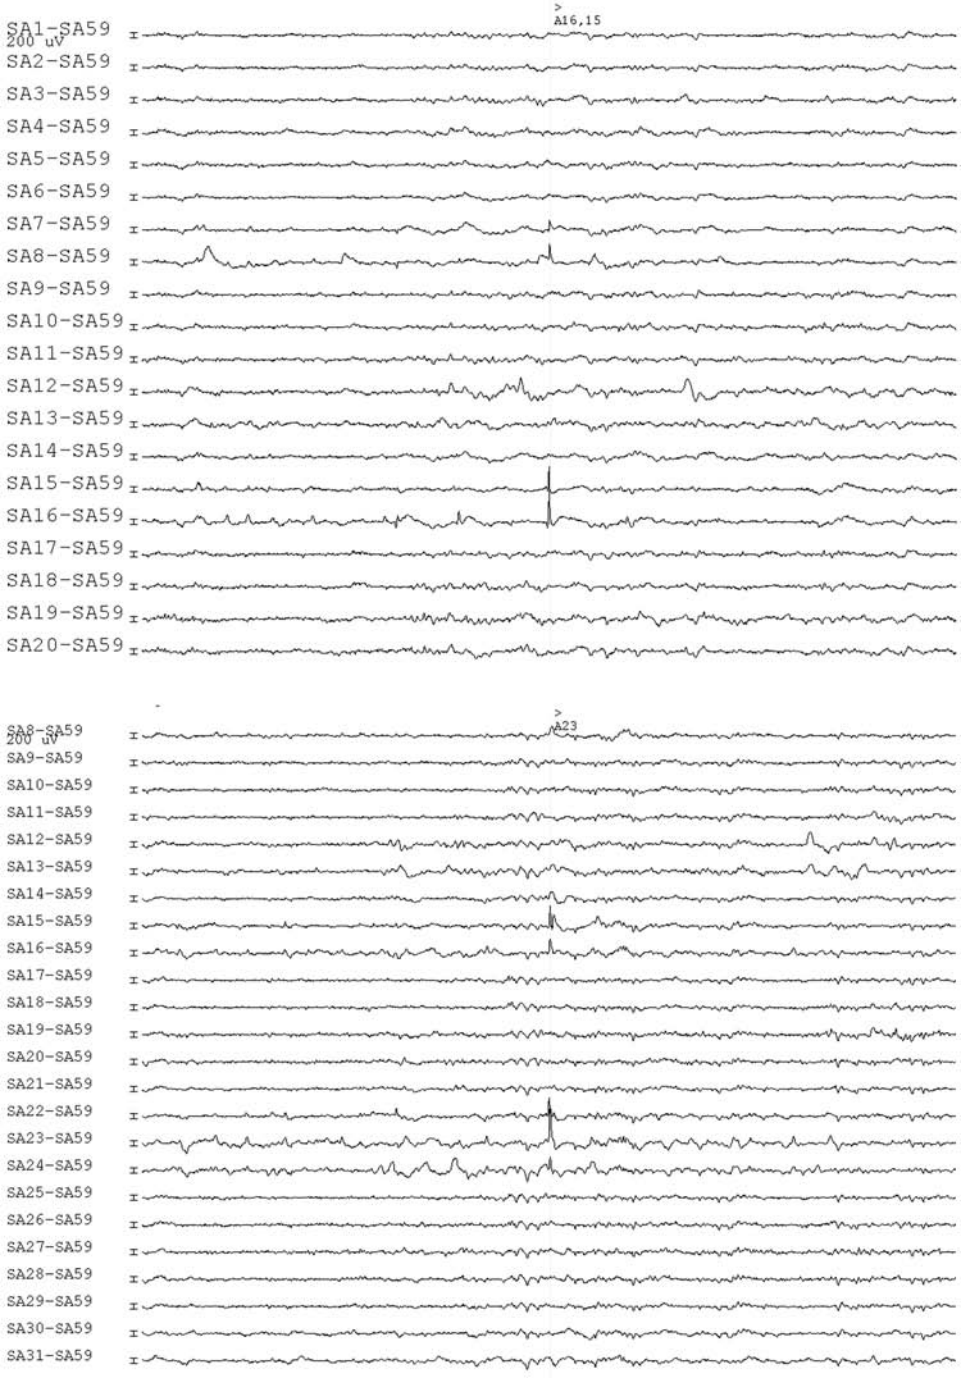

Figure 152.9 Intracranial EEG showing spikes on the A-plate (the other spike population seen in this patient). The top image shows spikes with maxima over A15–16 electrodes (also seen at A7–8). The bottom image shows spikes over A23–24 electrodes (also seen at A15–16).

EEG seizure onset, theta rhythms were seen over the basal temporal region (C-plate), followed by similar rhythms over the lateral temporal neocortex (A-plate). Rhythms slowed down to delta frequency about 40 seconds after EEG seizure onset and finally diffuse suppression was seen (Figure 152.11).

Evoked potential studies

Median nerve SSEPs localized the central sulcus between the A59 and A57 electrodes.

Cortical stimulation mapping

Receptive language function was localized to mid- and posterior temporal regions (A29, A37–39, A62–63), with the patient having difficulty with speech comprehension on stimulation of this area. Face and tongue motor responses were recorded from the A-plate above the sylvian fissure (A45, A53). Visual symptoms were reported on stimulation of the temporoparietal region (A54, A56, A61). A brief (5–8 second) seizure with clonic movements of the right face, was provoked by stimulation of the A36 electrode. Results of cortical stimulation are summarized in Table 152.2.

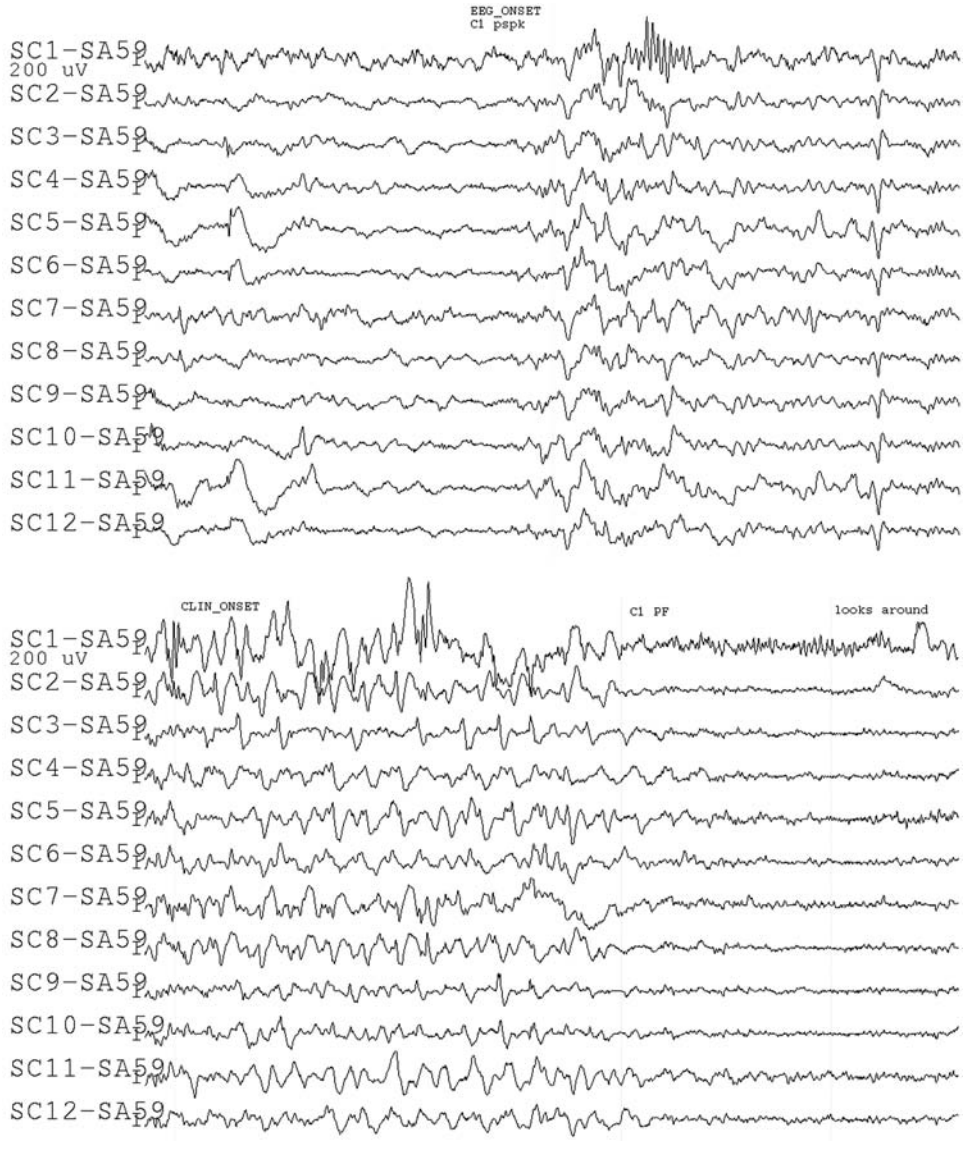

Figure 152.10 Intracranial EEG seizure. The top image demonstrates the EEG seizure onset with a polyspike discharge at the C1 electrode. This is followed by rhythmic spiking (bottom image) at the C-plate, maximally seen over the mesial temporal electrodes (C1–3, C7–8). Also appreciated, in the second half of the bottom image is a diffuse suppression over the entire C-plate along with paroxysmal fast activity, again best appreciated over the C1 electrode.

Summary of invasive evaluation

Left mesial temporal lobe epilepsy was confirmed. The majority of interictal discharges originated from the left mesial temporal region with the remaining discharges from the left anterior temporal lobe. The first EEG changes during seizures were over the left mesial temporal electrodes, confirming the latter as the ictal onset zone. Seizures spread rapidly to the basal temporal, followed by lateral temporal neocortex. Language function was localized to the mid to posterior temporal regions, well away from the ictal onset zone.

Overall summary; surgical strategy

The noninvasive and the invasive video-EEG monitoring were both suggestive of left mesial temporal lobe epilepsy. Concern remained about the relatively high preoperative neuropsychological verbal memory scores as well as the bilateral memory representation on Wada. However, from the point of view of seizure control, a left temporal lobectomy was felt to be the optimal procedure. Informed consent for this procedure was taken after the risks and benefits of the procedure were explained to the patient and her family.

Epilepsy surgery

The patient underwent a 4.5-cm left temporal lobectomy. A standard subpial technique was employed for dissection down to the temporal horn. The lateral temporal lobe was then amputated followed by resection of the left amygdala and the left hippocampus.

Histopathology (Figure 152.12)

Left temporal lobe: mild cortical dysplasia.
Left amygdala: microscopic dysplastic foci.
Left hippocampus: no significant pathology.

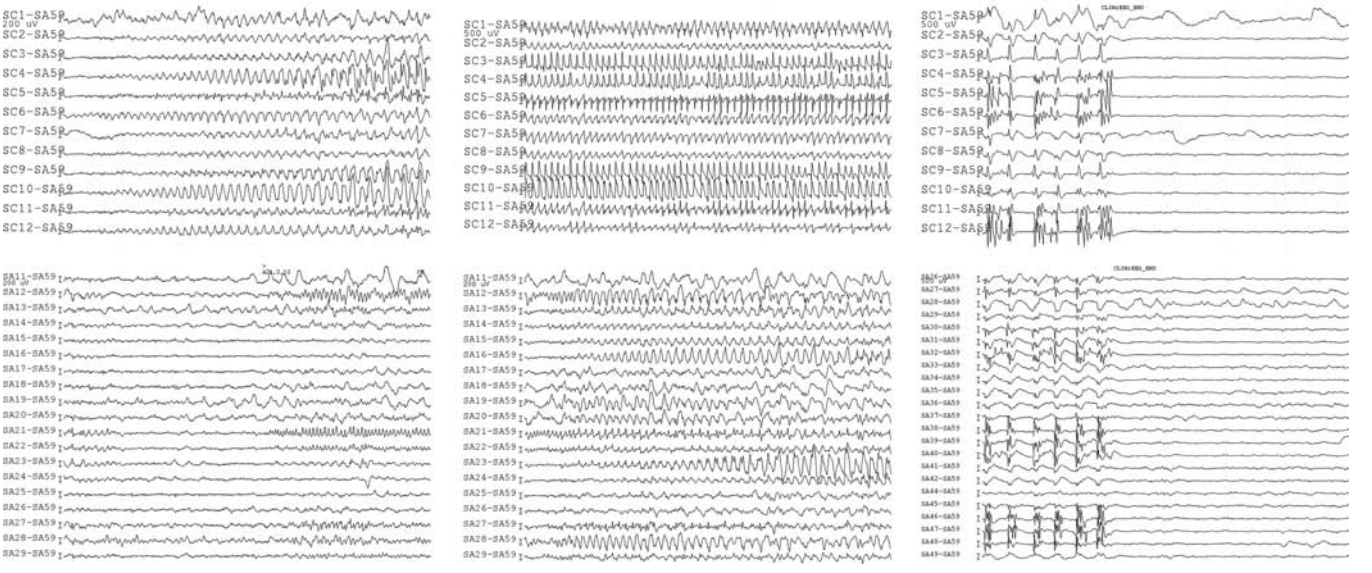

Figure 152.11 Intracranial seizure progression at 20 (left panel), 40 (middle panel) and 60 seconds (right panel) following EEG seizure onset. The top images demonstrate seizure rhythms over the C-plate and the bottom images demonstrate simultaneous seizure rhythms at the A-plate.

Follow-up

No postoperative motor deficits were observed. Seizure outcome was excellent, with no seizures during a 4-year outpatient follow-up period. The patient now has driving privileges. She remains on zonisamide 200 mg daily. Repeat neuropsychological evaluation was performed once, 6 months after surgery. The patient elected against having a further interval evaluation. Details of the former appear in Table 152.3 (right-hand column). Overall memory remained impaired, with a slight postoperative deterioration. However, this was entirely due to a significant (and expected) drop in both immediate and delayed verbal recall. Visual memory, on the other hand improved considerably, for both immediate and delayed items. This pattern carried over to IQ testing, with verbal IQ dropping modestly, but performance and full-scale IQ improving over preoperative scores.

In conclusion, the patient experienced an overall improvement from her epilepsy surgery in terms of physiological distress. Mood and adjustment issues were of some persisting concern when she was last interviewed.

Discussion

The management of a patient with mesial temporal lobe epilepsy associated with hippocampal sclerosis (HS) on brain MRI is now considered relatively straightforward. Most centers report good seizure outcome from anterior temporal lobectomy in a typical case; postoperative neuropsychological deficits are thought to be somewhat mitigated by the presence of HS. Temporal lobe epilepsy in a patient with a normal MRI is more challenging; identification of the ictal onset zone requires further investigation, and postoperative neuropsychological deficits are of more concern. Epilepsy surgery centers vary in their approach to this issue; at the Cleveland Clinic, subdural grid evaluation similar to that performed in this patient is the favored invasive electroencephalographic approach for purposes of localization. Controversies regarding neuropsychological issues are outlined below.

An early report of Penfield and Milner[4] described memory decline in two patients following standard unilateral left temporal resection. Subsequent reports[5,6] have documented

Table 152.2 Cortical stimulation

Symptom elicited	Electrodes stimulated
Difficulty with comprehension	A29, A37–39, A62–63
Tongue and face motor response	A45, A53
Visual symptoms	A54, A56, A61
Right face clonic seizure	A36

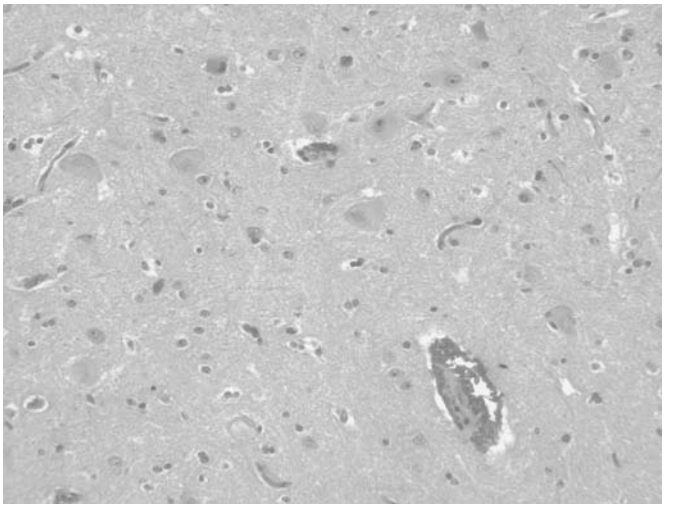

Figure 152.12 Neuronal cytomegaly seen at layer 6 of the temporal neocortex suggestive of cortical dysplasia. No significant pathology was seen in the hippocampus.

Table 152.3 Pre- and postoperative neuropsychological evaluation

Neuropsychological parameter	Presurgical evaluation	6-month postoperative evaluation
Overall memory	74 (4th percentile; mild impairment)	68 (2nd percentile; significant impairment)
Verbal immediate memory	78 (7th percentile; low-average to mildly impaired)	54 (0.1 percentile; significant impairment)
Verbal delayed memory	97 (42nd percentile; average)	54 (0.1 percentile; significant impairment)
Visual immediate memory	69 (2nd percentile; impaired)	100 (50th percentile; average)
Visual delayed memory	85 (16th percentile; low-average)	103 (58th percentile; average)
Full Scale IQ	90 (average)	93 (average)
Verbal IQ	98 (average)	89 (low-average)
Performance IQ	83 (low-average)	99 (average)

similar findings. Prediction of which patients are at particular risk for postoperative memory decline has prompted two explanatory neuropsychological models.[7]

The functional reserve model

This model, now somewhat dated, postulated that memory function in the normal (i.e. contralateral to the epileptic) temporal lobe (the 'functional reserve') was predictive of postoperative memory decline. Thus, poor memory function of the contralateral (normal) temporal lobe on Wada testing predicted postoperative memory decline. This model was based on the observation[8,9] that patients who passed the Wada memory test with ipsilateral injection (i.e. demonstrated adequate contralateral functional reserve), did not have significant postoperative memory complaints. This observation was however contradicted by the study of Wyllie and co-workers,[10] who found no significant differences in postoperative memory outcome in patients who had passed or failed the Wada memory test after ipsilateral injection.

The functional adequacy model

According to this model,[11–13] good ipsilateral memory scores on the Wada test predict poor memory outcomes after temporal lobectomy. This correlates with MRI hippocampal volumetric studies that suggest that patients with larger hippocampi experience more memory decline after left temporal resection.[14] Neuropathologic studies also suggest that higher degrees of hippocampal sclerosis are associated with less postoperative memory decline after dominant temporal resection.[15] However, it has also been demonstrated that patients with unequivocal hippocampal sclerosis on brain MRI and good preoperative verbal memory scores experience memory decline after dominant temporal lobe resection.[18,19] Thus, it appears that good preoperative verbal memory scores and a structurally normal dominant hippocampus are independent predictors of post-operative memory decline.[20,21]

Synthesis

While the functional adequacy model appeared sound in the 1990s, towards the end of that decade and the early years of the current century, the validity of this model was also questioned. Various studies[22–24] demonstrated that good preoperative right side memory scores on the Wada test in fact predicted a favorable memory outcome after dominant temporal lobectomy, if the age of seizure onset was taken into account. It has been postulated that early damage to the dominant temporal lobe possibly results in transfer of memory to the right temporal lobe resulting in a better postoperative memory outcome.

In summary, while there is no clear consensus on which of these above models is correct, it may be that the risk of memory decline in individual patients is along a spectrum between these two extremes. Our patient's outcome was concordant with the functional adequacy model, possibly in view of her relatively late onset of seizures.

153 Patient with bitemporal lobe epilepsy

AV Alexopoulos and HO Lüders

History of present illness

The patient is a 30-year-old right-handed woman, who presents for evaluation of poorly-controlled seizures. Her birth and development were normal. She reports a history of minor head trauma without associated loss of consciousness at the age of 5 years. Otherwise, she has no identifiable risk factors for epilepsy.

Her history of seizures starts around the age of 20 years. Seizures consist of initial loss of awareness, a fixed stare and hand automatisms (described by her husband as 'rubbing her hands together'). The patient does not report an aura and is amnestic for events during seizures. Average duration is 2 to 3 minutes, followed by a brief period of postictal confusion. Seizure frequency is approximately 1–2/week (predominantly around her menses). Exact seizure frequency has been difficult to estimate, as the patient may remain unaware of her seizures, when no one is with her. On one occasion, a seizure while cooking resulted in first degree burns of both hands. Several years ago the patient used to have episodes of 'smelling something like ammonia'; these spells were not clearly linked to her habitual seizures and have not recurred in recent years.

The patient is a high school graduate, who went on to complete all but three classes for an associate's degree in general studies. According to her account she was forced to stop taking classes because of continued seizures and medication side effects. She then worked for several years as an assistant at a group home for handicapped children, but has been able to do so in the last 4 years.

She is married and lives with her husband and their four children. She reports that seizures have taken away her independence, as she is afraid to go out on her own and '... can't do the things I want to do with the kids'. She has a history of two seizure-related motor vehicle accidents in the past and is not allowed to drive. Her father provides transportation when her husband is at work.

The patient does not smoke and does not consume alcohol. She denies use of any other recreational or illicit drugs. Her general physical and neurological examination is unremarkable. Formal psychological evaluation reveals that the patient has been depressed for several years in response to her ongoing, seizures and the multiple consequences associated with uncontrolled epilepsy including interference with college, employment and driving. She is currently on antidepressant therapy with a selective serotonin and norepinephrine reuptake inhibitor (venlafaxine) and participates in bimonthly counseling. Past medical history is otherwise unremarkable with the exception of a previous cholecystectomy and surgical removal of an ovarian cyst. Chronic anticonvulsant therapy consists of a combination of topiramate (500 mg/d) and valproic acid (1,000 mg/day). She has failed maximum tolerated doses of carbamazepine, levetiracetam, and phenytoin in the past. She is not under treatment for any other active medical condition. The patient is considering epilepsy surgery and expresses motivation to return to college in the future (she states that she would be interested in pursuing a degree in psychology and working to support single mothers and their children).

Presurgical investigations

As seizures proved resistant to multiple antiepileptic medications the patient was admitted to the epilepsy monitoring unit for a noninvasive video-EEG evaluation using a combination of scalp and sphenoidal electrodes. Interictal EEG (Figure 153.1) showed sharp waves arising independently from the left and right anterior temporal regions (maximum at the ipsilateral sphenoidal electrode), with an estimated left (Sp1) to right (Sp2) ratio of approximately 60:40 overall (during one week of recording). No other temporal or extratemporal spike foci were noted.

All recorded seizures had similar electroclinical features and were associated with a stereotyped ictal EEG, characterized by a rhythmic buildup of 5–6 Hz rhythmic theta localized in the left temporal region maximal in the left sphenoidal electrode (Figures 153.2a and b). Ictal patterns remained restricted in the left temporal distribution throughout the seizure without spreading to other brain regions. None of the recorded ictal patterns showed evidence of right hemisphere lateralization. Semiologically all of the patient's recorded episodes were classified as automotor seizures. Her typical seizures were punctuated by an initial motionless stare heralding a period of unresponsiveness. Oral (lip-smacking) and distal hand automatisms were observed with all seizures, starting approximately 15–20 seconds after clinical onset. There were no other motor manifestations. Such seizures are most frequently seen with temporal lobe epilepsies.[1,2]

Detailed semiological analysis of video recordings did not reveal any distinct lateralizing signs. During the noninvasive evaluation a total of nine seizures were recorded, six of which

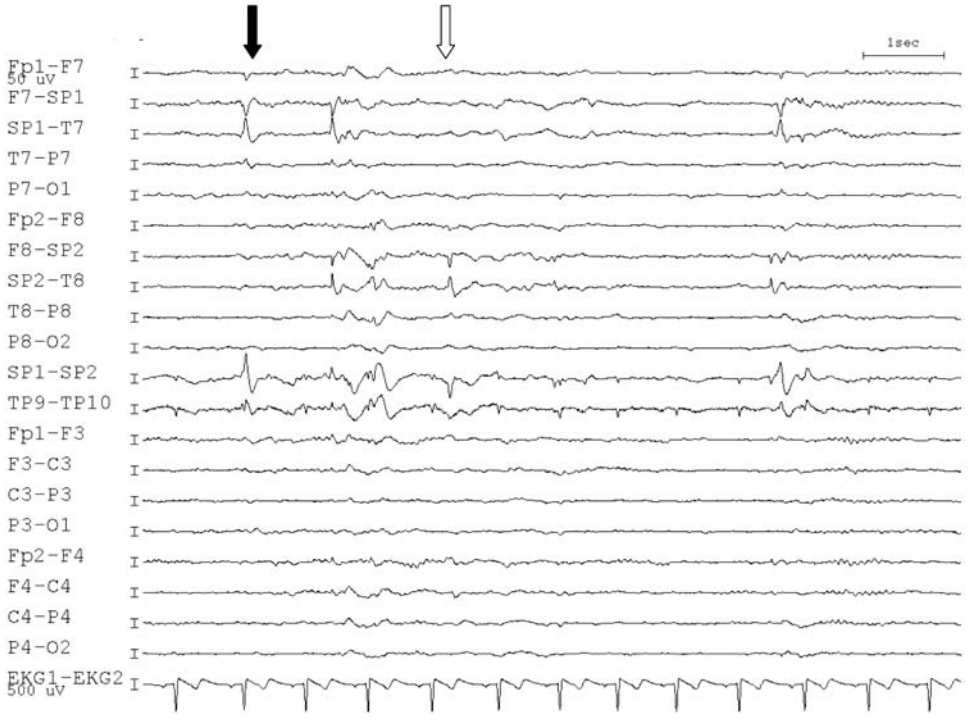

Figure 153.1 Scalp-EEG tracings demonstrating interictal, independent left (dark arrow) and right (white arrow) anterior temporal spikes, maximum at the ipsilateral sphenoidal electrode as seen on a longitudinal bipolar montage (the temporal chains have been extended with the addition of sphenoidal electrodes).

arose from sleep and three from wakefulness. No secondarily generalized seizures were recorded. The patient did not press the seizure button with any of these spells. Seizure duration based on EEG ranged from 30 to 80 seconds. Postictally, she was noted to be confused for a brief period lasting less than a minute. The patient was amnestic of her seizures.

Results of noninvasive video-EEG studies pointed to a left temporal seizure focus, and prompted referral for further presurgical investigation (phase 1.5 testing), which included a high-resolution anatomical MRI with thin cuts through the temporal lobes (temporal lobe epilepsy protocol),[3] an interictal FDG-PET study and formal, standardized neuropsychological evaluation.

Initial qualitative review of the patient's MRI did not reveal clear asymmetries of hippocampal size and/or signal intensity (a subtle decrease in the size of the right hippocampos was questioned). Careful visual inspection of contiguous 3D slices, however, provided no evidence to suggest unilateral atrophy, developmental dysplasia or a subtle mass lesion within the temporal lobes (Figure 153.3). On quantitative analysis the hippocampal formations were found to be volumetrically symmetrical.[3]

Axial and coronal interictal ^{18}FDG-PET images (coregistered to the patient's MRI) demonstrated bilateral hypometabolism involving the left and right mesial temporal regions. In addition, a small area of restricted hypermetabolism was seen within the region of the left amygdala (extending to a lesser degree to the left temporal pole). Otherwise, metabolic activity throughout the cortex and subcortical structures was uniform and symmetric (Figure 153.4).

The presence of bilateral hypometabolism on ^{18}FDG-PET is suggestive of an interictal functional deficit zone involving the left and right temporal regions and has been associated with bitemporal or less commonly diffuse or extratemporal seizure foci.[4–6] The patient's interictal PET study was unusual in that it also showed a distinct hypermetabolic focus in the region of the left amygdala. No electroencephalographic or clinical seizures were recorded during acquisition of these PET images, as confirmed by concurrent scalp EEG recordings (which started approximately 20 minutes before injection of radiotracer and continued for a period of 60 minutes).

Preoperative neuropsychological testing was notable for mild diffuse dysfunction involving multiple cognitive domains (Figure 153.5a). In addition, there were indications of at least mild level of psychological distress characterized by symptoms a verbal and nonverbal memory tests administered. Auditory memory index scores fell in the impaired range, and visual memory index scores ranged from mildly impaired to the lower end of the borderline range (Figures 153.5b and c).

The interpreting neuropsychologist suggested that some of the patient's difficulties on testing may be attributable to her uncontrolled seizures, level of psychological distress and/or medication adverse effects. The results of this extensive preoperative neuropsychological battery did not reveal a lateralized pattern of impairment and were consistent with other preoperative evidence pointing to 'bilateral mesial temporal dysfunction'. Because memory function was significantly impaired it was felt that the patient would be at relatively little risk for decline, if she were to have a left (presumably dominant) temporal lobectomy.

Summary of presurgical evaluation and surgical plan

The patient's noninvasive EEG recordings incriminated the left temporal region. Her structural MRI, however, did not provide lateralizing information in support of a left temporal epileptogenic focus. Furthermore, interictal EEG, interictal PET and preoperative neuropsychological findings indicated a bilateral functional deficit zone involving both mesial

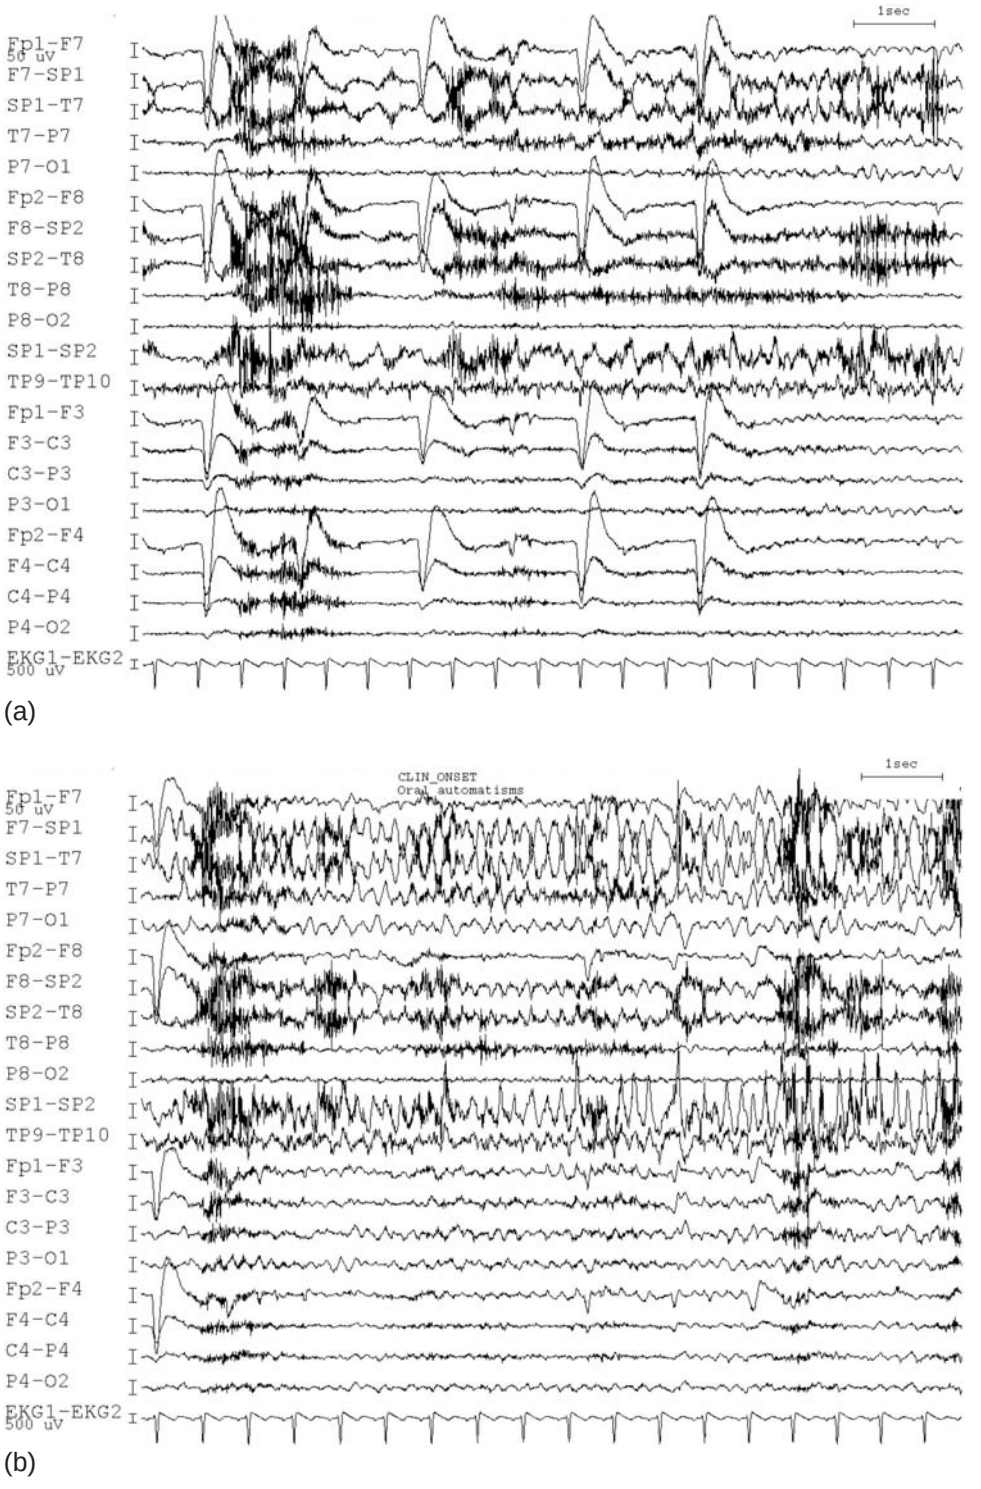

Figure 153.2 Scalp video-EEG evaluation: Two consecutive 10-second scalp-EEG tracings of a typical seizure occurring out of wakefulness, characterized by arrest of activity followed by unresponsiveness and oral automatisms (same montage as seen in Figure 153.1). (a) Electrographic onset with the emergence of initially arrhythmic, sharply contoured delta activity at the left temporal region (left sphenoidal electrode); (b) Evolving ictal pattern: a well-developed left temporal rhythmic discharge (5–6 Hz) is seen within 10 seconds of electrographic onset. As the seizure progresses the left temporal ictal discharge appears to gradually slow down, and ends after a total duration of ~40 seconds (not shown).

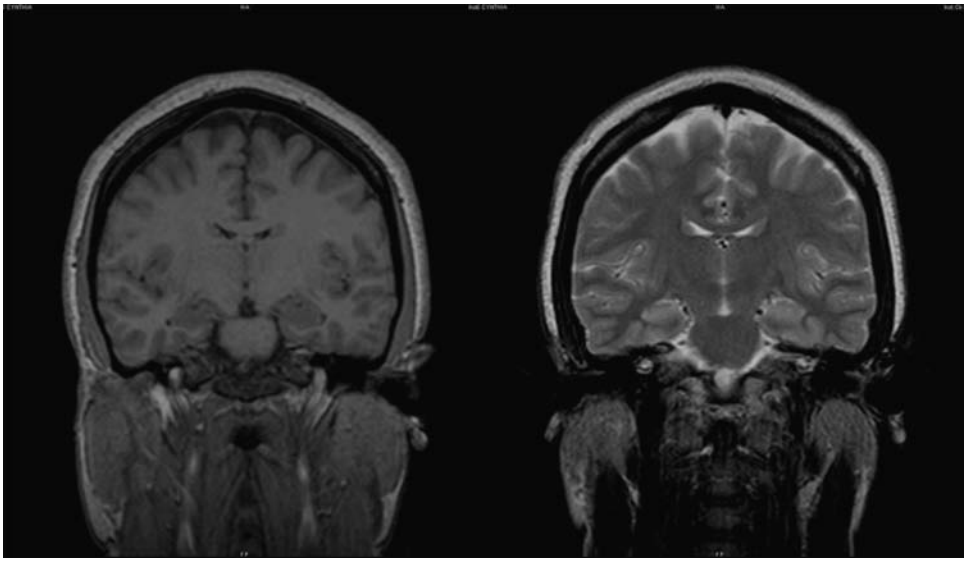

Figure 153.3 Preoperative MRI: Coronal high-resolution T1-weighted and corresponding T2-weighted images at the level of the hippocampal head depicting the normal basal and lateral surface of both temporal lobes along with the hippocampal formations. Qualitative visual analysis of preoperative MRI images did not reveal any clear asymmetries of hippocampal size and/or signal intensity. The neuroradiologist suggested a subtle decrease in the size of the right hippocampal head, but this was not confirmed upon reviewing the reformatted 3D MPRAGE images. The two hippocampi were volumetrically symmetrical on formal quantitative analysis.

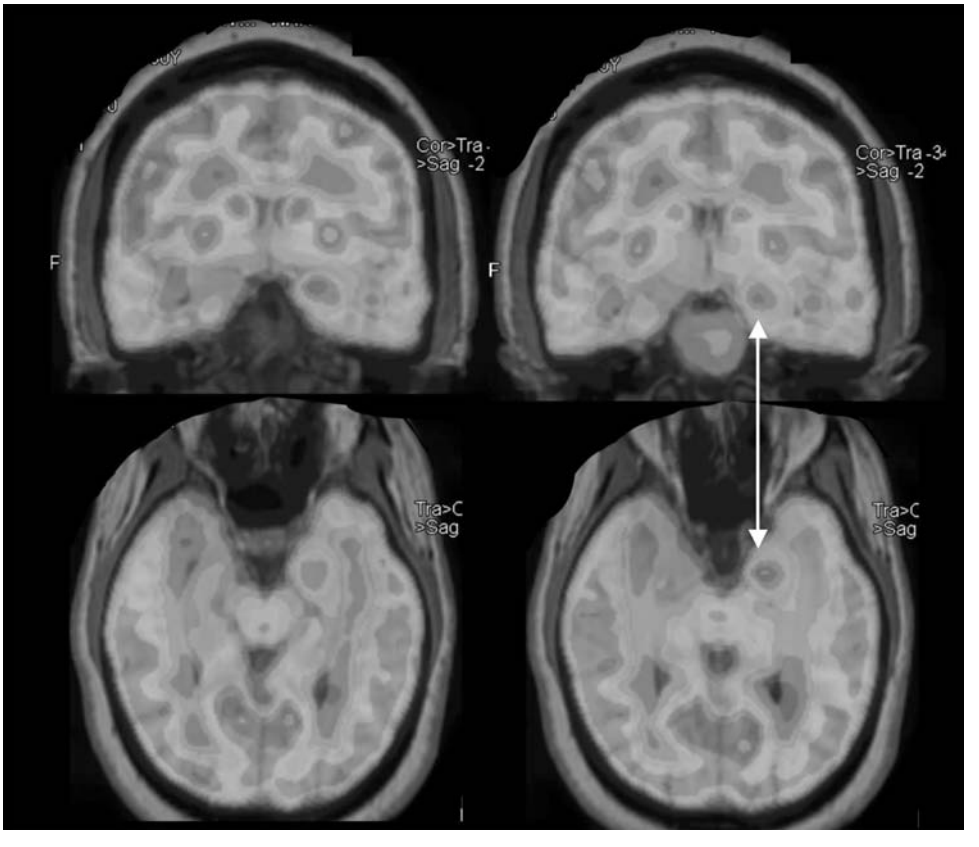

Figure 153.4 Coronal and axial preoperative interictal ^{18}FDG-PET images (coregistered to the patient's MRI) demonstrate bilateral hypometabolism involving the left and right mesial temporal regions. In addition, a small area of restricted hypermetabolism is present within the region of the left amygdala (double arrow). This restricted area of increased uptake overshadows any evidence of lateralized/asymmetric temporal hypometabolism. Otherwise, metabolic activity throughout the cortex and subcortical structures is uniform and symmetric.

(b)

Figure 153.5 Preoperative neuropsychological battery results. The shadowed area corresponds to the mean ± 1SD of normative values. (a) Overall, the cognitive data suggest a pattern of a mild, diffuse dysfunction involving multiple-cognitive domains. Indicators of general level of ability, depicted on the left, include: the Reading score based on the WRAT (Wide Range Achievement Test), the Information and Vocabulary subtest scores based on the WAIS-III (Wechsler Adult Intelligence Scale-Third Edition), and the FSIQ (Full Scale IQ) results of the WAIS-III. Two of the factor index scores derived from the WAIS-III, the VCI (Verbal Comprehension Index) and POI (Perceptual Organization Index) are plotted on the right. The WAIS-III yielded a full scale IQ of 77 with a VCI of 76 and a POI of 84; the difference between VCI and POI is not statistically significant; (b) Both verbal and visual memory scores were below normal, without evidence of significant discrepancy between the two sides.

temporal regions. During review of this case in the interdisciplinary patient management conference, participants noted the bitemporal interictal sharp waves and lack of an unequivocal abnormality on MRI. Most noninvasive tests were suggestive of bitemporal dysfunction. It was also noted that aside from the curious left-sided 'hot spot' on the interictal PET, the MRI and semiology of recorded seizures failed to provide any additional lateralizing information.

It was therefore decided to proceed with an invasive evaluation with bitemporal depth electrodes to confirm or refute the hypothesis that all of the patient's habitual seizures arise from the left temporal lobe.[7,8] Concepts and implications related to the presence of unitemporal versus independent bitemporal seizure foci were reviewed with the patient and her family, and the patient's expectations of surgery were clearly discussed.[9,10]

Invasive evaluation

Three pairs of depth electrodes were inserted symmetrically by an orthogonal approach. Each depth electrode consisted of eight platinum contacts (with a contact diameter of 1mm; Ad-Tech, Racine, WI, USA) located 5mm apart.[11] They penetrated the temporal lobe horizontally through the middle temporal gyrus, and their tips (most distal contacts) were aimed at the amygdala, anterior hippocampus and mid/posterior hippocampus (Figure 153.6).

Invasive video-EEG evaluation with bitemporal depth (and 10–20 scalp) electrodes

Interictal depth EEG showed frequent, independent bitemporal abnormalities with spikes arising from the left and right hippocampal contacts (Figures 153.7 and 153.8). In contrast to the noninvasive findings (on sphenoidal electrodes) the majority of the depth-recorded spikes originated from the right hippocampus (with an approximate left-to-right ratio of 25:75).

A total of 30 electrographic seizures were recorded during the period of stereotactic depth investigation. All seizures were characterized by a focal onset[8] involving the left anterior hippocampus (nine seizures, Figure 153.9) or the right anterior hippocampus (17 seizures, Figure 153.10) or the left amygdalar contacts (four seizures). The majority (almost 70%) of the 13 left-sided seizures (Figure 153.9) were reflected

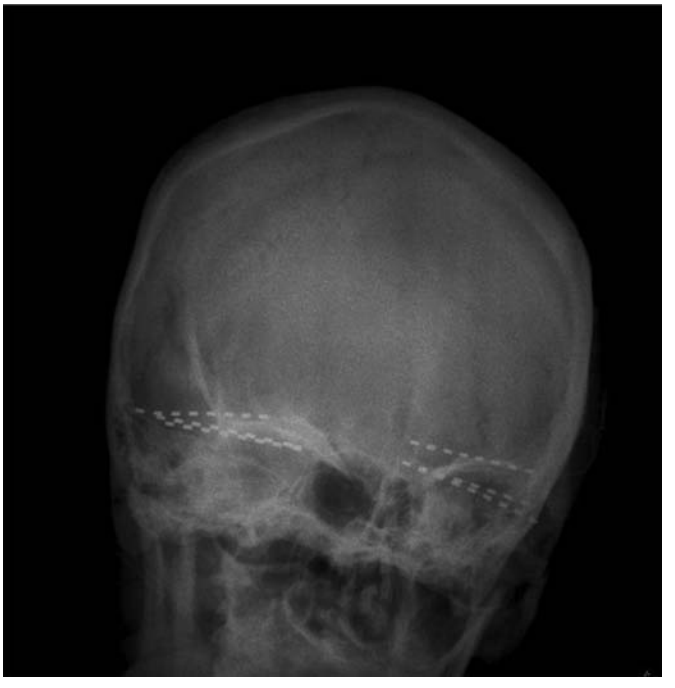

Figure 153.6 Skull X-ray following placement of pairs of temporal depth electrodes targeting bilaterally the amygdala, and the anterior and posterior hippocampus.

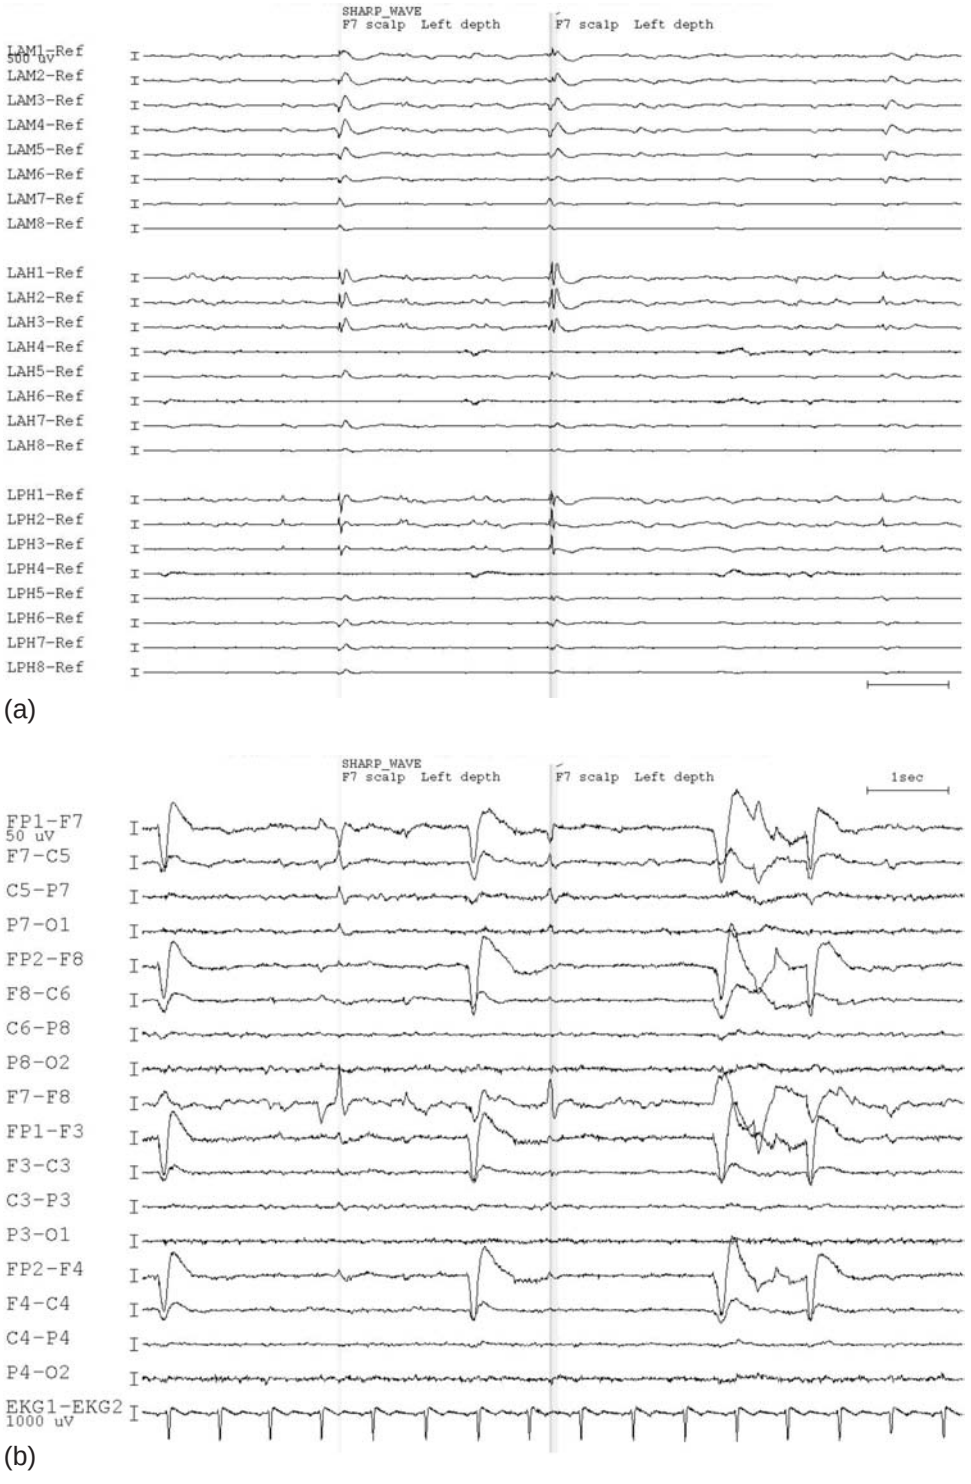

Figure 153.7 Simultaneous scalp and depth electrode recordings depicting interictal epileptiform activity arising from the left anterior temporal region: (a) Depth electrodes in the left mesial temporal structures (LAM = left amygdalar, LAH = left anterior hippocampus and LPH = left posterior hippocampus; contact 1 is the most distal and contact 8 the most proximal electrode). Referential montage using the extracranial vertex (Pz) electrode as reference. Interictal spikes appear to form a dipole with maximum negativity at the most distal left anterior (and posterior) hippocampal contacts and positivity at the left amygdalar electrodes; (b) The same interictal discharges as reflected on the scalp on this longitudinal bipolar montage (note that the standard T7 and T8 electrodes have been replaced by the adjacent C5 and C6 on the international 10–10 system to allow for concurrent depth and surface EEG recordings).

Figure 153.8 Simultaneous scalp and depth electrode recordings depicting independent interictal epileptiform activity arising from the right anterior temporal region (Abbreviations as for Figure 153.7. RAM = right amygdalar, RAH = right anterior hippocampus and RPH = right posterior hippocampus depth electrodes). Interictal spike appears to form a dipole with a maximum negativity at the most distal left posterior hippocampal contacts and positivity at the right amygdalar electrodes. Note that the right-sided anterior temporal epileptiform discharge has a less conspicuous appearance on scalp electrodes, compared to the left-sided abnormalities (compare with Figure 153.7).

on scalp electrodes. Right-sided seizures were typically not reflected on the scalp except for occasional right temporal delta/theta slowing.

A clinical accompaniment was observed with all nine left-sided seizures. Clinically these were similar to the seizures captured during the noninvasive video-EEG study, and lasted for less than 90 seconds. Most right-sided seizures were subclinical except for one clearly dialeptic seizure, which was recognized by the patient's husband as one of her habitual spells. Electrographic seizures lasted for 70–120 seconds except for one seizure, which was sustained for a period of 3.5 minutes. Almost half of these subclinical seizures were identified by the technologist or nursing staff on the basis of EEG changes. When tested, the patient appeared to respond promptly and appropriately to verbal and nonverbal commands. There were no outward manifestations and no evidence to suggest speech or cognitive impairment.

Summary of invasive evaluation and surgical plan

The invasive evaluation lends support to the presumptive noninvasive diagnosis of bitemporal epileptogenicity and demonstrates independent interictal activity and electrographic as well as clinical seizures arising from the left and right mesial temporal structures. Prolonged recordings with bitemporal depth electrodes showed that the vast majority of electrographic seizures from the right temporal contacts occurred in the absence of clinical signs. On the other hand, seizures emanating from the left temporal contacts were almost always associated with alteration of awareness. It was also noted that left temporal onset seizures persisted after resumption of full doses of antiepileptic medications during the latter part of invasive video-EEG recordings. Thus, the left mesial temporal region constitutes the predominant epileptogenic focus responsible for the majority of the patient's habitual seizures. Given the patient's seizure burden and lack of good alternative therapeutic options it was decided to proceed with a left temporal resection.

Pathology and outcome

Rare seizures were noted by the patient and her family at the 6- and 9-month postoperative follow-up intervals – an estimated total of 4 seizure-days corresponding to a class II Engel[12] or class 4 Wieser seizure outcome.[13] No further seizures were reported at 12 months and following adjustment of the patient's antiepileptic medications. Although, the patient has experienced 2–3-month periods of seizure freedom following surgery, she has not been completely seizure free for longer periods of time, and has not been allowed to resume driving.

Neither the patient nor her relatives noticed any significant memory changes following surgery. However at the time of this report the patient has not had a formal postoperative neuropsychological assessment.[14] As she has recently relocated efforts are being made to have her come back for testing at our institution.

Pathology only showed nonspecific changes characterized by a mild degree of gliosis and neuronal loss involving the CA4 (cornus ammonis or Ammon's horn, subfield 4) region of the left hippocampus. The neuropathologist commented that the specimen was 'somewhat fragmented', and that qualitatively there was evidence for a mild degree of neuronal loss.

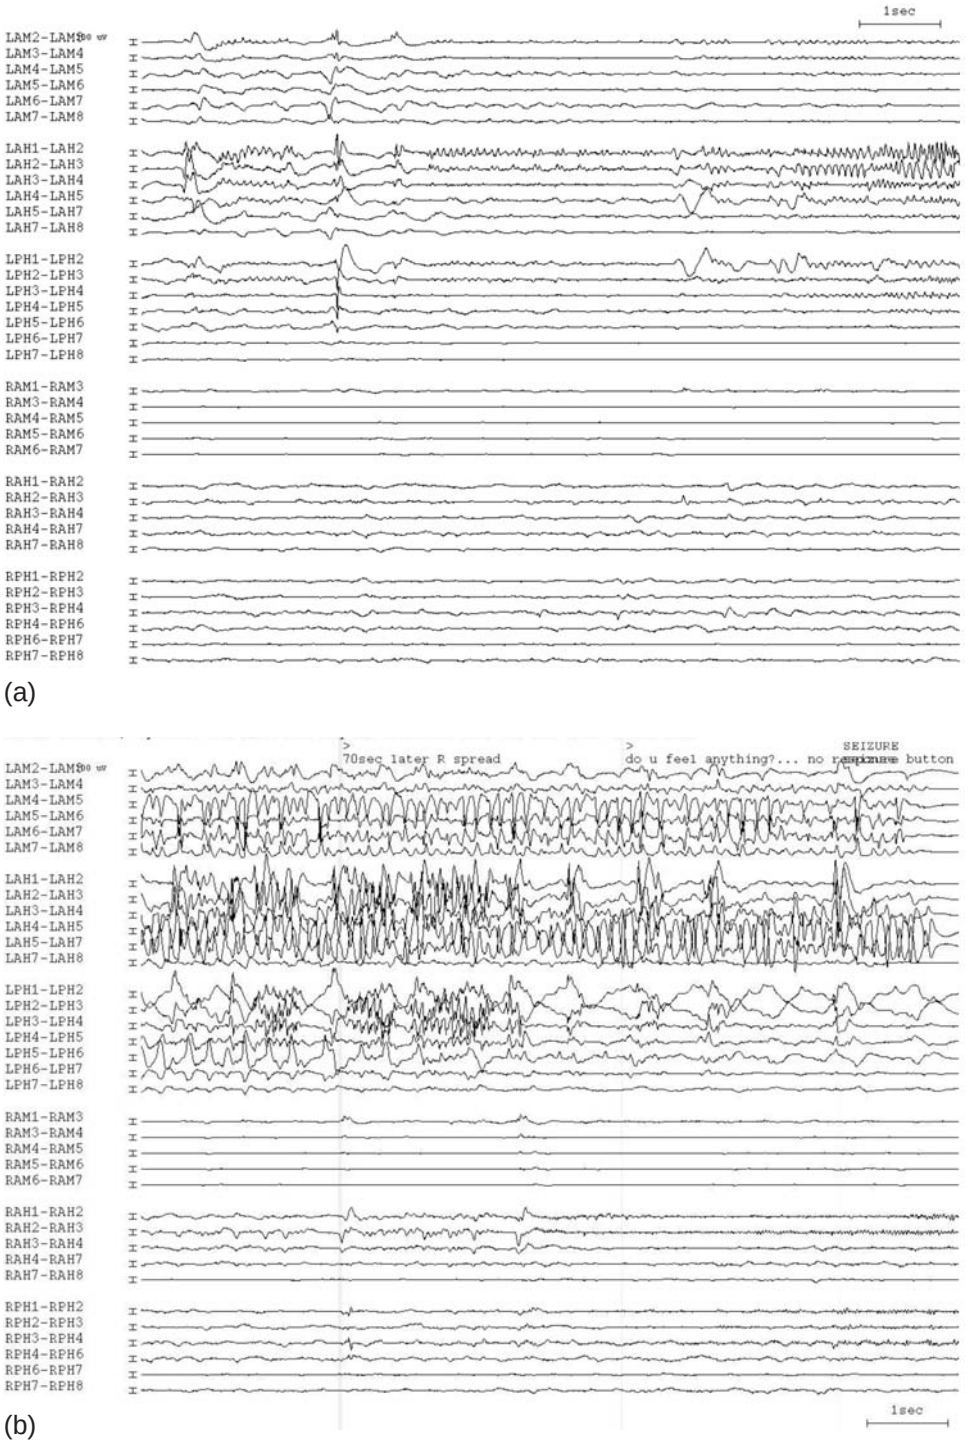

Figure 153.9 Invasive video-EEG evaluation: Bitemporal depth electrode tracings of a typical automotor seizure as displayed on a bipolar montage connecting adjacent depth electrode contacts (10-second epochs). *Note that 'bad' electrode contacts (such as the left-sided LAM1 and LAH6 in this instance and RAM2, RAM8, RAH5, RAH6, and RPH6) have been omitted to facilitate visual analysis*. (a) Electrographic onset with spike discharges – similar to the patient's interictal activity (see Figure 153.7a) – but now accompanied by an emerging low voltage fast (alpha-beta) rhythm. This rhythm is first seen at the most distal left anterior hippocampal contacts (Figure 153.9a). Sustained fast-rhythmic activity involves the most distal left anterior and posterior hippocampal contacts (not shown). At the time, that this activity spreads to involve the left amygdalar leads an ictal pattern becomes apparent on the scalp electrodes, and the seizure follows its stereotyped electroclinical evolution (similar to Figure 153.2); (b) Approximately 70 seconds after the appearance of ictal activity on the left-sided contacts, a fast ictal rhythm is now seen on the right-sided depth electrodes, which persists after the end of the left-sided seizure. Note, that at the end of the left-sided ictal pattern the patient appears to recover clinically and is again responsive and able to follow commands in spite of evolving right-sided ictal activity.

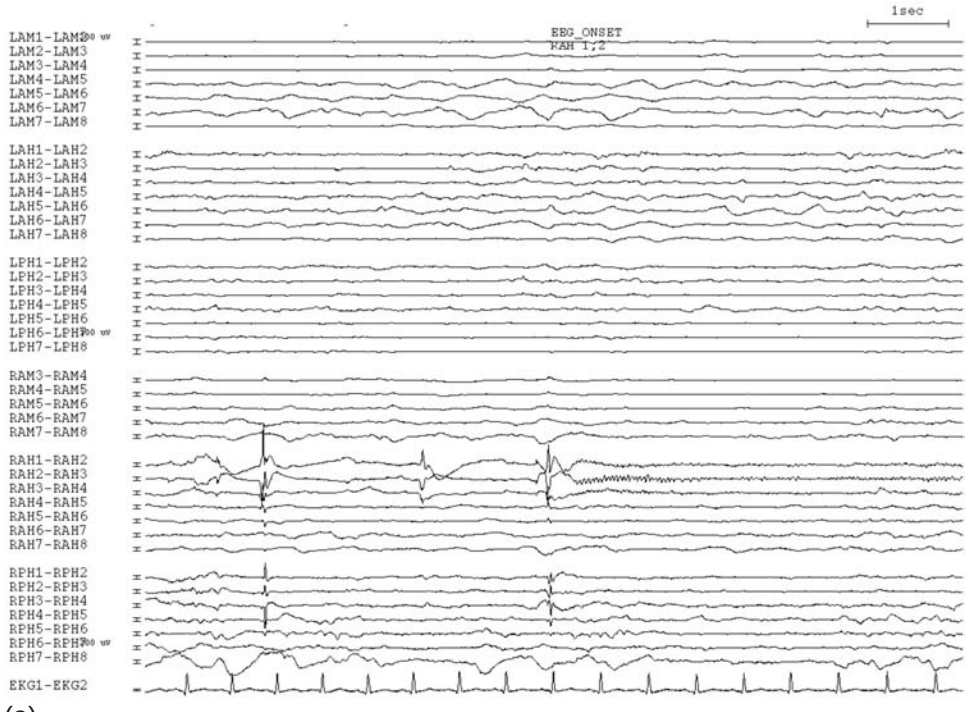
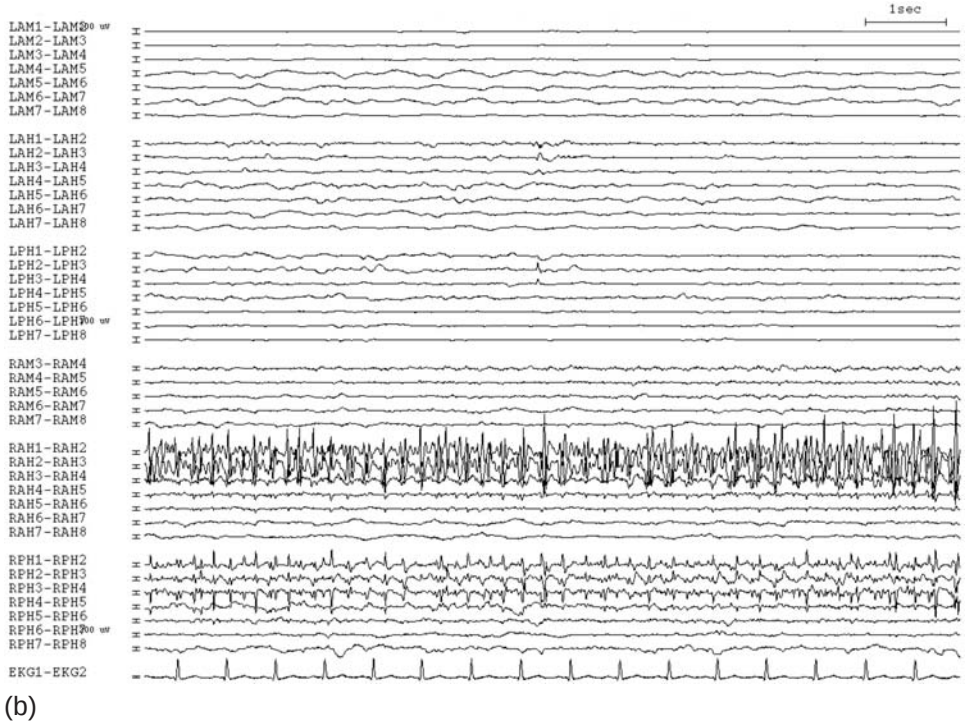


(a)



(b)

Figure 153.10 Bitemporal depth electrode tracings showing a typical subclinical electrographic seizure originating from the right hippocampus (same montage as Figure 153.9). (a) Onset in the latter half of the page punctuated by a spike discharge with superimposed, evolving low voltage fast activity arising from the most distal right anterior hippocampal contacts; (b) Involvement of the right posterior hippocampal contacts and evolution to repetitive high amplitude spiking is seen 20 seconds later. (Total duration of ictal activity: approximately 70seconds).

Detailed histopathological analysis of the amygdala was not feasible because of tissue fragmentation during surgery. It was felt that the amygdala section also showed evidence of mild gliosis and cell loss. Interestingly, a few microglial nodules were seen in the amygdalar area. Such nodules have been likened to 'the tombstones of dying neurons' and are occasionally seen in patients with temporal lobe epilepsy.[15] The resected temporal specimen did not show any other pathological abnormalities outside the mesial temporal area.

Discussion

The patient has bitemporal lobe epilepsy as defined by bitemporal depth EEG recordings, which demonstrate independent

seizure onsets arising from each temporal lobe.[16,17] The clinical history, video-EEG monitoring results, neuroimaging and neuropsychological evaluation support this diagnosis. The observed seizure semiology with arrest of activity, staring and altered responsiveness followed by automatisms is typical of temporal lobe epilepsy.[1,18,19] In this case, neither the patient herself nor other observers provided a history of aura. Such lack of aura experience has been correlated with bitemporal dysfunction in patients with temporal lobe epilepsy.[20–22]

Temporal lobe epilepsy is frequently a bilateral disease.[2,16,23] Up to one-third (or more) of patients with surgically-proven unitemporal epilepsy present evidence of bilateral irritability in the form of bilateral independent interictal epileptiform abnormalities.[7,8,24,25] Temporal lobe seizures can propagate directly to the contralateral temporal region as evidenced by scalp or intracranial recordings.[23,26,27] Moreover, structural and/or functional neuroimaging reveals a spectrum of bitemporal abnormalities.[2,5,28] Bilateral atrophy may be seen in approximately 10% of patients with intractable focal epilepsy and MRI evidence of hippocampal atrophy.[29] Finally, bilateral hippocampal neuropathological abnormalities are a common autopsy finding in patients with a clinical diagnosis of temporal lobe seizures.[24,30,31]

The ictal and interictal electroencephalographic findings suggest that the epileptogenic zone resides within the mesial temporal region. Indeed, hippocampal epilepsy is often accompanied by a highly characteristic epileptiform abnormality with maximal amplitude in the anterior and inferior temporal region.[24] These findings have been described as 'the interictal EEG signature' of epilepsy arising from the mesial temporal limbic structures,[19] and are best seen using basal derivations (such as sphenoidal electrodes; Figure 153.1). Bilateral independent temporal interictal epileptiform discharges (IEDs) are seen in approximately one third of patients with temporal lobe epilepsy.[8,32–34] The majority of patients with bitemporal IEDs have seizures arising exclusively (or with a strong predominance) from a single temporal lobe.[8,35] On that ground, most patients with bitemporal IEDs on surface EEG may be appropriate candidates for surgical treatment with anterior temporal lobectomy.

At the same time, the probability of independent seizure onset from both temporal regions is higher in the presence of bitemporal IEDs.[33,36] The degree of lateralization of independent bitemporal IEDs on scalp EEG may predict the likelihood of unitemporal seizure onset and/or favorable surgical outcome following anterior temporal lobectomy.[37] Chung and colleagues reviewed the operative seizure outcome in the second year after temporal lobectomy in 52 patients with preoperative evidence of bitemporal IEDs (interictal spikes and sharp waves). The authors established that there was a significant and progressive decrease in the number of good operative results that mirrored increasingly lower degrees of lateralization. The risk for poorer operative results was found to be considerably higher in patients with less than 90% lateralization of temporal IEDs, even in cases where subsequent depth electroencephalography indicated that all recorded seizures emerged from a single temporal lobe.[33] It should be noted, however, that such measures of IED lateralization are susceptible to sampling effects and may be affected by a number of other factors, including sleep stage and antiepileptic drug levels.[38–40]

In cases of suspected bitemporal lobe epilepsy or temporal lobe epilepsy with inconclusive lateralization, investigation with bitemporal intracranial depth electrodes may show that the patient's habitual seizures arise exclusively or predominantly from one temporal lobe.[8] Hirsch and colleagues performed a retrospective review of a large cohort of 166 consecutive patients studied with stereotactic depth electroencephalography. In this series 87 patients were found to have seizures arising from a single temporal lobe (unitemporal group), while 23 patients had seizures arising independently from either temporal lobe (bitemporal group). When comparing these two groups the authors did not find any statistically significant differences in terms of age at onset of seizures, duration of epilepsy, localization of scalp EEG abnormalities, surgical results or pathological findings. It was noted, however, that the bitemporal group had significantly fewer patients with a history of febrile seizures.[16] No history of febrile seizures was reported in our patient or her immediate family.

The typical ictal pattern seen with scalp EEG recordings consists of rhythmic theta activity in one sphenoidal electrode evident at the onset of the automotor or dialeptic temporal lobe seizure.[79] When present on scalp-sphenoidal electrode derivations such strictly defined, unilateral temporal ictal patterns can correctly predict the findings of depth electrode investigations in 82 to 94% of patients.[79] However, the reliability of scalp/sphenoidal ictal EEG recordings is considerably reduced in patients with bitemporal IEDs, in whom ictal scalp-sphenoidal EEG is significantly less likely to predict the correct side of surgery (only 64 to 77% of the time in one study).[41]

Patients with suspected temporal lobe epilepsy should undergo detailed MRI studies that consist of multiple coronal T1, T2 and FLAIR (fluid-attenuated inversion recovery) images, sagittal T1 images, and axial T2 and FLAIR images. Coronal three-dimensional T1-weighted MP-RAGE (magnetization-prepared rapid gradient echo) sections with a 2 mm thickness and no interslice gap should be acquired and used for anatomical reconstruction. In the case discussed here, qualitative visual analysis suggested a subtle abnormality involving the right hippocampus (questionable decrease in size). In addition to visual inspection the volumes of the left and right hippocampal formations were measured from the coronal sections following standard anatomic guidelines.[42] Absolute measures of hippocampal volumes were compared to normative data obtained from a sample of healthy volunteers.[43] Although both right and left hippocampal volumes were relatively decreased, this decrease did not exceed two standard deviations, when compared to normative data. Furthermore, the right hippocampus al volume was slightly smaller, but the volumetric asymmetry between the two sides was not significant (volumetrically symmetrical 'normal' hippocampi). Previous studies suggest that temporal epilepsy may exhibit a spectrum of volumetric abnormalities ranging from bilateral asymmetrical or symmetrical hippocampal atrophy, to unilateral atrophy or no atrophy.[44] Our patient belongs to the challenging latter group – i.e., patients 'with marginal MRI abnormalities that approach the limit of normal variation'.[45]

Prognosis following temporal lobectomy in the nonlesional group is regarded as least favorable,[46] but postoperative seizure freedom or worthwhile improvement occurs. In a study of 74 consecutive patients with pharmacoresistant TLE, investigators

performed preoperative bilateral volumetric MRI measurements of the mesial temporal structures. Patients were divided into three groups according to volumetric findings: unilateral atrophy (63.5% of the patients), bilateral atrophy (23%) or no atrophy (13.5%) of the amygdalohippocampal formation. Surgical outcome was assessed at least 1 year after surgery. Excellent results – class I or II outcome using a modified Engel's classification[12] – were observed in 93.6% of patients with unilateral atrophy, 61.7% of those with bilateral atrophy and only 50% of the group with no significant atrophy of the amygdalohippocampal formation.[47]

The presence of bilateral hypometabolism on ^{18}FDG-PET suggests that the 'functional deficit zone' involves both the left and right mesial temporal regions.[4,48] In a study of 15 patients with temporal lobe epilepsy Koutroumanidis and colleagues reported that the finding of symmetric or even asymmetric bitemporal hypometabolism was associated with bilateral independent seizure onset in almost half of these patients – especially when involving the inferior temporal gyrus.[5]

Most human epilepsy studies have utilized ^{18}FDG-PET imaging to examine cerebral metabolic rates for glucose during the interictal state.[49,50] In this case however, the interictal PET study was also notable for the presence of a distinct and unusual, small hypermetabolic focus in the region of the left amygdala (extending to a lesser degree to the left temporal pole) (Figure 153.4). No electroencephalographic or clinical seizures and no repetitive epileptiform discharges were recorded from scalp electrodes during acquisition of these PET images.

It has been suggested that prolonged discharges confined to the amygdala and/or hippocampus may not be reflected on the surface EEG.[2,51] During her invasive evaluation it was estimated that less than 25% of the patient's depth-recorded, left-sided interictal spikes were visible on scalp electrodes. This lack of interictal epileptiform abnormalities on scalp recordings, while concurrent depth recordings show spiking activity, has been attributed to the distance separating scalp electrodes from a putative generator in the amygdalo-hippocampal complex.[51,52] It is also known that the amygdala tends to behave as a closed electrical field,[53–55] a fact that may contribute to discrepant scalp versus invasive recordings.

Neuropsychological testing commonly reveals an asymmetry in memory functions in patients with unilateral mesial temporal lobe epilepsy. Memory deficits are typically material-specific for the temporal lobe primarily involved,[2,19] but patients with mesial temporal lobe epilepsy may manifest a more generalized cognitive impairment.[56] Neuropsychological testing suggestive of bilateral or more diffuse functional deficit zones may identify surgical candidates with a poorer surgical outcome, presumably related to more extensive or diffuse epileptogenic zone(s).[57]

Neuropsychological data in our patient were nondiagnostic in terms of lateralization, and suggested bilaterally decreased memory function. The presence of independent bitemporal seizure foci has been associated with impairments of both verbal and spatial memory.[5,24,58] Patients with bitemporal epilepsy may have increased difficulties recalling personal events and may show a pattern of general memory impairments. Hence, it has been suggested that from a functional standpoint, patients with bitemporal epilepsy may be regarded as partially amnestic.[58]

In surgical decision making it is also important to consider and discuss the concept of *'apparent bitemporal epileptogenicity'*:[59] several authors have reported that seizure onset in a posterior epileptogenic focus can masquerade as bitemporal epilepsy.[16,60,61] In a recent study the Montreal group presented six patients with nonlesional focal epilepsy, who failed anterior temporal lobectomy despite localized EEG findings pointing to the anterior and inferomesial temporal region. It was noted that all six patients reported a soma tosensory aura, a clinical feature suggestive of a more posterior temporoparietal symptomatogenic origin.[62]

Because of their inherently narrow scope, invasive recordings with bitemporal depth electrodes may fail to disclose a posterior or other epileptogenic focus outside the temporal regions.[8] If the apparent bilateral EEG onset in mesial/basal structures results from a posterior epileptogenic region with variable propagation to these structures, then resection targeting the anteromesial temporal lobe (i.e., the site of propagation) is destined to fail.[59] Notwithstanding these limitations, there was no evidence from the noninvasive evaluation to suggest a posterior temporal or extratemporal focus in our case. Preoperative MRI did not reveal any structural abnormalities outside the temporal lobes.

Furthermore, neither the patient's surface EEG nor her interictal PET studies were suggestive of an extratemporal focus. Prolonged interictal scalp EEG recordings did not disclose additional spike foci outside the bilateral inferomesial regions. Ictal scalp EEG recordings were localized early on during seizures to the left (or right) temporal region and no diffuse or nonlocalizing patterns were recorded. Finally, the patient's stereotyped clinical semiology was not suggestive of a temporoparietal or extratemporal origin.[63]

Eccher and colleagues recently reviewed the Cleveland Clinic surgical database from 1990 to 2001 and identified a total of 105 patients, who underwent unilateral temporal lobectomy despite evidence of bitemporal epileptiform abnormalities (bilateral interictal spikes and/or seizures) on the preoperative surface EEG evaluation. In this cohort the majority of patients 48.6% (51/105, group A) had evidence of unilateral scalp EEG seizures and bilateral interictal epileptiform discharges. Another 24.8% (26/105, group C) had evidence of scalp EEG seizures arising independently from the left and right hemispheres. The remaining 26.7% (28/105, group B) presented with bilateral interictal spikes and a mixture of EEG seizures which consisted of strictly unilateral as well as nonlateralizable seizures–in the absence of scalp EEG evidence for strictly contralateral seizures (Eccher MAR *et al.*[64] and personal communication). Roughly one-third of patients in this cohort 32.3% (34/105) underwent an invasive evaluation with bilateral subdural and depth electrodes prior to surgery. Of note, seizure freedom at last follow-up (for duration of follow-up ranging from 2 years to more than 10 years) was found to be similar in the three groups: 58.8% for group A (30/51), 57.1% for group B (16/28), and 65.4% for group C (17/26). Regression analysis suggested that the following four factors were associated with a higher likelihood of postoperative seizure recurrence: a history of secondarily generalized seizures, a positive family history of epilepsy, the absence of a history of febrile convulsions, and a preoperative seizure frequency that exceeded 20 seizures/month. Invasive recordings revealed bilateral independent ictal onsets on depth electrodes in 23.5% of the patients referred for invasive evaluations (8/34). Four of these eight patients remained seizure free at last follow-up.[64]

The patient discussed here did not undergo a Wada test (intracarotid amobarbital procedure, IAP). Whether IAP testing provides meaningful clinical information that aids in predicting postoperative memory changes is controversial, more so in cases of suspected bitemporal epilepsy.[65] The IAP protocol used at our institution was evaluated in a study of 72 consecutive patients with unilateral temporal lobe epilepsy (39 left ATL and 33 right ATL). Neither the contralateral injection IAP memory score (a measure of functional adequacy) nor the ipsilateral injection IAP memory score (a measure of functional reserve) were shown to significantly predict verbal memory outcome, based on a model of backward stepwise regression analysis.[66] This model showed that the only variables predicting postoperative verbal memory were MRI hippocampal volume ratio, baseline verbal memory and side of surgery. A more recent study at our institution examined 12 patients with unilateral left (dominant) TLE who showed neuropsychological evidence of poor presurgical verbal and visual memory scores. None of these patients demonstrated a reliably meaningful decline in delayed verbal memory score following left ATL.[67] As expected, most reports review the value of presurgical studies (including Wada testing) in patients with a unilateral temporal lobe seizure focus. Consequently, very limitedinformation exists about the value of presurgical studies in predicting morbidity in patients with bitemporal epilepsies.

The incidence of TLE without an identifiable pathological substrate is difficult to estimate. Significant bias (sampling and ascertainment bias, for example) confound results of reported surgical series and autopsy studies.[68,69] Wieser points out that in patients without definite/specific histopathological abnormalities one cannot exclude the origin of seizures outside the resected temporal lobe–given that the surgical outcome in this group tends to be worse compared with patients with demonstrable pathological changes in the resected surgical specimen.[70] It has been estimated that approximately 10% of resected temporal specimens in patients with suspected temporal lobe epilepsy (TLE) show no significant histopathological abnormalities.[70] Ongoing surgical experience with TLE suggests that the absence of mesial temporal sclerosis is more common than previously suspected.[69] Such observations have led to the use of the term 'paradoxical TLE' or 'cryptogenic TLE' for these patients, because of the paucity of appreciable neuronal loss.[71] Lastly, hippocampal sclerosis can be so mild that it cannot be identified on structural MRI despite the use of high-resolution imaging, and in some cases it may even not be detectable by routine histopathological examination.[19]

Patients with bitemporal epilepsy without a predominant seizure focus are not considered candidates for resective surgery. Several authors have reported on the use of alternative therapies such as chronic vagus nerve stimulation[72] or experimental deep brain stimulation applied directly to the amygdalohippocampal structures[73,74] or to various modulatory subcortical structures such as the anterior nucleus of the thalamus[75,76] and the subthalamic nucleus.[77] An interesting neurosurgical approach, which may hold promise for patients with bitemporal epilepsy, is under development in Japan. The technique entails transection of the hippocampus in a manner similar to that of multiple subpial transections, performed under intraoperative electrocorticographic guidance. A recent report only included patients with unilateral temporal lobe epilepsy, and intact preoperative material specific memory function in the presence of a structurally normal-appearing hippocampus. The authors express their intent to further explore this technique in bitemporal lobe epilepsy encouraged by their positive, albeit very preliminary, seizure and functional results in patients with unitemporal seizures.[78]

Summary

A 30-year-old patient with a history of poorly-controlled seizures starting at the age of 20 years is presented. Her seizures consist of initial alteration of awareness and staring followed by bimanual and oral automatisms and a brief period of postictal confusion. Seizures have persisted despite multiple trials of appropriately chosen antiepileptic medications resulting in significant psychosocial disability.

A comprehensive noninvasive presurgical evaluation raised concerns for bitemporal epileptogenicity. Subsequent invasive evaluation with bilateral temporal depth electrodes demonstrated electrographic seizures arising from both the left and right temporal lobes. However, the majority of the patient's disabling clinical seizures were shown to originate from the left amygdalohippocampal complex. A left anterior temporal lobectomy was performed. One year later, the patient reports significant benefit in terms of seizure control, although at her last follow-up she has not achieved seizure freedom for a period longer than 6 months.

154 Patient with lesional neocortical focal epilepsy

B Abou-Khalil

Case presentation

A 42-year-old right-handed man presented for evaluation and treatment of seizures since age 10. He could not remember his initial seizures well. They started with a strange feeling in the head that he could not describe. He would then lose awareness and have picking motions of the hands. After the seizure, he would be very tired. Epilepsy was diagnosed, but seizures were never controlled for more than 1 year, and they changed over time. At the time of last presentation he had a consistent aura which he now described as a feeling like a 'pop' in his head. The aura would last 5–10 seconds, then he would lose awareness and would be noted to stare and to purse and smack his lips. He would repeat 'what' over and over. He fumbled and picked with either hand. He hummed at times. He reported seizure duration as 20 seconds, after which he was confused and had slurred speech for about 1 minute. He did report word finding difficulty postictally for about 5–10 minutes. He tended to have seizures in clusters. For example, 30 seizures had occurred in the previous year, but he had eight seizures in 1 month before presentation. In addition, he averaged about three isolated auras per month. He had had only four secondarily generalized tonic-clonic seizures in his life, all in one year, in 1984. With these, his wife thought that he had head-turning to one side, but she could not remember which side.

At presentation, he was taking lamotrigine, 200 mg three times a day, and carbamazepine, 500 mg in the morning and 600 mg at night. He had failed treatment with phenytoin, valproate, and tiagabine. He thought that his medications were all in combinations never in monotherapy. Past medical history revealed no clear risk factors for epilepsy, with the exception of a positive family history of seizures in one of his two sisters and in one paternal cousin. In both instances, seizures were outgrown. He had been a heavy drinker in the past, but had stopped drinking 20 years previously.

The review of systems was notable for complaints of memory loss, depression, and irritable mood.

Social history indicated that he graduated from high school with average grades. He was self-employed as a farmer. He had been married for 21 years with one 13-year-old daughter.

General and neurological examinations were completely normal, including mental status, cranial nerves, motor system, reflexes and sensory system.

Review of past evaluations indicated that he had had an MRI that was reported normal. No other outside data were available.

The patient was interested in a definitive treatment for his seizures, and had heard about epilepsy surgery. He underwent a complete presurgical evaluation.

MRI revealed a 20-mm lesion that had increased T2 signal in the center and decreased signal in the surround, suggesting old hemorrhage (Figure 154.1). This lesion was abutting the interior aspect of the left petrous pyramid laterally. There was no hippocampal sclerosis.

18F-Fluorodeoxyglucose positron emission tomography (PET) scan revealed a zone of reduced FDG uptake over the inferolateral region of the left temporal lobe, corresponding to the MRI lesion (Figure 154.2).

Inpatient video-EEG monitoring for 4 days in conjunction with medication withdrawal recorded six partial onset seizures, two of which secondarily generalized. Five events began in sleep, and were characterized by arousal with restless movements, glancing around, initial fumbling with the left hand in two events, right arm dystonic posturing or immobility of the right arm in four events, and lip-smacking and chewing in three events. In the two seizures that generalized, there was adversive head and eye deviation to the right in

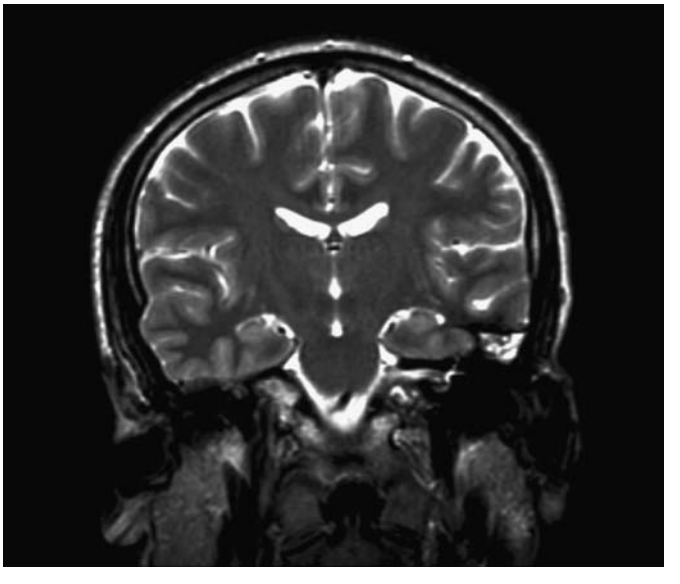

Figure 154.1 MRI shows a probable left inferior-lateral temporal cavernous angioma (arrow).

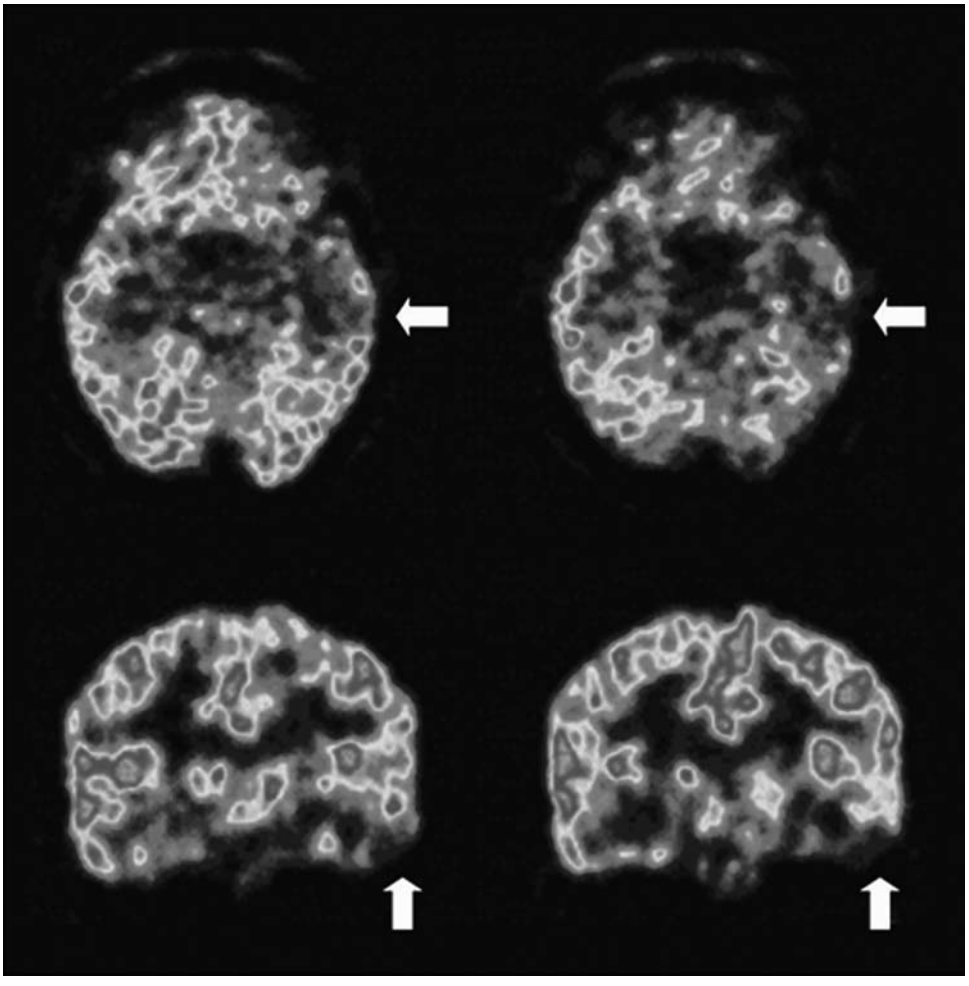

Figure 154.2 FDG PET (axial top row; coronal bottom row) shows a defect in FDG uptake in the left inferior-lateral temporal region, corresponding to the MRI lesion (arrows).

transition to generalization. There was nose-wiping postictally with the left hand in one event.

The associated ictal onset was consistently left temporal, but with predominance in the left sphenoidal electrode (Figure 154.3). Interictally, there were independent epileptiform discharges recorded from the left mesial-basal and lateral anterior-mid temporal region (with mesial-basal predominance), and from the left posterior and mid lateral temporal region with variable involvement of the left posterior quadrant. Finally, there was intermittent irregular left temporal slow activity (Figures 154.4 and 154.5).

Neuropsychological testing (see Table 154.1) revealed borderline abilities, with significantly stronger aptitude for nonverbal skills in comparison to verbal skills. He also had stronger visual memory skills in comparison to verbal recall on the Wechsler Memory Scale WMS-III. He did not do well with either Rey-O Complex Figure. Recall or Buschke Selective Reminding Recall.

The intracarotid sodium amobarbital procedure was performed with 125 mg of sodium amobarbital on each side, with about 30 minutes between injections. The left hemisphere was injected first. The patient developed global aphasia for more than 7 minutes, indicating left hemisphere dominance for language. He had only dysarthria (no language impairment) with right injection. He passed memory testing marginally with both left and right injection.

Summary of presurgical evaluation and surgical plan

The lateralization of the epileptogenic zone was confident to the left hemisphere, based on the combination of MRI and PET findings, seizure semiology (the strongest lateralizing signs were the right arm dystonic posturing and the versive head turning to the right in transition to generalization – the postictal aphasia was also an important features derived from the history), interictal epileptoform discharges, ictal EEG onset, and interictal slow activity. However, there was a discrepancy between the imaging findings which indicated a neocortical temporal structural and functional lesion, and the ictal EEG onset which favored a mesial-basal seizure onset. The EEG interictal epileptiform abnormalities were consistent with independent lateral temporal and mesial-basal temporal irritative zones. The aura of 'pop' in the head can be considered a cephalic aura. It is nonspecific with respect to localization, but may be more common with neocortical seizure foci. The remainder of the seizure semiology was consistent with mesial temporal seizures, but seizures can spread and the predominant seizure semiology may actually reflect involvement of structures after seizure spread. Since cavernous angiomas are highly epiletogenic, it was felt that the left neocortical temporal cavernous angioma was most probably the epileptogenic lesion. It is also not

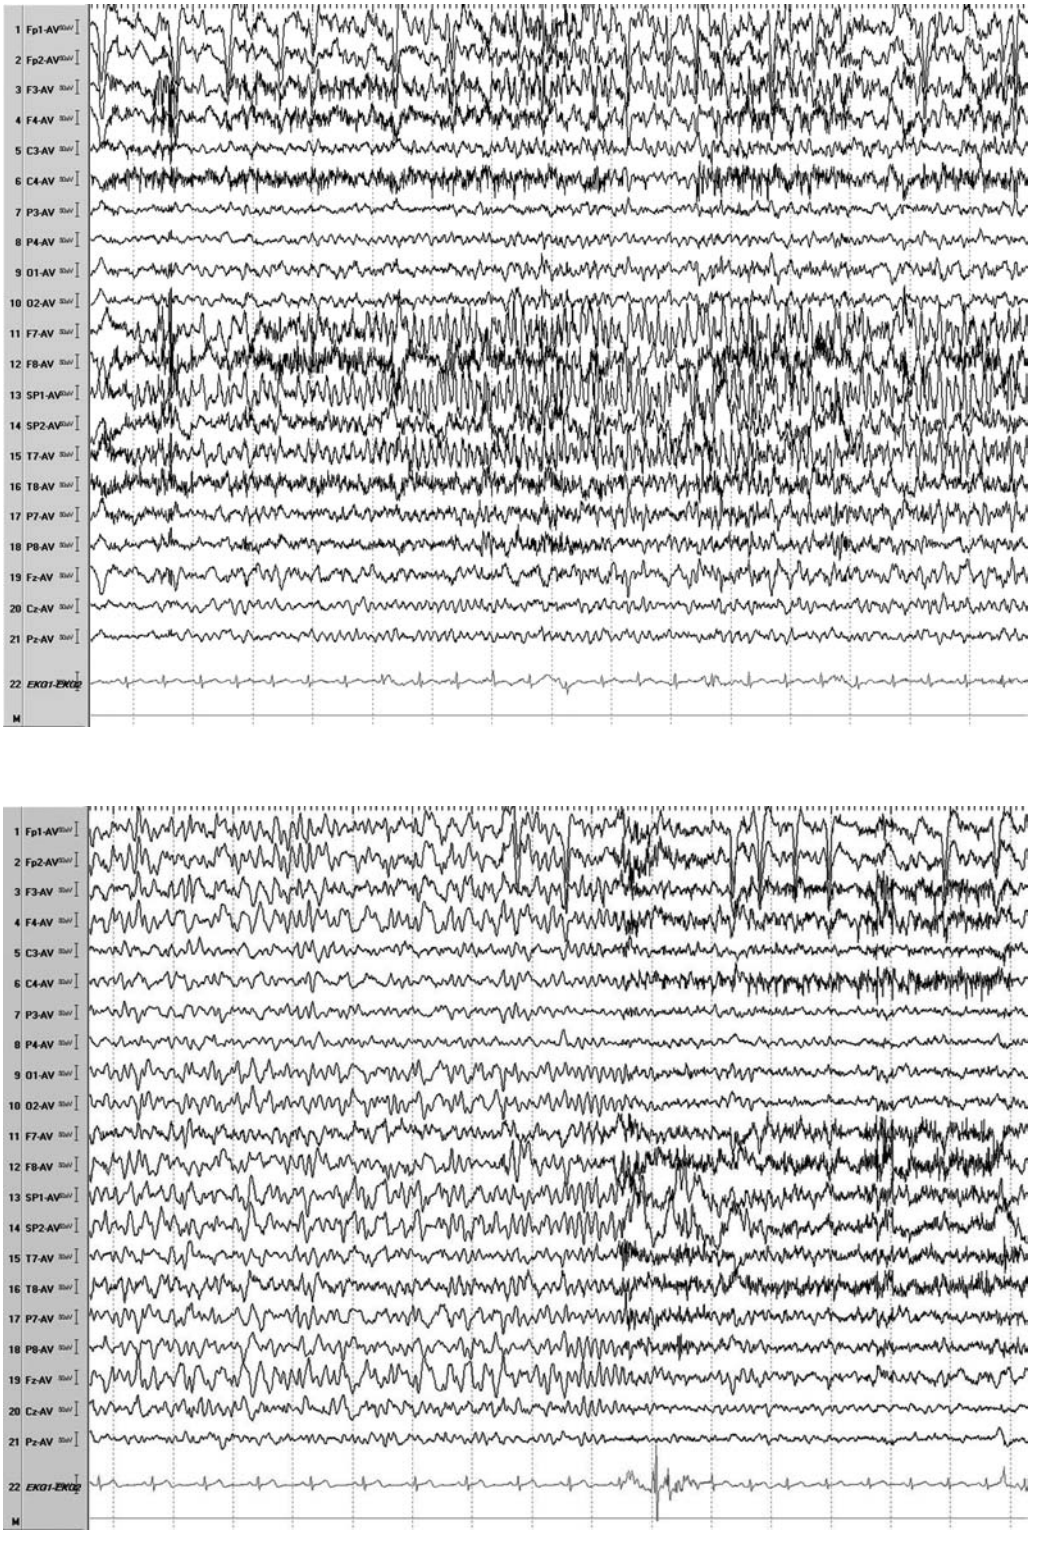

Figure 154.3 Ictal onset on an average referential montage. There was initially a voltage attenuation in conjunction with muscle artifact. The first definite rhythmic ictal activity was in the theta range. It was left temporal, with voltage predominance at Sp1.

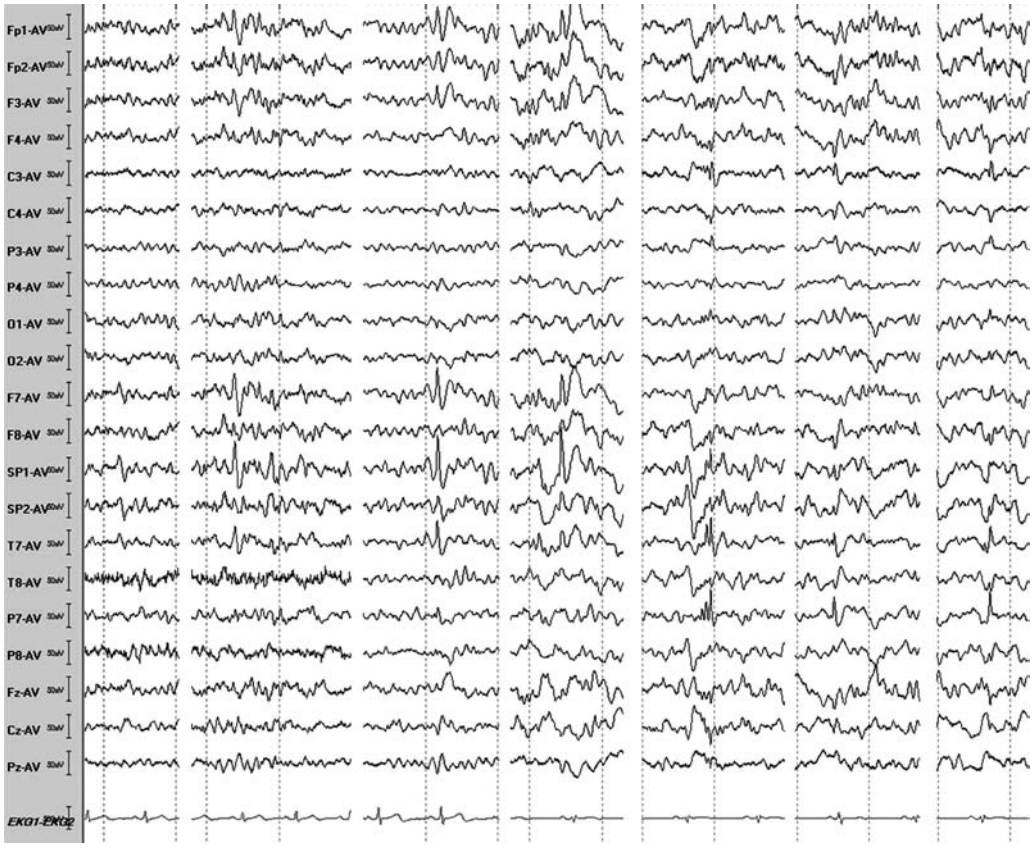

Figure 154.4 Interictal epileptiform activity was recorded independently from the left mesial-basal-anterior temporal and the left posterior-mid-temporal regions (a series of discharges from each field are illustrated).

unusual to see mesial-basal temporal epileptiform discharges with neocortical epilepsy, whether neocortical temporal or extratemporal. The posterior temporal interictal epileptiform discharges may reflect irritative activity from around the lesion itself, while the sphenoidal electrode discharges could represent a form of secondary epileptogenesis. We had the option of either pursuing the presurgical investigation with invasive monitoring, using subdural grid electrodes for recording seizures and localizing language cortex, or proceeding with a lesionectomy since the lesion was surgically accessible. With the latter choice, an invasive evaluation could be pursued if seizures persisted. It was decided to proceed without invasive monitoring. The patient was left hemisphere dominant for language, but since the lesion was in the inferior temporal gyrus, the risk to language was felt to be minimal, and it seemed reasonable to proceed with a lesionectomy, including hemosiderin stained margins of the lesion, without mapping language functions.

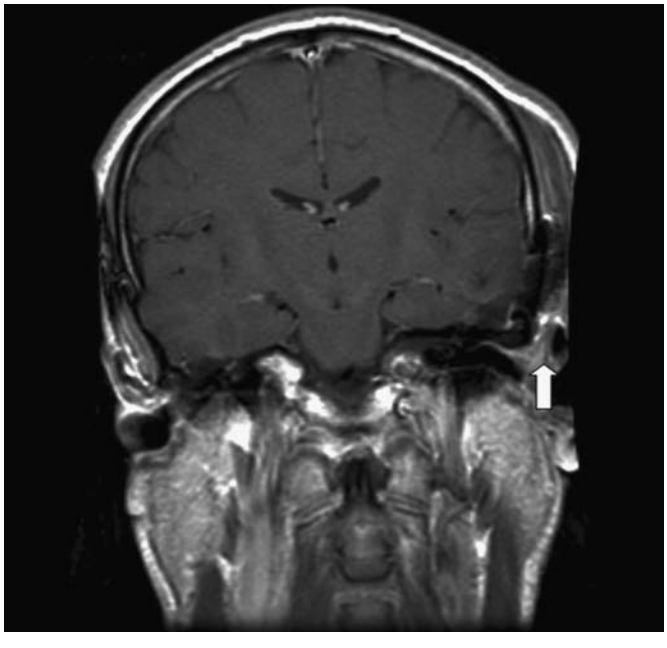

Figure 154.5 Postoperative MRI demonstrating extent of resection (see arrow).

One other decision was whether to extend the resection to remove the hippocampus, in view of the mesial-basal temporal irritative zone by EEG. This case illustrates a frequent dilemma that occurs with lateral temporal neocortical lesions, when the EEG supports a mesial-basal seizure origin and predominant epileptiform activity. When there is associated hippocampal sclerosis by MRI (dual pathology), there is evidence that surgical outcome is better with removal of both the neocortical lesion and the sclerotic hippocampus. In this particular patient, the ipsilateral hippocampus appeared to be structurally normal, even though it may have participated in seizure propagation. Therefore, it was decided to perform a lesionectomy sparing the hippocampus.

Table 154.1 Selected neuropsychological measures

Area/test	Score	Age/education expected
Intelligence – WAIS-III		
Verbal IQ	72	100 ± 15
Performance IQ	87	100 ± 15
Full-scale IQ	77	100 ± 15
Verbal comprehension	68	100 ± 15
Perceptual organization	91	100 ± 15
Working memory	97	100 ± 15
Processing speed	86	100 ± 15
Memory– Wechsler Memory Scale-III		
Immediate auditory	68	100 ± 15
Immediate visual	81	100 ± 15
Delayed auditory	64	100 ± 15
Delayed visual	75	100 ± 15
Rey-O-Complex figure copy	33.5/36	≥32/36
Rey-O-Complex figure immediate recall	6.5/36	≥32/36
Rey-O-Complex figure delayed recall	6.5/36	17/36
Buschke Selective Reminding Task-immediate	7/12 by 8th trial	≥10/12
Buschke Selective Reminding Task-delayed recall	1/12 after 30 min delay	8/12
Language		
Boston naming test	32/60	≥52/60
Reitan Aphasia Screening	3 errors	0 errors

Surgical procedure and surgical outcome

Surgery performed 28 months before this report was a left image-guided craniotomy for resection of the temporal lesion. It was performed under general anesthesia. The skin incision was made from the posterior aspect of the zygoma superiorly over the top of the ear for about 4 centimeters. Dissection was carried down to the squamous portion of the temporal bone. A craniectomy defect was created with a drill, exposing the inferior temporal gyrus and petrous apex area. After opening the dura, hemosiderin stained tissue was seen, along with a rather large vein presumed to be the vein of Labbe. The pia was separated from the inferior aspect of the vein, and the vein was retracted superiorly, then the hemosiderin stained area of the inferior temporal gyrus was slowly removed using bipolar and suction. The lesion measured 2–3 centimeters in diameter. Eventually, the entire nidus around the vascular lesion was delineated with a pedicle arising off the floor of the temporal lobe just over the petrous apex. The lesion was resected. The remaining portion of any hemosiderin stained brain was then aspirated. The wound was then irrigated and closed.

The anatomic pathology was cavernous angioma.

A postoperative MRI showed almost complete resection of the lesion (Figure 154.5).

There were no immediate postoperative seizures. There were no neurological deficits and specifically no difficulties with word finding or naming. On follow-up visit 3 months postoperatively, the patient reported no full-fledged seizures. However, he did report some isolated auras lasting a few seconds, occurring two to three times a month. He was now on lamotrigine, 300 mg twice daily. When he returned 6 months after surgery, he reported only a single possible aura, about 3 weeks before the visit, during the whole 3-month interval. At the 1-year postoperative visit he reported that seizure auras had recurred, sometimes up to three to four times per week. He said that they lasted only a second or so. He remained on lamotrigine, 300 mg twice daily. He continues to be self-employed as a farmer, working full-time. He reports no decline in his function.

The favorable outcome with respect to disappearance of disabling seizures supports the decision to limit the surgery to lesionectomy with removal of hemosiderin-stained margins, sparing the structurally normal hippocampus. However, the residual auras suggest that the epileptogenic zone may not have been fully resected.

Video seizure description

The patient was lying with eyes closed. He suddenly opened his eyes and reached for the event button, but did not push it. He seemed to freeze, staring straight ahead, with his right hand fisted around the event button. He then looked slightly to the left. He pursed his lips and had slight chewing motions, while his right hand continued to hold the event button in a fist, the right elbow flexed and the hand held up in the air, with a rotatory component consistent with a dystonic posture. He then began to have restless fumbling and picking motions with the left hand and restless motions of the legs and trunk. The right hand remained fisted, holding the event button. As he sat on the bed, he began to make rhythmic grunting sounds and had versive eye and head deviation to the right. This was followed by secondary generalization.

155 Patient with nonlesional neocortical epilepsy

L Tassi and GL Russo

Summary

We present the case of a 9-year-old boy, with a negative personal and familial history, who started having seizures at the age of 3 years. From the beginning, seizures have always been characterized by asymmetrical spasms, predominant on the left side. Brain MR was normal. His neurological examination was normal, but the IQ, 78 at the first evaluation (35 months) dropped to 55 three years later.

Interictal EEGs showed since the beginning, a continuous slow wave and spike and wave activity, well localized in the right frontal region.

We performed a stereo-EEG investigation, and on the basis of anatomo-electro-clinical correlation, a frontal corticectomy.

The histological examination showed an architectural dysplasia, and since then the patient is seizure free (more than 1 year).

Clinical data

Clinical history

G.F., when referred to our epilepsy surgery center, was a right-handed 9-year-old boy without any personal or familial antecedent for epilepsy, and normal delivery after a physiologic pregnancy. Psychomotor development was normal until the onset of seizures.

Ictal episodes started at 2 years and 9 months and from the beginning were characterized by a sudden bilateral elevation of the arms, predominant on the left side, sometime associated with a left oculo-cephalic deviation. Fits were very brief (1 second) and tended to present in clusters, lasting about 10 minutes, at the end of which no postictal deficit was present.

Seizure frequency rapidly worsened (1–5 series a day) during the following 2 months, until a pharmacological treatment (GVG) was started and induced a 2-month seizure-free period.

After that, episodes started again, occurring more than once a day only during wakefulness; they were always characterized by a cluster of spasms (abrupt asymmetric arms elevation with a left predominance) lasting 5–15 minutes during which the boy became more and more restless and was slightly pale and polypnoic; speech was preserved all along the cluster.

No more prolonged seizure-free interval has been obtained by drug treatment which, after GVG, included VPA, CBZ, LEV, TPM, Hydrocortison, and CLB, in various associations.

Neurological and neuropsychological investigation

Neurological examination was normal except for cognitive functions.

Serial neuropsychological evaluations documented a progressive decline in global IQ (Griffiths) from the very beginning of the illness (35 months: 78) with a sensible drop at 1 year (72) but namely at 2-year follow-up, when it was 55.

Preoperative evaluation showed a language deficit, and a loss in verbal and non-verbal memory. Furthermore there were a difficulty in visuo-spatial perception and motor ability.

Neuroimaging

MR evaluation, performed following our protocol also included some additional cuts targeting the right frontal lobe. The following sequences were obtained: transverse spin-echo double-echo of the entire brain and axial TSE inversion recovery (Figure 155.1), coronal turbo spin-echo (TSE) T2-weighted (W), coronal TSE fluid-attenuated inversion-recovery (FLAIR) T2W and coronal TSE inversion recovery (IR) T1W (Figure 155.2). Additional FLAIR images in the sagittal plane were acquired.

The MR was totally normal.

Video-EEG recordings

Long-term video-EEG monitoring allowed a further definition of interictal EEG features and, mainly the evaluation of three series of 'asymmetric spasms'.

Interictal EEG was characterized by a mid amplitude posterior background rhythm at 8–9 Hz, symmetric and reactive to eye opening.

Electrical activity was quite peculiar over the right frontal region, where theta-delta waves were almost constantly recorded, without arrest reaction but with the frequent intermixing of spikes and spike-and-waves (Figure 155.3a, b). This actual 'electrical' status epilepticus did not vary during wake and sleep cycle, almost always being present over the right fronto-temporal region.

The three ictal clusters recorded, lasting from 1 minute 16 seconds to 5 minutes 33 seconds, were characterized by a progressive restlessness, then interrupted by sudden, brief, abrupt movements (left arm, left shoulder, a forced inspiration) with different entity, sometimes unperceivable.

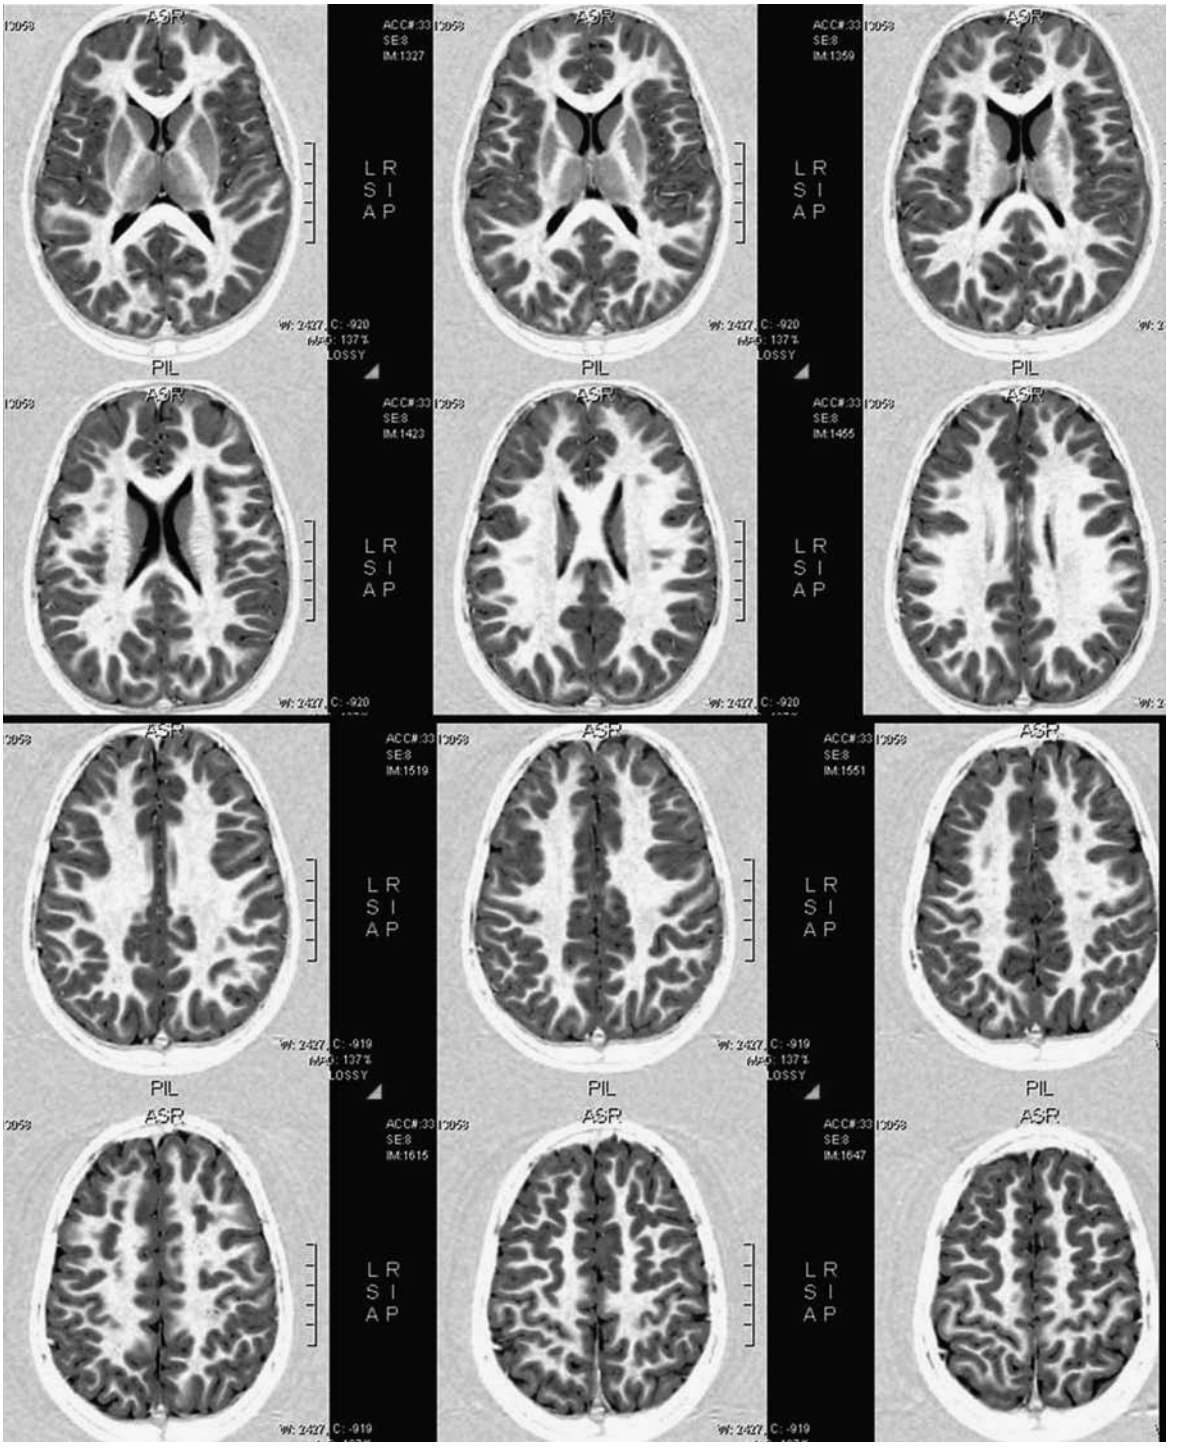

Figure 155.1 Preoperative brain MR showing an axial TSE inversion recovery (3 mm slices). No anatomical abnormalities were noticed.

On the EEG slow activities were gradually replaced by a non-tonic rhythmic activity (Figure 155.4a), localized on the right fronto-temporal region, and by the appearance of rhythmic high-amplitude slow-wave surcharged by a low-voltage fast activity (Figure 155.4b); these last, maintaining a clear right fronto-temporal predominance, represented the electrical correlate of the motor ictal manifestation. A concomitant increase of generalized slow-spike and waves have to also be noticed. At the end of clinical manifestations, EEG recovery was prompt and without postictal slowing.

Summary of presurgical evaluation

The clinical ictal semiology (including the presence of 'asymmetric spasms' predominantly localized on the left side of the body, associated with–or preceded by–an irritability and presenting in cluster with a high daily frequency) suggested a right hemispheric localization of the epileptogenic zone but could not indicate its lobar predominance.

EEG interictal and ictal features, notwithstanding a fast and consistent contralateral spread, demonstrated a constant right fronto-temporal involvement.

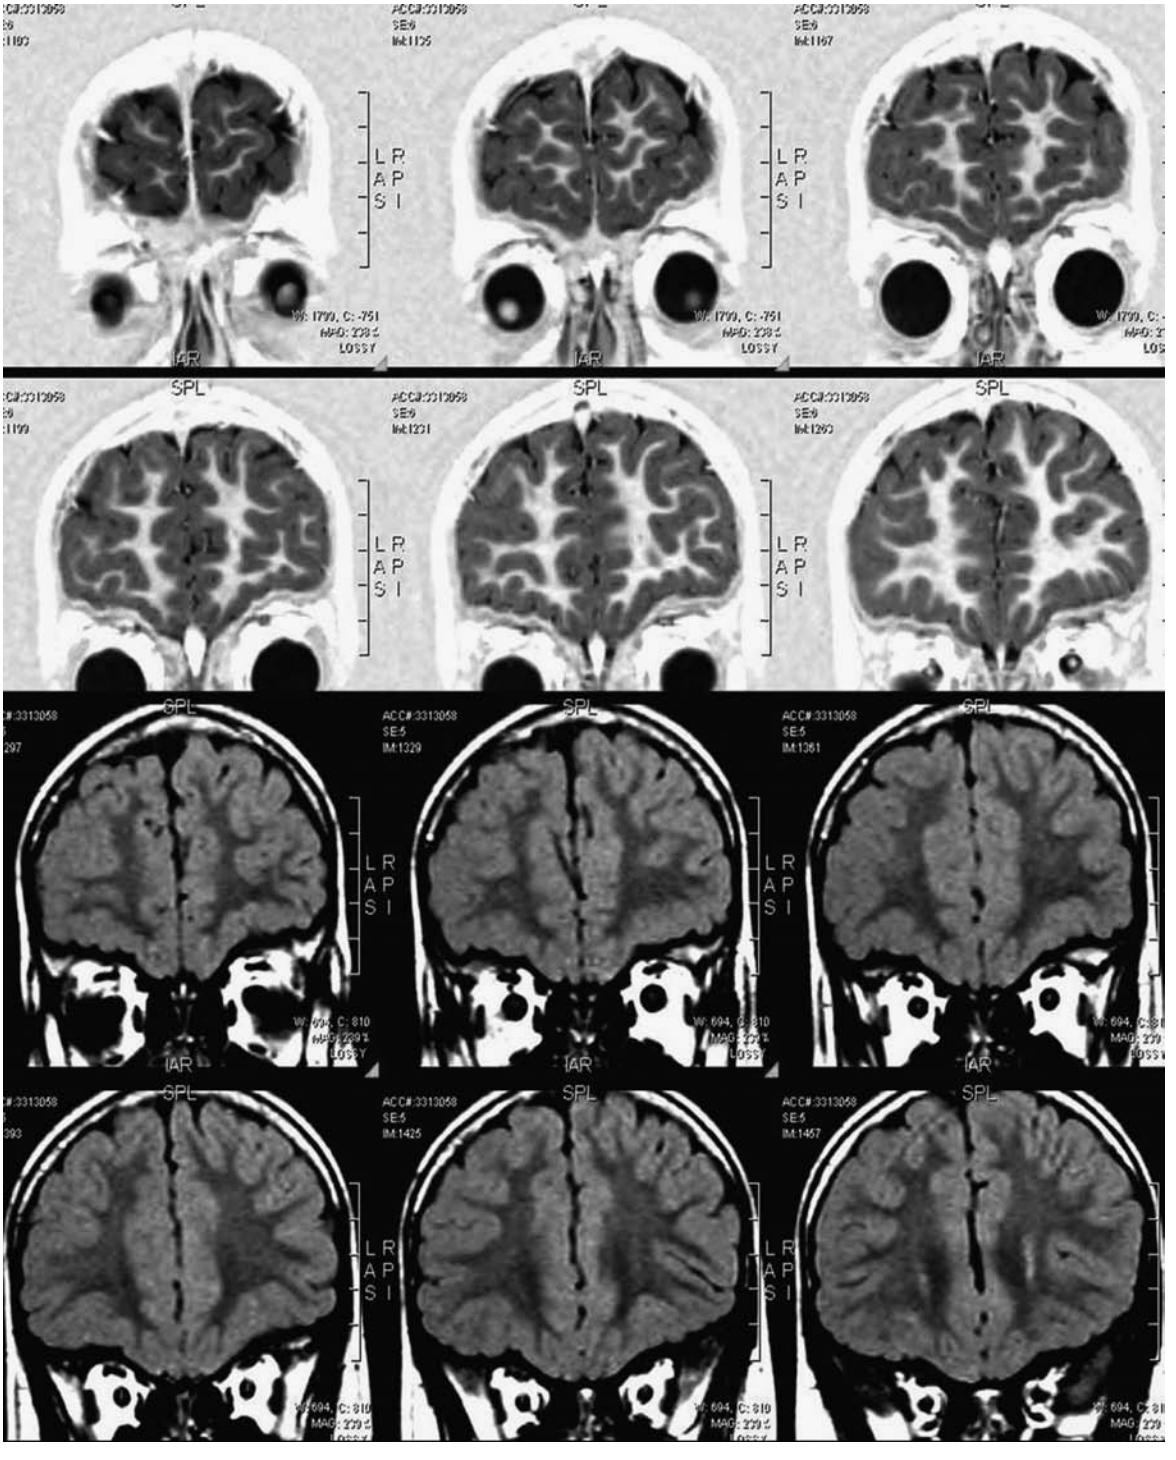

Figure 155.2 Preoperative MR, including coronal inversion recovery (a) and coronal FLAIR (b). The MR was completely normal.

MR was normal.

On these electro-clinical basis, a right frontal (-temporal) epileptogenic zone represented the most likelihood localization hypothesis, and stereo-EEG exploration by mean of stereotactically implanted intracerebral electrodes was judged necessary for verifying this hypothesis and, possibly, define the actual extension of the surgical exeresis.

The implantation strategy – once the lateralisation defined on clear electro-clinical basis – mainly followed the indications coming from EEG, showing a widespread right fronto-temporal origin of ictal discharges.

Stereo-EEG investigation

An unilateral, right fronto-temporal exploration was then realized, after an arteriographic study, by means of 14 multileads electrodes, ranging from five to 18 contacts (Figure 155.5).

Invasive recordings (interictal and ictal)

The patient was monitored for 7 consecutive days, during which seven series of spontaneous 'spasms' have been recorded. No ictal manifestations were induced by electrical stimulations.

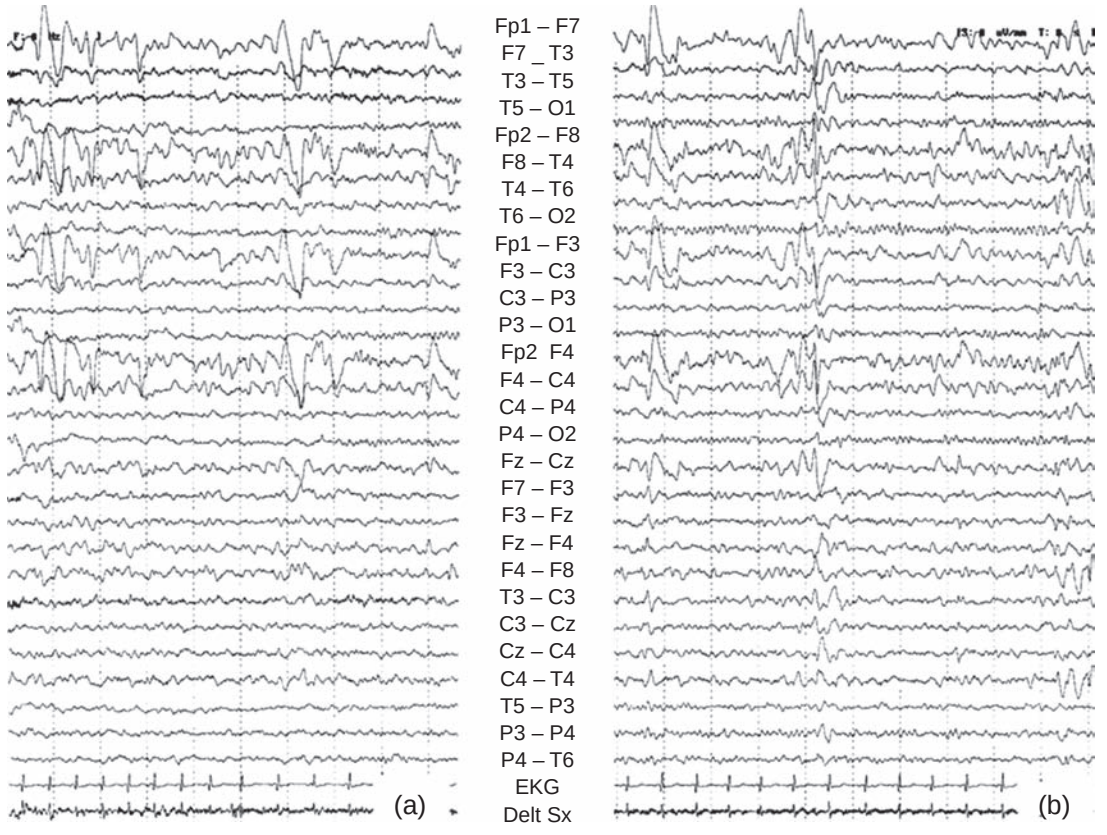

Figure 155.3 Interictal scalp activity: 8 Hz background activity, symmetrical. High-amplitude repetitive slow-waves and slow-spike and waves on the fronto-temporal regions, predominant on the right side (a). Slow-waves on the right fronto-temporal region may assume a rhythmic aspect (b).

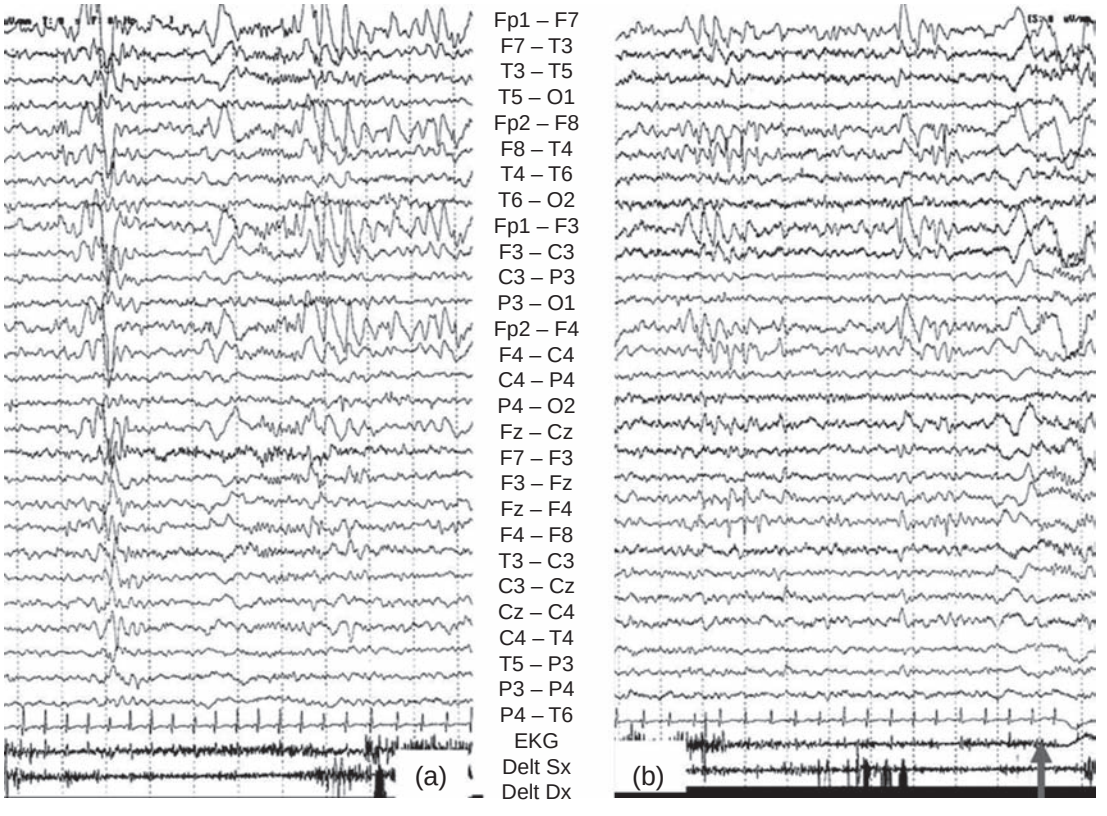

Figure 155.4 In the period immediately preceding ictal manifestation (a), there was a cut-down of slow-waves and a build-up of fast rhythmic activity, clustering in brief sequences. The first 'spasm' (red arrow) corresponds to a high-amplitude slow-wave probably preceded by and mixed with a rhythmic fast activity on the right fronto-temporal region (b). (See Color plates.)

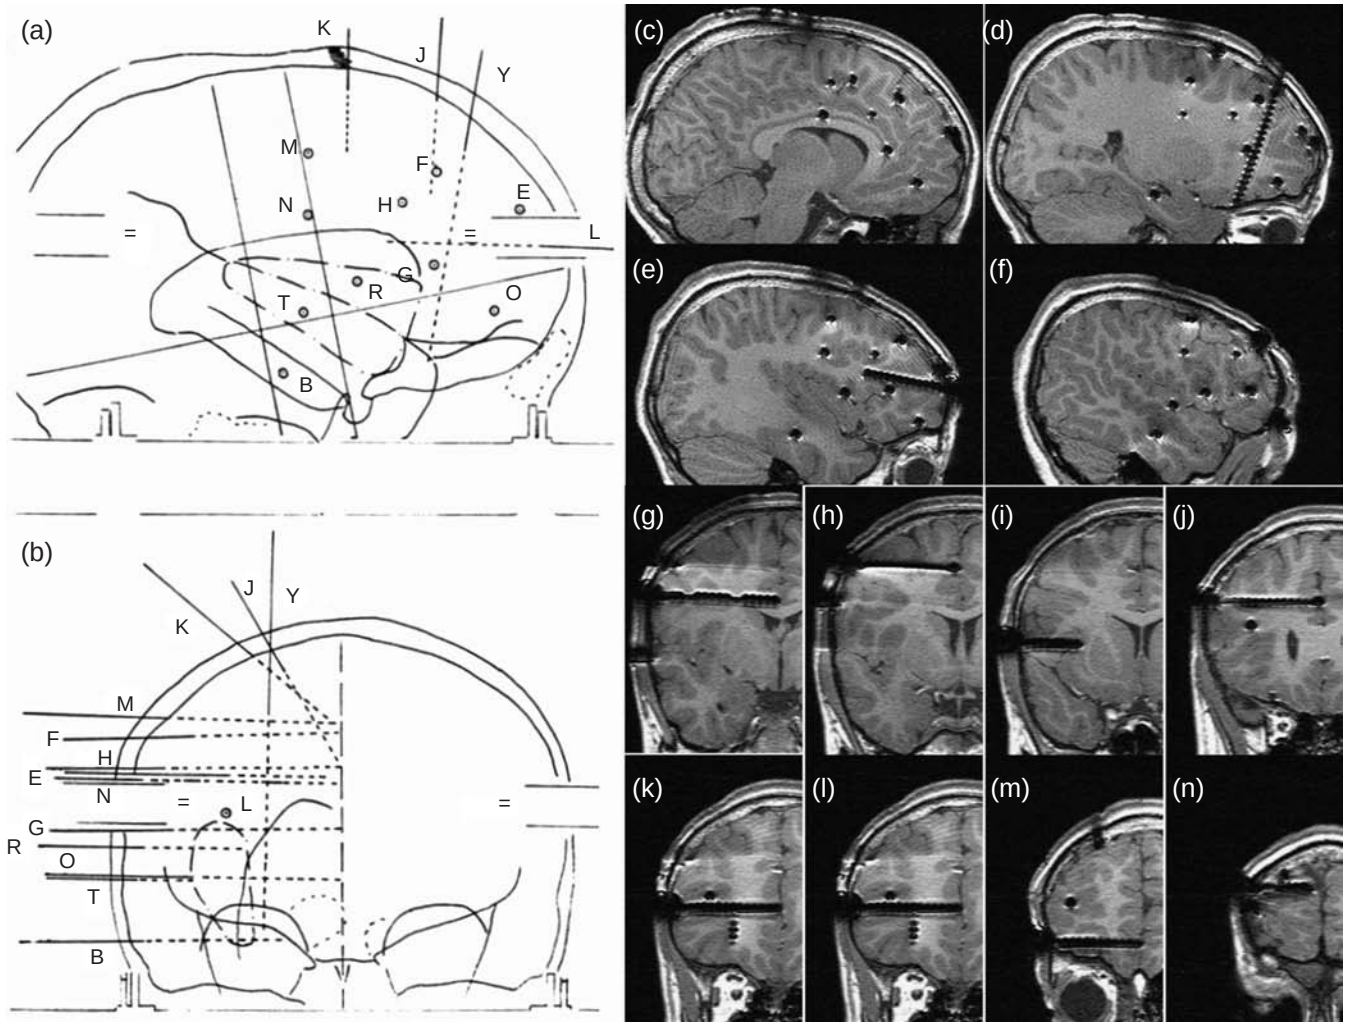

Figure 155.5 Lateral (a) and antero-posterior (b) views of the stereotactic scheme, according to the bicommissural reference system, of the SEEG exploration of this patient. Electrodes are indicated with either circled dots or dashed lines labelled by upper case letters. (c–f) T1-weighted 3D postimplantation MRI, sagittal slices from mesial to lateral. (g–n) same MRI, coronal slices from posterior to anterior. Intracerebral electrodes sample the following structures, from external to internal contacts: B: middle temporal gyrus, hippocampus, parahippocampal gyrus. T: superior temporal gyrus, Heschl's gyri. R: inferior frontal gyrus, insular cortex. G: inferior frontal gyrus, genu of cingulated gyrus. H: inferior frontal sulcus, anterior cingulated gyrus. N: precentral gyrus, central cingulated gyrus. M: middle frontal gyrus, mesial frontal cortex. F: middle frontal gyrus, mesial frontal cortex. O: inferior frontal gyrus, fronto-orbital gyri, mesial frontal cortex. E: frontal pole. L: frontal pole. Y: superior frontal sulcus, fronto-orbital cortex. J: superior frontal gyrus, mesial frontal cortex. K: superior frontal gyrus, mesial frontal cortex.

The interictal activity (Figure 155.6a) is characterized by the presence of very frequent slow waves (theta delta) and slow–spike and waves localized on the orbital region, the frontal pole, the very anterior part of the cingulated gyrus and the anterior part of the first, second and third frontal gyri. HPN doesn't modify the pathological activity and ILS was ineffective.

During sleep (Figure 155.6b) slow–spike and waves become more frequent and intermingled by the presence of some 'flattenings', mostly localized on the orbital region and the frontal pole.

During ictal episodes, as in surface recordings, ictal symptoms are preceded by clear electrical modifications: a dramatic reduction of slow waves, and the appearance of 1–2 seconds rhythmic fusiform discharges (Figure 155.7a), well localized, on the frontal pole and the orbital region.

Progressively these discharges involve the anterior part of F1, F2, and F3 as well as the anterior part of the cingulated gyrus (Figure 155.7b).

Later a low-voltage fast activity appears concomitantly with the fusiform anterior discharges (Figure 155.8a), involving almost all the explored structures, but only when a high-amplitude slow wave emerges, the clinical 'spasm' becomes evident (Figure 155.8b).

Then the EEG becomes slower and slower (Figure 155.9a), and at the end of the episode, no postictal slow–waves were noticed, and it exists an impressive decrease of the previous interictal slow activity (Figure 155.9b).

Video

The boy, seated in the bed, is doing his homework with his father.

Since 13.47.50 (10 seconds after the beginning of the fusiform fast activity in the anterior part of the frontal lobe) he becomes confused, restless, and he speaks with a feeble voice. The first spasm is at 13.49.21, and the last one at 13.52.22.

Figure 155.6 Stereo-EEG recording, during wakefulness (a) and sleep (b), demonstrating the presence of persistent slow waves and slow spike and waves in the anterior part of the frontal lobe, worsening during sleep. Mes Orb: mesial orbital region. Ant: anterior. F2: second frontal circumvolution. F3: third frontal circumvolution. F: frontal. Mid: middle. F1: first frontal circumvolution. Ant Cing: anterior part of the cingulated gyrus. Post: posterior. Mid. T1: middle part of the first temporal gyrus. Hippo: hippocampus. Mid. T2: middle part of the second temporal gyrus. Delt: deltoid. Genu Cing: genu of the cingulated gyrus. Centr. Cing: central part of the cingulated gyrus. PreC Gyrus: precentral gyrus.

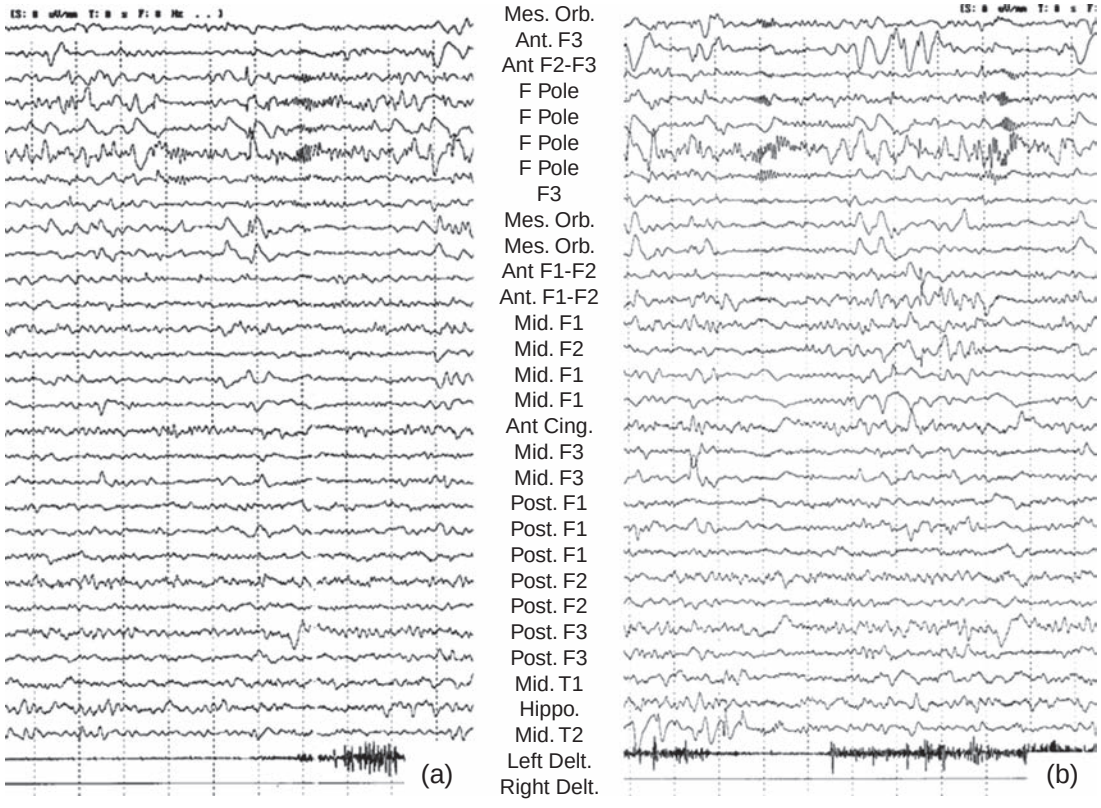

Figure 155.7 Stereo-EEG recordings, showing the onset of fusiform fast activity (a), becoming more and more frequent (b), well localized in the frontal pole and the mesial orbital regions.

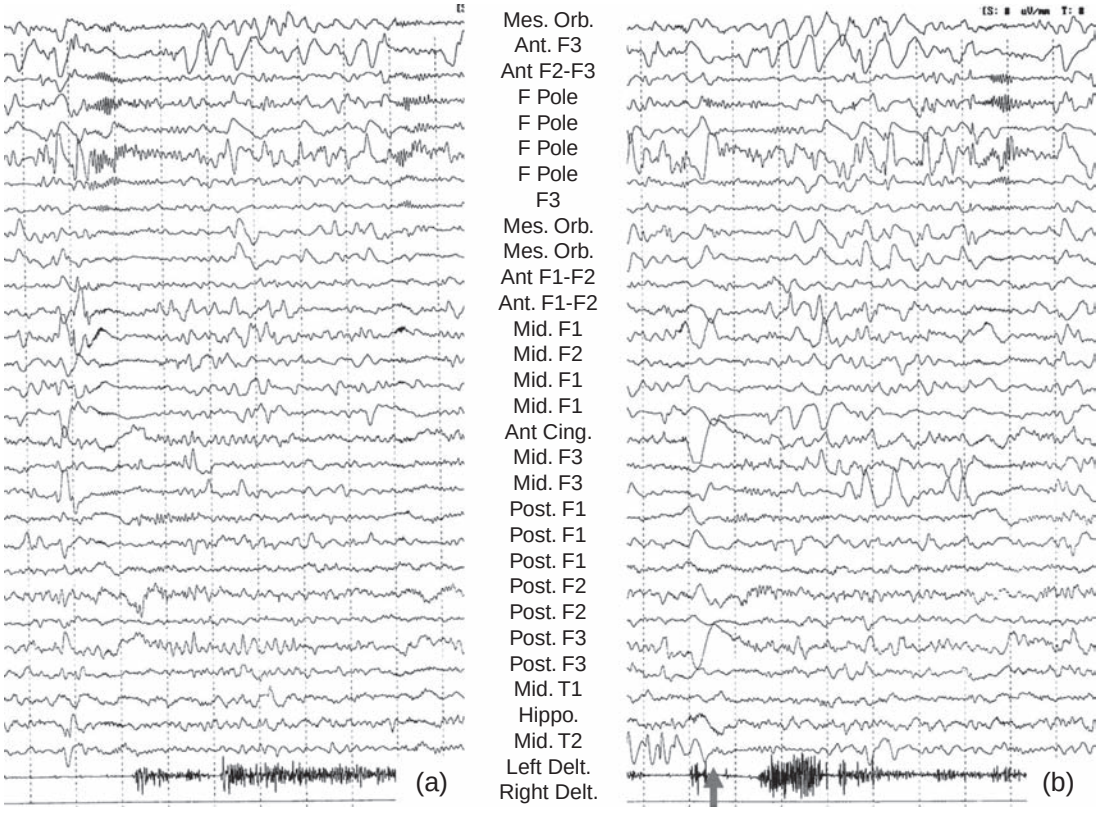

Figure 155.8 Stereo-EEG recordings: the fusiform activities are associated with a faster activity, spreading to the posterior part of the frontal lobe, as well as to the temporal structures, with no symptoms, except for the irritability (a). The first spasm (red arrow) coincide with a high-amplitude slow wave. (See Color plates.)

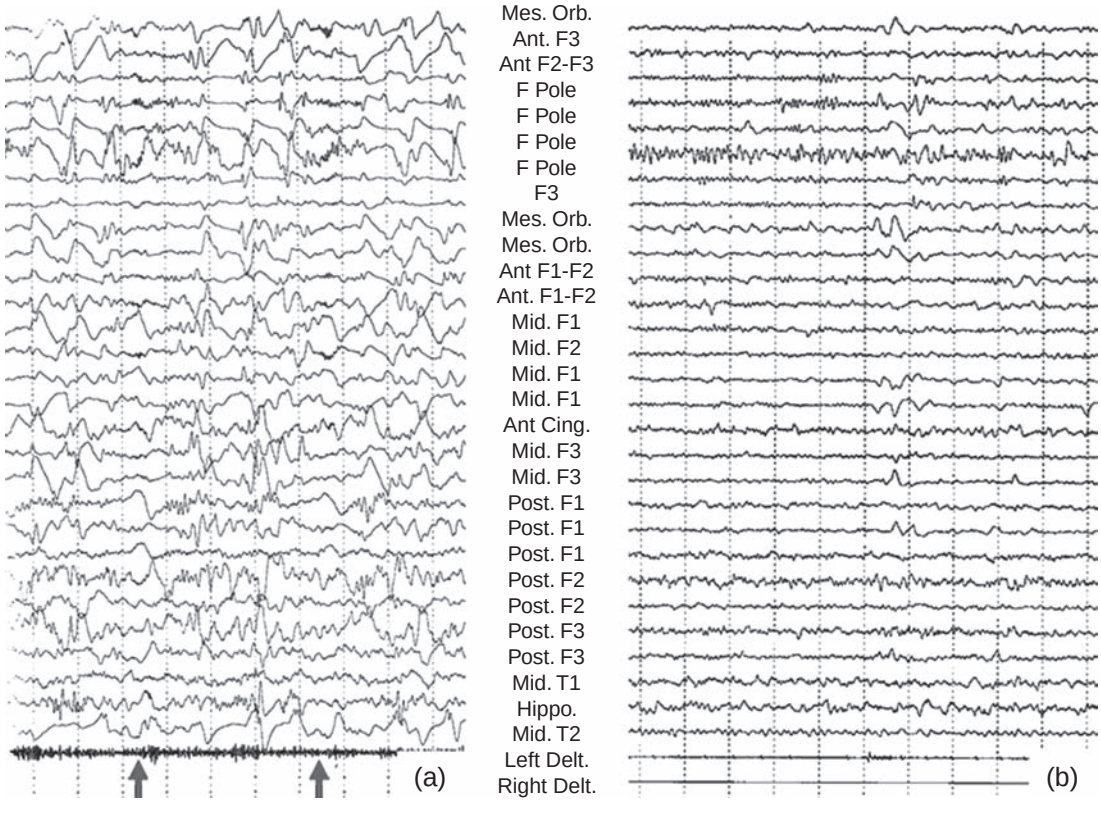

Figure 155.9 Stereo-EEG recordings: slow waves grow up and the spasms are repetitive (red arrows) (a). At the end of the cluster, the total and abrupt disappearance of the slow activities is the main electrical feature. (See Color plates.)

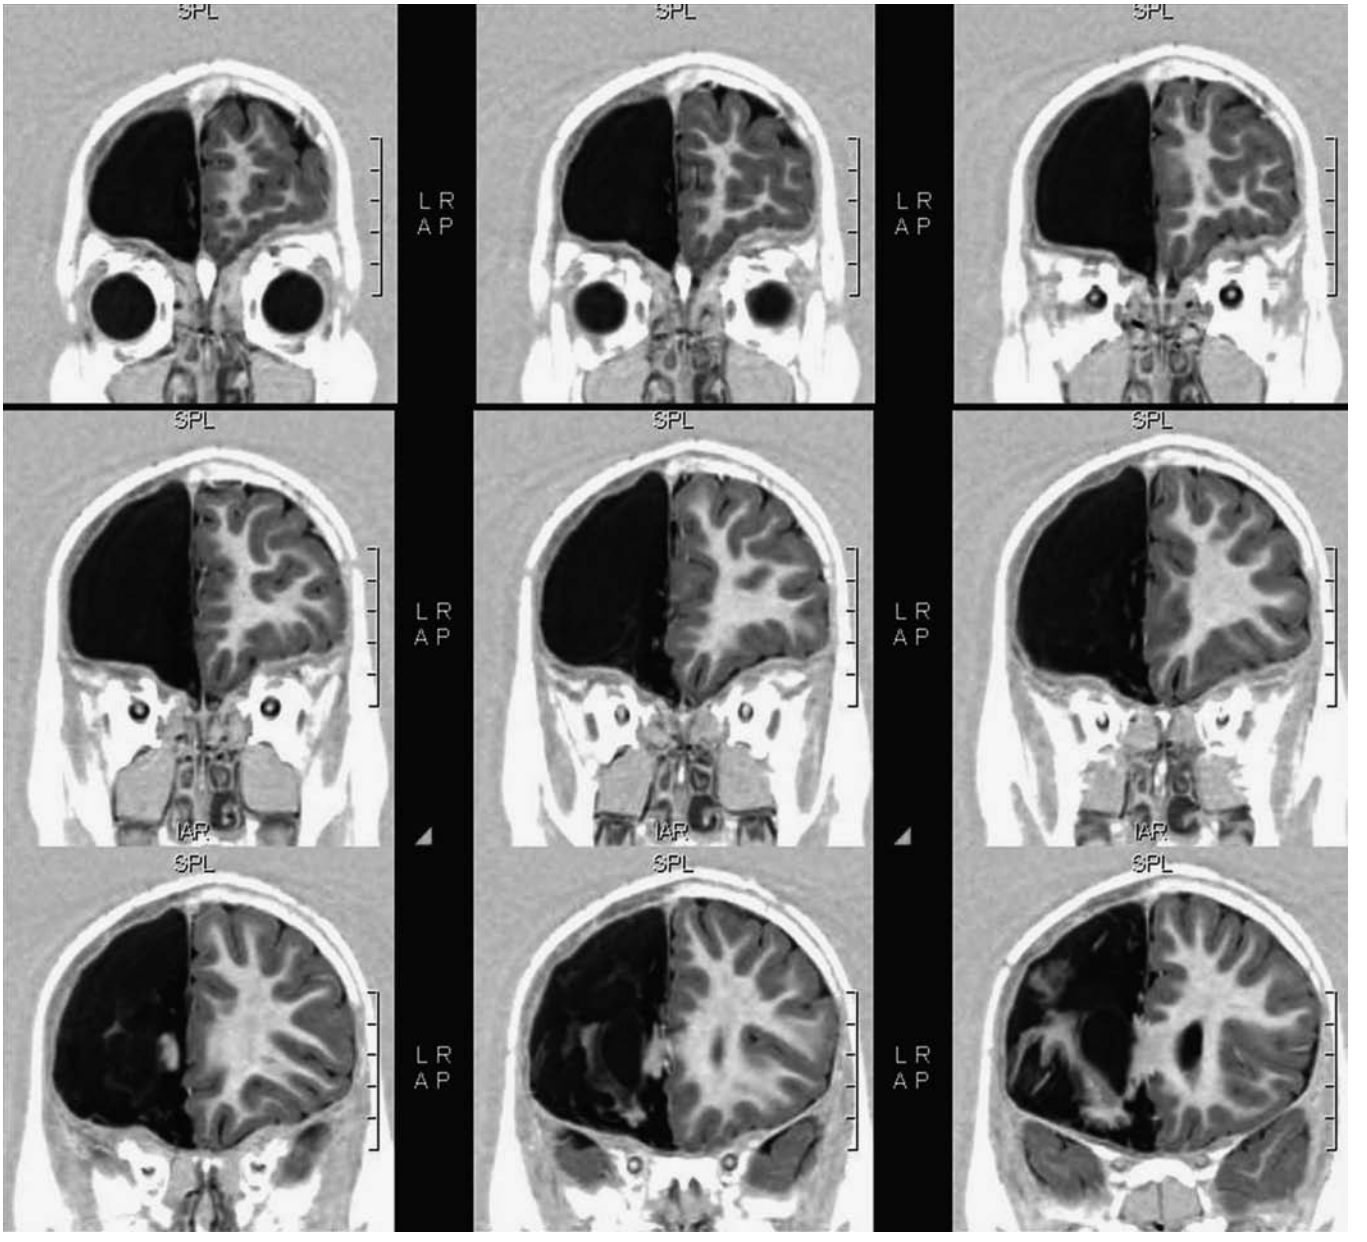

Figure 155.10 Postoperative MR, coronal TSE inversion recovery (3 mm slices), demonstrating the right frontal corticetomy.

Electrical intracerebral stimulations

The neurophysiological mapping obtained by electrical stimulations, pointed out clonic jerks (hand motor area) in the right hand, only in contact R6–7 (posterior F3).

No other clinical or electrical effect has been induced.

Definition of epileptogenic zone and surgical plan

According to the electro-clinical data obtained during the stereo-EEG, the definition of the epileptogenic zone was mainly based on the following electrical features:

- slow waves and spike and waves were prevalently localized on the frontal pole, the orbital region, the anterior part of the cingulated gyrus and the anterior third of F1, F2, and F3;
- during sleep, on the same regions, we noticed spike and waves intermingled with brief periods of flattening;
- ictal symptomatology was preceded (in some cases 2–3 minutes before) by the appearance of rhythmic fusiform discharges, always localized on the frontal pole and the orbital region, and then involving the anterior part of F1, F2, and F3, and the anterior part of the cingulated gyrus; these localized electrical modifications have always been the prelude for a widespread (almost all the explored structures) electrical change, characterized by an high-amplitude slow wave associated with the motor ictal phenomena.

Therefore we proposed a right frontal corticectomy, including the frontal pole, the orbital cortex, the cingulated gyrus and the superior, middle and inferior frontal circumvolutions, up to the projection of the electrode H, expecting a good outcome concerning seizure freedom. On the other hand, the evolution of cognitive functions could be hardly anticipated in

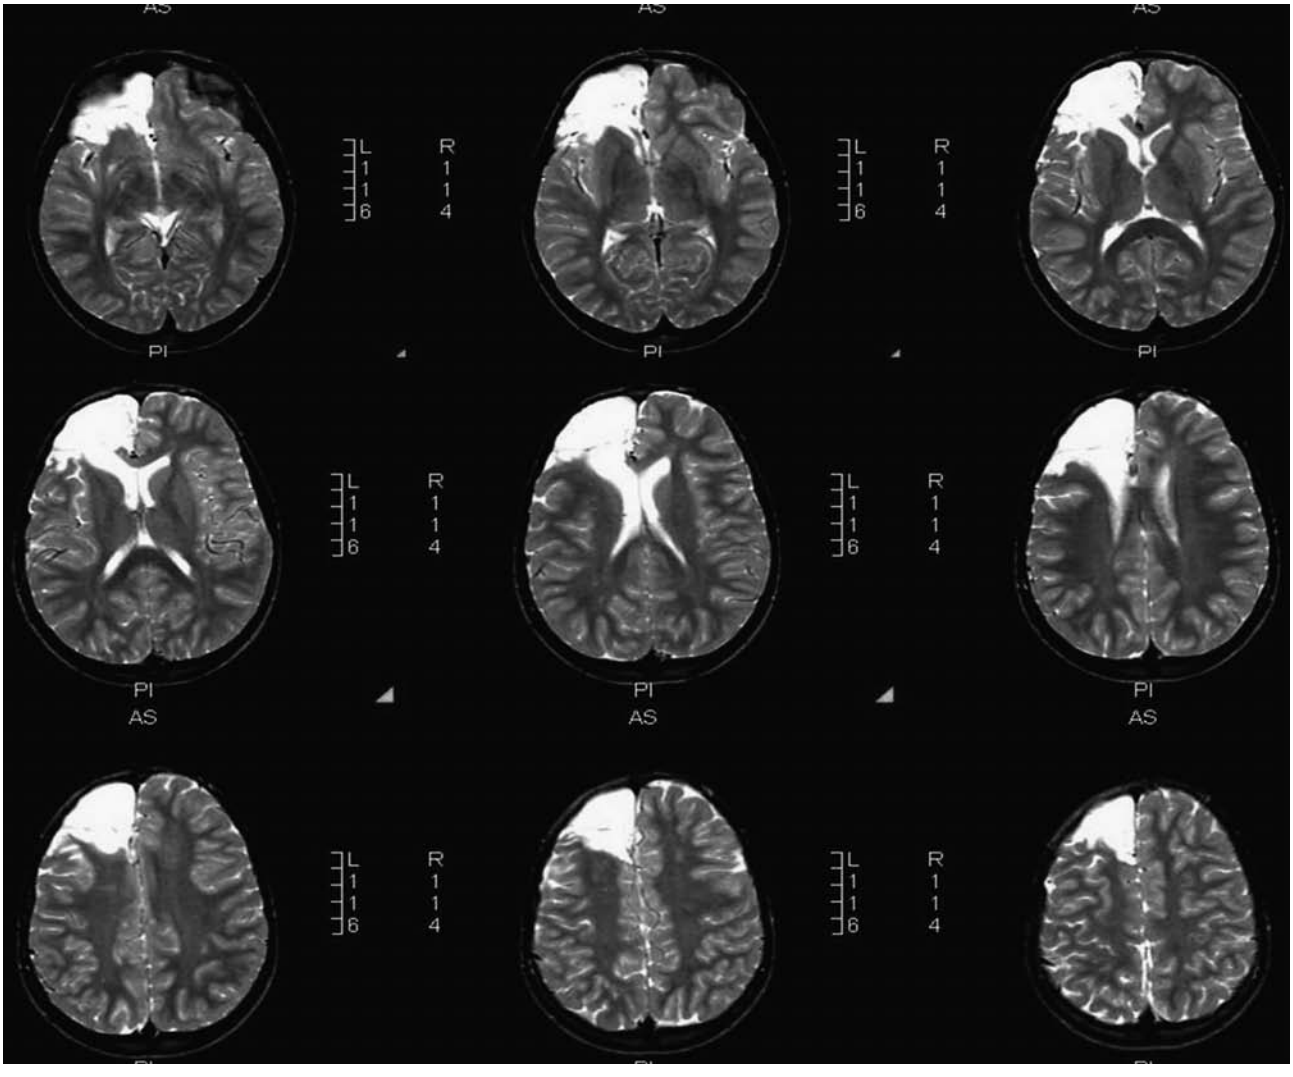

Figure 155.11 Postoperative MR, transverse turbo spin-echo (TSE) T2-weighted.

view of the electrical 'status epilepticus' persistent from the beginning of the epilepsy.

Surgical procedure

Anatomo-pathological results

The histological examination showed a laminar cortical disruption, configuring an architectural focal cortical dysplasia (Type Ia), well localized in the gyrus rectus and in the very anterior part of the second and third frontal circumvolutions.

A gliosis was also present in all the surgical specimens.

Postoperative MR

The postoperative MR (Figures 155.10 and 155.11) illustrates the frontal corticectomy, complying with the presurgical plan.

Outcome

Since the intervention the patient is seizure free (18 months). The pharmacological treatment is unchanged.

Follow-up

The postoperative EEG shows the disappearance of the continuous slow-waves and slow-spike and waves which characterized the two fronto-temporal regions with a right side predominance.

The first neuropsychological (6 months of follow-up) fails in putting in evidence a remarkable variation concerning the IQ, which is now assessed at 58; however the boy is more attentive and concerned with the proposed tests. A further evaluation is scheduled two years after the intervention.

156 Patient with extensive malformation of cortical development

DK Lachhwani

Case history

DC was 8 weeks old when he presented to our practice with medically refractory epilepsy. Seizures had started on day 3 of life and were increasing in frequency and intensity despite use of multiple antiepileptic medications.

His current seizures were occurring daily in clusters, with 10–30 seizures per cluster and five seizure clusters every day. Mother described the individual seizures as facial grimacing and tonic stiffening of all four extremities, followed by rapid eye blinking lasting up to 30 seconds. During some seizures, the eye blinking was more noticeable on the right side. After the cluster of seizures, DC was tired and exhausted for 2–3 hours with very few spontaneous movements.

Initial seizures were very brief and involved a subtle flexion of trunk and facial grimacing, lasting < 3–5 seconds. These occurred sporadically, a few times per day. By the second week of life, episodes had picked up in intensity and DC had lost the sparkle in his eyes. A diagnosis of infantile spasms was made when a stronger episode was witnessed in the pediatrician's office. DC suffered a cardiac arrest while being transported to the nearest hospital from the pediatrician's office, however he was successfully resuscitated. Since then, he had mostly remained in the hospital for management of refractory epilepsy, before being transferred to our epilepsy service. Attempts to discharge him home had failed, and he would inadvertently present to the emergency room within 24 hours of discharge with an intense seizure cluster or an acute life-threatening emergency due to cyanosis, respiratory depression, and bradycardia.

Antenatal and perinatal course

Mother had received adequate perinatal care with close follow-up due to polyhydramnios. DC was born at 36 weeks of gestation, with a birth weight of 6 lbs 3 oz. His postnatal course was unremarkable and he was discharged home on day 2 with no concerns.

Neurodevelopment

His development had been delayed. At 8 weeks of age, he made eye contact and registered his mother's presence; however he did not have a social smile and had little head control. Mother felt that this was largely due to heavy doses of medications and frequent seizures. She noted that on days with fewer or less intense seizures, he looked brighter and attempted to hold his head better.

Epilepsy risk factors

No history of head trauma or meningitis.

Medications

He was on therapeutic doses of four antiepileptic medications – lamotrigine, leviteracetam, oxcarbazepine, and phenobarbital. He had previously failed a trial of phenytoin and intravenous pyridoxine.

Family history

DC's mother had a history of cerebral vascular malformation and had experienced two generalized motor seizures. She remained seizure free on oxcarbazepine. Two maternal first cousins had history of seizures; one with febrile seizures and the other with epilepsy of unknown etiology.

Pertinent positive findings on physical exam

Length and head circumference were appropriate for age. (Weight 4.7 kilograms.) Airway conducted sounds suggestive of moderate to severe resistance in the upper airways.

Subtle decrease in spontaneous movements and mild hypotonia of the right upper extremity was noted. He also showed an intermittent fisting with flexion of thumb across the palm in the right hand. Strength and reflex testing did not demonstrate any obvious asymmetry.

Non-invasive epilepsy evaluation

Interictal abnormalities

Modified hypsarrhythmia, lateralized left hemisphere. This was characterized by high amplitude (50–200 uV) bursts of multiregional (F7, P3, F3) spikes, and spikes lateralized to the left hemisphere which occupied 40–50% of the record. In between the bursts, there was a generalized, continuous slowing (20–40 μV). Rarely (<2%) the spikes were seen over the right temporal region.

Ictal abnormalities

First clinical seizure

Epileptic spasms (>20–30 recorded per day) characterized by clusters of sudden forward head flexion associated with bilateral arm and leg flexion, lasting for 1–5 seconds at a time were seen.

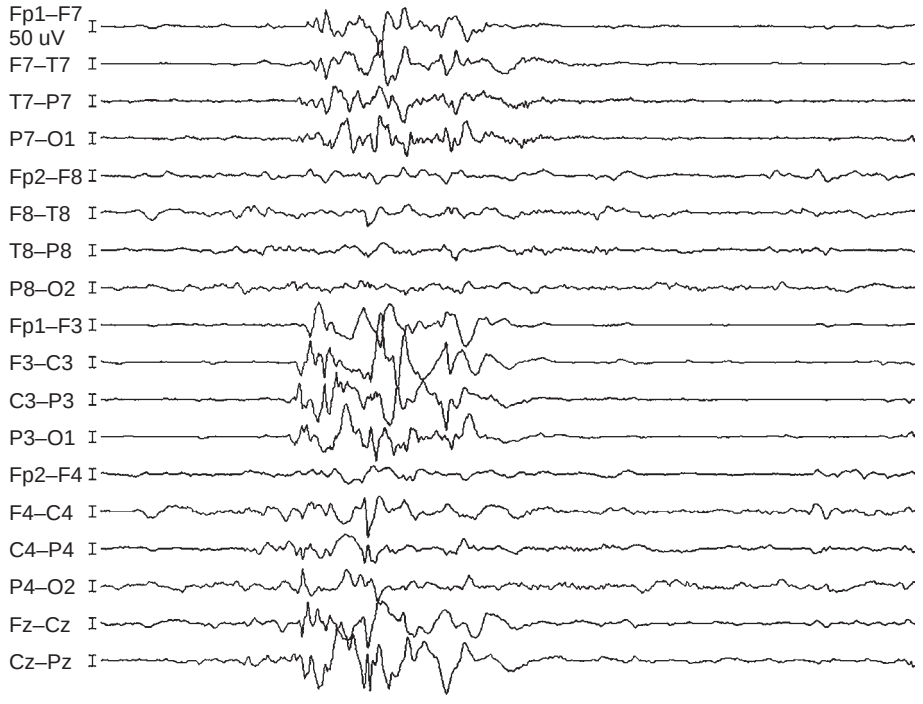

Figure 156.1 Interictal EEG showing modified hyppsarrhythmia involving left hemisphere.

Clusters lasted 2–30 minutes each, and consisted of a spasm every 10–20 seconds.

EEG seizure

Generalized (20–30 per day recorded) ictal pattern, characterized by diffuse electrodecrement followed by superimposed low-amplitude (10–50 μV) paroxysmal fast (20–40 Hz) activity, lasting 2–5 seconds.

Second clinical seizure

Right face clonic followed by generalized clonic seizure (20–30 recorded per day): Intermixed with the spasms described above, DC would have episodes of arrest of activity, bilateral eye blinking, right face pulling followed by right arm extension prior to a more generalized clonic pattern.

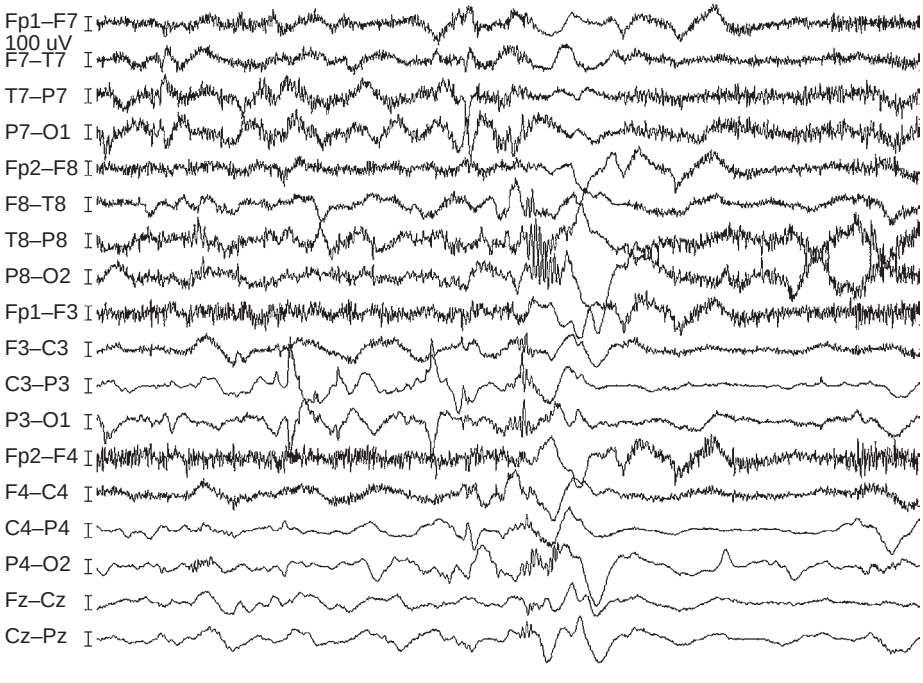

Figure 156.2 Ictal EEG showing diffuse electrodecrement during epileptic spasm.

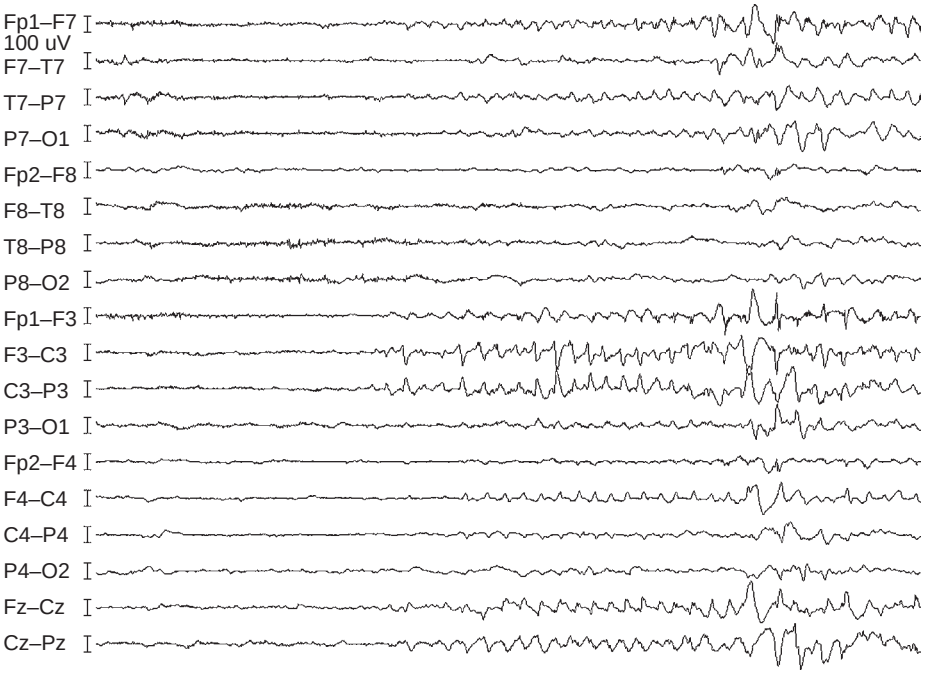

Figure 156.3 Ictal EEG showing evolution of the ictal rhythms over left hemisphere coinciding with bilateral (right>left) eyelid myoclonia.

EEG seizure

Ictal pattern was lateralized to the left hemisphere and showed rhythmic (3–4 Hz) high amplitude(50–300 μV) spike- and slow-wave complexes starting at C3 or P3 before becoming diffuse and evolving within the left hemisphere or both hemispheres.

MRI brain

Extensive malformation of cortical development involving the left cerebral hemisphere.

FDG PET scan

Moderately increased FDG uptake in the dysmorphic left hemisphere.

Neuropsychological assessment

Due to the young age, and the frequency of seizures, the Bayley Scales of Infant Development were not attempted. Mother's responses to The Vineland Adaptive Behavior Scales suggested that the motor and cognitive skills were within the adequate adaptive level range for a two-month infant.

Pediatric ENT consultation

Congenital Pyriform aperture stenosis, resulting in severe compromise of air exchange through nasal passages. This was felt to have contributed to previously observed life threatening apnea and bradycardia episodes during seizures.

Summary of epilepsy evaluation and plan

The discussion at patient management conference included experts in pediatric and adult epilepsy, neurosurgical team, neuropsychologists, neuroradiologists, bioethicists, and other support staff. The group unanimously appreciated that DC had left hemispheric epilepsy due to an underlying cerebral malformation, since 3 days of age, with medically refractory clinical and EEG status epilepticus. At presentation he had a subtle left hemiparesis, but no other fixed neurological deficits.

Experts were unanimous that continued medication trials were likely to be futile and would expose him to a significant risk of morbidity and mortality due to refractory status epilepticus. His risks were further compounded due to his very young age and a comorbid congenital upper airway stenosis (predisposing to airway obstruction and bradycardia during seizures).

Therefore, surgical correction of the airway malformation followed by surgical removal of the brain malformation (left hemispherectomy), was felt to be the preferred treatment option. His young age (2 months, 4.7 kg weight) was a significant mitigating factor, and it was appreciated that this would add to the risk inherent to brain surgery involving a large resection. It was also realized that epilepsy surgery would result in worsening of the pre-existing subtle hemiparesis and a new fixed homonymous visual field deficit.

Overall, it was felt that the risk of continued refractory status epilepticus would outweigh the surgical risks and therefore epilepsy surgery should be pursued imminently. Bioethics team was urged to meet the family to highlight the complicating features of the case before pursuing any treatment options. The family elected surgery.

Further management considerations

Identification of surgical candidates

Careful attention to clinical details is impertinent when evaluating and treating patients with epilepsy. It is well known that infantile spasms may be the presenting feature of focal epileptogenic substrates.[1] Careful investigation for the underlying cause and an accurate diagnosis of the epilepsy syndrome

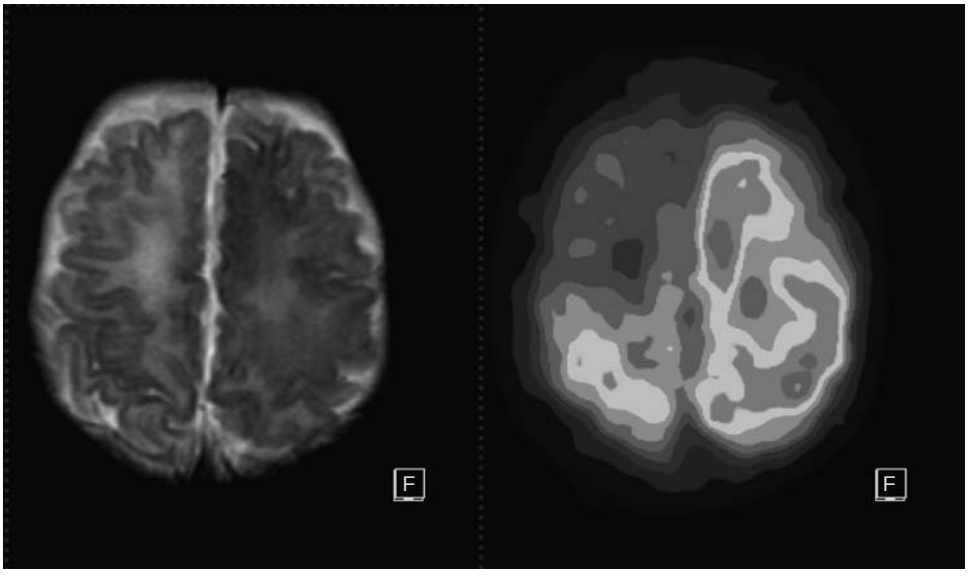

Figure 156.4 Axial MRI T2-weighted image showing diffuse left hemispheric malformation of cortical development and corresponding FDG-PET scan showing increased FDG. uptake in the dysplastic hemisphere.

(focal vs multifocal or generalized) is very important for the planning of treatment strategy. Indicators of focal epilepsy in our case include the asymmetric features in motor manifestation of the seizures as well as a subtle hemiparesis on neurological exam. Such clinical details indicating possible focal epilepsy syndrome may not always be evident in very young patients and therefore, a video-EEG evaluation, MRI brain and other adjunctive neuroimaging tests are important investigative tools that must be considered early in the course of investigation of infants with epilepsy.

Refractory status epilepticus

Medically refractory status epilepticus has significant morbidity and mortality risks associated with it. Currently accepted line of treatment involves high dose suppressive therapy with intravenous medications.[2,3] The improvement in our capability to offer multidisciplinary symptomatic and supportive care for very young patients in an intensive care unit enables us to prolong medical management form several days to several weeks. However this approach is not without a heavy price. In one study[2] authors found universal morbidity at follow-up in children who survived prolonged high-dose suppressive therapy. None of the children in this series returned to baseline neurological function and all of them continued to have epilepsy.[2] Just as morbidity rates are very high, the risk to life is also substantial during the course of aggressive and prolonged pharmacotherapy for unremitting seizures. Mortality rates as a result of refractory status epilepticus may range from 16–43.5%.[4–6]

Unfortunately, the paradigm of aggressive and prolonged medical management with intravenous agents may be the only recourse for patients with non-existent surgical options. However, symptomatic refractory status epilepticus with available surgical options need not be subject to a similar stratagem. In favorable surgical candidates, resective surgery may offer an immediate cure from status epilepticus as well as future epilepsy.[7,8] This approach is not commonly utilized. Until recently, the literature referring to such surgical experience was limited to rare case reports or very small case series.[9–13] Lately, experienced pediatric epilepsy centers have published more data supporting the role of resective approach to symptomatic refractory status epilepticus. In one series, status was stopped in all patients after surgery, 67% patients continued to be seizure free at follow-up and 33% had a significant improvement in their seizures.[7] Another surgical series found seizure control in >71% patients at most recent follow-up.[8]

Status epilepticus is an acute medical emergency and surgical removal of epileptogenic cortex during such a crisis is a delicate decision, fraught with potential for complications. The hesitancy to pursue surgery is valid, and only centers with adequate medical and surgical experience with complicated cases may be suited to offer such expertise. Authors of the above mentioned study reported that the morbidity related to the surgical intervention was seen in a third of the patients, and none of the patients died.[7] This rate of morbidity due to epilepsy surgery in refractory status epilepticus is certainly not any worse than the frequency of complications related to prolonged medical therapy, and further underscores that only comprehensive epilepsy centers with expertise may be well suited for exploring surgical options in this patient subpopulation.[2,5]

Upper airway disease

The objective influence of additional comorbid medical conditions on the overall risk of status epilepticus per se is not quantifiable due to lack of specific data. It may be reasonable to assume that the odds would favor an increased risk of complications when there are other concomitant medical problems. The presence of a congenital stenosis of the pyriform aperture predisposed this young infant to acute life threatening apnea and bradycardia episodes during seizure clusters. Indeed, these resulted in at least one episode of cardiopulmonary arrest needing resuscitation and several other emergency room visits culminating in endotracheal intubation to

stabilize respiration. Risk of hypoxemic ischemic cerebral insult seemed cumulative and compounded the pre-existing morbidity risks related to status epilepticus itself.

Body weight

Very young patients have a relatively small blood volume and are less well adapted to withstand major surgical stress. Traditionally, surgical teams are inclined to defer major surgical procedures until the age of one year or a body weight of 10 kilograms is achieved, to offset some of the increased surgical risks noted at a lower body weight and younger age. Estimated blood volume of less than 400 cc in our patient (average blood volume 80 cc/kg, operative body weight 4.7 kg) immature and delicate intracranial tissues of an 8-week-old; are factors that elevate the surgical of bleeding, DIC, or shock associated with large resections such as hemispherectomy. Surgical interventions in younger infants carry immense gravity and these are best relegated to the judgment of only the most experienced surgical teams. Under extreme circumstances, when the risks of not doing surgery (i.e., continued medical management) outweigh the operative risks, resective surgery may become a consideration in the hands of experienced personnel.

Developmental plasticity

Early intervention to control seizures is especially relevant in infancy for reasons of neuronal plasticity – a virtue which rapidly declines during early childhood.[14] One of the factors determining good neurocognitive outcome in infants with epileptic spasms, is the ability to rapidly control seizures after onset of epilepsy.[15] On the other hand infants with poorly controlled seizures are more likely to have an irreversible epileptic encephalopathy.[16]

It is also recognized that if an immature brain suffers a regional insult, it stands a better chance to compensate for this insult and transfer the impairment in function to preserved areas. For instance, transfer of language to the non-dominant hemisphere is more likely if the injury to the language dominant hemisphere is incurred in early childhood rather than later in life.

The plasticity of a young brain offers this unique and somewhat narrow window of opportunity to improve upon development, if an intervention to halt seizures is made early. It also offers the best chance to recover function by recruiting the adaptive potential of preserved areas.

Early identification of medically refractory epilepsy should therefore, prompt a diligent evaluation for surgical options. Compelling data suggest that failure of two antiepileptic drugs implicates medical refractoriness and while this cautions against the futility of further AED trials, it also provides an opportunity to consider alternate options early in the course of epilepsy.

Neurological deficits

Expected neurological deficits as a result of surgery in this young infant included worsening of a subtle pre-existing hemiparesis and a homonymous hemianopia. The prospect of continued status with no clear endpoint with medical management, exposure to mortality risk of acute life-threatening events and imminent neurocognitive morbidity were unique features urging towards surgical intervention. Even though these may seem exceedingly pressing reasons, the sensitivity and perceptions regarding fixed neurological deficits are unique to each clinical challenge and must be adequately addressed with aid of medical ethics and other appropriate team members.

Surgical procedures

Congenital pyriform stenosis

Prior to the epilepsy surgery, a midfacial degloving procedure involving bilateral medial maxillectomies was performed with an uneventful recovery. This was done with the goal to achieve physiological upper airway patency and relieve the underlying congenital stenosis.

Anatomic vs functional hemispherectomy

Anatomic hemispherectomy was preferred over a functional disconnection in our patient. Experience at our and other specialized epilepsy centers suggests that patients with large, hemispheric cortical malformations may not achieve complete seizure freedom after functional hemispherectomy.[19,20] In our series authors reported that an incomplete disconnection after functional hemispherectomy was the single statistically significant variable associated with persistent seizures postoperatively.[19] Revision to an anatomic hemispherectomy resulted in improved outcome in previously failed patients and authors advocate an anatomic removal of the malformed hemisphere as the preferred procedure of choice.[19]

Brain histopathology

This showed a severe cortical dysplasia with microcalcifications and gliosis.

Outcome

Immediate post operative

Status epilepticus was stopped immediately following surgery. After acute convalescence, DC was discharged home on antiepileptic medications with no further seizures and a stable respiratory status.

Eighteen months later

At most recent follow-up, DC remains seizure free with reduction of his seizure medications. Neuropsychological testing was performed at 10-months' age. He had a normal cognitive development for age and was noted to have a strong propensity for language development. His motor development lagged on account of the hemiparesis. His family shares that he has a very bright and cheerful disposition and that he continues to make developmental progress.

Summary and conclusion

Infantile spasms may result from a focal epileptogenic substrate and careful evaluation including attention to clinical detail, neurophysiological and neuroimaging data is important. If a focal epileptogenic substrate is appreciated and

seizures are medically refractory, an early intervention may offer the best chance for seizure relief and neurodevelepmental rehabilitation due to the plasticity of an immature brain. Undertaking a major neurosurgical procedure in the midst of a medical emergency such as status epilepticus needs careful consideration due to several compounding factors and may be offered at centers with multispeciality state of the art expertise. In the hands of an experienced team, status epilepticus need not delay epilepsy surgery for carefully selected candidates and may even be life saving.

157 Hemispherectomy in a patient with catastrophic epilepsy

A Gupta

Introduction

Hemispherectomy is a not uncommon surgery that is performed usually in infants and children for the treatment of intractable epilepsy. This procedure, often quoted as being radical in the media and journal articles, is obviously reserved for catastrophic epilepsies that usually present with daily and some times life-threatening seizures or status epilepticus, progressive or malignant course, rapid cognitive decline, neurological deficits, lack of seizure response and toxicity from multiple antiepileptic medications, poor prediction for prognosis and mortality risk (unless surgery is imminently considered), and parental anxiety and stress. Common indications for hemispherectomy are congenital hemispheric malformations such as hemimegalencephaly or extensive cortical dysplasias, perinatal ischemic stroke, Rassmussen's encephalitis, and Sturge-Weber syndrome.[1] The goal of this chapter is to present an instructive case to illustrate important presurgical findings, decision-making steps, and surgical planning in an infant who underwent hemispherectomy. This case also exemplifies some of the unique aspects of evaluating infants who are candidates for surgery (also see Chapter 46). Hemispherectomy procedure and techniques are discussed elsewhere in this book (see Chapter 121).

Case history and examination

A 6-month-old female baby presented with daily seizures that began soon after her birth. This was mother's first and twin pregnancy induced by in vitro fertilization. She was on ovulation stimulation agents before pregnancy. Pregnancy was uneventful except for mild gestational diabetes managed by dietary modifications. Around 36 weeks period of gestation, mother went into spontaneous labor. However, the labor failed to progress, and twins were delivered by cesarean section. The first twin, our patient, was 2 kg birth weight and required supplemental blow-by oxygen for a few minutes after birth. The second twin was noted to be pink and active at birth with no subsequent medical concerns after delivery.

In the nursery, on the second day after birth, it became clear from repeated observations that the infant was having seizures. Initially, her seizures were behavior arrest, rapid eye fluttering, facial twitching, and multifocal clonic movements (all extremities) occurring for 20–45 seconds 5–6 times a day. Medication management failed to control her seizures while parents went through many frightening procedures, hospital admissions, emergency room visits, nutritional and feeding difficulties, and researching on their daughter's condition. Around the age of 6 weeks, she developed typical infantile (epileptic) spasms and her epilepsy took a course for the worse. Her seizures (described above) were now mixed with infantile spasms in clusters of 5–10 seizures every few seconds lasting for 2–5 minutes. She was having 30–60 clusters daily by the time she was referred for surgery. During this time, she attained no developmental milestones, did not smile or even make eye contact with the parents, became hypotonic laying in bed sleepy and encephalopathic, was supplemented by nasogastric tube for failure to thrive, and was taking Valproate, Phenobarb, and Levetiracetam in toxic doses along with a ketogenic diet. She had previously failed to respond to Topiramate and Clonazepam. Parents also noted decreased spontaneous movements in the right arm and leg. It was now clear to the treating physicians and the parents that the child's condition demanded some critical decisions. At this point, the child was referred for surgical options.

At the time of our first examination at 6 months of age, she was an encephalopathic infant with severe developmental delay and generalized hypotonia. Her weight was 7 kg. Her scalp examination and head circumference were normal. She had one or more seizure clusters every hour. Repeated observations and careful examinations revealed right hemiparesis with extreme paucity of right hand and finger movements, but without any asymmetry in the deep tendon reflexes, tone or plantar responses (generalized hyptonia and hyporeflexia). Skin examination revealed a linear nevus on the bridge of the nose and small overgrowth over the left lip (Figure 157.1) suggesting a diagnosis of Epidermal Nevus Syndrome. Dilated eye examination was normal. Visual tracking or field deficits were untestable.

Presurgical evaluation

Video-EEG evaluation at 6 months of age showed absence of normal awake rhythms and physiological sleep elements. The interictal EEG showed high-voltage, almost continuous sharp waves (1–2 per second) in the bioccipital regions with maximum in the left occipital region (Figures 157.2 and 157.3). Many clusters of seizures were recorded with behavior arrest, whole-body stiffening, rapid eye fluttering, and multifocal clonic jerking. Ictal onset (Figure 157.4) was again noted in

Figure 157.1 Facial photograph of the infant with arrows showing linear nevus in the midline over the bridge of the nose and overgrowth of the left lip ipsilateral to the hemimegalencephaly.

the bioccipital regions, however, maximum distribution was in the left occipito-parietal and mesial parietal channels. A brain MRI (Figure 157.5) revealed left hemimegalencephaly, agenesis of corpus callosum, and midline lipoma confirming the diagnosis of Epidermal Nevus Syndrome. No abnormalities were noted in the right cerebral hemisphere. Brain FDG-PET showed marked left cerebral hypometabolism concordant with the MRI and EEG findings. Only limited neuropsychological evaluation was possible by parental report, and it revealed profound developmental delay.

Epilepsy management conference and decision making

The case was presented and discussed in the Epilepsy Management Conference. It was the consensus that the infant had catastrophic left hemispheric epilepsy and surgery could have been considered even earlier given the diagnosis and expected intractability of her epilepsy. The burden of seizures, degree of encephalopathy and developmental delay, toxic doses of multiple antiepileptic medications, pre-existing right motor deficit, and the etiology argue favorably in considering urgent left hemispherectomy.[2] No further studies such as invasive recordings were needed to refine surgical strategy. Extensive resective surgery in the face of small size (weight 7 kg) and encephalopathic state would entail higher perioperative risks of mortality and morbidity. However, the risk of mortality from surgery compares favorably to nonsurgical options, and is likely to be only higher if surgery is further delayed or not performed. The literature suggests 50% chance of seizure freedom with additional 20–30% chances of >75% seizure improvement on lesser medications.[2,3] It is likely that the patient will remain developmentally delayed, however, significant gains in global development and affect are expected. All this information was presented to the parents who were already on the verge of giving up on their child. After considering benefits, risks and no promising nonsurgical alternatives in the future, they agreed to proceed with hemispherectomy, the thought of which they had so far resisted.

Surgery and outcome

A modified left anatomic hemispherectomy was performed (Figure 157.6). Perioperative course was unremarkable for any acute complication. The child did not have any seizure in the acute postoperative period. She was discharged from the hospital with intensive motor rehab and intervention for cognitive development. Two years since surgery, the child remains seizure free. She was on one medication in low doses at the 2-year follow-up visit. At two and a half years of age, she made significant motor and cognitive gains. She was learning to stand and did not yet have any clear words with meaning. Surgical pathology showed increase bulkiness of the resected left hemispheric tissue with thick and smooth gray matter in the left occipital, parietal and temporal lobes. Predominant microscopic findings included lack of cortical organization, dysmorphic neurons, regions of polymicrogyric cortex, and areas of nodular neuronal heterotopia. Numerous islands of microcalcifications were noted in the subcortical white matter. These findings confirmed the diagnosis of hemimegalencephaly.

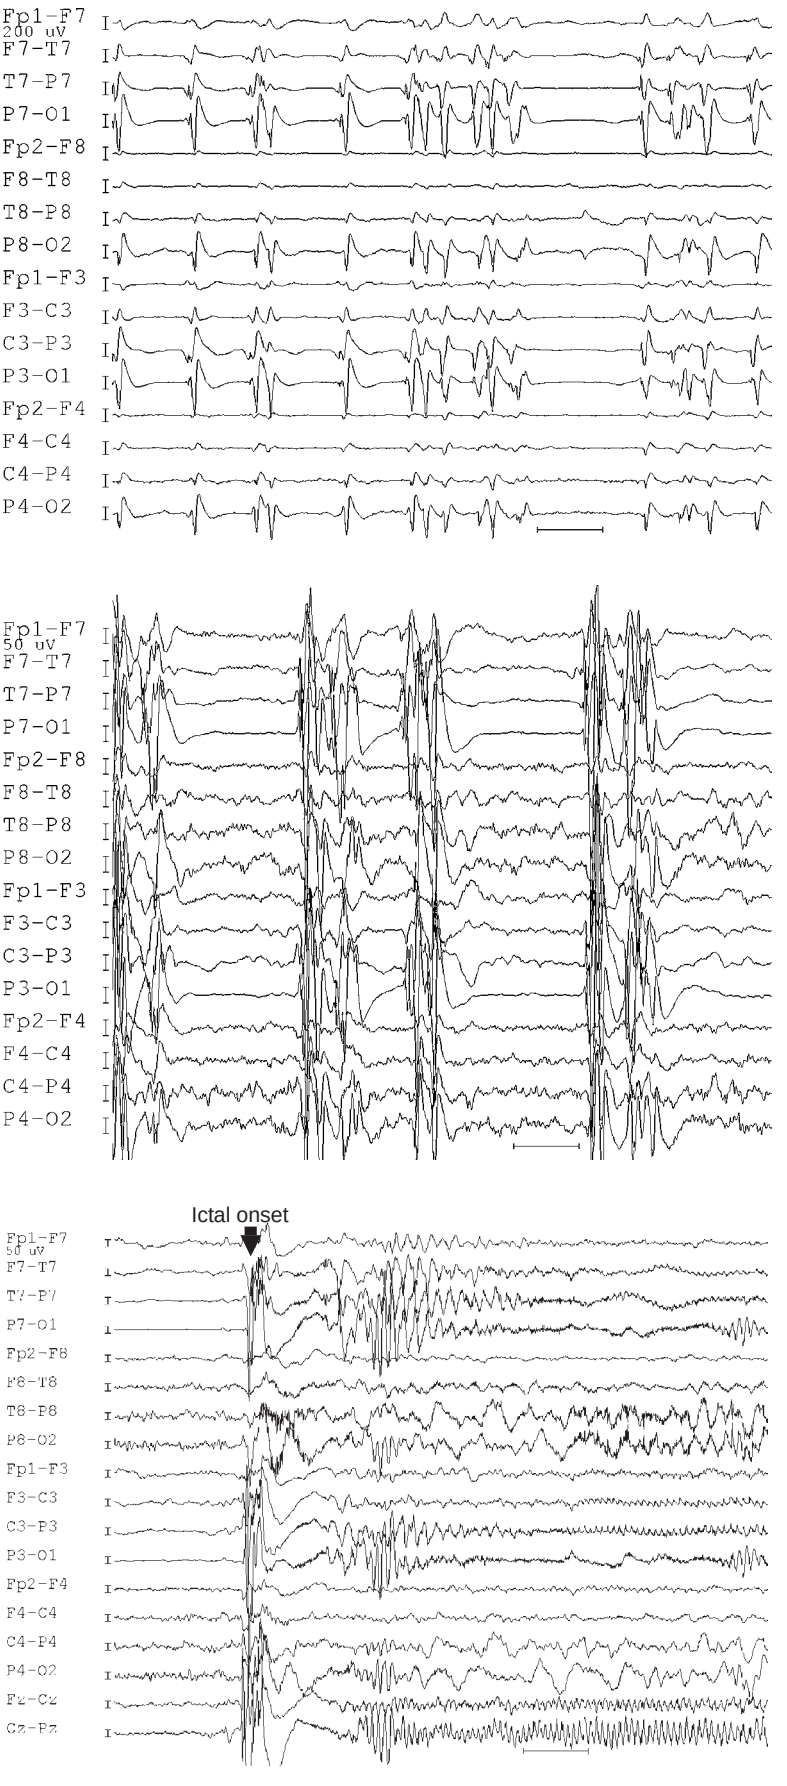

Figure 157.2–4 Interictal EEG showing high voltage repetitive generalized (maximum bioccipital) sharp waves every 1–2 seconds (Figure 157.2) maximum in the left and mesial occipital (O1 and Pz) regions. On increasing the voltage gain, left hemispheric burst suppression pattern (modified hypsarrhythmia) is seen with relative preservation of the faster frequencies over the right hemisphere. Ictal onset (Figure 157.3) showed a burst of high voltage generalized sharp waves maximum in the left occipital and mesial parietal electrodes followed by emergence of sharp alpha in the same region. Note that due to hemimegalencephaly and protrusion of left parieto-occipital region across the midline, the mesial parietal (Pz) electrode is most likely over the left parieto-occipital lobe (Figure 157.4).

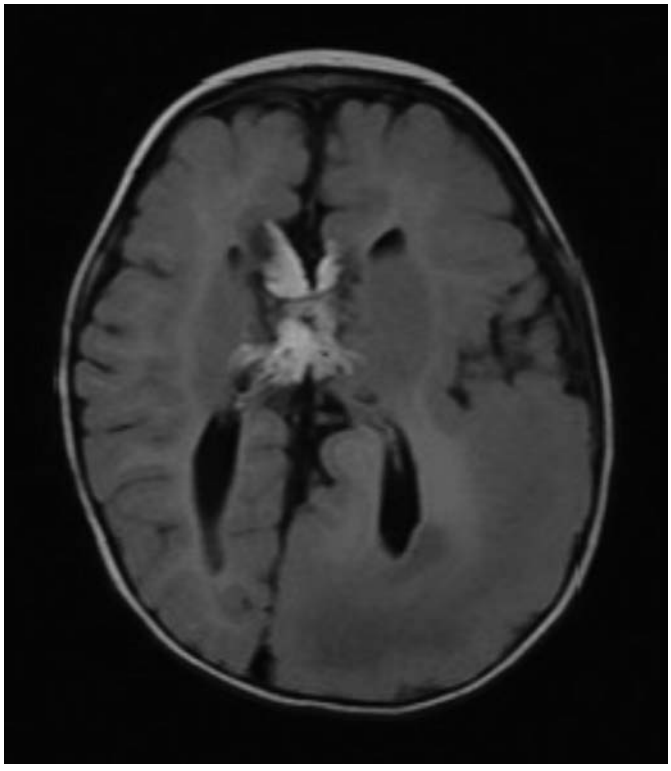

Figure 157.5 T1 weighted brain MRI of the infant showing left hemimegalencephaly with left hemispheric enlargement, thickened cortex, poor gray-white differentiation, and a midline lipoma with hypoplastic corpus callosum. Right hemisphere appeared normal on MRI.

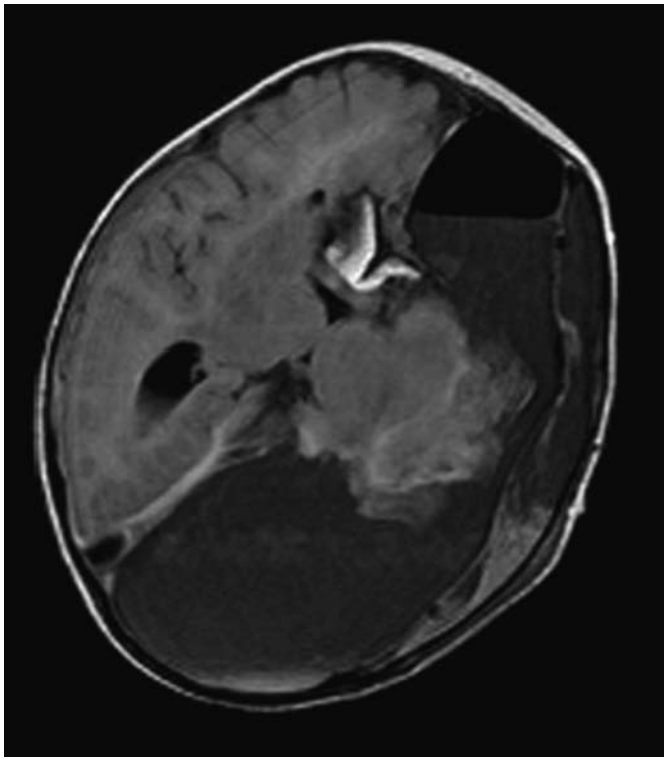

Figure 157.6 Postoperative brain MRI showing modified anatomic hemispherectomy with resection and disconnection of the brain except for insular region and deep gray nuclei.

Discussion

Our case illustrates several unique age-related aspects of infants who are candidates for epilepsy surgery (discussed in Chapter 49). First, the clinical course was catastrophic from the onset to the time of surgery. Beginning life with daily seizures due to extensive brain malformation (hemimegalencephaly) was further complicated by the toxic doses of antiepileptic medications, stupor state with encephalopathy, feeding difficulties and failure to thrive. This rendered accurate assessment of motor function, visual function, and neuropsychological assessment difficult, if not impossible. In addition, the stress of taking care of such an infant for new parents, especially so in the presence of a normal twin sibling, can not be underestimated. There usually is tremendous grief, guilt, anger, with psychosocial and economic impact on the family, and the family may be averse to making decisions for surgery (often considered more risky) early on in the course. Second, the intractability of seizures in infants such as our case is not just a function of time and trial of medications, but also, the evaluation of underlying etiology. Daily seizures that begin at birth due to hemimegalencephaly are most unlikely to respond to medical management, and surgical planning should start at the time of diagnosis. Surgical timing is crucial, and recent studies suggest that consideration for early surgery reduces the impact of daily seizures and encephalopathy on cognition and developmental outcome.[4] With advances in pediatric anesthesia, critical care, neurosurgery, and epilepsy management, tertiary care centers with experience in pediatric epilepsy are able to operate with low mortality and morbidity even in infants weighing <10 kg.[1] Therefore, age is no bar for hemispherectomy, if the situation so demands. However, parental lack of understanding and fear of radical surgery coupled with physician's persistence to try more medical treatment often delays consideration for surgery. Third, our case points out challenges in pediatric epilepsy for evaluating an infant who despite focal (hemispheric) epilepsy manifested with generalized seizure phenotype and poorly localizing scalp-EEG. Brain MRI is the most important element in infants being considered for epilepsy surgery. Ictal SPECT, PET or other invasive studies and brain mapping are often impractical or difficult to interpret alone (in the absence of MRI lesion) or not contributory. Fourth, brain malformations such as hemimegalencephaly[2] have important implications for making the correct genetic diagnosis. Our patient had Epidermal Nevus Syndrome, a sporadic condition that may involve other organ and systems (eyes, bones, etc.), required further evaluation and management for co-morbid conditions. Genetic counseling is also important, as certain autosomal dominant diseases like tuberosis sclerosis complex may be associated with hemimegalencephaly with high risk of recurrence in subsequent pregnancy, if one of the parents have subtle unrecognized disease. Fifth, psychosocial support to the parents and the family, assessing parental understanding and level of education, repeated hospital admissions and procedures, need for prolonged intensive rehabilitation after surgery, life-long cognitive and behavior interventions, and long-term special multidisciplinary needs of such a child are often underestimated by most physicians, and therefore, require emphasis and attention to provide the best overall outcome to infants such as the one illustrated in this chapter.

158 Case studies: Landau–Kleffner syndrome

AM Kanner, MA Rossi, and MC Smith

Introduction

Landau–Kleffner syndrome (LKS) or acquired epileptic aphasia of childhood is a rare disorder characterized by the development of expressive and receptive language disturbances following a normal development of language functions, that results from an epileptogenic lesion in speech cortex (or that impacts speech cortex) during a critical period of language development.[1,2] At the height of receptive aphasia, the child may display an auditory agnosia consisting of an inability of recognizing common sounds.[3,4] In addition to the language disturbances, children exhibit psychiatric problems consisting of motor hyperactivity, impulsive behavior, poor frustration tolerance that may even reach to overt aggression, or withdrawn behavior. While the epileptic seizures may be absent in up to 30% of children, EEG recordings of children with LKS present a characteristic pattern of continuous spike and wave during slow wave sleep (CSWS), which consists of bisynchronous discharges originating from intra- and peri-sylvian cortex unilaterally with a rapid propagation to homologous regions contralaterally. A certain percentage (unknown as of yet) of children with LKS experiences a spontaneous remission of their language disturbances.[3,4] In others, trials with steroid therapy may result in symptom remission, while the success of antiepileptic drugs (AED) in LKS has been rather disappointing. Epilepsy surgery has been advocated in children with a classic presentation of LKS who failed to regained functional language for a period of at least one year either spontaneously or in the absence of response to pharmacologic interventions (including an inability to tolerate steroid therapy because of serious adverse events) as these children are at a very significant risk of not having any functional language by the time they reach adulthood.[5–7]

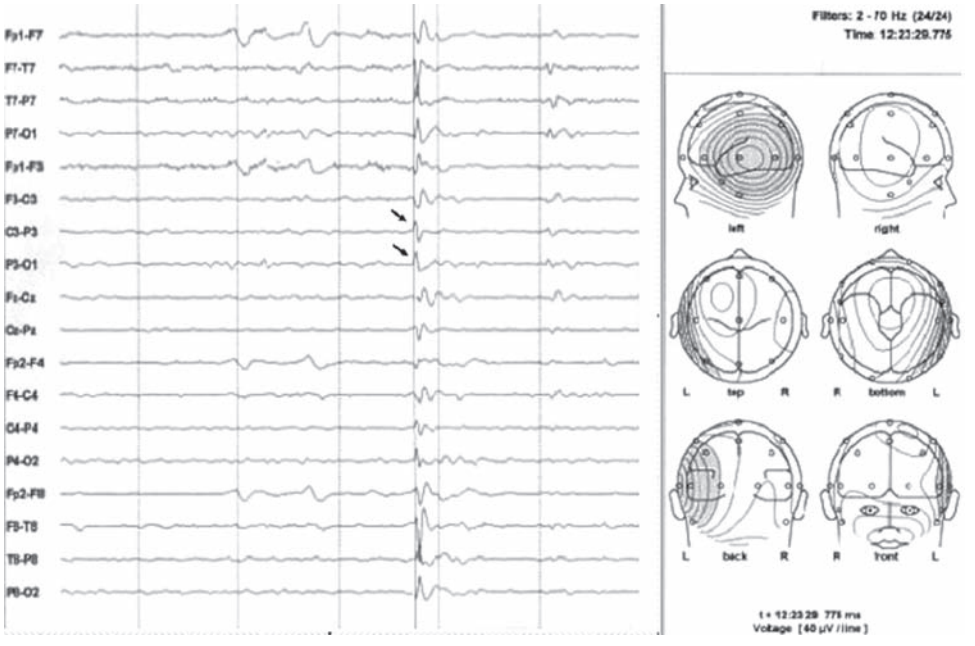
The clinical, neurophysiologic and neuropsychological characteristics of LKS have been reviewed in great detail in Chapter 45. The diagnostic evaluations including pre-surgical work-up and treatment strategies have also been reviewed in that chapter. The aim of this chapter is to present three representative cases that help illustrate various aspects of the pre-surgical evaluation and surgical treatment in LKS.

Case 1: SF

SF was born at 36 weeks gestation with APGAR scores of 8 and 9. He met normal motor developmental milestones, sitting up at 6 months and walking at 12 months. Since an early age, he suffered from recurrent middle ear infections requiring the placement of myringotomy tubes at 7 months of age and at 4.5 years a tonsillectomy with adenoidectomy was performed. Compared to his male sibling, speech and language were slow to develop. At 2 years 4 months, SF was diagnosed with verbal dyspraxia, but he was able to learn American sign language without difficulty. Language continued to develop until five years of age at which time his expressive language consisted of sentences of 10–14 words in length. At that age, however, his parents began noticing 'periods of inattentiveness' and an EEG at this time revealed a CSWS pattern. Carbamazepine (CBZ) was started which was followed by the immediate occurrence of overt clinical seizures consisting of myoclonic jerking associated with staring. Soon after the start of CBZ, language functions deteriorated rapidly with greater involvement of expressive than receptive language. Within two months he stopped responding to directives and his receptive speech began to noticeably worsen. At that time he was diagnosed with LKS and was started on valproic acid (VPA) and clonazepam (CZP) followed by a pulse-dose course of prednisone. Steroid treatment was associated with severe behavioral disturbances that included marked agitation diagnosed as steroid psychosis. Steroids were stopped; his receptive and expressive language functions continued to worsen and one month later he became totally mute. Topiramate (TPM) and phenytoin (PHT) were started. His behavior improved but his language did not. Following sedation with propofol for a lumbar puncture he transiently produced words and simple sentences.

Since the patient had failed to regain any functional language for more than 12 months, he was admitted to the Rush Epilepsy Center where he underwent a pre-surgical evaluation that consisted of the following tests:

a) A scalp video-EEG monitoring study: *Interictal recordings* revealed during awake states abundant epileptiform activity consisting of bifocal independent sharp wave activity of left frontal and left mid-posterior temporal origin, with a predominance of the latter.
   Sleep recordings revealed a CSWS pattern. Mapping of epileptiform discharges revealed a bisynchronous posterior temporal lateral source.
b) *Methohexital suppression test* had to be carried out to lateralize the source of the epileptiform activity. It revealed a left posterior temporal source with frequent propagation to the left frontal region. Of note, no independent frontal source was identified (see Figure 159.1A).



(a)

Figure 158.1a The last epileptiform discharge is seen during methohexital suppression testing using scalp electrodes. Left focal posterior quadrant epileptiform activity is seen with rapid propagation frontally. A voltage map generated in BESA represents the negative polarity onset (shaded contours).

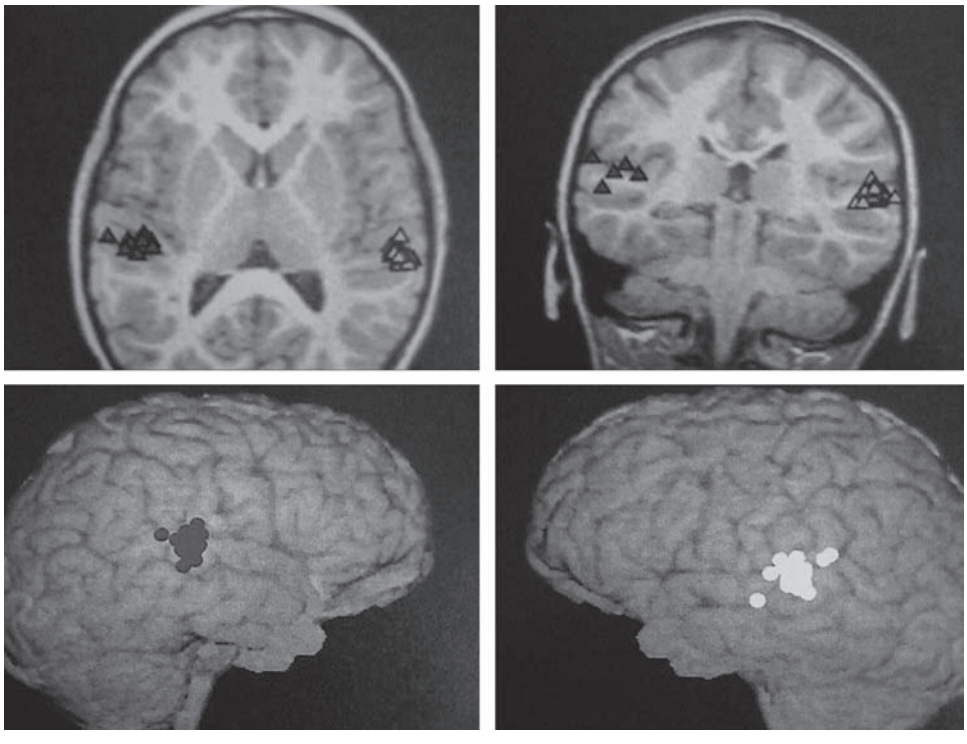
c) *A speech evaluation* was carried out using the Expressive One Word Picture Vocabulary Test-Revised (EOWPVT-R) (expressed as age equivalent in months old) and the Peabody Picture Vocabulary Test-Revised (PPVT-R) for evaluation of expressive and receptive language functions, respectively. A severe expressive and receptive language disturbance was demonstrated with a severe verbal auditory agnosia, the latter evidenced by not responding to any verbal commands given verbally with the exception of his name. SF was only able to identify simple pictures (i.e., fish, bathroom, eat, color, and turtle). He verbalized 'you', 'me', 'mom', 'da', and imitated a dog. SF was presented with letters and did not demonstrate any understanding of them or their sound symbol relationships.
d) *A neuropsychological evaluation* to assess non-verbal cognitive functions was complicated by repeated refusals by SF to participate in testing. No inappropriate or unusual behaviors were noted. SF completed the Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R). Perceptual and constructional skills measured by Object Assembly and Block Design were at the 63rd and 2nd percentiles, respectively. His copying and drawing skills (Mazes, VMI) were measured at the 6th percentile. SF did not complete the Picture Completion or Coding subtests.
e) *A positron emission test (PET)* with 18-fluoro-deoxyglucose (18-FDG-PET) revealed an asymmetry in the posterior temporal cortices bilaterally with lower activity on the left.
f) *A magentoencephalogram study (MEG)* revealed focal left posterior sylvian interictal activity with rapid propagation to the contralateral homotopic region (see Figure 159.1B).

Eighteen months after the onset of symptoms. SF underwent surgical treatment consisting of MST of the epileptogenic zone. Specifically, an exquisitely focal MST was performed limited to the left posterior infrasylvian fissure. Intraoperative monitoring at the site of MST did not reveal any epileptiform activity post-transection. SF was started on PHT and phenobarbital (PB) postoperatively, which was then replaced by levetiracetam (LEV).

Postsurgical course: SF had an uneventful immediate and delayed post-surgical course. However, return of language functions was first identified approximately 6 months after surgery, when his parents noticed the return of receptive language and the use of sign language more frequently to communicate. Previously, SF would attend to signs but rarely use them spontaneously or in imitation. Expressive speech similarly improved at about the same time, but to a lesser extent. SF was observed to spontaneously, meaningfully and intelligibly say, 'you', 'mine', 'no', 'ya ma', 'I do'. Nonverbal abilities were similar to what was seen prior to surgery. One exception was noted on Block Design, where his score improved from the 2nd percentile to the 50th percentile.

His expressive and verbal receptive language markedly improved over a 15–18 month period after resection when he was able to use five to ten word sentences to communicate. His speech remained mildly dysarthric but fluent. He demonstrated an inability to pronounce consonants at the beginning of the sentences. His last formal speech evaluation was carried out four years after surgery. The EOWPVT-R and PPVT-R revealed age equivalent of 78 months each.

The child was kept on LEV at daily doses of 750 mg/day. Repeat EEG studies revealed rare left frontal epileptiform discharges that persisted for three years and was recorded as well on an overnight video-EEG monitoring study. CSWS, however, was no longer observed. No further seizures were witnessed since his surgery and behavioral problems had also remitted.



(b)

Figure 158.1b Magnetoencephalography demonstrates localization of interictal activity in the inferior bank of posterior sylvian fissure. Rapid propagation occurred from left to right homotopic cortex (not shown).

Case 2: NB

NB was an eight-year-old, right-handed boy at the time that he was first evaluated at the Rush Epilepsy Center. He was born following a full-term, uneventful pregnancy and had a normal motor and cognitive developmental history. According to his parents, he started to use single words at the age of ten months, and was speaking in full sentences by three years of age. The first evidence of this child's LKS was identified at the age of five by his kindergarten teacher and consisted of psychiatric rather than cognitive and/or epileptic symptomatology, as he was noticed to have become very hyperactive and impulsive displaying short attention span during his classroom activities. He was started on a regimen of methylphenidate at a dose of 10 mg/day without any significant improvement. Four months later, his parents identified the first disturbance in language functions consisting of problems in comprehensive language which was initially interpreted by the parents as difficulty hearing, which prompted them to request an auditory evaluation. This evaluation identified minor hearing loss which involved high and low frequency ranges bilaterally. However, receptive problems continued to progress, and three months later he started to display clear difficulty in expressing himself. He was unable to use words that he had already learned; his sentences tended to become increasingly shorter, and his speech acquired a strong, dysarthric quality. His expressive language deteriorated progressively, but obvious comprehensive difficulties started to deteriorate at only three months after overt expressive language problems became apparent. Once the comprehensive language had deteriorated, it only took two months before the child was unable to express himself and understand what was said to him and soon after he became mute. At the same time that his expressive and receptive language deteriorated, his behavior worsened significantly with further deterioration of motor hyperactivity, impulsivity and marked difficulty with concentration in any activity. The dose of methylphenidate was increased to a total of 35 mg/day without any improvement.

Approximately one year after the first behavioral disturbances were reported by his kindergarten teacher, a diagnosis of LKS was established with EEG recordings which revealed a CSWS pattern. During that evaluation, the patient was witnessed to display subtle seizures consisting of brief periods of unresponsiveness during which he was also noticed to have eye fluttering for periods of as long as 30–45 seconds. One of these seizures was captured during the EEG recordings. At that point, he was started on a regimen of valproic acid with doses of up to 500 mg/day without any significant change. He was then started on a regimen of prednisone at a dose of 2 mg/k/day, which resulted in gradual improvement of expressive and receptive language functions over the course of four to six weeks with a final return of comprehensive and expressive language equivalent to 85% of baseline. The trial with prednisone, however, was complicated by a weight gain of 30 lb. and worsening of behavior consisting of aggressive outbursts and further deterioration in his impulsive behavior. The combination of these adverse events prompted the discontinuation of the prednisone over the course of a three-month period. During the trial with prednisone, subtle seizures that had been identified were not witnessed any longer. However, after the prednisone was stopped, seizure activity recurred, associated with a loss of language gains noted during the trial with prednisone. Four months later, he was restarted on prednisone at doses of up to 30 mg/day which resulted in regaining of both expressive and receptive

language functions. This trial, however, was complicated again with the development of significant Cushingoid features. During his trial with prednisone, he was able to attend school, although he needed to get additional help from a special education teacher, and he required daily speech therapy. The severity of the adverse events of prednisone prompted the discontinuation of this drug again, which was again followed four weeks later by the recurrence of severe receptive and expressive language dysfunction and the recurrence of seizure activity.

At the time that he was seen at the Rush Epilepsy Center, he underwent a pre-surgical evaluation to see if he could be a candidate for epilepsy surgery. The evaluation consisted of the following:

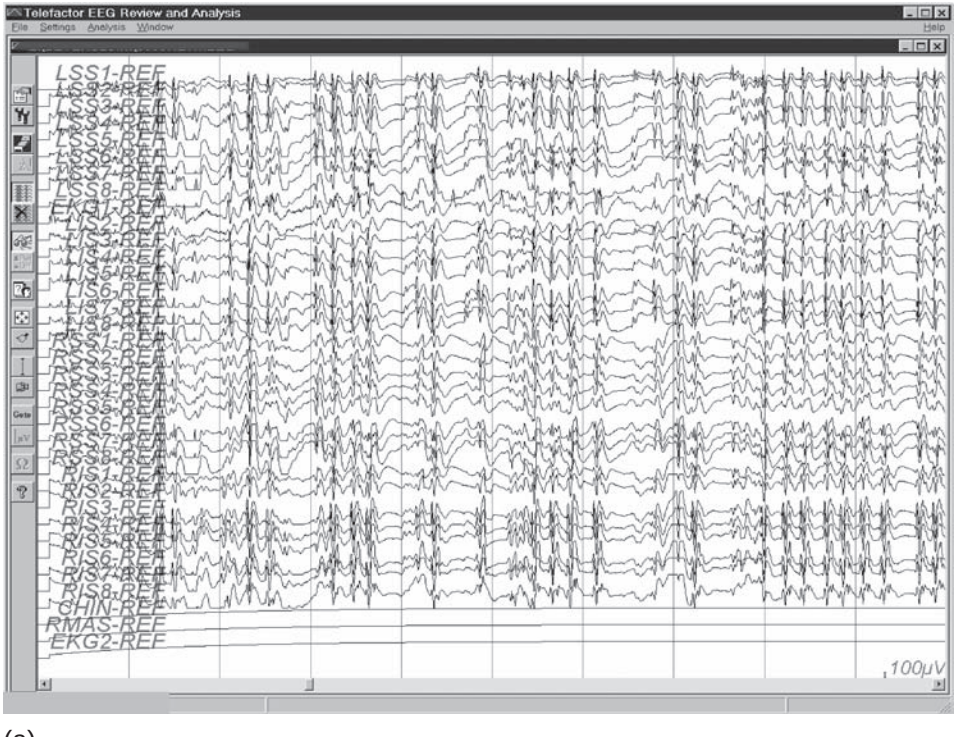
a) *A high resolution MRI* of the brain was unremarkable.
b) *A prolonged video-EEG monitoring study* revealed the presence of a CSWS pattern with bisynchronous discharges originating from posterior temporal lateral regions.
c) *Methohexital suppression test* carried out with scalp recordings could not lateralize the source of the epileptic activity, however.
d) *Speech evaluation* revealed a severe auditory-verbal agnosia with an expressive language function equivalent to an age of less than 12 months of age. The child was identified using gestures to communicate.
e) *A neuropsychological evaluation* revealed that NB performed according to the expected level for his chronological age in nonverbal cognitive functions.

Given that the epileptic source could not be lateralized on scalp electrodes with a methohexital suppression test, the patient underwent a prolonged video-EEG monitoring study with intracranial recordings which consisted of a pair of epidural strips of eight contacts each, positioned superior and inferior to the Sylvian fissure. Figure 159.2A shows a CSWS pattern recorded with these intracranial electrodes.

A methohexital suppression test done with these electrodes revealed the source of epileptic activity in the right intrasylvian cortex (see Figures 159.2B and 159.2C). NB underwent a topectomy of the planum temporale on the right side, given that he was strong right-handed at the time of the onset of his symptomatology and throughout the duration of his illness, indicating that the right hemisphere was non-dominant for speech.

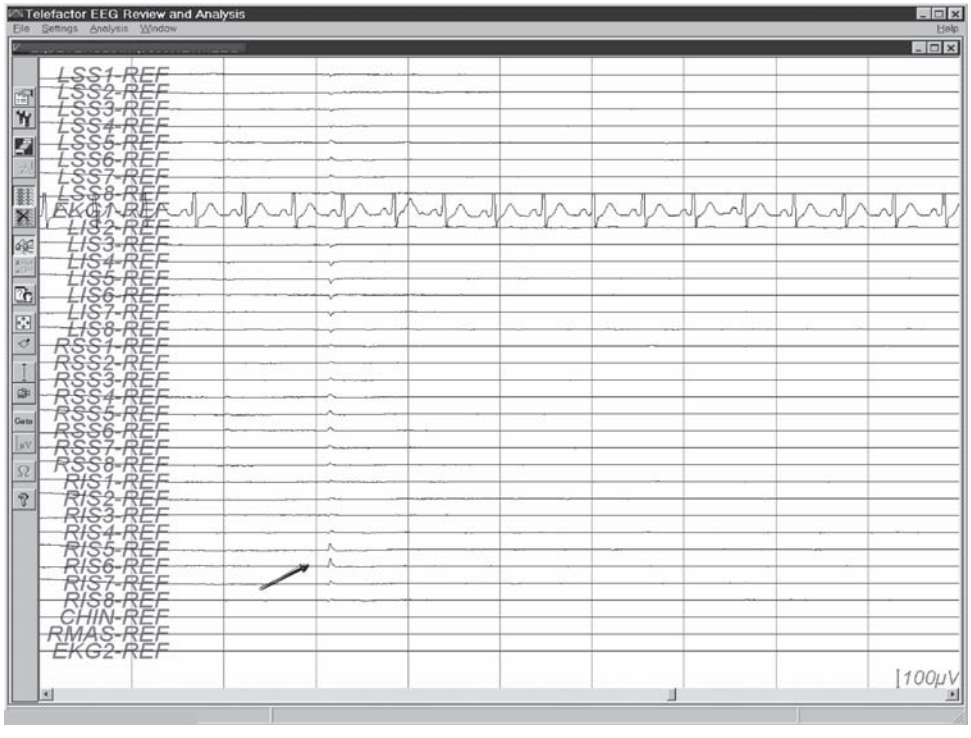
Postsurgical course: The patient had an uneventful, immediate postoperative course. He was discharged home five days after surgery on a regimen of valproic acid and clonazepam and instructions to resume speech therapy. He started to display expressive language one week after surgery, and his ability to understand was also noted by his parents by that time. Since the child was placed on prednisone for two weeks after surgery, this improvement was attributed to the trial with dexamethasone. However, discontinuation of the dexamethasone was not followed by loss of the gains noticed. On the contrary, NB continued to display steady improvement in both receptive and expressive language functions, and by three weeks after surgery he was using three and four word sentences. An EEG study done two months after surgery revealed no epileptiform activity (see Figure 159.2D).

EEG recordings done six months after surgery revealed the presence of the recurrence of epileptiform activity in the temporal lateral region in electrodes T4 and T6 (see Figure 159.2E). This activity, however, did not propagate to the contralateral side or to suprasylvian regions and was not



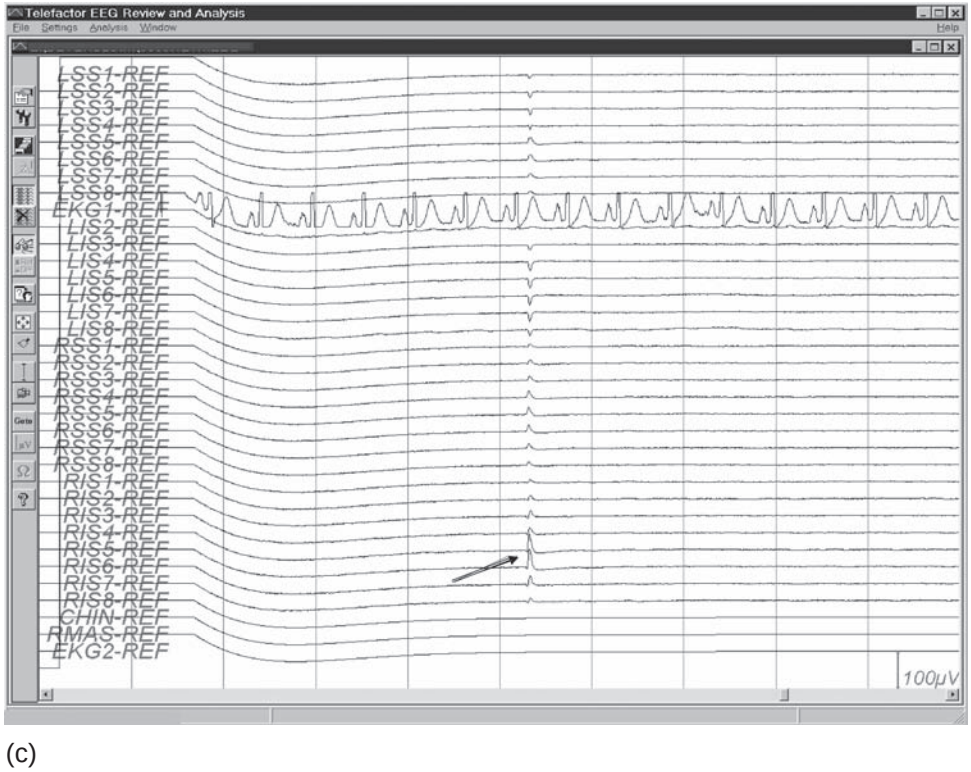
(a)

Figure 158.2a CSWS pattern of patient NB recorded with two pairs of epidural electrodes consisting of eight contact strips positioned parallel to the sylvian fissure 1 cm above (suprasylvian strips (LSS1-8 and RSS1-8)) and 1 cm below (Infrasylvian strips (LIS1-8 and RIS1-8)).



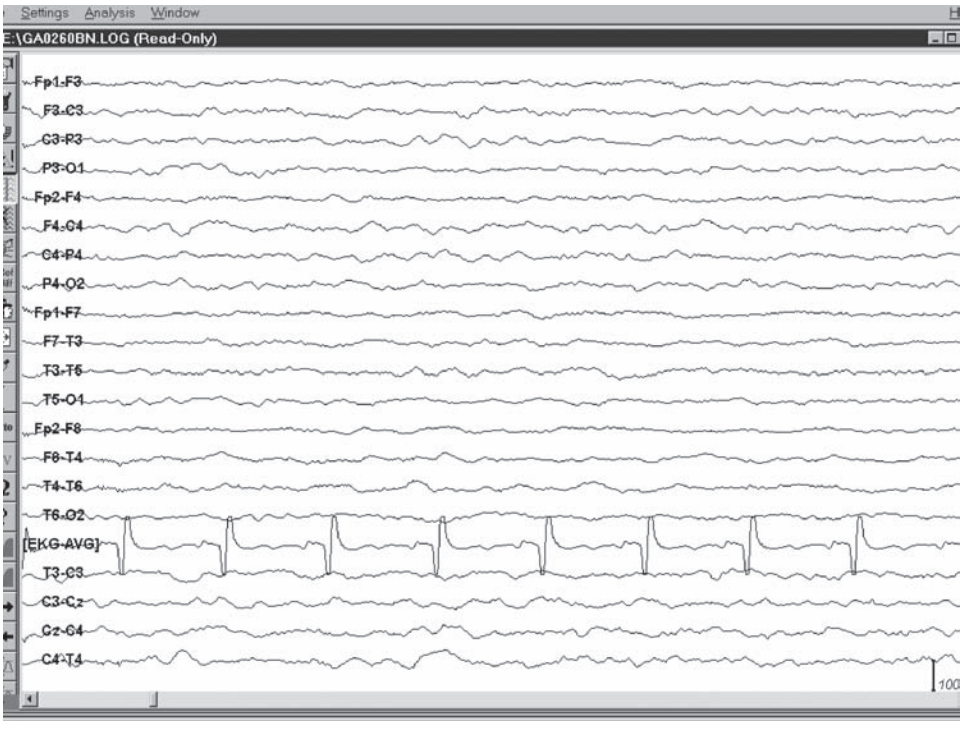
(b)

Figure 158.2b Methohexital suppression test. The arrow shows the last discharge in the right strips to be identified before complete suppression of the electrical activity. There is a rapid propagation to the contralateral side.



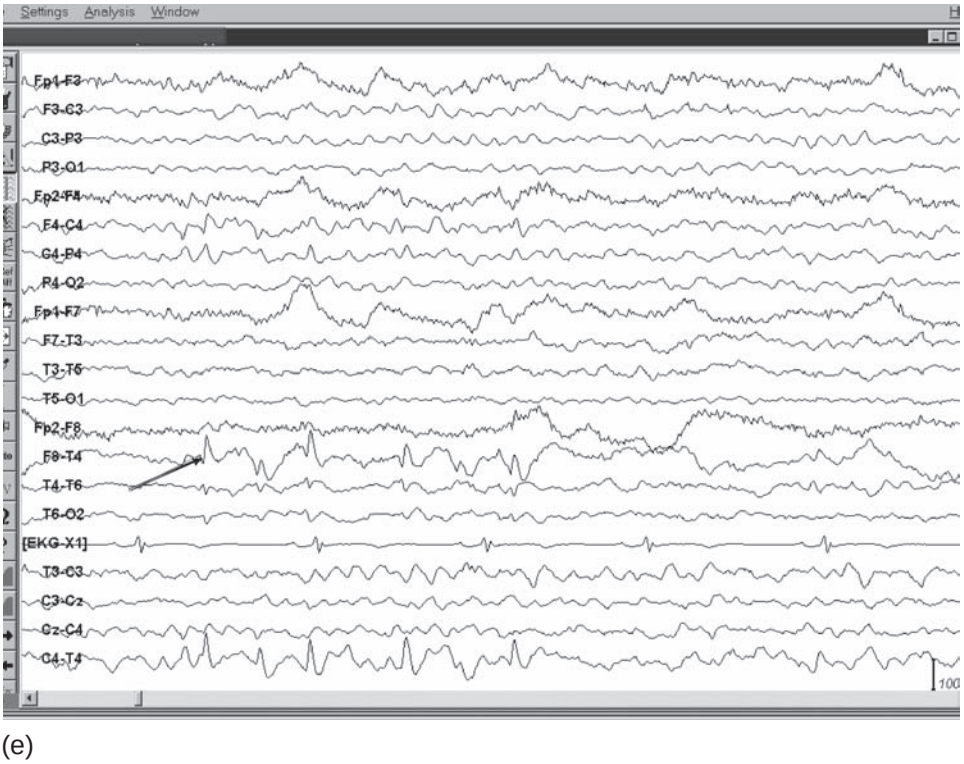
(c)

Figure 158.2c Methohexital suppression test: the arrow shows the first discharge in the right infrasylvian strip to be identified following a complete suppression of the electrical activity. This discharge rapidly propagates to the contralateral side (25 ms).



(d)

Figure 158.2d Stage 1 sleep recording 2 months after surgery.



(e)

Figure 158.2e Awake recordings obtained six months after surgery reveal recurrence of epileptiform discharges in right temporal regions (ipsilateral to the side of the topectomy).

associated with recurrence of seizures or any loss of gains made in the language domain. Since that time, he has had an EEG study done at six month intervals which have continued to show long runs of epileptiform activity in the temporal lateral neocortical region involving electrodes T4 and T6 with a field of distribution at times, including electrodes F8 and occasionally spreading to suprasylvian regions (see Figure 159.2F). Despite the widening of the electric field of this epileptiform activity, no deterioration in receptive or expressive language functions was identified, and he continued to improve steadily and attend school in regular classes, but with additional help from a special education teacher. He continued to receive speech therapy several times a week. He has been maintained on valproic acid monotherapy and has remained seizure-free since surgery.

Speech evaluation done two years and six months after surgery (when he was 11 years old) revealed that his expressive language was equivalent to an eight-year-old boy, while the receptive language functions were equivalent to that of a nine-year-old boy. The patient at that time was reading at a third grade level.

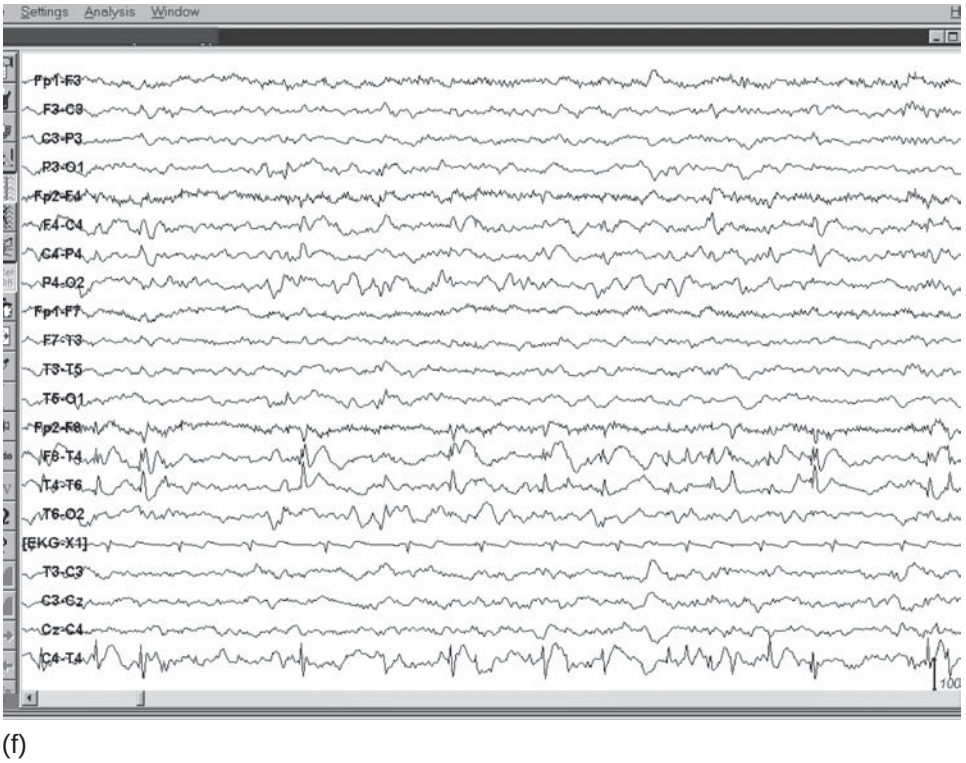
His last follow-up was six years after his surgery, and at that time he was attending regular classes with some remedial help in reading and writing. The parents reported however persistent problems with behavior, particularly, impulsivity and poor frustration tolerance.

Case 3: MP

MP was a six-year-old, right-handed girl at the time that she was evaluated at the Rush Epilepsy Center for epilepsy surgery for the treatment of LKS, which was diagnosed at the age of four years and six months. MP was born following a full-term pregnancy and had an uneventful growth and development. She was one year of age when she started to use single words and was speaking in full sentences by three years of age. The first manifestation of her LKS was at the age of four years, eleven months when she began having difficulty with expressive language. She could not repeat certain sounds and had difficulty saying the name of her favorite cartoon and she could not repeat a sentence without leaving words out. At that time, she underwent an evaluation by a local pediatric neurologist who, on an EEG study, identified the presence of CSWS pattern with a source in the left temporal region.

At the time that MP started to display expressive language, she began experiencing epileptic seizures consisting of motionless staring episodes of 10–20 seconds duration on an almost daily basis. A few weeks later, she was noticed to have difficulty understanding what was being said to her. Expressive and receptive language disturbances worsened over the course of the following two months. She was initially treated with VPA, and then underwent trials with TPM and LEV, but it was not until she was placed on prednisone that she experienced a significant improvement in both receptive and expressive language function. After three months of being on prednisone, a repeat EEG study revealed the disappearance of epileptiform activity after which the prednisone was tapered down and discontinued, but one month later she had a recurrence of expressive language disturbances, which rapidly deteriorated, and she was left with only ten words in her vocabulary. Receptive language functions were also reported to deteriorate, but at a slower pace than expressive language.

Concurrent with the deterioration in language functions, there was deterioration in her behavior. She was noted to become prone to outbursts of anger and poor frustration tolerance, though no motor hyperactivity or problems with



(f)

Figure 158.2f Recordings obtained two years after surgery reveal runs of epileptiform discharges in right temporal regions with a filed of distribution involving fronto-central electrode as well.

attention span were identified. She was able to continue playing with her friends throughout this time. MP underwent a second trial of steroids, but this time they were not associated with any improvement in language function. She was then tried on three trials of IVIG without any improvement. Under these conditions, MP underwent a pre-surgical evaluation at a local University hospital, which consisted of the following:

(a) *High-resolution MRI of the brain* which was normal.
(b) *Video-EEG monitoring study* with scalp electrodes revealed the presence of a CSWS pattern with a source in the left temporal region.
(c) *A MEG* revealed dipoles in the left intrasylvian region.
(d) *Speech evaluation* revealed the presence of a severe auditory agnosia. Her expressive language was at a 2 year-old, age-equivalent level and her receptive language was at a 2.3 year age-equivalent level.
(e) *A neuropsychological evaluation* placed the nonverbal cognitive functions at the 50th percentile,

Under these conditions, she underwent MST on a small area along the margin of the superior temporal gyrus where the MEG study had identified the epileptiform activity. Intraoperative electrocorticography confirmed the MEG data. No epileptiform activity was identified at the completion of the MST and she was discharged off antiepileptic medication.

The immediate postoperative period was unremarkable and parents reported noticing improvement in expressive and receptive language functions within the first four weeks, consisting of understanding complex commands and using one and two words. Two months after the surgery, however, she had a recurrence of epileptic seizures followed by rapid loss of any gains in expressive and receptive language functions. MP was restarted on VPA and prednisone without any improvement in language functions. She was then placed on lamotrigine (LTG) without any benefit, after which she was evaluated at the Rush Epilepsy Center and a repeat pre-surgical evaluation revealed the following:

(a) *The video-EEG monitoring study:* CSWS with bisynchronous spike and slow wave activity during slow wave sleep that revealed a left-sided onset during which sustained, occasional isolated bisynchronous spike and slow-wave activity was seen superimposed. No clinical seizures were recorded.
(b) *A methohexital suppression test*: the source of the epileptiform activity was identified in the left intrasylvian region.
(c) *Speech evaluation:* Receptive language functions were estimated to be at a two years three months of age equivalent on the EOWPVT-R and her expressive language at fourteen months of age on the PPVT-R.

Under these conditions, MP underwent a MST of the entire superior and inferior bank of the Sylvian fissure. Figures 159.3A shows a CSWS pattern recorded during intraoperative electrocorticography and Figure 159.3B a sylvian dipole also recorded during electrocorticography.

Following surgery, MP was placed on a regimen of VPA and LTG and discharged home with instructions to resume speech therapy.

Postoperative course was uneventful and she was noticed to start regaining language functions during the following eight weeks. Four months after her surgery, she was noticed to talk in three to four word sentences as she was attending kindergarten and was receiving speech therapy five times a week. The parents reported that MP could understand most of what was said to her, especially when instructions were given to her in one step commands. From the standpoint of behavior, they reported that she continued to display poor frustration tolerance. No further seizures were identified since her surgery.

Two years after her surgery, MP remained seizure-free. A repeat speech evaluation done at the last visit placed her receptive language function at an age-equivalent level of 5.8 years (she was 9 years old). Improvement in expressive language function was also impressive, but was marked by errors in syntax and grammar which lowered her scores. However, she was able to complete sentences when communicating with others. Repeat EEG studies at that time failed to reveal any epileptiform activity. On a recent telephone contact, MP's parents reported that she was attending a regular third-grade class with remedial help in reading and grammar. She was at age level for reading and six months behind in writing and behavioral problems had remitted.

Discussion

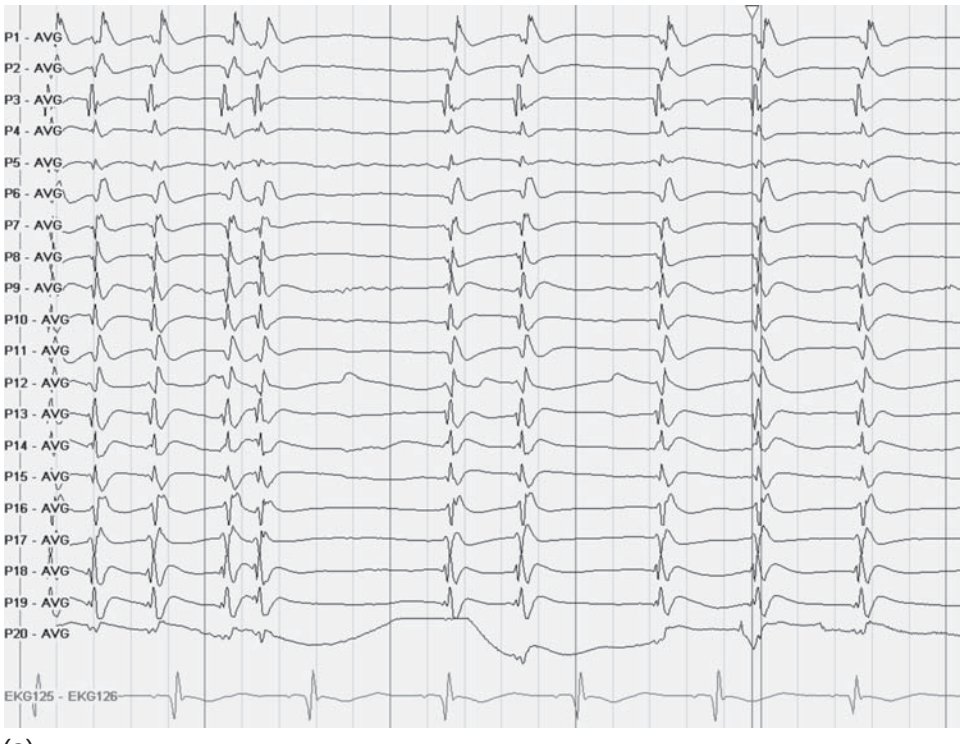
The three children with LKS included in this chapter illustrate unique and representative findings of pre-surgical evaluations, surgical techniques and post-surgical outcome with respect to seizure control, recovery of language functions and remission of psychiatric complications.

Some AEDs may actually worsen the course of LKS

The use of AEDs constitutes the initial treatment of LKS. Yet, as illustrated by Case 1, the use of CBZ can worsen the severity of the language disturbances and epileptic seizures. This has been our own experience and that of other authors, but no controlled study is available to support these observations. By the same token, there are anecdotal data on the efficacy of various AEDs, but no controlled studies, primarily due to the small number of patients afflicted by this disorder (see Chapter 45). Our preference is to consider trials with VPA and a benzodiazepine, particularly in children whose language and behavior disturbances improve or remit following a rectal diazepam protocol (see Chapter 45).

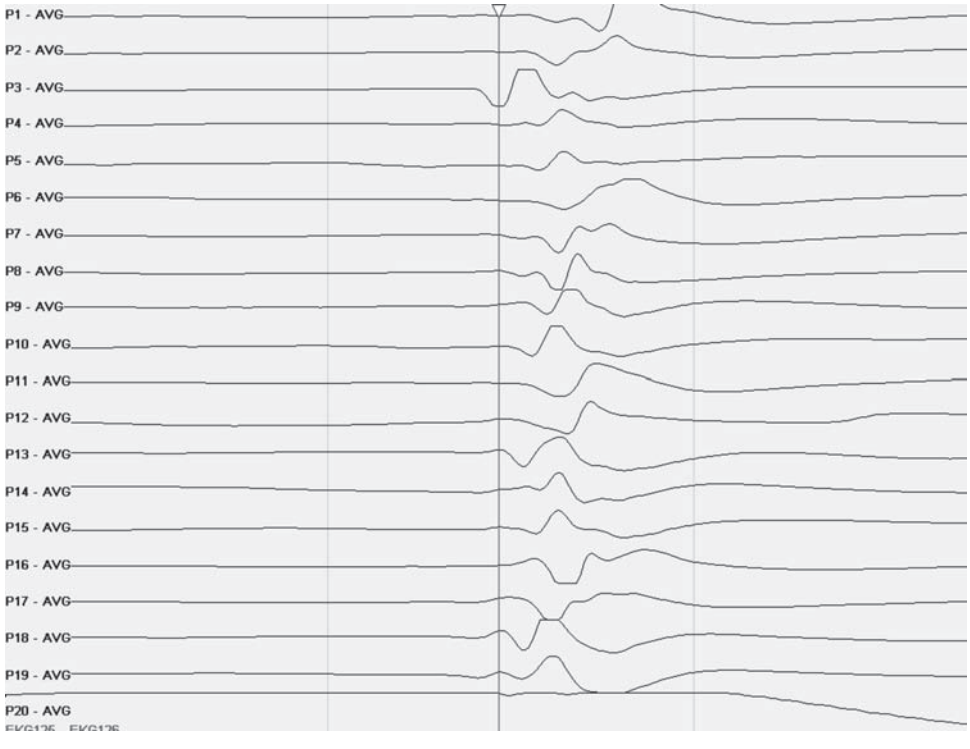
Is MST the only surgical option?

When it comes to the choice of a surgical technique in the treatment of LKS, MST has been the one always considered. The rationale behind using MST is based on the premise that epilepsy surgery is performed on 'eloquent language cortex'. Two of the children (Cases 1 and 3) underwent MST of the intrasylvian region in the (left) hemisphere 'suspected' to be dominant, as these children were right-handed at the time of the onset of the symptomatology. Yet, in Case 2 the epileptogenic was localized in the non-dominant hemisphere (right hemisphere in a (strong) right-handed child) which allowed the surgeon to consider the option of topectomy of the right planum temporale



(a)

Figure 158.3a Intraoperative electrocorticography recording revealing a CSWS pattern. The 20 electrode pad was position over the lateral convexity of the left hemisphere with contact 1 in a most anterior and superior position. Contacts 1–10 covered suprasylvian and contacts 11–20 infrasylvian cortex. Contacts 6–10 and 11–15 were adjacent to the sylvian fissure, the former above and the latter below the fissure.



(b)

Figure 158.3b Epileptiform discharge recorded during Intraoperative electrocorticography reveals a sylvian dipole in the posterior segment of the sylvian fissure. Contact P3 positioned in suprasylvian cortex shows an initial positivity and the infrasylvian contacts P13 and P18 reveal a simultaneous negativity.

over MST. Since the potential to abolish epileptic activity is greater with a resection than transection, it is worth highlighting the option of a topectomy of the planum temporale instead of MST in a child in whom the source of epileptic activity is clearly established in the non-dominant hemisphere.

Post-surgical recovery of language functions

There are significant differences in the rate of language recovery among the three children which merit to be reviewed. The rapid recovery during the two first post-surgical weeks in Case 2, contrasts with the slower recovery rates in Cases 1 and 3. Initial gains were made of lesser magnitude in Case 3, while no meaningful changes were identified until the sixth month. Location of the epileptogenic source in the dominant vs. non-dominant hemisphere probably accounts for the observed differences in the rate of language recovery. Indeed, interference of language cortex by propagated 'bombardment' of epileptic activity from the contralateral hemisphere may play a less serious impact on the pathogenic mechanisms mediating language regression than having the epileptogenic zone within language cortex. Morrell hypothesized a lesser disruption of the synaptic 'anlage' in the former circumstances than in the latter, despite abolition of epileptiform activity and clinical seizures (as illustrated by Case 1) is not unusual after MST (see also Chapter 45).

This supposition is supported by a more likely response to steroid challenges in children with epileptogenic zones in 'presumed' non-dominant hemisphere, as displayed by Case 2.[8] Case 3 started to show signs of recovery within the first month but it was of lesser magnitude and significantly slower than Case 2. In Case 3, the epileptogenic zone was in a presumed dominant hemisphere and recovery of language was observed after the first but not a second steroid challenge. Finally, Case 1 had the slowest rate of language recovery. This may be accounted by having an epileptogenic zone in a presumed dominant hemisphere, having a history of verbal dyspraxia and not having shown any language improvement during a short challenge with steroids.

Significance of post-surgical epileptiform activity on EEG

The post-surgical EEG studies of the two children with a seizure focus in a presumed dominant hemisphere continued to show sparse interictal epileptiform activity, while the EEG recordings of Case 2 revealed recurrence of epileptiform activity in runs in the temporal-lateral neocortical regions of the operated hemisphere. Yet, recurrence of language disturbance only occurred with recurrence of a CSWS pattern that involved both hemispheres, as illustrated in Case 3. Hence the prognostic significance of isolated epileptiform discharges on post-surgical EEG studies does not appear to bear great significance in the long-term recovery of language function (see also Chapter 45).

The uninterrupted recovery of language functions observed in Case 2, despite recurrence of 'abundant' epileptiform activity six months postsurgically in the ipsilateral temporal lateral neocortical region to the epileptogenic area further supports the hypothesis cited above. Indeed, the findings of the serial EEG recordings done postsurgically were remarkable for a failure of the epileptiform activity to propagate to the contralateral (dominant) hemisphere. Clearly, this case may be important in understanding the pathophysiology of LKS, suggesting that a unilateral involvement of epileptiform activity may not be sufficient to compromise language function when it originates in the non-dominant hemisphere, in which case it is necessary to engage both sides of the brain, i.e., language cortex, to elicit language disturbances.

Psychiatric complications of LKS

Behavioral and other psychiatric disturbances are the third clinical expression of LKS. This is clearly illustrated in all three cases presented in this chapter. Of note, a clinical picture consistent with an ADHD was the initial clinical manifestation of LKS in Case 2 and these have persisted despite the marked improvement of language functions. On the other hand, in Cases 1 and 3, the pre-surgical behavioral disturbances improved significantly postsurgically. We can hypothesize that the persistence of behavioral disturbances postsurgically in Case 2 may be associated with the persistent epileptiform activity in the right hemisphere, akin to the findings with epileptic encephalopathies. Likewise, improvement of behavioral problems in Cases 1 and 3 are associated with sparse or no epileptiform activity on post-surgical EEG recordings. This hypothesis, while attractive, needs to be proven in controlled studies.

159 Deep brain stimulation in a patient with medically intractable generalized seizures

M Hodaie, C Hamani, D Zumsteg, DM Andrade, R Wennberg, and AM Lozano

Introduction

There is a significant subset of epilepsy patients for which there is currently no adequate form of surgical treatment available. Patients with diffuse, non-localized, or multifocal epilepsy currently have very limited surgical options, if medications alone cannot result in adequate seizure control. Neuromodulation is gaining increasing interest as a possible new surgical modality for treatment, particularly in these type of patients.[1–3] Deep brain stimulation (DBS) for epilepsy aims to influence key 'pacemaker' areas in the brain that are thought to be important in seizure genesis or propagation, thereby decreasing seizure severity and frequency. This rationale is based on both animal experiments and human studies.[2,4] A number of lines of evidence point to the thalamus, and particularly to the anterior nucleus of the thalamus, as having an important role in this regard. Initial animal experiments showed evidence of increased metabolic activity in the anterior thalamic nucleus with seizures.[5] High frequency stimulation and lesioning, whether in the AN or its connections also resulted in decreased seizure activity in the pentylenetetrazol model of seizures.[6–8]

In 2002, we published a study of five patients with intractable epilepsy who underwent bilateral DBS of the anterior nucleus of the thalamus.[2] Our initial results were reported with a mean follow-up of 15 months. There was a marked reduction in the number of seizures, with a mean reduction of 54%. Two patients showed a reduction of 75% or more. We recently reported the long-term benefit of this treatment, with a 60 month average follow-up, and it appears that the beneficial results have been sustained in the long-term.[9]

In this chapter, we illustrate the details of one of these patients, who was part of the study reported in 2002. Seizure history, surgical treatment and outcome are presented.

Case report

The patient is a 25-year-old male initially seen at the Toronto Western Hospital at the age of 18. His seizures started when he was seven months of age and he was assessed by multiple pediatric neurologists. There were no reported problems during gestation and he was the product of an unremarkable natural birth. Associated with the seizure history is a history of mental retardation and developmental delay. Family history was positive for at least one more male member in the extended family who had mental retardation. Testing for fragile X syndrome was negative. Examination of the neurological system was remarkable for microcephaly, elevated tone in his upper and lower extremities, and mental retardation.

The patient had been managed with multiple anticonvulsant medications, including carbamazepine, valproic acid, phenobarbital, lamotrigine, gabapentin, phenytoin, and different forms of benzodiazepines. A trial of the ketogenic diet did not result in any significant benefit.

Seizures typically included abrupt stiffening of the limbs, usually beginning on the left side, tonic clonic movements, unresponsiveness and visual staring, generally lasting about 45 seconds. As a child these occurred approximately 3–5 times per week and eventually became progressively more frequent, increasing to multiple seizures per day.

MRI of the brain revealed atrophy out of keeping with the age of the patient. No hemispheric abnormality and no mass lesions could be visualized.

Interictal scalp EEG recordings showed the presence of multifocal epileptiform discharges recorded independently over both hemispheres, maximal over the frontal lobe structures with a right-sided predominance. Less frequently, bursts of generalized, frontally predominant, bilaterally synchronous spike-and-wave discharges were recorded. The background activity was abnormal and compatible with a diffuse encephalopathy of moderate severity.

Ictal scalp video-EEG recordings documented several motor seizures with a clinical pattern at onset consisting of a left-sided fencing posture indicative of right hemispheric lateralization, however, the concomitant ictal EEG recordings were always apparent bilaterally, contaminated by muscle artifact, and did not favor a discrete localization.

Neuropsychological testing was limited secondary to global delay. Tests of higher cognition and expressive language could not be carried out. Responses were limited to an auditory vocabulary task and matching spoken words. It was estimated that the patient functions at approximately a 2-year-old level. Overall performance was rated below the first percentile.

Based on the severity of the patient's seizures and lack of benefit from other means of treatment, as well as the results of video-EEG recordings indicating the patient to not be a candidate for resective epilepsy surgery, bilateral DBS of the anterior thalamic nucleus was offered as part of a pilot study at the Toronto Western Hospital. The study had been previously reviewed and accepted by the hospital's research ethics board.

As part of the study protocol, the patient's caregivers were asked to keep a daily diary of the number of seizures. Seizure count during a 3 month baseline preoperative period averaged approximately 60 seizures per month. Pre- and postoperative seizure frequencies are detailed in Table 159.1. As per the study protocol, antiepileptic medications were not changed during the baseline preoperative period nor during the first year postimplantation of DBS electrodes.

Surgical procedure

The surgical procedure can be categorized in the following stages:

1. Frame placement: Under local anesthesia, the patient undergoes placement of a Leksell frame. The frame attaches firmly to the skull with four pins. The anterior pins are placed approximately one inch above the eyebrows, and we typically carry out a local block of the supraoptic nerve. The desired orientation of the frame is parallel to a line between the lateral canthus and the tragus of the ear, thereby aligning as much as possible the anterior and posterior commissures. We routinely place these frames under local anesthesia only, and we find that patients do not require further sedation.
2. After placement of the frame, the patient is taken to the MRI suite. A 1.5 T MR with T1, T2 sequences are carried out. The MR localized box for the Leksell frame contains cupper sulfate solution, which results in an MR signal. This signal is used as a fiducial marker for calculation of stereotactic coordinates.
3. The coordinates for the anterior and posterior commissures are calculated on the MRI images, together with the midcommissural point. The coordinates for the anterior nucleus are determined as follows: 6 mm lateral to the midcommissural point, 8 mm anterior to the posterior commissure, and 12 mm above the AC/PC line. The angle trajectory is approximately 60 degrees in the anterior superior to posterior inferior direction.
4. In the operating room and with the Leksell frame attached to the surgical bed, the head is shaved and the area of the coronal suture widely prepped and draped. Two parasagittal incisions centered at the coronal suture are performed and burr holes drilled. The dura is opened and the pia is coagulated. Tisseal is applied to the burr hole to minimize CSF loss, which may result in shifting of brain structures with resultant change in the relative position of the calculated coordinates.
5. Intraoperative microelectrode recordings are carried out. Given the location of the anterior nucleus, the trajectory is invariably through the lateral ventricle. Once the border of the ventricle is crossed, we find action potentials, corresponding to cells of the thalamus. Our recordings typically start 10 mm above the intended target and extend between 5–10 mm beyond intended target. A sample digitized Schaltenbrand–Wahren atlas map of the area of the anterior nucleus is represented in Figure 159.1.
6. After the microelectrode recordings and under fluoroscopic guidance quadripolar DBS electrodes (Medtronic model 3387, Medtronic, Minneapolis, MN, USA) are placed in the intended target. The electrodes are inserted with the bottom contact being typically in the dorsomedian nucleus, because of the size discrepancy between the anterior nucleus and the electrode. The anterior nucleus spans approximately 6 mm, while the contacts of the electrode used span 10.5 mm. Therefore at least one electrode must be either deep to the anterior nucleus or in the ventricle.
7. After placement of the DBS electrodes, the wires are connected to extension cables and externalized through the skin through a separate incision. The wound is then appropriately irrigated and closed. The externalized wires are marked for identification of the appropriate side and the patient is discharged to the epilepsy monitoring unit (EMU). The patient is continued on the same antiepileptic medications as in the preoperative period.
8. After 3–4 days in the EMU, allowing for video-EEG recordings with scalp and thalamic depth electrodes, the patient is returned to the operating room for internalization of the DBS electrodes and connection to a pulse generator. In this case, a Medtronic model Itrel II (Medtronic, Minneapolis, MN, USA). This procedure is performed under general anesthesia. The subclavicular and neck areas are prepped and draped. After adequate identification of the DBS electrode, a connector is passed between the intracranial compartment and a subclavicular incision at either side of the chest. The system is connected and the wounds closed. The left DBS electrode is connected to the left pulse generator and the right DBS electrode to the right. Each Itrel II pulse generator is therefore programmed separately.

Postoperative course

The patient spent three days in the EMU, during which time he underwent combined scalp EEG and thalamic depth

Table 159.1 Pre- and post-operative seizure frequency at 1 year follow-up

Pre-operative seizure frequency per month	60 ± 7.75
Seizure frequency in early (first month) post-operative period (stimulation OFF)	9
Post-operative seizure frequency per month after stimulation	15.9 ± 1.23
Mean seizure reduction	75%

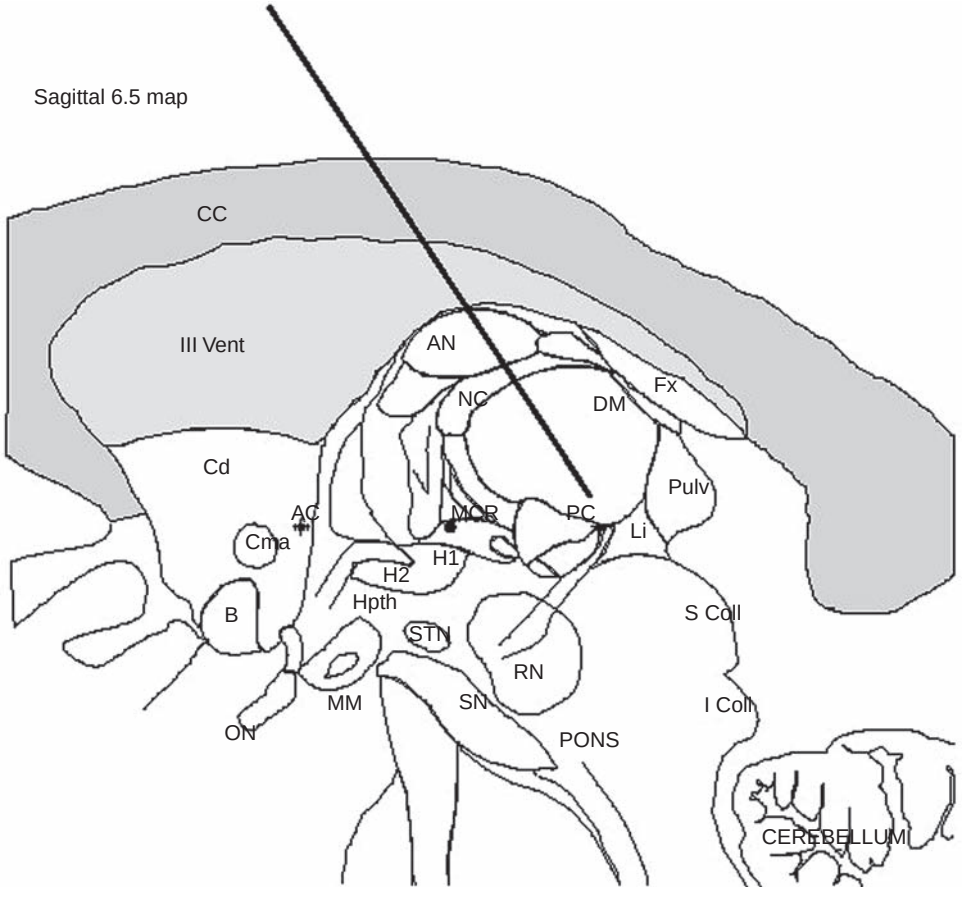

Figure 159.1 Digitized Schaltenbrand–Wahren atlas map of the area of the anterior thalamic nucleus, 6.5 mm from midline. Relationship of the anterior nucleus (AN) and dorsomedian nucleus (DM) can be observed, as well as a typical trajectory of microelectrode recording tract.

electrode recordings via the implanted DBS electrodes. He had a total of 31 focal motor seizures with secondary generalization during this period. A generalized alteration in scalp EEG background activity and the appearance of low amplitude muscle artifact preceded by many seconds the first rhythmic ictal activity. This rhythmic ictal activity was invariably recorded from the right thalamic DBS electrode, initially appearing as an indistinct 5–6 Hz sharp theta activity maximal at the deepest contact of the right thalamic electrode approximately 2 s prior to the clinical onset of the tonic-clonic motor manifestations. This was not accompanied by an identifiable rhythmic ictal correlate on the scalp recording before the appearance of widespread muscle artifact in the scalp recordings. At this point a low amplitude rhythmic ictal discharge was evident in the thalamic electrodes on the right side in the low beta and upper alpha frequency bands, best seen in the deepest contact of the DBS electrode (Figure 159.2). With diminution of the scalp muscle artifact, synchronous rhythmic ictal activity could ultimately be appreciated over the right fronto-parietal region (Figure 159.2) prior to bilateral scalp and thalamic involvement during seizure generalization. Coherence analysis (Rhythm 10.0, Stellate Systems, Montreal, QC, Canada) between the phase locked scalp and thalamic right hemispheric ictal activity before generalization showed a cortical lead on the order of 24 ms with 98% coherence.[10]

Interictally, the high amplitude spikes evident on the scalp EEG were recorded synchronously, and with opposite polarity, from the thalamic DBS electrodes, of slightly higher intracranial amplitude ipsilateral to the maximal scalp potential (Figure 159.3), with a field of distribution indicative of subcortical volume conduction from the superficial cortical spike source.[11]

To assess the influence of thalamic DBS on cortical activity in the early postoperative period, we carried out brief trials of bipolar low frequency stimulation (2–10 Hz, 0.5–10 V, 330–450 μs pulse duration) using various electrode contact combinations while recording the scalp EEG. We were able to elicit a mild recruiting rhythm recorded maximally over the ipsilateral frontal lobe region using bipolar stimulation through contacts 1+3− in this patient. We have since carried out extensive source localization studies of the cerebral responses evoked by low frequency thalamic DBS, as reported elsewhere.[12]

Effect on seizure frequency

A decrease in seizure frequency was observed in the first month after implantation of the DBS electrodes, which continued after the stimulators were turned On. Stimulation was started with the following parameters: 1+/3−, 90 μs pulsewidth, 10 V, 100 Hz, cycling 1 min on/4 min off. At month 3, stimulation contacts were changed to 1−2+ and at month 5 changed back again to 1+3−. At month 6, the stimulation parameters were changed to monopolar stimulation through contacts 0-1− (with the pulse generator case as the

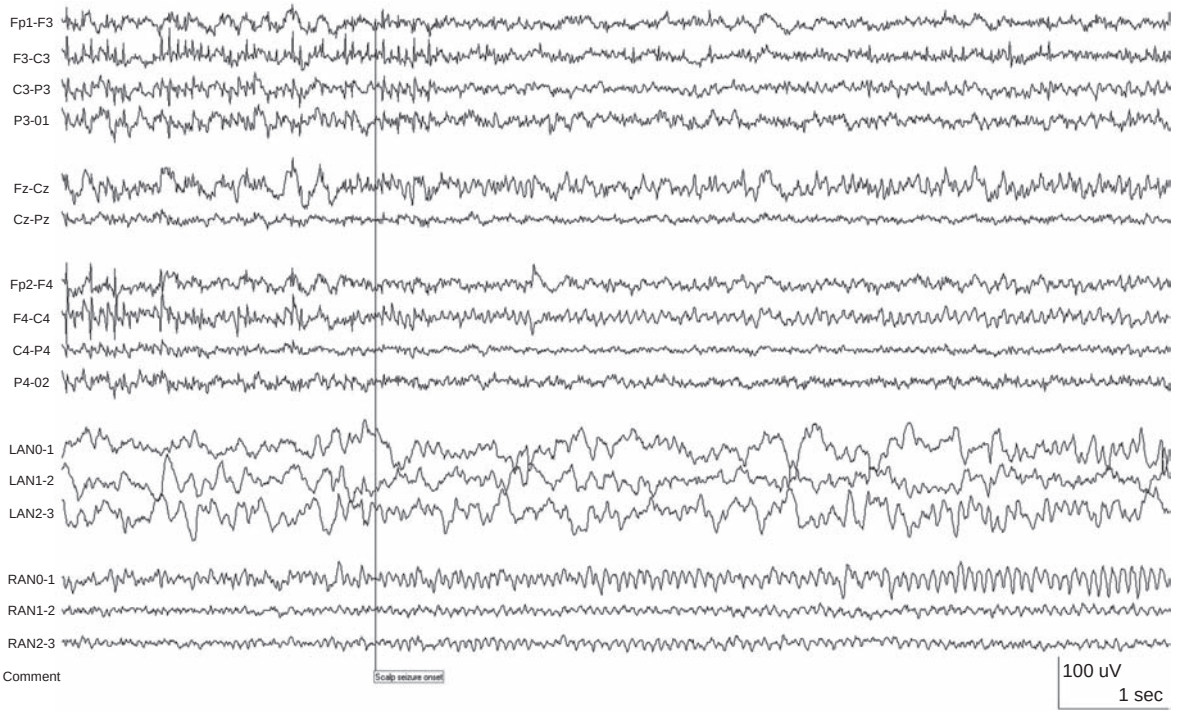

Figure 159.2 Combined scalp-thalamic ictal EEG recording, bipolar montage, left focal motor seizure stage. The clinical seizure commenced before the segment of EEG shown. Rhythmic ictal activity can be appreciated in the right thalamic DBS electrode contacts from the beginning of the sample, increasing in amplitude over time. The first identifiable rhythmic ictal changes in the scalp EEG can be appreciated along with disappearance of the muscle artifact over the right fronto-parietal region, marked by the vertical line. The ictal activity subsequently spread to the left DBS electrode contacts and left scalp electrodes prior to clinical generalization (not shown). LAN = left anterior nucleus DBS electrode; RAN = right anterior nucleus depth electrode; contact 0 = deepest, contact 3 = most superficial. Time constant = 0.3 s; high frequency filter = 70 Hz.

anode). None of these changes, nor any of a number of other alterations in stimulation parameters made over the subsequent 4 years of follow-up, was associated a significant difference in the postimplantation seizure frequency. The benefit has been sustained over 5 years of follow-up, with a 90% seizure reduction compared to preimplantation baseline at last follow-up. The only change to the anticonvulsant regime took place in year 4 post surgery, with the addition of levetiracetam. The patient has been described by his caregivers to be more alert, cooperative and participatory in daily activities such as feeding with DBS, though this could not be quantified.

Discussion

This patient showed a marked and sustained improvement in seizure control associated with DBS of the anterior thalamic nucleus. There are several issues of interest with respect to the surgical intervention that merit further mention. Firstly, the acute benefit observed without stimulation is reminiscent of the microthalamotomy-like effect described with similar procedures for movement disorders.[13] The relative effects of electrode insertion versus active stimulation need to be further studied, something that is currently being investigated in a multi-center clinical trial.[14] Secondly, the possibility of a surgical placebo effect cannot be ignored in open trials such as this, however, it seems unlikely that such a long-lasting benefit would be based on placebo effect alone. Also, the possibility of a regression-to-the-mean phenomenon cannot be entirely ignored as a contributor to the measured decrease in seizure frequency.

We were able to elicit a recruiting rhythm with stimulation of the thalamic depth electrodes during the externalization phase in the immediate postoperative period. We have observed that of the three patients who responded best to stimulation in our initial published study, all showed evidence of a recruiting rhythm, whereas the two patients that failed to a similar benefit from stimulation during the first postoperative year did not show evidence of a recruiting rhythm on EEG. Although we cannot draw any definitive conclusions from the small sample of patients in our pilot study, it appears that the ability to record a recruiting rhythm on EEG might be predictive of benefit from stimulation.

The combined scalp-thalamic ictal EEG recordings in this patient are of some interest in that they demonstrate the potential for early ictal recruitment of the anterior thalamic structures even in patients with extratemporal, suprasylvian neocortical partial epilepsy. This is of interest given the remoteness of seizure onset from the temporolimbic-thalamic circuit of Papez structures, in which the anterior thalamic nucleus might be expected to have its most pronounced involvement.

A further matter to consider is the stimulation parameters used. The selected high frequency stimulation parameters are largely drawn from our experience with DBS in movement disorders. To date, we have been unable to associate changes in seizure frequency with alterations in stimulation parameters. Adequate investigation needs to be carried out in this regard to determine if optimal stimulation parameters can be identified.

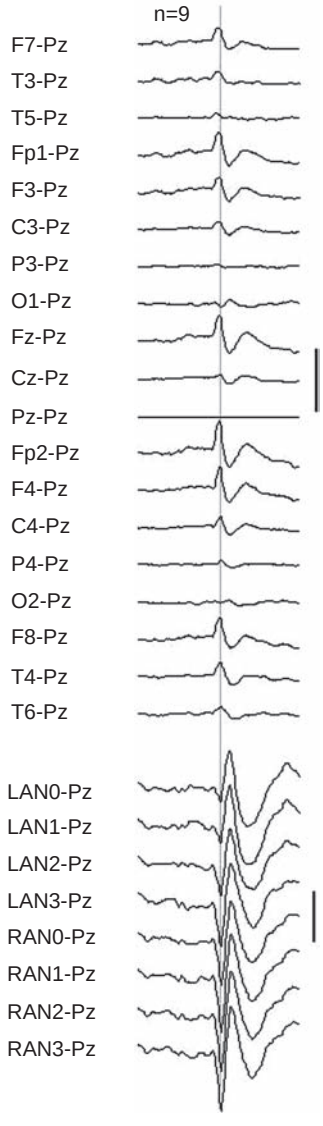

Figure 159.3 Combined scalp-thalamic interictal EEG, Pz reference montage. Shown is an average of nine interictal spikes with a right anterior frontal predominance. Vertical amplitude scale bars for scalp and thalamic intracranial EEG = 100 μV.

160 Successful transcranial magnetic stimulation in a patient with medically intractable focal epilepsy

F Fregni, G Thut, A Rotenberg, and A Pascual-Leone

Introduction: applications of TMS in epilepsy

Transcranial magnetic stimulation (TMS) is a noninvasive technique that can be used to transiently induce, modulate or interfere with neuronal activity in relatively circumscribed brain regions. In epilepsy research, it was initially proposed that single pulse TMS could be helpful for seizure focus localization by activation of epileptic activity or seizure induction through TMS over the epileptogenic zone. However, initially promising results could not be confirmed.[1,2] Indeed, the risk of observing a TMS-associated seizure in patients with epilepsy has been estimated to be small in a recent meta-analysis of 49 publications, and doubt has been expressed whether such seizures were induced by TMS or merely coincidental.[3] Instead, TMS today is under evaluation for its possible antiepileptic potential when multiple consecutive TMS pulses, referred to as repetitive TMS (rTMS), are applied in trains at low frequency (around 1 Hz). Such clinical trials in epilepsy with a therapeutic prospect are motivated by the finding that low-frequency rTMS leads to a reduction of cortical excitability that outlasts the duration of stimulation, frequently replicated in studies on motor physiology in healthy controls[4–7] and also confirmed through TMS-studies on non-motor functions.[8,9] Accordingly, it has been argued that low-frequency rTMS might be of potential therapeutic value in epilepsy patients by increasing seizure threshold through reduction of cortical excitability. The clinical trials performed so far have provided overall encouraging results revealing antiepileptic effects of low-frequency cortical stimulation in patients with medically uncontrolled epilepsy. Antiepileptic effects have been reported following 1 day to 4 weeks of rTMS treatment with a significant improvement of number and/or severity of seizures,[10–12] interictal spikes[11,12] or EEG activity associated with epilepsy partialis continua.[13] Others, however, have observed only a trend toward a short-term decrease in seizures following a 1-week treatment.[14,15] Clearly, further studies are needed to contrast different stimulation protocols, and to study prognostic factors and interactions with medications. In the present chapter we aim to provide illustrative examples of the potential utility of TMS in pharmaco-resistant epilepsy. The chapter is structured in three parts. First, a clinical case report is discussed to illustrate the potential of rTMS in humans. Next, the technical challenges faced when combining TMS with EEG recording, critical for properly-guided therapeutic applications of TMS are addressed in a 'technical case report'. Finally, an 'experimental case report' serves to illustrate ongoing research on underlying mechanisms of action and approaches to optimize translational applications of TMS for treatment of epilpetic patients.

Clinical case reports: TMS for treatment of pharmacoresistant epilepsy

Malformations of cortical development (MCD) represent an important etiology of refractory epilepsy and, therefore, a common cause of referrals for epilepsy surgery. However, a large proportion of patients with diffuse MCD and those with lesion in the eloquent cortex are poor surgical candidates. Such patients represent a challenge for treatment and a focus of continuous interest for alternative therapeutic approaches.

A few human studies[11,16] have shown that low-frequency repetitive transcranial magnetic stimulation (rTMS) might be clinically effective in seizure control in patients with MCD and refractory epilepsy. The rationale for the use of rTMS in patients with epilepsy is that this technique modulates brain excitability in a noninvasive and painless way and thus inhibitory effects are possible if low-frequency rTMS is employed[4,7] We describe the outcome of this approach in two patients with MCD, one with focal epileptic activity and the other with multifocal epileptic activity. In addition we discuss the longer follow-up and treatment of these two patients initially after a single session and then for five consecutive TMS sessions.

Clinical case 1: rTMS in a case of focal epileptic activity

A 16-year-old boy with bilateral posterior quadrant polymicrogyria received two different rTMS treatments for epilepsy. Although this patient had received several antiepileptic drugs, he continued to have very frequent complex partial seizures (15 episodes per day, on average) and sporadic secondarily generalized tonic clonic seizures (one episode per month). The complex partial seizures were characterized by episodes of fixed gaze that lasted less than 1 minute. The patient was taking lamotrigine (25 mg/day), valproate (1500 mg/day), carbamazepine (1800 mg/day) and nitrazepam (10 mg/day). His baseline electroencephalogram was characterized by frequent epileptiform discharges (ED) that were predominant in the posterior areas, especially in O1 and O2 (10/10 international EEG system). This patient underwent two different rTMS treatments as follows.

Treatment 1: single session of 1 Hz rTMS

Initially this patient received rTMS over the epileptogenic focus with the following parameters: a continuous train of 10 minutes with a frequency of 1 Hz and an intensity of 60% of the maximum stimulator device. This type of rTMS is expected to increase intracortical inhibition in the targeted brain region, and would thus be expected to suppress epileptic activity in the epileptic focus. Because this patient had two epileptogenic foci, we decided to stimulate O1 for 10 minutes and O2 for 10 minutes (therefore a total of 1,200 pulses). There were no adverse events related to this treatment. At baseline this patient had an average of 15 complex partial seizures per day. Following the rTMS this number decreased to six seizures per day and 1 month after to eight episodes per day. His EEG at baseline showed 313 epileptiform discharges that decreased to 191 immediately after treatment. Remarkably, he had only one epileptiform discharge in the standard clinical EEG performed at day 15. At day 30, there was an increase to 194 epileptiform discharges.

Treatment 2: five consecutive sessions of 1 Hz rTMS

One year after the first rTMS session, this patient received five consecutive sessions of 'inhibitory' rTMS over the epileptogenic focus with the following parameters: a continuous train of 20 minutes with a frequency of 1 Hz and an intensity of 70% of the maximum stimulator output – 1,200 pulses were then applied per day (total of 6,000 pulses). Because the epileptogenic focus of this patient extended to the left and right hemisphere, we decided to stimulate O1 for 10 minutes and O2 for 10 minutes. There were no adverse events related to this treatment. At baseline the patient was again having on average 15 complex partial seizures per day. Following the 5-day course of rTMS the number decreased to three episodes per day as average for the 15 subsequent days and, 1 month after treatment, he maintained the improvement and was having three to four episodes per day. His EEG at baseline disclosed 354 epileptiform discharges that decreased to 252 immediately after treatment and continued to decrease to 120 and 100 ED after 30 and 60 days, respectively.

Clinical case 2: rTMS in a case of multifocal epileptic activity

A 14-year-old girl with band heterotopia received two different rTMS treatments for epilepsy. This patient had also tried several antiepileptic drugs regimen and none of them was able to control her seizures. At the moment of the treatment, she was taking lamotrigine (275 mg/day) and valproate (1250 mg/day). She was having frequent simple partial seizures (one episode per day, on average) and rare secondarily generalized tonic clonic seizures (one episode in the past 3 months). The simple partial seizures were characterized by myoclonic jerks of predominantly the upper extremities and trunk in which she had to be assisted to avoid a fall. Her baseline electroencephalogram (EEG) was characterized by frequent multifocal epileptiform discharges. Similar to case report 1, this patient underwent two different rTMS treatments as detailed below.

Treatment 1: single session of 1 Hz rTMS

Initially this patient received inhibitory rTMS over the vertex (Cz) using a nonfocal circular stimulation coil – as she had multifocal epileptic activity – with the following parameters: a continuous train of 10 minutes with a frequency of 1 Hz and an intensity of 60% of the maximum stimulator device – 600 pulses were then applied. There were no adverse events related to this treatment. At baseline this patient had an average of one simple partial seizure per day and 15 days after the treatment, this number decreased to one simple partial seizure every 4 days. The benefit continued 1 month after the rTMS, when she was having an average of one seizure every other day. Her EEG at baseline showed 106 epileptiform discharges that decreased to 67 immediately after treatment, and then varied between 96 and 27 ED after 15 and 30 days of treatment, respectively.

Treatment 2: five consecutive sessions of 1 Hz rTMS

A year later, this patient received five consecutive daily sessions of inhibitory rTMS over the vertex (Cz) using a circular stimulation coil (thus targeting diffusely both hemispheres) with the following parameters: a continuous train of 20 minutes with a frequency of 1 Hz and an intensity of 70% of the maximum stimulator device – 1,200 pulses were then applied per day (total of 6,000 pulses). There were no adverse events related to this treatment. At baseline this patient had an average of four simple partial seizures per day and 15 days later, this number decreased to an average of only one seizure every 3 days and, 1 month after the treatment, she remained having the same frequency of seizures. Her EEG at baseline disclosed 70 epileptiform discharges that decreased to 38 immediately after treatment and remained decreased when compared to baseline (50 and 46 ED, after 30 and 60 days, respectively).

Discussion

These two cases illustrate that low-frequency rTMS, which is thought to induce an increase in intracortical inhibition in the targeted brain region, can reduce the number of seizures and epileptiform discharges in patients with refractory epilepsy due to malformations of cortical development. In addition, the effects of five sessions of rTMS appear to have a greater magnitude and longer duration when compared to a single session of rTMS. Finally there were no adverse effects associated with this treatment in any of these two patient, nor in others similarly treated.

The first important point that should be discussed is the site of stimulation. For patients with focal lesions and epileptogenic

activity, the first, logical approach would be the stimulation of the dysfunctional brain area. This approach was successful in the case 1, in which the patient had a focal lesion and epileptic activity. This is in accordance with the presumed rTMS mechanism of action: a focal modulation of the stimulated area.[17] For patients with discordant lesion location and epileptiform focus (as indexed by EEG), we speculate that the functional (EEG) focus might be the one that should be targeted. Finally, for patients with multifocal epileptic activity (case 2), the stimulation of a central area, such as the vertex (Cz), using a large circular coil might be the best approach (as we showed in case 2). We showed that the patient in case 2 also had a clinical and electroencephalographic improvement, however it was less pronounced than the patient in case 1 – with focal epileptogenic activity. The local and distant (via neural network) effects of rTMS might be responsible for this improvement in this patient with multifocal epileptic activity.

Another important point in this treatment is the number of sessions. These two cases suggest that five sessions of rTMS might be superior to a single session. In this regard, much has been learnt from studies using rTMS for the treatment of medication-resistant depression. Several trials have shown that a prolonged rTMS course has an additional benefit of this strategy. Rumi *et al.* demonstrated the relationship between clinical antidepressant effects and number of rTMS sessions. In addition, several studies have shown that consecutive sessions of rTMS are safe. Loo *et al.* elegantly demonstrated, through a detailed and extensive cognitive testing, that the treatment with rTMS over a 4-week period is safe.

Finally, an interesting effect was observed in case 1 in whom the beneficial effect of the rTMS treatment continued to enhance even after the end of the treatment as shown by the number of ED after 15 days and 30 days of stimulation. Such an effect might indicate that plastic changes induced by rTMS might have occurred, e.g., synaptic strengthening (long-term potentiation and depression). This finding is reminiscent of observations in patients with stroke who received rTMS treatment for the treatment of aphasia.

Only a few studies have investigated the effects of rTMS in patients with refractory epilepsy and the results of these studies are mixed.[11,12,14,16] Further larger studies should explore the best parameters of stimulation in order to increase the magnitude and the duration of the rTMS effects. What seems critical is precise targeting of the epileptic focus, and given the rapid decay of the magnetic field with the square of the distance from the TMS coil, concentration on patients with foci in the cortical convexity seems indicated.

Technical case report: simultaneous EEG and TMS

In parallel to the probing of rTMS protocols for the treatment of epilepsy, new technological developments have been made rendering EEG recording online to TMS feasible. The continuous monitoring of EEG signals during rTMS in epilepsy research is of interest in several regards, e.g., for the early detection of TMS-induced epileptic discharges that could lead to a seizure or for the evaluation of the immediate beneficial effects of rTMS treatment during stimulation. However, EEG recording during TMS has proven difficult due to the artifact problem. This consists of magnetically elicited high-voltage peaks potentially saturating the EEG system.[18] To avoid TMS-induced contaminations of the EEG signal, two main methods have been proposed. One approach, introduced by Ilmoniemi and colleagues,[18,19] is based on special preamplifiers with sample-and-hold circuits and gaincontrol. This circuitry has been shown to block electrical contamination in the EEG hardware components, but necessitates switching off the preamplifier during the TMS pulse.[18] Others have proposed slow-rate limiting preamplifier modules to allow for continuous EEG recording without saturation of the EEG signals despite TMS pulse delivery.[20,21] The latter approach is devoid of any loss of data, as the preamplifier output does not have to be pinned to a constant level for the duration of the TMS pulse. It does however not fully prevent the magnetically elicited voltage peak from proceeding into EEG hardware components leading to electrical contaminations of short duration that however can be corrected offline to the recordings.[21]

Technical case: online EEG during 1 Hz rTMS

EEG monitoring online to TMS is illustrated in Figure 160.1, that depicts interictal scalp EEG of a patient with pharmacoresistant epilepsy before (Figure 160.1a) and during the application of 1 Hz rTMS (Figure 160.1b). This patient showed regular epileptic spikes that were generated both with or without TMS and that were clearly independent from TMS (see Figure 160.1b). The patient tolerated TMS well and no seizure occurred either during or in the first 24 hours after rTMS. EEG monitoring in epilepsy patients is useful to immediately discontinue the rTMS trial in case EEG abnormalities are induced by TMS.[22] In addition, being able to assess the immediate impact of TMS on epileptic discharges provides new possibilities for epilepsy research that, we hope, go beyond the use of EEG to document the long-term effects of rTMS treatment.[11–13] More information on the mechanisms how rTMS interferes with the generation of epileptic activity is definitely needed to further develop rTMS into an effective, alternative treatment strategy for pharmacoresistant epilepsy. Finally, online EEG recording may allow to develop a system of EEG-guided TMS by which the pulses of TMS could be precisely timed with the epileptic spike for maximal efficacy and to prevent progression of seizures.

Experimental case report: EEG-guided TMS in rat seizure model

TMS is emerging as a safe new therapeutic tool in epilepsy. In simple terms, TMS can be delivered during the interictal phase to reduce seizure frequency, or during the ictal phase to abort ongoing seizures (such as status epilepticus). Encouragingly, and as demonstrated by the patients illustrated above, a few human trials demonstrate the capacity of interictal TMS to reduce seizure frequency.[10–12] However, the potential for ictal TMS to terminate ongoing seizures has not been extensively studied. In part, this research has been limited by lack of adequate animal models and the difficulties of recording artifact-free EEG during TMS.

For experimental purposes, animal models, particularly rat epilepsy models, offer two important advantages: (1) time-coupling of seizure and TMS, and (2) the capacity

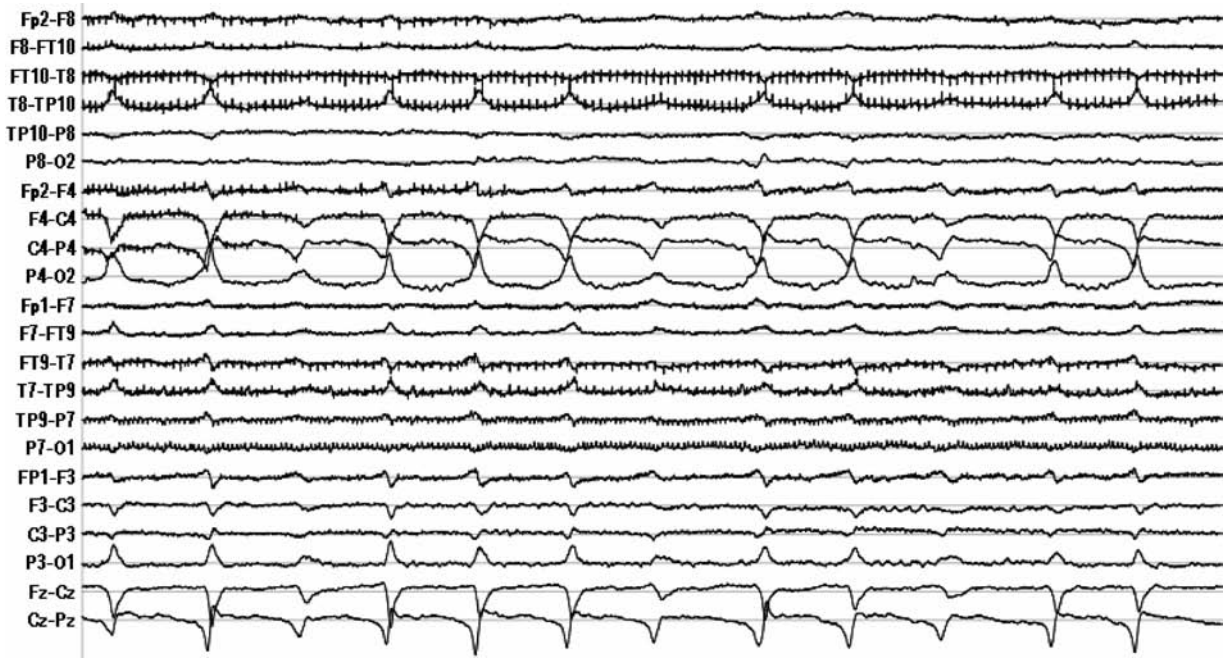

Figure 160.1 EEG monitoring during rTMS. Interictal EEG was recorded from 23 electrodes before rTMS treatment in a patient with pharmacoresistant complex partial epilepsy and regular spikes originating from parietal cortex (A) and during the application of 1 Hz rTMS over the spike origin (B). The spike origin was identified through interictal EEG, spike-triggered fMRI[28] as well as source localization algorithms in the patient's own MRI[29] and the TMS coil was places over this site using a Neuronavigation device. The TMS-induced artifacts correspond to the vertical black lines associated with each pulse, only transiently interfering with the EEG signal. In this example, the artifact lasts for maximally 15 ms after the TMS discharge. Plastic-body electrodes were used to prevent scalp burns due to overheating.[17,30] The protocol was approved by the local ethical committee and the patient gave written informed consent to stimulation. (courtesy of Dr. Margitta Seeck).

to generate large numbers of seizures to measure the therapeutic TMS effect. With respect to the first rat model advantage, the investigator can precisely time TMS delivery relative to seizure onset, or alternatively time the delivery of a convulsant relative to the TMS. For instance, a delay in pentylenetetrazole (PTZ)-induced seizure onset and reduction in incidence of status epilepticus was shown in rats pretreated with 1,000 pulses of 0.5 Hz rTMS.[23] With respect to the second advantage, large seizure numbers provide a readily-quantifiable outcome measure when investigating the potential of TMS to shorten average seizure duration. This was recently demonstrated in kainite induced seizures whose duration was abbreviated by EEG-guided 0.5 Hz rTMS.[24]

Furthermore, seizures in animal subjects can be timed to start during continuous EEG recording such that the electrographic seizure onset and offset, as well as timing of the TMS pulse can be analyzed online. This can provide a means of real-time assessment of anticonvulsive TMS effects, and forms the basis for EEG-guided TMS treatment of seizures.

A schematic of the methods for TMS in gently-restrained seizing rats is shown in Figure 160.2. With this method, the torso is restrained with broad straps such that the limbs, tail and head have full freedom of movement, but the rat cannot propel forward or backward.[24] This enables clinical as well as electrographic seizure monitoring while maintaining the TMS coil in a relatively fixed position overhead. The pictured setup is welltolerated by rats who show no apparent signs of distress during the restraint or TMS.

Experimental case reports: EEG-guided anticonvulsive TMS

The application of EEG-guided TMS is shown in Figure 160.2 where two spontaneous seizures appear in close proximity. The first (with onset before the displayed tracing) was not treated. The second seizure was treated by TMS applied as soon as the ictal pattern was recognized. A series of similar seizures are seen in Figure 160.3 that shows a comparison of seizures in a spontaneously-epileptic Long Evans rat treated with the TMS coil over the rat's head, with the coil over the rat's tail (sham control), and untreated seizures (untreated control) in the same animal.

Discussion

A natural extension of the pilot work with EEG-guided TMS is the development of a closed-circuit system where (1) the ictal EEG is recognized by an automatic seizure detection system, (2) TMS is delivered to the seizing subject, and (3) the EEG is reanalyzed to determine whether another TMS pulse should be delivered if the ictal pattern continues. Another series of experiments that can follow from the preliminary rat seizure work are the investigation of optimal TMS timing relative to the seizure onset, and at a finer time scale, relative to the spike-wave complex. That is, triggered seizures in animals may provide the opportunity to test whether seizure abortion is more likely when the TMS pulse is delivered at a particular phase of the spike-wave complex akin to a cardiac pacemaker that is phase-locked to the QRS complex.

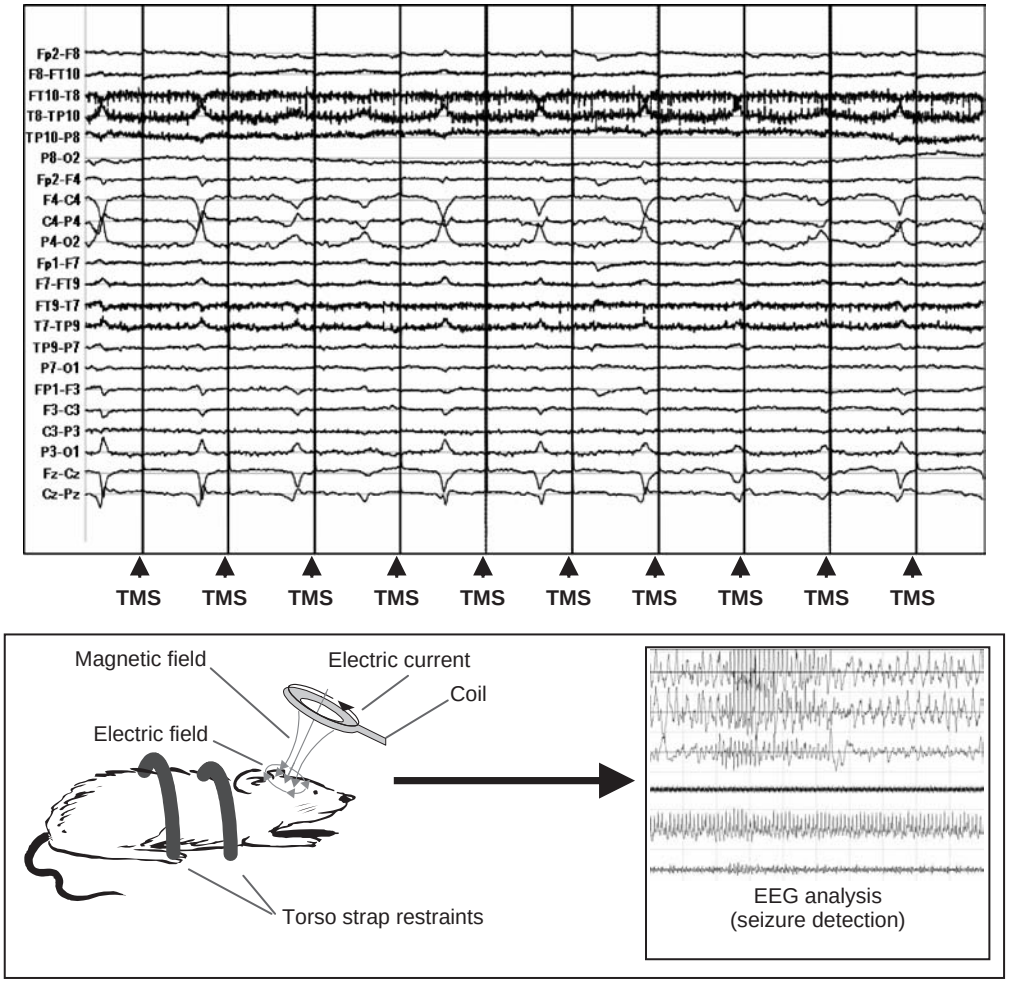

Figure 160.2 Schematic of rat with torso restraint, TMS coil and EEG. Torso restraint permits clinical observation of seizures and full access of head to the TMS coil. EEG (and EKG) can be analyzed in real time by experimenter to trigger TMS device.

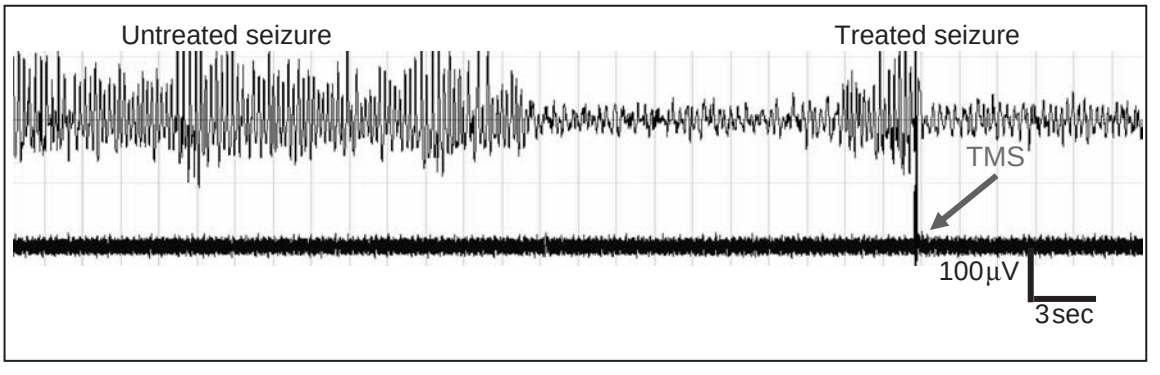

Figure 160.3 Treated and untreated spontaneous seizures. Online seizure analysis permits reliable seizure detection and real-time assessment of TMS anticonvulsant effect.

In addition to investigating the capacity of TMS to abort seizures, animal models offer a means to evaluate the potential for TMS to interfere with epileptogenesis. For example, kainite-induced status epilepticus reliably leads to spontaneous recurrent seizures in rats a after a several-week seizure-free latent period.[25,26] This latent phase during which epilptogenic changes that lead to a net increase in cortical excitability and eventually to spontaneous seizures provides a potential therapeutic target for low-frequency repetitive TMS. The hypothesis to test during the latent phase is that low-frequency repetitive stimulation that may decrease cortical excitability can interfere with the epileptogenic process.

Furthermore, as changes in synaptic efficacy resembling long-term potentiation (LTP) may be involved in epileptogenesis, low-frequency repetitive TMS provides an opportunity to

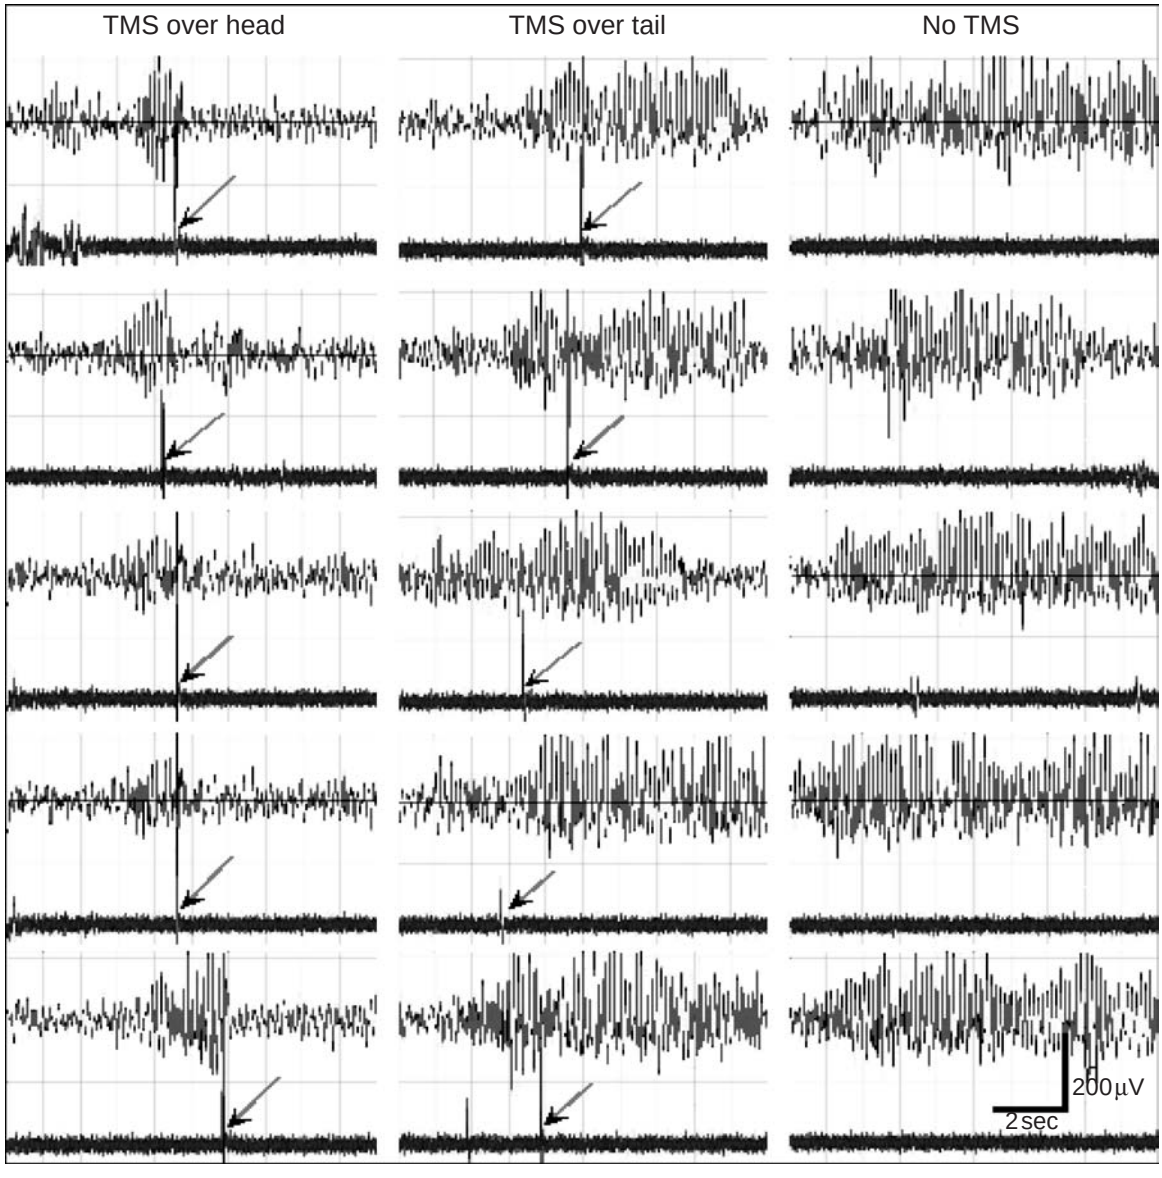

Figure 160.4 Spontaneous seizures aborted with overhead TMS. EEG (black tracing) and TMS output (blue tracing) were recorded for a spontaneously-seizing rat. Arrows point to time of TMS discharge. Seizure detection was performed by real-time visual EEG review – the EEG was monitored for ictal discharges and the TMS was triggered as soon as an ictal pattern was recognized. Five consecutive seizures were treated with coil over the rat's head (left column), five with coil over tail (center column) and the last five were untreated (right column). Each seizure treated with coil overhead terminated with rapid return to normal EEG. (See Color plates.)

investigate whether it can reverse the epileptogenigc process, perhaps by inducing changes resembling ling-term depression (LTD) that is LTP's inhibitory counterpart. In this regard, investigators working with rat models can take advantage of the extensive LTP and LTD literature[27] to evaluate the effects of repetitive TMS in vivo, ex vivo and in vitro, and compare them to the large body of work with direct cortical and hippocampal stimulation–such work should provide valuable insight into the therapeutic mechanisms of repetitive TMS.

161 Surgery in a patient with medically intractable gelastic seizures and a hypothalamic hamartoma

S Mittal, JL Montes, J-P Farmer, and JD Atkinson

Introduction

Hypothalamic hamartomas are non-neoplastic congenital malformations resembling gray matter, composed of hyperplastic neuronal tissue. They are of varying size and usually take the form of nodules attached to the ventral hypothalamus and tuber cinereum or mamillary bodies.[1] These relatively rare lesions may be asymptomatic but are often associated with precocious puberty and/or an unusual epileptic syndrome characterized by gelastic seizures, behavioral disturbance, and suboptimal response to antiepileptic drug treatment.[2]

Gelastic epilepsy is characterized by pathological ictal laughter and often begins in childhood. In addition to the laughing spells, these patients have concomitant seizures of other types.[3–4] Morbid personality disorders and progressive cognitive deterioration further complicate the gelastic epilepsy related to hypothalamic hamartomas.[5–7] The management of affected patients remains difficult and controversial.[8] In this chapter, we report our surgical experience in a 3-year-old boy who was admitted to our service for investigation of longstanding uncontrolled gelastic seizures and associated generalized attacks. The case effectively illustrates the difficulties in the management of this challenging condition.

Clinical presentation

The patient was born at 40 weeks gestation by spontaneous vaginal delivery as the older of a set of non-identical twins. The patient's mother reported an uneventful pregnancy. He had good Apgar scores and had mild neonatal hyperbilirubinemia. He was discharged home within 36 hours of birth. However, in the following days, the patient experienced what later were identified as gelastic seizures. Over the next few months, he continued to have episodes of pathological laughter. It was noted that at 6 months of age, spells typically lasted less than 5 seconds and occurred up to 20 times per day. These brief but repetitive episodes persisted in the first year of life but remained largely unrecognized until the patient was 18 months old. At that time, he had a usual non-emotional laughing spell lasting a few seconds, but contrary to all previous episodes; this attack was followed by a generalized tonic-clonic seizure. He was referred to a regional epilepsy center for investigation of the 'new onset' seizure.

Over the subsequent months, the patient continued to experience approximately 20 gelastic seizures and seven to 20 generalized seizures per day. At this time, he was started on vigabatrin. However, not finding any change in the frequency or severity of the seizures, the parents decided to discontinue the anticonvulsant and refused any further antiepileptic medications.

His developmental milestones were also somewhat delayed. He was crawling at 8 months and began walking at 16 months. At that time, his gross and fine motor skills were felt to be marginally below the normal range. From a speech and language developmental perspective, the patient had a vocabulary of six to eight words at 14 months of age.

Over the following year, the patient's seizures continued to worsen. In addition to gelastic and secondary tonic-clonic seizures, he started having drop attacks primarily involving the head. During this period, the patient began to regress developmentally. His level of interaction and communication deteriorated. He also failed to develop any new motor or language skills and, in fact, lost the few words he had spoken previously. Behaviorally, he became very aggressive with frequent temper tantrums.

The patient was normocephalic with a slight strabismus with alternating esotropy. The motor and sensory, as well as the rest of the neurological examinations were within normal limits.

Video-EEG evaluation

In typical severe cases of hypothalamic hamartoma, an association is seen with slow spike-wave with or without multifocal (typically frontal or temporal) epileptiform abnormalities.[9–10] In addition, some seizures can closely resemble complex partial seizures of temporal or frontal origin on clinical and ictal EEG criteria.[11–12] Despite ictal recordings which may demonstrate the cortex as the site of origin of seizures, cortical resection uniformly is ineffective in treating the seizures.[3] These hamartomas are now known to be intrinsically epileptogenic and the site of origin for gelastic seizures.[12–14]

In our patient, EEG video telemetry revealed two electrographic and clinical seizure types. Clinically, the patient appeared afraid and made guttural sounds at seizure onset. This was followed by an emotionless laugh. The patient also had head drops and associated arm extension. Electrographically, an eletrodecremental pattern was observed followed by generalized slow wave and at times intermingled generalized spike and wave complexes. Figure 162.1 demonstrates rhythmic sharp activity starting in the left frontal region rapidly becoming rhythmic spikes. Head drop attacks were associated with generalized sharp waves. Seizure duration was between 50 and 75 seconds. Interictally, a generalized epileptiform abnormality was observed. Additionally, a bifrontal epileptiform abnormality with right-sided predominance was also noted.

Neuroimaging

The intimate association of the hamartomas to the mamillary bodies appears to be crucial for genesis of seizures.[15] In our patient, high-resolution magnetic resonance imaging scans demonstrated a well-defined, rounded soft-tissue mass in the region of the tuber cinerium (Figure 162.2). The lesion measured 12 mm in diameter and was isointense to gray matter on both T1- and T2- weighted sequences. The lesion did not enhance following administration of gadolinium. The mass showed heterogeneous signal intensities on the FLAIR images. There was no evidence of restrictive diffusion. There was no hydrocephalus associated with the hypothalmic hamartoma and no other lesions were identified.

Neuropsychological testing

The isolated hypothalamic hamartoma patients are known to perform poorly on the Woodcock-Johnson Battery, a broad cognitive ability standard score.[4,16] No correlation has been found between age at seizure onset and cognitive abilities. However, the frequency of gelastic and complex partial seizures do negatively correlate with the broad cognitive ability score.[17] A conclusive correlation between age at seizure onset or seizure frequency, and verbal or nonverbal abilities remains to be elucidated.

In our patient, progressive worsening of cognition and behavior was noted on the neuropsychological examination performed at the time of surgery. The evaluation showed moderate mental deficiency, borderline developmental quotients, and delayed speech. In addition, he had behavioral problems that encompassed hyperkinesias, aggressiveness, and autistic features.

Surgical management and outcome

Microsurgical excision of the hypothalamic hamartoma was proposed to the patient's parents given the intractability of the seizure disorder, the developmental regression, and behavioral and cognitive disabilities. Despite earlier views to the contrary, there is now good evidence that these clinical features are caused, directly or indirectly, by the hamartoma. Furthermore, there is now ample evidence that long-lasting control of seizures or even seizure freedom can be achieved by complete removal, destruction, or disconnection of the hypothalamic

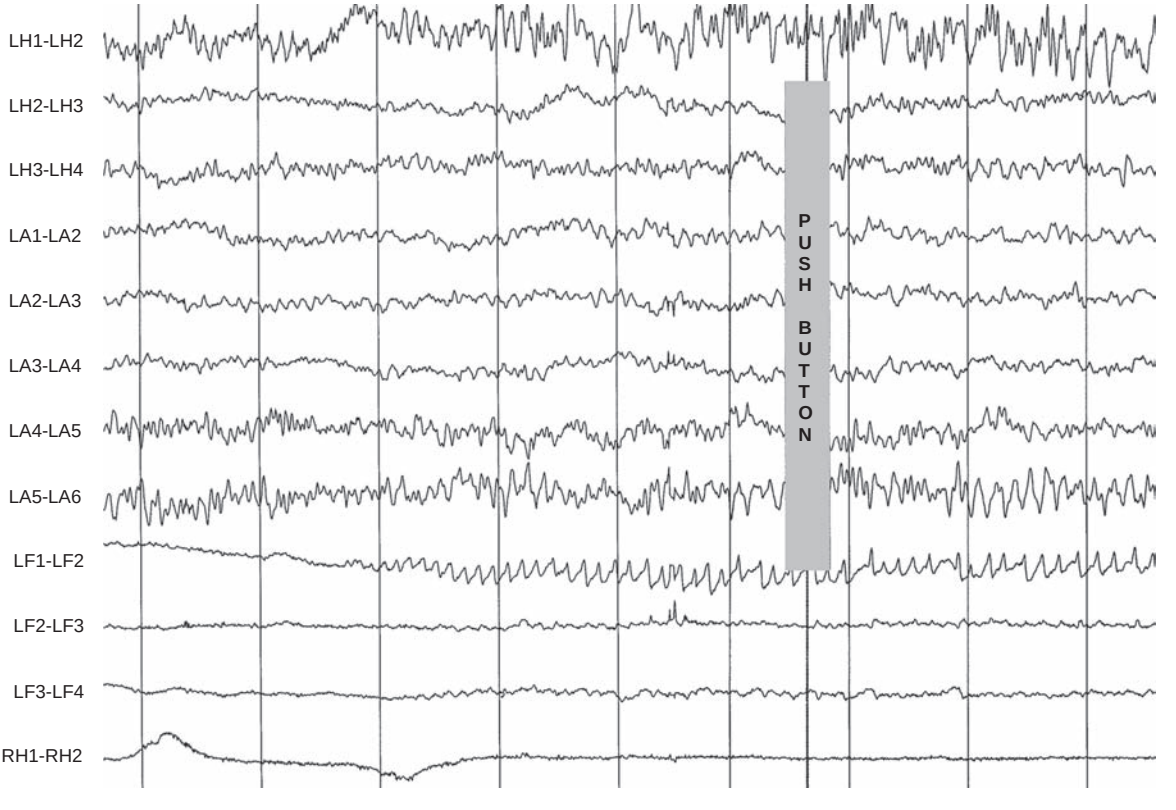

Figure 162.1 Preoperative scalp-EEG showing rhythmic sharp activity at LF1–LF2 rapidly becoming rhythmic spikes with push button denoting clinical seizure.

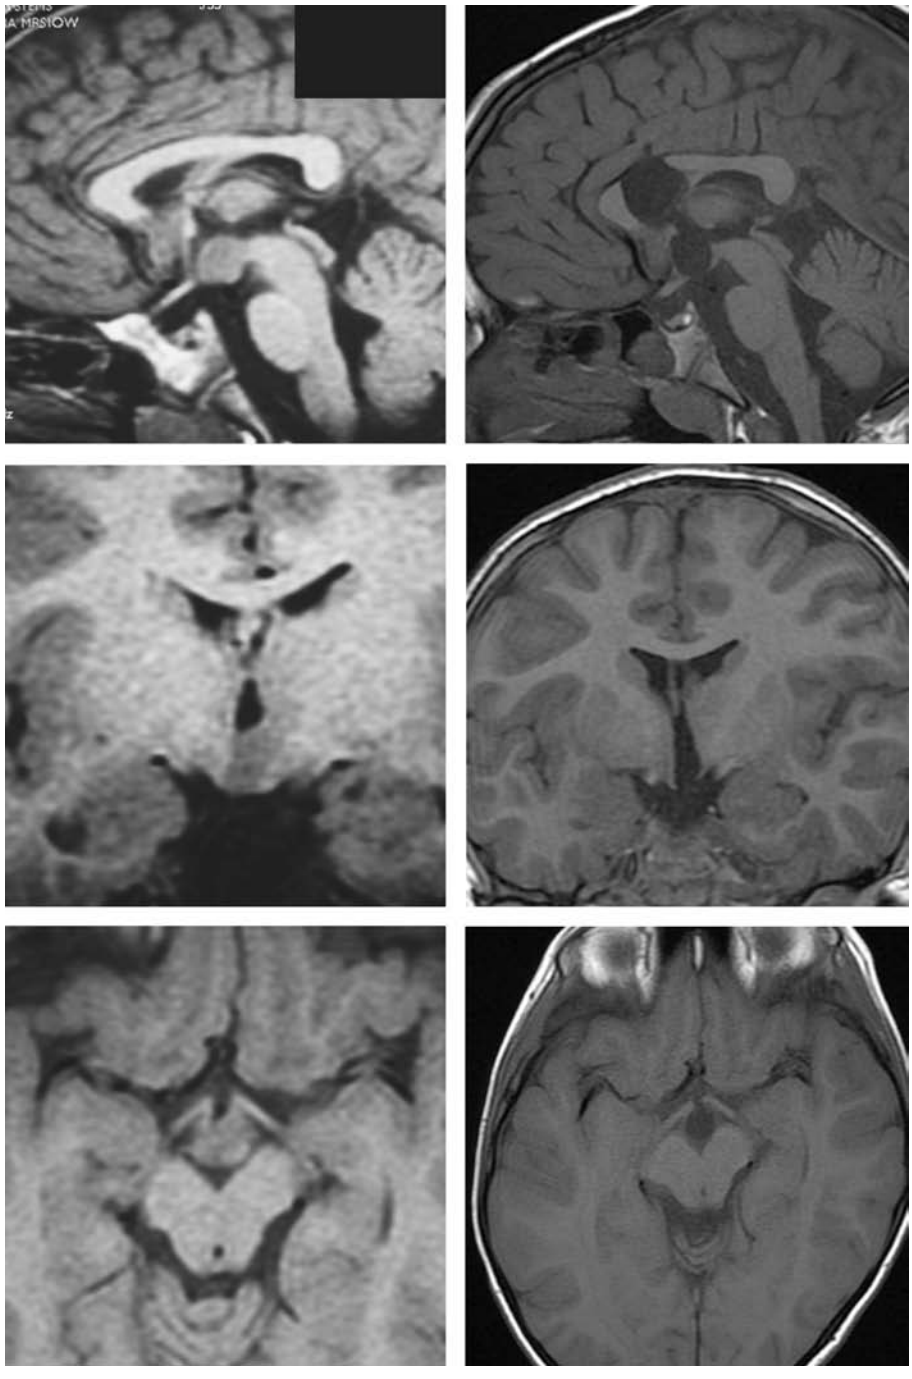

Figure 162.2 High-resolution MRI scans of demonstrating a well-defined, hypointense, non-enhancing hypothalamic hamartoma measuring 12 mm in diameter. Sagittal, coronal, and axial views obtained preoperatively (left panel) and following surgery (right panel).

hamartoma. Multiple surgical approaches and techniques have been described and should be tailored according to the surgical anatomy of the lesion and the surgeon's experience. We have used the traditional surgical approaches such as the transcallosal anterior interforniceal, the pterional, and the subfrontal translaminal terminalis approaches for resection of hypothalamic hamartomas. Because the main component of the hamartoma was within the third ventricle, it was felt that the interhemispheric, anterior transcallosal route, as described by Rosenfeld,[18] would be best suited for this patient. Craniotomy using frameless stereotaxy was performed. The corpus callosum was split and the two leaflets of the septum pellucidum and the columns of the fornix were separated, providing direct entry into the third ventricle at the level of and anterior to the foramina of Monro. Clear and direct visualization of the intraventricular component of the hamartoma was possible. Using a microdissector and an ultrasonic aspirator, complete removal of the lesion was achieved. Differentiation of the hamartoma from the ventricular walls and mamillary bodies can be a challenge. The lesion is typically slightly firmer and more gray compared to the surrounding neural structures. The plane of the third ventricle, the mamillary bodies posterolaterally, and the pia above the interpeduncular cistern provide resective surgical margins.

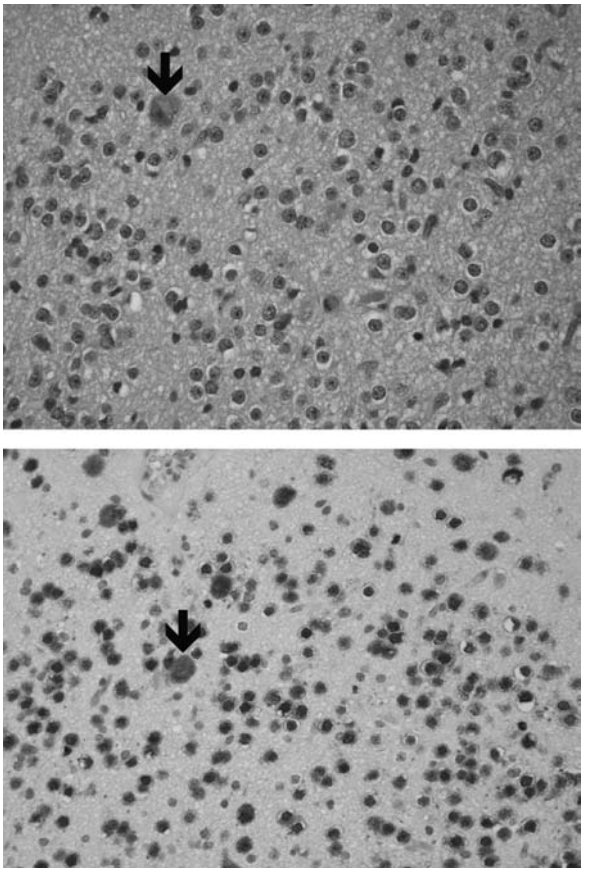

Figure 162.3 Histology of a hypothalamic hamartoma. Upper panel: On a routine H&E stain, there are both large neurons (ganglion cells; arrow) and smaller neuronal cells called 'neurocytes'. They are surrounded by a neuropil-like matrix. Lower panel: When stained immunohistochemically with an antibody against NeuN, a neuronal marker, both cell types are intensely positive (arrow, ganglion cell). (Original magnification 400× on both images. Photomicrographs courtesy of Dr. S. Albrecht, Dept. of Pathology, Montreal Children's Hospital.)

Postoperatively, he became seizure free and is no longer taking any antiepileptic medications. His overall behavioral functioning after surgery was significantly improved. He also showed considerable progress in his cognitive development, both verbal and nonverbal. However, he developed diabetes insipidus requiring desmopressin (DDAVP).

Histopathological analysis

Histological examination of the surgical specimens revealed a disorganized mixture of scattered large, neurons similar to those commonly found in the normal tuber cinerium. These mature hypothalamic neurons were interspersed with clusters of neurocytoid cells with round, monotonous nuclei and clear cytoplasm (Figure 162.3). These cells stained intensely for NeuN, a marker for mature neurons, and were surrounded by a fine fibrillary matrix positive for synaptophysin immunostaining. Immunocytochemistry with GFAP showed scanty astrocytes and oligodendrocytes without neoplastic differentiation. No mitotic figures were seen with absence of MIB1 positivity. There was no evidence of microvascular proliferation or necrosis.

162 Surgery in a patient with focal epilepsy and dual pathology

N Foldvary-Schaefer

Clinical history and examination

LK is a 53-year-old right-handed woman with seizures since the age of 13 months. She was the full-term product of a normal pregnancy, labor and delivery. She had a generalized motor seizure of unknown duration at 13 months of life without fever. Her mother was told she had 'injured a vein on the right side of her brain'. She developed recurrent afebrile seizures in childhood, beginning with nausea often accompanied by a sensation ascending into her neck and a feeling of having a 'lump in her throat'. This was followed by an arrest of activity with unresponsiveness, staring and drawing up of the left arm, occurring 15–20 times per month. Isolated auras occurred over a dozen times per day. Generalized motor seizures occurred in the order of once per year and she had one episode of generalized convulsive status epilepticus and two episodes of nonconvulsive status epilepticus in the two years prior to presentation. Seizures proved resistant to a variety of antiepileptic drugs in monotherapy and polytherapy including phenobarbital, mysoline, phenytoin, valproic acid, carbamazepine, gabapentin, felbamate, topiramate, lamotrigine, oxcarbazepine and levetiracetam.

Her past medical history was positive for hypertension, depression and viral myocarditis. She was married with two adult children. She did not drive. She had 12 years of education and was last employed part-time for a medical answering service five years prior.

The neurological examination revealed poor short-term memory, slow response time and bilateral gaze-evoked nystagmus. The gait was wide-based and she was unable to tandem.

Presurgical noninvasive epilepsy monitoring unit evaluation

Noninvasive video-EEG was performed using the 10–20 system electrode placements and additional anterior temporal scalp electrodes. The interictal EEG revealed intermittent slowing in the right temporo-parietal region (Figure 162.1a). Rare sharp transients were seen in the right temporal region but no definite epileptiform discharges were recorded (Figure 162.1b).

Two auras and three seizures were recorded. Auras were described as a sensation of nausea ascending to her neck. Seizures began with her typical aura evolving to staring, unresponsive and subtle oral automatisms (repetitive swallowing) during which time the patient continued to speak and follow commands. During this phase, the left arm began to assume a dystonic posture by drawing up repeatedly, each time in a nonsustained fashion. All seizures were secondarily generalized with more prominent clonus on the left side. In one seizure, this was preceded by left face clonic activity.

The seizure classification was: abdominal aura → right hemisphere automotor seizure → left face clonic seizure → generalized asymmetric clonic seizure.

The video illustrates the following features:

- The patient notified her husband at the time of her aura and described it as nausea ascending to the neck.
- Several seconds later, she had repetitive swallowing movements but continued to speak, name an object and follow commands. During this time, the left arm drew up toward the chest repeatedly, but was not sustained.
- This evolved to left face clonic activity that was prolonged.
- The final phase is a generalized clonic seizure in which the clonus is asymmetric, initially restricted to the left face and arm. Toward the end of the seizure, the right arm develops clonus while the left arm becomes extended.

Auras were not accompanied by discernable EEG change. Seizures were accompanied by right hemispheric rhythmic delta, maximal in the temporal region, beginning 8 to 32 seconds after clinical onset (Figure 162.2a, b). This pattern later spread to the left hemisphere and did not evolve in frequency (Figure 162.2c).

Neuroimaging

High-resolution MRI demonstrated slight asymmetry of the head and body of the hippocampal formations with the right being smaller than the left on T1-weighted coronal images (Figure 162.3A). Increased signal on the FLAIR sequence was observed in the body and tail of the right hippocampal formation (Figure 162.3B). An area of susceptibility artifact (Figure 162. 3D, arrow) was observed on the T2-weighted images in the right parietal region in the area of the angular gyrus, thought to represent an area of prior hemorrhage or occult arterial venous malformation. Corresponding to this area on the T1-weighted images, the gyrus was somewhat small, although the cortical mantle was thought to be normal in thickness (Figure 162.3C).

(a) (b)

(c) (d)

Figure 162.3 High-resolution MRI demonstrating mild right hippocampal atrophy (a) and increased signal intensity (b). An area of susceptibility artifact in the right lateral parietal lobe in the region of the angular gyrus (d, arrow) is seen on the T2-weighted image, thought to represent an area of prior hemorrhage or occult arterial venous malformation. Corresponding to this area on the T1-weighted image (c), the gyrus is somewhat small, although the cortical mantle is normal in thickness.

Neuropsychological testing

Neuropsychologicical testing revealed low-average general intellectual functions (Full Scale IQ: 91; Verbal Comprehension Index 81; Perceptual Organization Index 81; and Processing Speed Index 76). On tests of higher cognitive functioning, the patient was mildly impaired on a measure of visual search and ability to follow sequential procedures and a more complex task of selective attention. She was moderately perseverative on the Wisconsin Card Sorting Test and had some difficulty in both generating and maintaining problem-solving strategies. Measures of language functions were average, with the exception of markedly constricted verbal fluency and initiation and impaired sentence repetition. Oral and expressive reading skills were in the average and high average ranges, respectively. In contrast, math calculation skills were in the low average range. There was no evidence of significant visuo-constructional dyspraxia or spatial disorientation. Fine motor speed was normal bilaterally.

The patient was administered the Wechsler Memory Scale-III to assess learning and memory. Her overall span or Working Memory was constricted and in the borderline range (79). Her Immediate Memory Index score was 80 with a 17-point discrepancy between the Auditory Immediate Memory Index (92) and Visual Immediate Memory Index (75). Her delayed General Memory Index was in the borderline range (74) with a significant 33-point discrepancy between her Auditory and Visual Delayed Memory Index scores (92 versus 59, respectively).

Her score on the Beck Depression Inventory was 18, indicating a mild degree of affective distress.

Intracarotid amobarbital procedure

An intracarotid amobarbital procedure (IAP) was performed with bilateral injections of 200 mg and 175 mg in the left and right internal carotid arteries, respectively (the higher injection was required to produce an adequate hemiparesis). Both injections filled the ipsilateral ACA and MCA; limited crossover to the contralateral ACA was observed following the right injection.

The first verbal response was 03:45 minutes following the left injection and 00:00 minutes following the right injection, supporting left hemisphere language representation. Memory was impaired in the right hemisphere (retention score 44% after the left injection) and better in the left hemisphere (retention score 69% after the right injection). The pretest memory score was 100%. No abnormalities were identified on angiography.

Summary of presurgical evaluation and surgical plan

The MRI suggested the presence of dual pathology with a possible vascular malformation or remote hemorrhage in the right inferior parietal lobe and mild atrophy and increased signal intensity in the ipsilateral hippocampal formation, suggestive of hippocampal sclerosis. The seizure semiology (abdominal aura → right hemisphere automotor seizure → left face clonic → generalized clonic seizure) is consistent with right mesial temporal seizure origin. The interictal EEG finding of intermittent right temporo-parietal slowing is supportive of dysfunction in this area of the brain.

Findings on neuropsychological testing reflected some mild, fairly generalized neurocognitive deficits, although she manifested a relatively striking and circumscribed pattern of memory deficit for visual material, suggesting significant involvement of the right temporal region. She was judged to be limited risk for neurocognitive morbidity with respect to visual memory should she undergo a right temporal resection. The IAP findings were consistent with the neuropsychological testing, demonstrating impaired memory in the right (nondominant) hemisphere.

However, the lack of risk factors for epilepsy and absence of localizing epileptiform features on the ictal and interictal noninvasive EEG were somewhat unusual for isolated mesial temporal lobe epilepsy. On the other hand, parietal lobe epilepsy may produce poorly-localized seizures and a paucity of interictal discharges on noninvasive EEG, as seen in this case. Taken together, it was the recommendation of the Patient Management Conference to proceed with a subdural grid evaluation to better define the epileptogenic zone and map eloquent cortex.

Invasive evaluation

Subdural electrodes were placed over the right lateral temporo-parieto-occipital region (A plate – 8 × 6), the right temporal pole and inferior frontal gyrus (B plate – 4 × 4) and the anterior and posterior basal temporal surface (C and D plate, respectively – 2 × 6) as shown in Figure 162.4a.

Interictal spikes were seen very frequently (1 to 10 per 10-second epoch) in the mesial part of the C plate (contacts 7-1 > 2-8) representing 80% of interictal discharges (Figure 162.4a–b). Less frequent independent spikes were seen in the A plate (contacts 8, 9, 12, 13, 14, and 15), B plate (contacts 1, 5, and 6), C plate (contacts 3, 4, 9, and 10) and D plate (contacts 3, 4, 9, and 10). Spikes were observed at these locations every 1 to 2 minutes, each representing 5% of interictal discharges. In addition, low voltage repetitive spikes were seen nearly continuously in the anterior aspect of the parietal lesion involving contacts 28, 29, 36, 37, 38, 44, and 45 of the A plate (Figure 162.4c).

Eleven auras and 13 seizures were recorded over 10 days of monitoring. Seizure symptomatology was similar to that of the noninvasive evaluation (abdominal aura → right hemisphere automotor seizure). In two seizures, this evolved to left face and arm clonic activity and then to extension of the left and flexion of the right arm (sign of four) during the initial phase of the generalized motor seizure.

The first three auras, recorded during ongoing antiepileptic drug therapy, were not associated with EEG change. The ictal EEG was stereotyped for subsequent auras and clinical seizures and EEG onset preceded clinical onset by 10 to 76 seconds. EEG onset was characterized by low voltage fast activity appearing at the most mesial temporal contacts on the C plate (1, 7) as shown in Figure 162.5a. This pattern gradually spread to adjacent electrodes on the C plate (2, 8) and later to the inferolateral temporal lobe as shown in Figure 162.5b (arrows) after which the seizure spread more posteriorly.

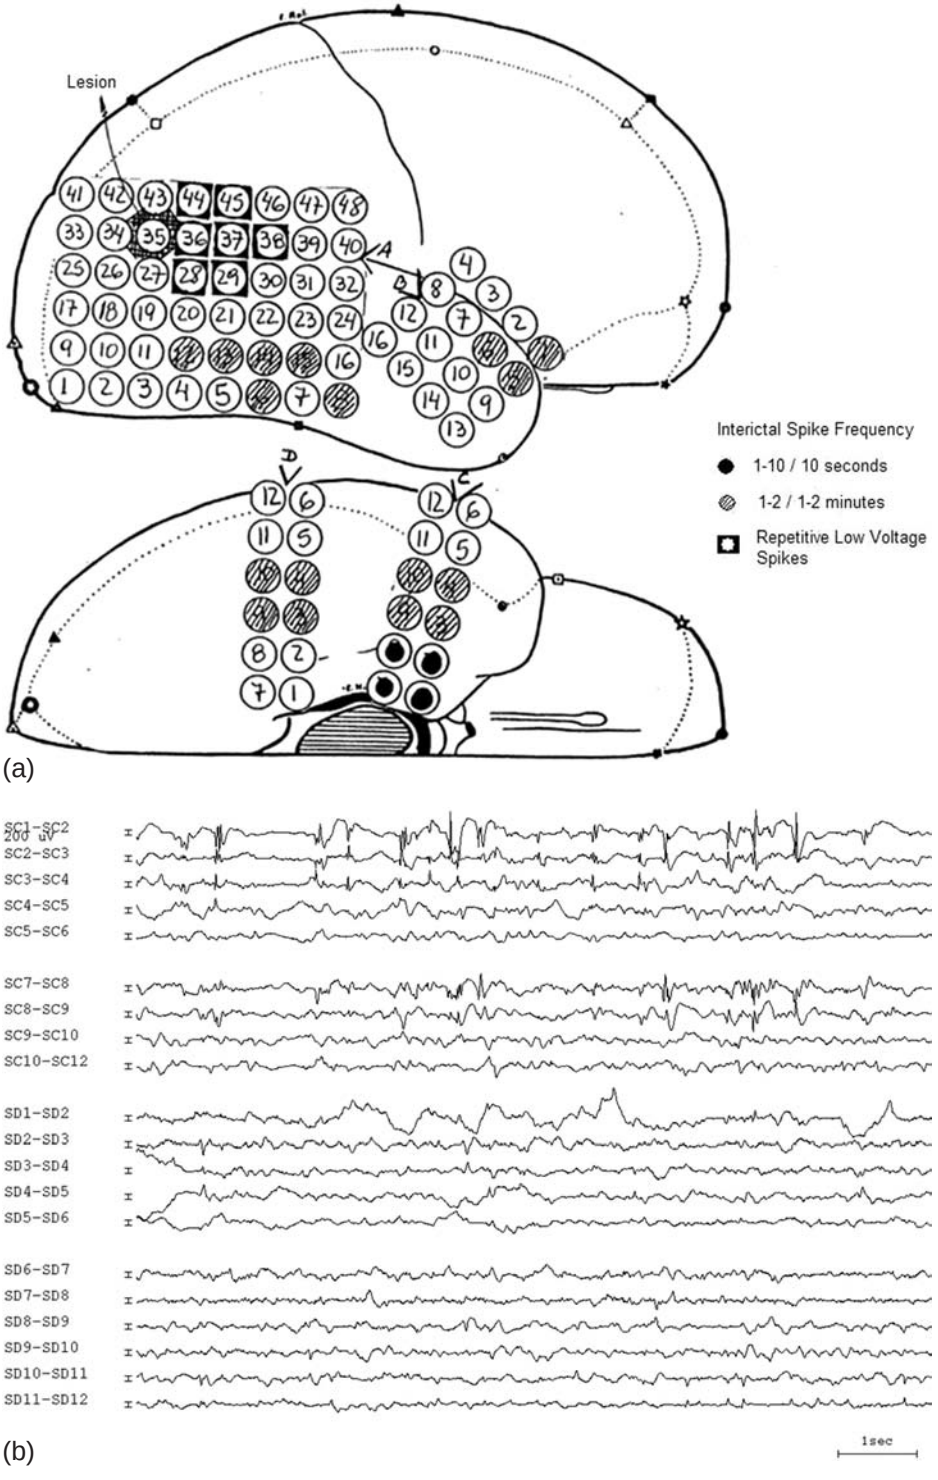

Figure 162.4 Invasive map showing electrode placement over the right lateral temporo-parieto-occipital region (A plate), temporal pole and inferior frontal gyrus (B plate) and mesiobasal temporal surface (C and D plates) and distribution of the various interictal populations (a). The most frequent spikes were recorded from the most mesial contacts on the inferior temporal strips at electrode contacts C1 and C7 (b).

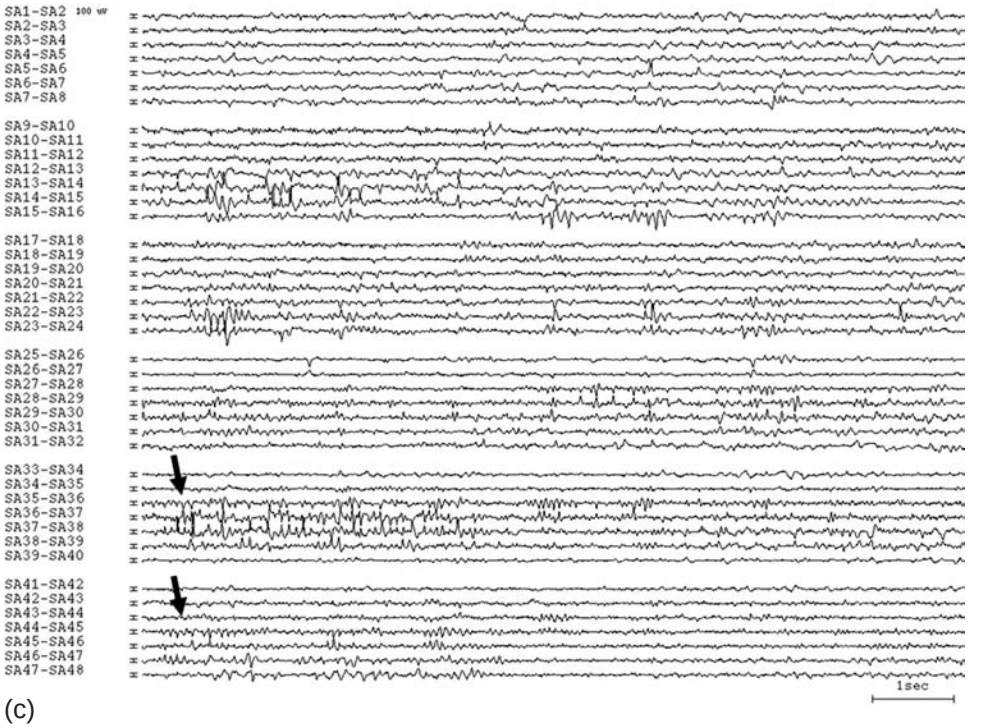

(c)

Figure 162.4 cont'd Low voltage fast activity was recorded from electrodes corresponding to the anterior aspect of the parietal lesion (c).

Electrical stimulation of the four posterior rows of the A plate did not identify any eloquent areas. The patient was able to read, write and recognize pictures during the stimulation and no seizures were produced.

Summary of invasive evaluation and surgical plan

The subdural grid evaluation gives evidence of a large irritative zone involving the temporal lobe both mesial and lateral (although the mesial temporal region was most active) and the inferior parietal lobe near the MRI lesion. However, seizures arise from the anterior part of the right mesial temporal lobe, spreading relatively late to the parietal region. The seizure semiology suggests right mesial temporal origin. As a result of this evaluation, an anterior temporal resection including mesial temporal structures and resection of the parietal lesion was recommended. The patient was judged to be at no significant risk for neurological deficits related to the proposed resection.

Surgical procedure and outcome

The patient was taken to the operating room where the right temporoparietal craniotomy flap was reopened and subdural electrodes removed. Subsequently, a 3.5 cm lateral temporal resection was performed. The inferior temporal horn was then opened and the right amygdala and hippocampus were resected with microsurgical techniques. Attention was then directed to the posterior aspect of the incision, where there was a 2.2 cm calcified lesion in the right parietal lobe at the posterior aspect of the sylvian fissure. This was resected in its entirety using bipolar technique and microdissection.

The pathological findings are shown in Figure 162.6. The hippocampal specimen demonstrated focal neuronal loss and gliosis consistent with hippocampal sclerosis (Figure 162.6a). The parietal specimen revealed abnormal proliferation of blood vessels associated with dystrophic calcification consistent with a vascular malformation (Figure 162.6b). The temporal neocortex revealed focal leptomeningeal chronic inflammation and gliosis. The amygdalar specimen was relatively unremarkable.

During the first 2 years postoperatively, auras were reduced to approximately two per day and were less intense, although similar in character. She was otherwise seizure free. Thereafter, seizures recurred gradually increasing to approximately four per month despite toxic antiepileptic drug levels. Seizures were similar in character to those described preoperatively.

The postoperative MRI is shown in Figure 162.7. There is a parenchymal defect in the right temporal pole and resection of the amygdala and head and body of the hippocampal formation (A, C). Another parenchymal defect is noted in the region of the right angular gyrus (B, C) where the calcified lesion was resected.

Neuropsychology was repeated 6 months postoperatively. Findings are compared with preoperative scores in the table below (Table 162.1.) The 6-month postoperative assessment indicated some deterioration in general perceptual organization abilities and nonverbal fluency, in addition to less efficient higher executive functions. However, her performance on other neuropsychological measures, including verbal and visuospatial memory tasks, improved. Antiepileptic drug

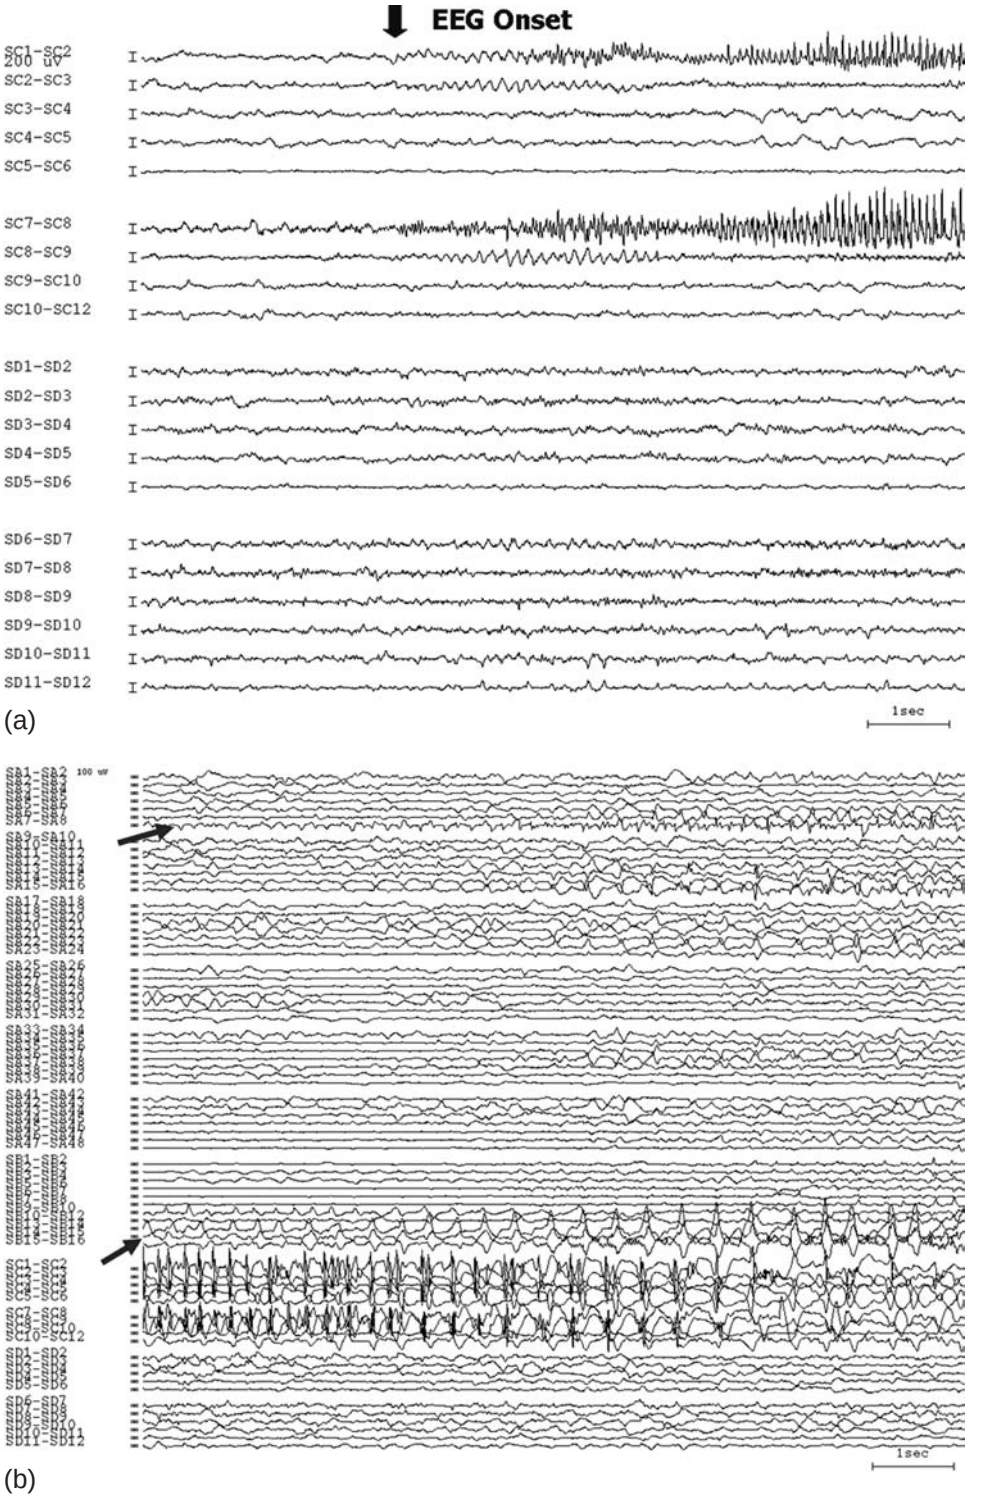

Figure 162.5 Ictal invasive EEG recordings showing the ictal onset (a) with low voltage fast activity at electrode contacts C1 and C7 suggesting mesial temporal origin. Approximately 20 seconds later, the pattern spread to the inferolateral temporal lobe on the A and B plates and as indicated by the arrows in (b).

Table 162.1 Neuropsychological test scores

Measure	Preoperative	Postoperative
Verbal comprehension index	91	91
Perceptual organization index	91	78
Processing speed index	76	86
Working memory	79	85
Immediate memory	80	100
Auditory immediate	92	102
Visual immediate	75	97
Delayed general memory	94	96
Auditory delayed	92	111
Visual delayed	59	88

therapy (carbamazepine and topiramate) and other medications were similar at both testing intervals.

Noninvasive EEG monitoring was repeated 5 years after surgery to evaluate for reoperation. This evaluation revealed continuous slowing and frequent interictal discharges in the right temporal region (maximum T8>P8) as shown in Figure 162.8. Six seizures were recorded, characterized by an aura of nausea evolving to staring and unresponsiveness with subtle oral and manual automatisms. Seizure semiology was similar to that recorded preoperatively. All seizures were localized to the right temporal region, maximum at T8 (Figure 162.9), suggestive of seizure origin from the residual temporal lobe. The patient is considering whether she would like to proceed with further surgical options.

Conclusion

This case illustrates some of the challenges in the surgical treatment of patients with dual pathology. Many of the features of this case, including seizure semiology, MRI and neuropsychological testing, strongly implicated an epileptogenic zone in the mesial temporal structures. However, the noninvasive EEG did not provide supportive localization

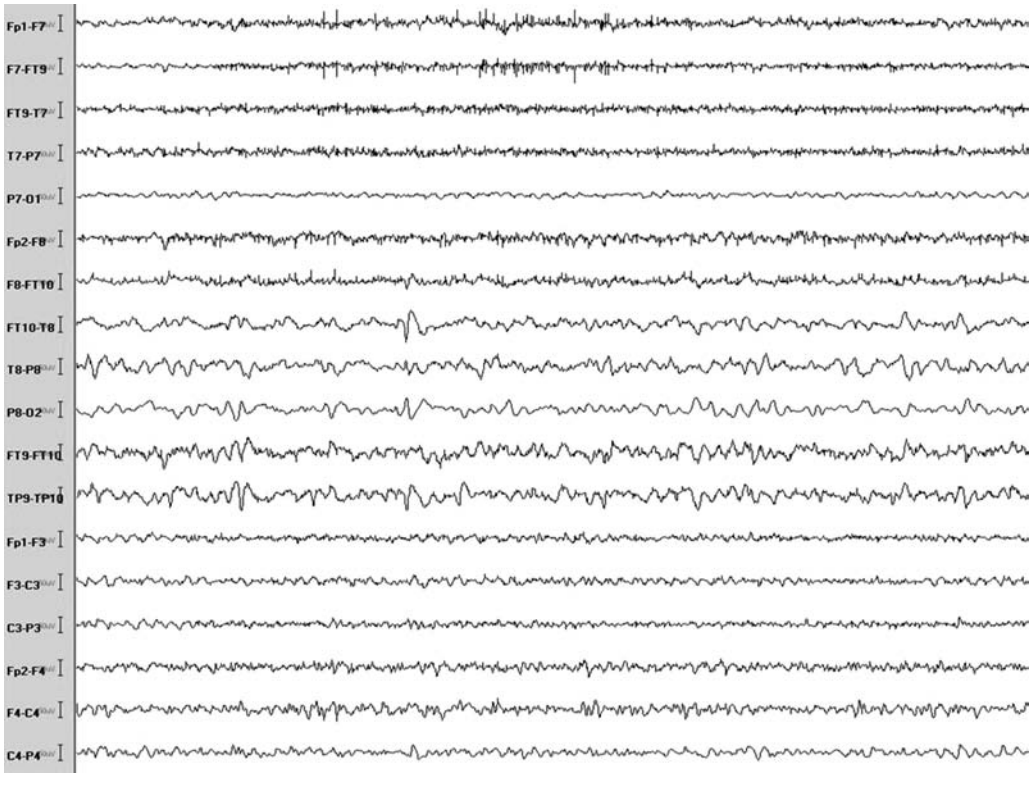

Figure 162.8 Postoperative noninvasive monitoring revealed continuous slowing and frequent interictal discharges in the right temporal region.

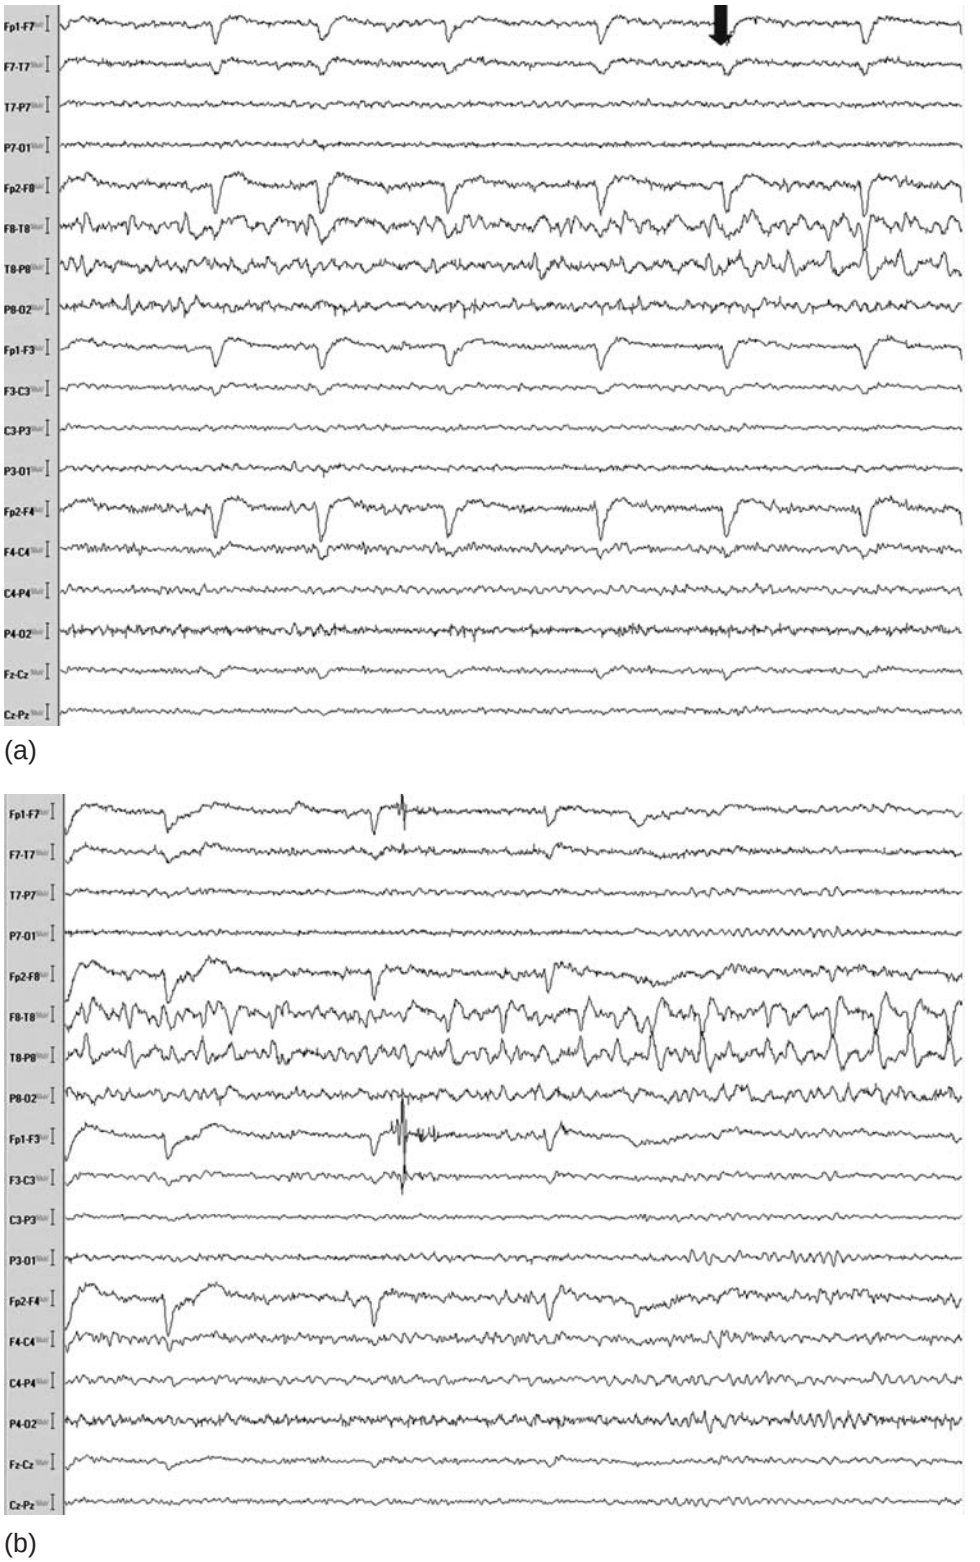

Figure 162.9 Postoperative ictal EEG of a habitual seizure characterized by nausea evolving to an automotor seizure. EEG onset (arrow) begins with repetitive spiking in the right temporal region, maximum at T8 (a) evolving in the same distribution on the next 10-second epoch (b). This pattern is suggestive of seizure origin in the residual temporal lobe.

and in fact, suggested the possibility that seizures may be arising from the lesion in the right parietal lobe and propagating to the temporal lobe. Findings of the invasive evaluation helped to clarify that the epileptogenic zone was in the temporal lobe, in the face of a much larger irritative zone. The planned procedure was to include both lesions. The unfavorable seizure outcome likely relates to an incomplete resection of the lateral and basal temporal lobe based on postoperative noninvasive EEG recordings. In settings such as this, the goal of the planned surgery is to perform a complete resection of both lesions and surrounding irritative tissue, sparing eloquent areas.

SECTION 22

Appendices

163 Essentials for the establishment of an epilepsy surgery program

MG Campos, HB Pomata, MA Vanegas, and AC Sakamoto

Introduction

This chapter presents small differences compared to the last version published in 2001[1] because there has not been sufficient progress in technology to improve the results of epilepsy surgery, nor was the introduction of new antiepileptic drugs (AEDs) able to produce changes in the control of seizures in surgical candidates. In this context, the main new issues to consider are the following: first, the fact that epilepsy surgery programs have had great development worldwide in recent years[2–4] and, second, that resective epilepsy surgery has succeeded in establishing a good seizure outcome. A prospective and randomized study of temporal lobe resection showed a result of 58% of seizure-free patients 1 year after surgery.[5] In observational studies, 41–56% of patients were seizure free within 10 years of follow-up.[6,7] These results are better than those obtained by the best new AEDs (see Chapter 32).

In the adult population, at least 20% of epilepsy patients have uncontrolled seizures with rational AEDs.[8–10] This percentage is even greater in children.[11,12] On average, approximately 10% of the whole epileptic population could be considered good candidates for epilepsy surgery. However, less than 2–4% of potential candidates are actually surgically treated in developed countries like Germany and the United States. The number of patients with refractory epilepsy without surgical alternatives is higher in developing countries.[1]

An adequate presurgical selection is basic to optimize the studies.[13–16] In a multicenter study of epilepsy surgery, only 30% of the patients who had undergone presurgical evaluations for resective epilepsy surgery were not ultimately subjected to this form of surgery. The abnormal MRI and consistent localized EEG findings were associated with having undergone surgery.[17] The success of epilepsy surgery depends upon the early identification of potential surgical candidates as well as the selection from this group of ideal candidates destined to have a postoperative seizure-free outcome.[6,7,18,19]

Epilepsy surgery can be classified as curative, when the goal is seizure-free patients, or palliative, when the target is to decrease the frequency of seizures. Diverse surgical procedures – such as disconnections, subpial transections, and comissurotomies – can reduce the seizures. Usually, the intent of curative surgery contemplates a resection of tissue; this procedure is a definitive and nonreversible surgery, with risks similar to those of other neurosurgical interventions. Nevertheless, the mortality and morbidity rates of epilepsy surgery are lower compared with other intracranial neurosurgical procedures.[5–7,18–20]

Epileptogenic zone (EZ) is defined as the minimum amount of tissue that must be excerpted to produce seizure freedom. Success – meaning seizure-free patients – depends on the correct resection of the EZ and good assessment of the eloquent brain near the EZ (language areas, motor cortex, sensory cortex, etc.). False localization of the EZ can lead to dramatic and adverse consequences such as: (a) persistence of epileptic seizures due to the incomplete or erroneous resection of the EZ, and (b) new neurological deficits due to resection of 'normal' and functionally eloquent cortex. Therefore, prevention of postoperative neurological deficits and reduction of morbidity to a minimum level involve careful and extensive presurgical testing and solid knowledge of the functional anatomy of brain cortical areas.

Presurgical evaluation and surgery require a well-trained multidisciplinary team of specialists in epileptology, clinical neurophysiology, neurosurgery, neuroradiology, neuranesthesiology, and intensive care medicine as well as pediatry, psychiatry, neuropathology, psychology, and other fields, since all risks need to be carefully weighed and only minor new neurological deficits should be acceptable.[1,15,21,22]

The low cost of the new methodologies is reducing the technological 'gap' between developed and developing regions and will certainly help the establishment of new epilepsy surgery centers in the whole world.[2–4] Based on the previous information, it is thus essential to establish more epilepsy surgical programs in developed countries and to ensure their creation in developing countries.

In order to perform a rational evaluation and treatment of patients with intractable epilepsy, we elaborated recommendations to establish two different levels of epilepsy surgical centers. One considers the *absolute minimum requirements* for an entry-level or *basic epilepsy surgery center* (BESC) while the other refers to the ideal conditions and qualifications or the *gold standard* for an *advanced or referral epilepsy surgery center* (AESC) (Table 163.1) nevertheless, these considerations do not negate the existence of the many centers around the world that remain between both categories.

Table 163.1 Minimum requirements for basic and advanced epilepsy surgery centers

	Basic epilepsy surgery center	Advanced epilepsy surgery center
Patients	Children Adolescents Adults	Infants Children Adolescents Adults
Types of surgeries	Temporal lobectomies Extratemporal (extralimbic) lesional resections, excluding eloquentareas Callosotomies	Temporal lobectomies Extratemporal (extralimbic) lesional/ nonlesional resections, including eloquent cortex Functional hemispherectomies, hemispherotomies Callosotomies Multiple subpial transactions Special surgical techniques (vagus nerve stimulation)
Video-EEG monitoring	Digital EEG – minimum of 32 channels 24-hours monitoring Noninvasive monitoring (additional + sphenoidal 'Less invasive' monitoring (foramen ovale)	Digital EEG – minimum of 64 channels 24-hours monitoring Noninvasive monitoring (additional + sphenoidal Invasive monitoring (foramen ovale, subdural strips and grids, epidural electrodes, depth electrodes)
Structural imaging	High-resolution 1.5-T equipment (0.5–1.0 T acceptable)	High-resolution 1.5-T equipment
Advance MRI techniques[a]		MR volumetric quantification MR spectroscopy Functional MRI T2 relaxometry 3D reconstruction Curvilinear reconstruction Coregistration and experimental techniques
Functional Imaging[b]	SPECT (optional study)	SPECT (interictal/ictal studies) PET MSI MEG
Electrocorticography	Intraoperative (optional)	Intraoperative
Cortical stimulation	Intraoperative (optional)	Intraoperative Extraoperative
Neuropsychological tests	Children	Children
Wada test	Adults Optional	Adults Yes
AED monitoring	Yes	Yes

[a] MR, magnetic resonance; 3D, three-dimensional; MEG, magnetoencephalography.
[b] SPECT, single-photon emission computerized tomography; PET, positron emission tomography; MRSI, magnetic resonance spectroscopic imaging.

Epilepsy surgical programs

Epilepsy surgical programs must always be part of a comprehensive epilepsy program and should not become an isolated issue in a medical institution.

Diffusion of epilepsy surgical programs to the community

First, it should be emphasized that – due to the particular characteristics of developing countries – the design of epilepsy surgery programs must include medical and social education for the communities which are far away from the primary epilepsy centers, as part of their pre-established tasks and budgetary considerations. This means that it is not reasonable to expect the personnel in charge of public health to be aware of, and able to appreciate the surgical options for refractory epilepsy patients. The surgical programs themselves must research and design the mechanisms and resources for diffusion of this option, which may include cooperation and coordination with the national organization in charge of primary healthcare. To cite an example, in Mexico, the Epilepsy Priority Program, which is a Federal State-funded organization and is in charge of primary epilepsy care, has been instrumental in coordinating the surgical program's efforts to discover knowledge of the surgical option. Contrary to what happens in Europe and North America, patients in developing countries usually do not independently seek other options for treatment due to their limited access to the Internet and health journals as well as the widespread fatalistic conception of disease as God's will. Thus, recognition of other modalities or alternatives for treatment depends solely on the primary medical caregivers, whose information and training must fall under the responsibility of the surgical programs.

Selection of candidates for presurgical evaluation

All patients with medically intractable epilepsy should be viewed as potential candidates for surgery. The exceptions to this rule include patients with generalized cryptogenic/ idiopathic epilepsies, and patients with epilepsy associated with progressive neurological diseases (except for Rasmussen's encephalitis). Even children initially classified as having

benign focal epilepsy, if not satisfactorily controlled, should be fully investigated, since some of them may eventually be found to have symptomatic focal epilepsy associated, for example, with perirolandic cortical dysplasia.

Definition of refractory

There is not a determinate seizure frequency to define refractory epilepsy. Seizures must interfere with the patients' quality of life (QOL) and fail to be controlled by at least two first line AEDs trials in monotherapy at the maximum tolerated doses. Usually a minimum of 2 years of medical treatment is carried out in most of the adult cases. The resistance to pharmacotherapy has to be established by a neurologist with a special training in the treatment of the epilepsies.

Establishment of patient's commitment

Presurgical evaluation will be offered to patients who are refractory to medical treatment and who are considered to be potential candidates for epilepsy surgery. Patients and their family will be counseled about the nature and risks of the various tests to be performed during the presurgical evaluation, as well as the postsurgical seizure outcome and potential morbidity and mortality risks of the surgical procedure. Patients will be asked to sign an informed consent. Only patients who have the intention to complete the presurgical evaluation will be entered in the protocol. This, however, does not preclude the patients' right to stop the evaluation at any time or to refuse surgery at the completion of the presurgical evaluation.

Special groups

Temporal lobe epilepsy (TLE)

TLE associated with mesial temporal sclerosis is the most common and intractable type of epilepsy. Also, unilateral medial temporal lobe resections have the best postsurgical seizure outcome.[5,20,22–25] In adults, 70–80% of the epilepsy resective surgeries are performed in temporal lobe[1,17,24,25] while around 80% of these patients do not need invasive presurgical evaluation, which means that approximately 60% of all the resective epilepsy surgeries can be performed in a BESC. We have recommendations of exclusion criteria for TLE in BESC, but some of these patients can be evaluated in AESCs (Table 163.2).

Table 163.2 Recommendations of exclusion criteria for temporal lobe epilepsy in basic epilepsy surgery centers

1 – Controlled epilepsy.
2 – Progressive medical disease.
3 – Patient or family who is not interested in surgery.
4 – Uncertain ictal onsets on scalp EEG.*
5 – Language involved in epileptogenic zone.*
6 – Normal MRI.*
7 – Memory ipsilateral to the mesial temporal sclerosis.*

* The last four exclusion criteria are not meant for advanced epilepsy surgical centers.

Extratemporal lobe epilepsy (ETLE)

ETLE is associated with several specific problems with respect to epilepsy surgery. Many times, the origins of seizures may not be limited to a circumscribed anatomic region and seizures can be widespread within the same lobe or hemisphere and even on the contralateral side. Another problem is the eloquent cortex (motor, sensory, language, etc.), which could surround or be part of the EZ. Several patients with ETLE need precise mapping of the eloquent cortex through invasive presurgical evaluation with subdural electrodes or complex functional techniques; these cases must be treated at AESCs. Extralimbic epilepsies (neocortical extratemporal and temporal) associated with focal lesion, outlying to the eloquent cortex, can generally be properly evaluated and treated at BESCs and AESCs.[26,27]

Children with intractable epilepsy

The epilepsy surgery must be considered very soon (6–12 months) in children with uncontrolled seizures, because many brain functions are affected with refractory epilepsy – such as the brain maturation, cognitive development, brain plasticity, etc. Special attention should be given to infants and younger children with catastrophic epilepsy, who require a high degree of selection to begin presurgical study, which should define cortical abnormalities and normal function, type of surgery, etc. We believe that genuine pediatric epilepsy centers should be considered as AESCs, especially for babies and young children, and all members of their team ought to fulfill the established standards for AESCs. Older children can be operated at BESCs, when they have diagnostics and need surgical approaches similar to those of adults.

Presurgical evaluation

Presurgical evaluation is a series of tests whose main objective is to localize the EZ. No single test provides definitive information,[1,14,15,22,28] which is the reason why convergence between different tests is essential to properly select the candidates and reach a better definition of the surgical strategy. To this purpose, presurgical evaluation includes several modalities of different features.

Imaging

Structural imaging

Magnetic resonance imaging (MRI)

Usually, brain MRI is performed before the video-EEG monitoring. MRI is the most important structural test of the presurgical evaluation and should be considered as absolutely essential to the process of identifying candidates for surgery. MRI will be performed with at least a 0.5 Tesla machine (but ideally with a high resolution 1.5 Tesla machine). The MRI must always be guided by the clinical features; for example, when TLE is suspected, both axial and coronal 2 mm cuts (and ideally 1 mm) will be performed in the hippocampus axis (30° from cranial basis). Sequences will include T1, T1-inversion recovery (IR), T2, and fluid attenuance inversion recovery (FLAIR).

For AESCs, high resolution MRI is absolutely essential. AESCs need also to have the capability to perform one or more of the various modalities of advanced MRI techniques, such as volumetric quantification, spectroscopy, T2 relaxometry, 3D reconstruction, curvilinear reconstruction, functional MRI (fMRI), co-registration techniques, and experimental methodologies. MRI can be repeated according to the video-EEG results.

Computerized tomography (CT)

CT can be perform in developing countries, where parasitic infections are endemic, in order to detect calcified lesions.

Functional imaging

We recommend these evaluations according to the video-EEG findings.

Single-photon emission computerized tomography (SPECT)

Currently, SPECT is available mostly in BESCs but is not obligatory in these centers. We need two examinations, interictal and ictal; the second is usually performed during the video-EEG monitoring, but the injection time is fundamental.

Positron emission tomography (PET)

This is a metabolic exam which should be performed in AESCs.

Inpatient video-electroencephalographic monitoring

Noninvasive studies

Continuous scalp video-electroencephalographic (video-EEG) monitoring will be performed with sphenoidal or at least anterior temporal electrodes using digital systems with a minimum of 32 channels. EEG data will include analysis of interictal nonepileptic abnormalities, interictal epileptiform activity and ictal activity. Patients and family members will be asked to review the recorded seizures to insure that their typical seizures were captured during the monitoring study. The interictal and ictal activity should be concordant and demonstrate a seizure focus. In patients with TLE, only those with hippocampal sclerosis or a lesion in anterior temporal region and concordant interictal and ictal data will be considered for surgery in BESC. EEG data must be concordant with neuroimaging and neuropsychological findings. To facilitate seizures, the AED dose will be reduced at the discretion of the treating neurologist.

Neuropsychological evaluation

The neuropsychological evaluation of adults will include a determination of full scale, verbal and performance intellectual quotients (IQs), measures of concentration and language functions, as well as the evaluation of immediate and delayed visual and verbal memory processing. This evaluation will be performed with the patient at full doses of AEDs and with a minimum seizure-free interval of one day. The main goal of the neuropsychological study will be to identify those patients at risk for postsurgical memory deficits.

In children and handicapped patients, studies will be tailored to the patients' cognitive status. Wada Test (Intracarotid amobarbital test) is necessary at AESCs. Indications and technical aspects are discussed elsewhere in this book.

Psychiatric evaluation

A formal presurgical evaluation must be performed in all patients, in order to diagnose acute psychiatric disease. Depressive states or other comorbidities should be diagnosed and treated before the surgery.

Epilepsy conference

When the above studies are completed, the patient data will be discussed in an interdisciplinary conference attended by the neurologist (epileptologist), neurophysiologist, neuroradiologist, psychiatrist, neuropsychologist, and neurosurgeon as well as the nurses and EEG technicians. At the end of the conference, patient and family will be given a recommendation to proceed (or not) with a surgery. The probabilities of seizure freedom will be estimated together with the risks of the surgical procedure, including the risks of memory deficits and other potential morbidities that will be explained in details.

Invasive studies (only in AESC)

Studies with invasive video-EEG monitoring will be considered in the following cases: (1) patients with discordant interictal and ictal data; (2) patients with discordant EEG and MRI and/or neuropsychological data; (3) patients whose EZ is suspected to override eloquent cortex.

Surgery (second hospitalization)

A neurosurgeon with special training in epilepsy surgery will perform the procedure. The main goal of the surgery will be to achieve a complete resection of the EZ sparing eloquent areas as well as normal tissue. Whenever possible, the neurosurgeon will attempt to make 'in-block resections' in order to provide temporal lobe tissue for neuropathologic analysis.

Neuropathology

A good neuropathology analysis of the surgical tissue is basic to determinate the type of lesion and evaluate the prognosis of the seizure control.

Follow-up

Outpatient visits with the neurologist will be scheduled postsurgically one month after surgery and then every 3–6 months during the first year and thereafter according to the patients' status. A postsurgical EEG and MRI will be performed not earlier than three months after surgery. Neuropsychological evaluation should be repeated at least 6 months postoperatively.

Other evaluations

It is strongly recommended that every center includes social evaluations in its protocol and planning of the rehabilitation and postoperative QOL of these patients, given their long-standing difficulties in coping with a chronic and handicapping condition such a medically intractable and severe epilepsy. It is felt that most of these patients, besides social problems, also face difficulties in interpersonal relationship within their nuclear family; for that reason, the practice of including a family therapist in some centers is encouraging. In terms of follow-up evaluations, epilepsy centers should be prepared to follow the QOL parameters. *Seizure-free patients are the target, but a best QOL for our patient is the main objective.*

Multiprofessional team

Epilepsy surgery is only possible through the laborious work of a highly qualified and dedicated multiprofessional team, including the following key personnel (Table 163.3).

Epileptologist

An experienced adult and/or pediatric epileptologist with training in presurgical methodologies is a key professional in the core team of the multidisciplinary group involved in the selection of candidates for epilepsy surgery. Epileptologists should be trained at an AESC, where the whole armamentarium of presurgical methodologies is available, and where the decision process regarding interpretation of presurgical data, indications for surgery, definition of surgical strategies, criteria, and the like are fully and clearly established. They should be board certified, or have equivalent qualifications in countries where this certification is not applied. BESCs should have an adult and/or a pediatric epileptologist, depending upon their surgical program (adult, pediatric, or both). However, it is recommended that AESCs have both fully trained adult and pediatric epileptologists. The minimum duration of training at an AESC is 1 year.

Clinical neurophysiologist

In most epilepsy centers, epileptologists are also fully qualified clinical neurophysiologists; otherwise, an experienced adult and/or pediatric clinical neurophysiologist is also essential to the multidisciplinary team. They should also be board certified (or the equivalent) and have comprehensive training in clinical neurophysiology methodologies, including EEG, video-EEG and evoked potentials. The qualifications are basically similar for BESCs and AESCs; however, clinical

Table 163.3 Minimum qualifications of epilepsy surgery center multiprofessional team

Key personnel	Basic epilepsy surgery center	Advanced epilepsy surgery center
Epileptologist	Board-certified neurologist (or equivalent qualification) with 1 year special of training in an AESC	Board-certified adult neurologist (or equivalent qualification) with 1 year of special training in an AESC Board-certified pediatric epileptologist (or equivalent qualification) with 1 year of special training in an AESC
Clinical neurophysiologist[a]	Board-certified clinical neurophysiologist (or equivalent qualification) with training in conventional EEG, evoked potentials, and video-EEG monitoring (should have at least 1 year of special training in an AESC)	Board-certified clinical neurophysiologist (or equivalent qualification) with training in conventional EEG, evoked potentials, and video-EEG monitoring (should have at least 1 year of special training in an AESC
Neurosurgeon	Board-certified neurosurgeon (or equivalent qualification) with 6 months of special training in an AESC)	Board-certified neurosurgeon (or equivalent qualification) with 12 months of special training in an AESC)
Neuropsychologist	Three months of special training in neuropsychological methologies in an AESC	Six months of special training in neuropsychological methologies in an AESC
Neuroradiologist[b]	Board-certified neuroradiologist (or equivalent qualification) ideally with 3 months of training in an AESC	Board-certified neurologist (or equivalent qualification) with special training in in advanced imaging techniques
Anesthesiologist	Board-certified anesthesiologist (or equivalent qualification) with experience in neuroanesthesiology	Board-certified neurologist (or equivalent qualification) with experience in neuroanesthesiology
Psychiastrist	Board-certified psychiatrist (or equivalent qualification)	Board-certified psychiatrist (or equivalent qualification)
Nurses	Preferentially trained in an AESC	Preferentially trained in an AESC
EEG technician	Preferentially trained in an AESC	Preferentially trained in an AESC
Other support personnel (social worker, psychologist, family therapist, etc.)	Integrated in the multidisciplinary team	Integrated in the multidisciplinary team

[a] In many centers, a neurologist is trained and board certified in both epileptology and neurophysiology.
[b] In selected centers, neurologists are trained and board certified in neuradiology.

neurophysiologists at AESCs need to be additionally trained in the interpretation of chronic invasive recordings.

Neurosurgeon

An experienced and board-certified neurosurgeon (or the equivalent) is also a key person on the team. It is recommended that surgeons working in a BESC have an additional 6 months of training in an AESC, and surgeons working in an AESC have at least 12 months of additional training in epilepsy surgery techniques.

Neuropsychologist

The requirements for neuropsychologists are similar for BESCs and AESCs. It is recommended that neuropsychologists involved in presurgical evaluation have a minimum of 3–6 months training in an AESC.

Neuroradiologist and nuclear medicine specialist

An experienced an board-certified neuroradiologist and nuclear medicine specialist (or the equivalent) are also essential to the multidisciplinary team, as structural and functional imaging become more and more essential and central to the decision process involved in the selection of candidates and the definition of surgical strategies. In addition, AESCs require professionals with special training in advanced imaging techniques.

Neuroanesthesiologist

An experienced and board-certified anesthesiologist (or the equivalent) is also an important professional in the multidisciplinary team, especially in those circumstances where intraoperative evaluations such as electrocorticography and cortical stimulation are employed.

Psychiatrist

As mentioned earlier, an experienced and board-certified psychiatrist (or the equivalent) should also be a member of the presurgical evaluation team, ideally evaluating all patients included in the program, or at least acting as a consultant in selected cases.

Neuropathology

A pathologist trained in neuropathology, hopefully with experience in neuropathology of epilepsies, will be responsible for the analysis of the surgical tissue.

Nurses and electroencephalography technicians

These multidisciplinary team members should be preferentially trained at an AESC, or be locally trained by the other members of the multidisciplinary team in all special issues involved in the care and evaluation of epileptic patients. Support personnel should be given courses on basic clinical epileptology, basic clinical neurophysiology, surgical techniques, assistance of patients during seizures, instrumentation, and the like. EEG technicians, especially, are strongly encouraged to have additional exposure or training at an AESC.

Other support personnel

Many other support personnel are welcomed to the multidisciplinary team, and should actually be fully integrated to the group. This is the case for social workers, clinical psychologists, family therapists, occupational therapists, phonoaudiologists, physiotherapists, and rehabilitation therapists.

Concluding remarks

The definition of two classes of epilepsy surgery centers, which represent each end of a spectrum of epilepsy surgery centers, fulfills two major objectives: (a) to define minimum requirements for a BESC, protecting patients from mismanagement of their unfortunate condition; and (b) to define the gold standard of AESC; this gives clear directions for each individual center to continuously improve its infrastructure and personnel. These two limits are obviously theoretical and somewhat arbitrary. Most centers would be situated in an intermediate position between these two ends of the spectrum. However, centers that do not fulfill the minimum requirements for a BESC should not be admitted by medical societies or government institutions, due to the risks of inadequate treatment.

Another important point is related to the multidisciplinary team involved in the activities of an epilepsy surgery center. In these days of major technological breakthroughs that make sophisticated methodologies less costly and more widely available, it is even more critical that multidisciplinary team members at all epilepsy surgery centers fulfill the minimum intellectual and technical qualifications of the professionals responsible for the implementation of these methodologies and interpretation of the data generated by them. Sensitive neuroimaging techniques frequently reveal one or more lesions. However, the epileptogenicity of each detected lesion must be documented before 'lesion-based epilepsy surgery' can be recommended. In other words, we must define what each lesion produces in terms of epileptic signs and symptoms before deciding on a surgical strategy. In this sense, the role of an experienced epileptologist/clinical neurophysiologist/neurosurgeon is absolutely essential. Such individuals are ultimately responsible for the correct interpretation of the *whole set of presurgical data*, and for the *development of the best surgical strategy for each individual patient*. The active participation of all other professionals is also essential in terms of the final results of the interventions, if one considers not only the narrow and simplistic view of seizure outcome, but also the global functioning and quality-of-life issues.

Finally, it is also important that professionals involved in AESCs be motivated to develop research in addition to their clinical work. It is important not only to perform well established techniques, but also to stimulate innovative ideas and to generate new knowledge in the field. These characteristics and this scenario are extremely important not only for the patients (our ultimate goal), but also for the training of the new generations of professionals entering the field of epilepsy surgery.

Final considerations especially for developing countries

Technology

When considering minimal technological requirement for establishing an epilepsy center in developing countries (MRI, video-EEG), every effort should be made not to remain behind and thus deprive patients of the best available techniques for detection and delimitation of epileptogenic tissue and coexistent morbidity. At the same time, the country's specific needs and economical situation should be kept in mind to avoid a total foreign dependency. It cannot be sufficiently stressed that budgetary considerations in terms of equipment acquisition must contemplate not only the initial but also the maintenance and operational costs. It has often happened that working equipment is replaced by state of the art technology, which is later very difficult to maintain.

Personnel (physician)

It might seem somewhat paradoxical, especially in countries where lowincome is not limited to the patients but extends to young professionals as well, to state that establishing a much needed epilepsy center requires integration of a multidisciplinary group of experienced and trained professionals, when there are practically no AESC in that country. Thus, it is our suggestion that all existing AESC must include a well-designed and certified training program. We suggest the integration of an ILAE task force to address the regulation and certification of training programs, specifically for neurosurgeons. Due to the vast surgical procedures available today and the need to tailor resections and techniques according to each individual case and evidence-based delimitation of epileptogenic tissue, we consider that a neurosurgeon's training experience in an AESC should last at least 12 months.

Motivation

It is absolutely essential that seeking clinical and quality-of-life improvement for medically refractory epilepsy patients be the thriving force shaping any surgical program. This might certainly sound redundant, but it is the moral and ethical obligation of epilepsy surgery specialist to ensure that establishment of epilepsy centers is devoid of economical, political or prestige seeking interests. As is the case in many chronic incapacitating diseases, the patients and their families are particularly prone to embrace false expectations, and no effort incurred in by the multidisciplinary team to explain the procedure and outcome probabilities is superfluous.

164 Classification of seizure outcome following epilepsy surgery

HG Wieser and K Schindler

Introduction

Any medical–and specifically any surgical–procedure may be beneficial to the patient or may cause harmful (side-)effects. Therefore, the decision to engage in any therapeutic action should be based upon thoroughly assessing risks and benefits. In addition, in these times of widespread forced savings in the public health care sector, physicians are more and more often faced with having to justify therapeutic measures from the point of view of cost-effectiveness. However, to be able to efficiently advise an individual patient about whether to undergo surgery for pharmaco-resistant epilepsy or to convince health care authorities to invest money in this kind of therapy we have to document its effectiveness. Thus, we need powerful tools to assess the outcome of epilepsy surgery. This is why in recent years so much effort has been put into developing classifications of seizure outcome following epilepsy surgery. Seizure rate and severity were chosen as the variables, because they were thought to be rather easily to quantify. In the following we will describe the classification systems of Engel[1] and the one put forward by the Commission on Neurosurgery of the International League Against Epilepsy (ILAE).[2] We will highlight some of their advantages and disadvantages and thereby illustrate the difficulties of developing a quantitative measure of postoperative seizure outcome. We conclude with an outlook on possible future developments.

Engel's classification of postoperative outcome

The most important obstacles to quantitative measures of postoperative outcome with respect to epileptic seizures were initially analyzed at the first Palm Desert conference in 1986[3] and reviewed again by Engel in 1993.[1] Eleven points were raised, which will be briefly summarized here, because firstly they gave rise to Engel's original classification and secondly because most of them are still pertinent today.

1. Early postoperative seizures used to be considered to not necessarily indicating a bad long-term outcome.[4] This opinion was founded on the belief that pathophysiological processes in the postsurgical brain might be similar to the ones occurring following cerebrovascular strokes[5] or traumatic injuries. In these clinical situations early seizures do not predict further seizure recurrence. Engel pointed out that in 1991 a study at the Cleveland Clinic had found early postoperative seizures of any type to be associated with poorer seizure outcome,[6] a finding that keeps being studied and supported by very recent investigations.[7] Because there seems to be no such thing as a benign seizure early after surgery ('neighborhood seizure'), all seizures should be counted to assess postoperative outcome, a practice which had not been (and still is not) widely applied.
2. Late pattern changes of seizure occurrence are well known. Engel described the situations when, following surgery, there is a very slow running down and finally stop of seizures or, on the contrary, when there is initial seizure freedom for many years and then suddenly a reoccurrence of epilepsy. In the former case it is hardly possible to separate natural disease history from a beneficial effect of surgery, in the latter a new epileptogenic process may be responsible for the seizures. Independent from the difficulties of delineating the underlying pathophysiological processes these slow or late changes of seizure occurrence underline that the postsurgical brain is undergoing dynamic changes, which should be accounted for in the classification used to assess postoperative outcome.
3. Seizure severity and the impact of seizures on the performance of patients has to be considered when assessing the outcome. Obviously it makes a big difference for a patient to have simple seizures only at night or having secondarily generalized seizures during the day. While the former ones will most probably not interfere with social interactions and therefore may turn out to be 'nondisabling', the latter ones will strongly affect the quality of life. Therefore, merely documenting the seizure rate will not account for the very different impact of different seizures.
4. Closely related to the severity of single seizures is the time pattern of their occurrence. Depending on the character of the single seizure, a clustering may cause less or more disability for the individual patient. Again, simply counting the number of seizures relative to a specified time period will not reliably reflect this important aspect.
5. Report reliability of the patients about the postoperative seizure occurrence may be affected by many factors, ranging from unawareness of seizures to the development of nonepileptic seizure events or lasting psychosocial needs to remain dependent. Because there is still no reliable surrogate marker of epilepsy, physicians have to continue to rely on the reports of the patients or persons close to them.

6. Changes of seizure status occur with duration of follow-up. Late pattern changes of seizure occurrence as discussed above may be considered just as an extreme case of this well-recognized fact, again highlighting the importance of thinking about epilepsy as a dynamic disease, i.e., a process that develops in time. In regard to seizure outcome measures these changes of seizure status imply a dynamic approach, too. For example, assessing the year-by-year outcome relative to the time of surgery will assess the outcome much better than simply pooling the data into pre- versus postoperative groups.
7. The initial patient populations have to be characterized as precisely as possible to finally yield a measure that allows comparing the results of different surgery centers. In addition, at least a crude characterization of the goal of the surgical intervention should be attempted, for example by prospectively declaring a 'curative' or a 'palliative' approach.
8. Pharmacological factors are important because when and how antiepileptic drugs are withdrawn may well influence the reoccurrence of seizures.
9. Psychosocial factors of seizure occurrence are very difficult to measure and are certainly not accounted for by simply reporting seizure rates. Quality of life may even become worse for some patients who are not able to cope with their own or others' expectations for their independence.
10. Surgical complications can cause neurological defects that influence postoperative seizure rate to the better or to the worse. On one hand complications might lead to more extensive damage of the epileptogenic cortex than would have been achieved by the planned resection alone. On the other hand unintended lesions may cause scars, which may become epileptogenic and cause a postoperative increase of (new kinds of) seizures. In any case, the occurrence of surgical complications should be accounted for when pooling data for comparison between different groups of patients.
11. The natural history of different epilepsy syndromes has to be considered to separate it from effects of surgery.

Until today it seems to be impossible to develop a classification of postoperative seizure outcome that deals satisfactorily with all these obstacles. Thus, compromises have to be made as exemplified by the classification scheme of Engel,[1] displayed in Table 164.1, which is an altered version of the originally proposed outcome classification recommended at the first Palm Desert conference.

This altered version is still a compromise insofar, as effects of seizures on quality of life as subjectively experienced by the individual patients were combined with qualitatively assessing the number of seizures. Furthermore, many of the eleven points discussed above were not considered for the sake of applicability. Though this classification was considered to be work in progress, as already indicated by its footnotes, it was adopted by many epilepsy centers and is still one of the most widely used schemes to assess postoperative seizure outcome.[8] Another often used classification scheme was developed by the International League Against Epilepsy and was intended to improve on some of the disadvantages of Engel's classification.

ILAE classification of postoperative outcome

During the Ninth International Symposium 'Epilepsy Surgery' held in Cleveland in 1998 the participants of the workshop on seizure outcome, W.T. Blume, D. Fish, E. Goldensohn, A. Hufnagel, D. King, H.O. Lüders, M.R. Sperling, and H.G. Wieser (Chairman), agreed on the following new classification (see Table 164.2).

Table 164.1 Engel's classification of postoperative outcome

Outcome	Definition
Class I	Free of disabling seizures[a]
A	Completely seizure free since surgery
B	Nondisabling simple partial seizures only since surgery
C	Some disabling seizures after surgery, but free of disabling seizures for ≥2 years
D	Generalized convulsions with AED withdrawal only
Class II	Rare disabling seizures ('almost seizure free')
A	Initially free of disabling seizures but has rare seizures now
B	Rare disabling seizures since surgery
C	More than rare disabling seizures since surgery, but rare seizures for the last 2 years
D	Nocturnal seizures only
Class III	Worthwhile improvement[b]
A	Worthwhile seizure reduction
B	Prolonged seizure-free intervals amounting to greater than half the follow-up period, but not <2 years
Class IV	No worthwhile improvement
A	Significant seizure reduction
B	No appreciable change
C	Seizures worse

[a]Excludes early postoperative seizures (first few weeks)
[b]Determination of 'worthwhile improvement' will require quantitative analysis of additional data such as percentage seizure reduction, cognitive function, and quality of life.

Table 164.2 ILAE classification of postoperative outcome

Outcome	Definition
1	Completely seizure free; no auras
1a	Completely seizure free since surgery
2	Only auras; no auras other seizures
3	One to three seizure days per year; ±auras
4	Four seizure days per year to 50% reduction of baseline seizure days; ±auras
5	Less than 50% reduction of baseline seizure days to 100% increase of baseline seizure days; ±auras
6	More than 100% increase of baseline seizure days; ±auras

Two main lines of reasoning led to the proposal of a modification of Engel's classification system (see Table 164.1). These were on one hand some disadvantages of Engel's classification and on the other the intention to apply additional design principles. The main disadvantages of Engel's classification were considered to be:

- Despite the fact that Engel's classification was already widely adopted in 1998, results from center to center could not be compared objectively. Engel's category 'worthwhile improvement' was ambiguous and therefore differently interpreted from center to center. Some centers asked for a 90% reduction, others accepted 50, 60 or 75% seizure reduction. Furthermore, the term 'worthwhile' was a judgement that may not be entirely justified. Hence, this term was felt to best be avoided. In addition, the baseline for seizure counting was not defined precisely.
- In order to facilitate comparison of epilepsy surgery with AED drug trials, where a '50% seizure reduction' was increasingly reported as an end-point, a surgical seizure outcome category '50% seizure reduction' was desirable.
- Totally seizure-free patients are lumped together with others who still have seizures. Although Engel's category IA refers to completely seizure free patients, in reality most centers did not report Engel's subcategories. Therefore the actual number of seizure-free patients remained obscure. However, the category of seizure-free patients is obviously the most important, both in regard to clinical as well as scientific discourse. Since from a neurophysiological point of view, there is no difference between auras and simple partial seizures, including completely seizure-free patients together with those still having auras into the same class was sought to be avoided.
- A category postsurgical 'worsening' of seizures was needed.

Besides the intention to improve on these disadvantages of Engel's classification the following designing principles and goals were stated for the new classification:

- The new classification system was designed to be as simple as possible. The previous experience of various groups dealing with outcome measures (ILAE Commissions on Epilepsy Surgery and Outcome Classification, etc.) had clearly shown that only a simple classification system had realistic chances for worldwide acceptance and application. The new classification was therefore designed to avoid difficult-to-define terms, such as 'worthwhile' and 'disabling'.
- The new classification system was devised to be applicable to an *individual person*, to a *sample population*, on *a year-by-year* basis, and most importantly *cumulatively to the 'last available outcome'*. In addition, its application was intended to be not sensitive to different seizure types in order to fulfill the needs of 'palliative' procedures, such as corpus callosum sections, where very often only one type of seizure is targeted.
- It was designed to reasonably handle the special difficulties that appear when dealing with status epilepticus and with the differentiation between nocturnal/diurnal seizures. Counting 'seizure-days' instead of an absolute number of seizures was considered a more practical measure. In this context a 'seizure-day' was defined as a 24-hour period.
- The new classification system was designed to better account for the fact that some patients have at rare occasions seizures that, however, *occur in clusters*, or even *status epilepticus*, in response to or associated with highly provocative situations, such as antiepileptic drug (AED) withdrawal. Taking this into consideration 'seizure-days' instead of an absolute number of seizures is again the preferred measure.
- Finally the classification system was made in a way that further refinements could be easily adopted. Examples are the categories 'last available outcome' and 'completely seizure free *since* surgery', or the 'running-down phenomenon' of auras. The study of the latter phenomenon certainly was facilitated with this new classification system.

While these designing principles aimed at many of the the most important obstacles to quantitative measures of postoperative outcome as sketched in the section above, some issues were left aside. The following points were discussed in depth, but finally not included:

- It was considered to be desirable to state whether a patient was seizure free on AEDs or without AEDs. However, two separate categories are not justified, because many seizure-free patients on AEDs will not risk a possible seizure recurrence associated with the termination of AED treatment. For this reason, i.e., the impossibility of delineating how many patients would be seizure free off AEDs, it was decided against splitting category 1 into 'seizure-free without AEDs' and 'seizure-free with AEDs'.
- 'Quality-of-life' outcome measurements were considered to be very important. However, it was either not reported or not comprehensive. The inclusion of the term 'worthwhile' in the seizure outcome classification may be clinically useful, but it might also prevent a more comprehensive quality of life assessment. It was agreed therefore to avoid a 'quality-of-life' measure in a seizure outcome classification and to use a 'quality-of-life' outcome scale separately and in parallel. 'Quality-of-life' outcome measurement should be comprehensive and reflect behavioral, schooling, occupation, psychosocial, self-sufficiency, marriage and reproduction, mental, and cognitive states.
- Some authors (see references in Taylor *et al.*[9]) have argued that an outcome classification should allow one to measure whether surgery reached the contracted aim

(individually formulated in precise terms) or not. Though this approach was considered to be interesting, it was concluded not to be possible to integrate such a measure in the new classification system.

- The fact that there was a growing need to measure postsurgical results in a way to allow 'cost-benefit' analysis was discussed, but finally felt to be better covered in an additional 'quality-of-life' classification. Nevertheless the proposed seizure outcome classification, when properly used on a year-by-year basis, provides cumulative outcome data that will permit more sophisticated analyses, also in this regard.

The ILAE classification is displayed in Table 164.2.

In the following we comment on some important points of this classification:

1. Seizure outcome class is determined dynamically, i.e., for each year at yearly intervals following the date of surgery. Patients often change from one classification to another from year to year.
2. Seizures during the first month postsurgery are not counted. This should, however, be specifically indicated (see Introduction Section).
3. An aura is defined as a simple partial seizure that is not observable by witnesses, i.e., a pure psychic experience, which does not affect the patient's function. Auras should be counted only if they are of short duration and are similar or identical to the auras the patient experienced prior to surgery. If the history is not clear, auras should not be counted. Postoperatively, a large number of patients are anxious and may report subjective feelings that are not epileptic.
4. Class 3 is included because it is quite common for patients to have 'rare seizures' postoperatively. These are often nocturnal and often tonic-clonic. It is practical experience that some patients may have these rare seizures on certain – usually provocative – occasions, and usually can cope with fairly well. For plain statistical reasons class 3 could otherwise be part of Class 4 >90% seizure-days reduction.
5. A 'seizure-day' is a 24-hour period with one or more seizures. This may include status epilepticus or seizure clusters.
6. The number of 'baseline seizure days' is calculated by determining the seizure-day rate during 12 months (at least 3 months) prior to surgery, with correction for the effects of AED reduction during diagnostic evaluation.
7. In Classes 4, 5, and 6 the change of seizure-free days with reference to baseline should further be detailed at least in 10% subcategories, or – better – in absolute numbers to allow for cumulative data reporting.
8. Class 5 means that the surgery did neither significantly improve nor significantly worsen the clinical situation of the patient. After a long discussion and advised by statisticians it was decided for the 100% increase of baseline seizure-days (versus 50%) on the argument that for mathematical and biological reasons it is justified to assume that seizure frequencies and their changes after surgery have a normal log distribution. This implies that a 50% decrease is equivalent to a 100% increase.
9. In the year-by-year reporting Class 1 should contain a subgroup 'completely seizure free *since surgery*; no auras' (see Table 164.3 and Figure 164.1). It is recommended that those patients being Class 1 without antiepileptic drugs are also separately reported.
10. The 'last available outcome' can be indicated in a separate column with the specification that a minimal follow-up of 1 year postsurgery is required. It should further be specified by mean±standard deviation, and minimal and maximal follow-up. It is understood that the last available year has to be taken into consideration. For example; a patient was operated on 5 September 1992 and is followed to end of July 1998. The period which counts for the 'last available outcome' would then be 5 September 1996 to 5 September 1997. Only where the length of the follow-up period is critical, the last available outcome can be calculated for the last 12-month period, i.e., in this example 31 July 1997 to 31 July 1998. It should be indicated whether the year prior to the last surgical anniversary or the last 12-month period is taken into account.

A practical example: long-term seizure outcomes following amygdalohippocampectomy

As a practical example how to report seizure outcome using the Engel and ILAE classification systems we display some results of the outcome studies of the Zürich amygdalohippocampectomy (AHE) series (10–13) as graphs in Figures 164.1 to 164.3. Data are plotted for postoperative years 1–15 (or 17 or 18), and the last available outcome (using the year prior to the last surgical anniversary). The number of patients at a given year can be easily added into such an outcome classification (Figure 164.3) or given as a table with the graphs (Figures 164.1 and 164.2). Note also that in these examples ILAE Class 1 has been split in order to report the number of patients who are 'completely seizure free *since* surgery' (ILAE Class 1a). For more detailed data on the AED treatment following AHE see Wieser and Häne.[12,13] Neuropsychological outcome data[14,15] and some quality-of-life data[16] of our Zürich AHE series have been summarized elsewhere.[11,14,15]

Quality of life

In a recent survey (August 2004) of the International Bureau for Epilepsy it was found that 56% of participating epilepsy patients linked their cognitive impairment with their epilepsy medication (alone or combined with their epilepsy). Of these, 45–50% felt that the cognitive and other effects of their epilepsy and its treatment had a moderate or severe effect on their work, education, leisure activities, families and relationships and 63% felt that the effects they had experienced had prevented them doing a particular activity or achieving a specific goal. These numbers underline the importance of quality-of-life assessments in epilepsy patients (see Trimble and Dodson, 1994).[16] Although we cannot deal here with this very important aspect of quality of life outcome studies, we shall mention several available valid inventories, such as.

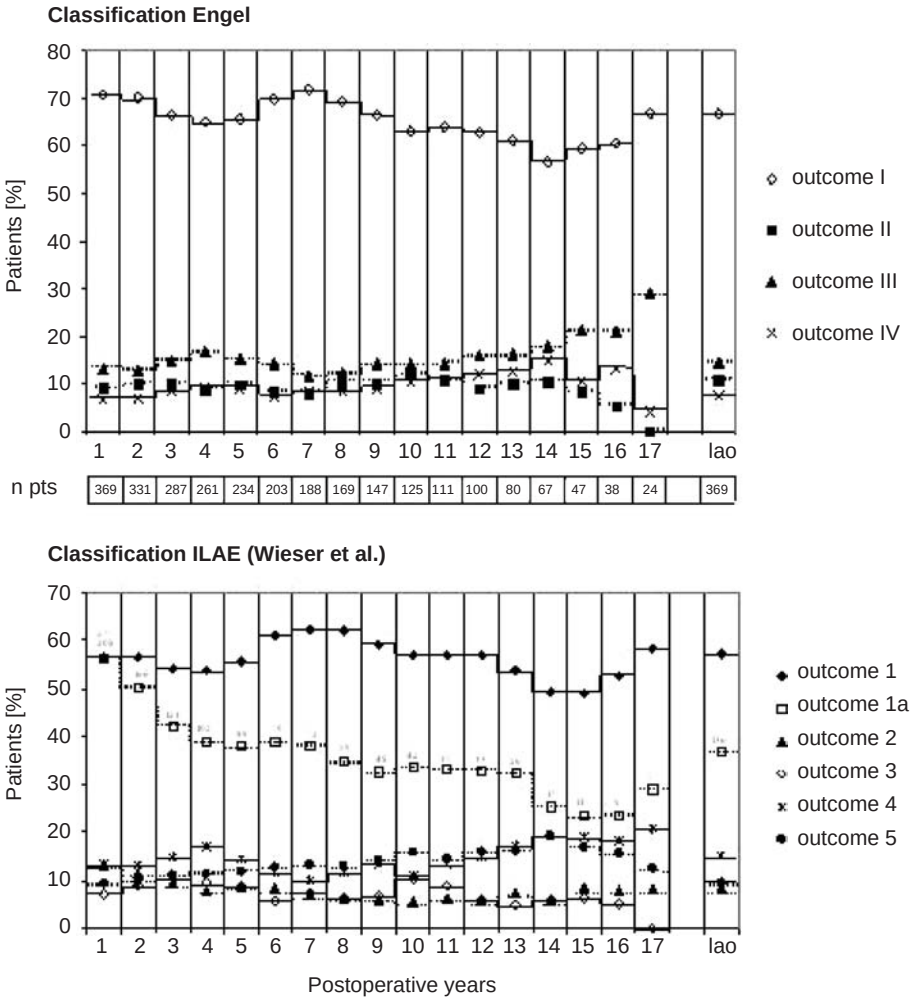

Figure 164.1 Year-to-year seizure outcome classification as well as last available outcome (lao) of the Zürich selective amygdalohippocampectomy series (1975–1999) with sufficient follow-up (≥1 year; n=369) according to Engel (see Table 164.1) and ILAE (see Table 164.2). No patient had an ILAE Class 6 seizure outcome. Years with fewer than 20 patients are not plotted. Numbers in boxes indicate the numbers of patients in the given year or overall. Outlook

Although considerable effort has been put in and success has been made during the last years with outcome measures, the interpretation of published reports on the long-term outcome of patients undergoing epilepsy surgery is still difficult because of several methodological issues. The lack of appropriate standard classification systems for both seizure outcome and quality of life outcome over time is one important reason.

The task to revise Engel's currently already widely used seizure outcome classification is certainly only justified if it is done in an as thoughtful manner as possible, and if it is generally accepted by the entire international epilepsy community. We feel that the ILAE classification has become a useful improvement, though it remains a special effort to calculate outcome on the basis of preoperative seizure days. While for retrospective studies many centers are not able to do this due to lack of preoperative data, or will use it in addition to the current Engel classification, we suggest the ILAE classification to be used for prospective studies, because of its discussed advantages.

165 Protocol for storage and processing of brain tissue for molecular studies

PB Crino

Introduction

The use of human brain tissue for epilepsy research has rapidly expanded over the past decade. Tissue resected during epilepsy surgery or obtained postmortem from epilepsy patients can provides a new window to view the cellular processes that are involved in epileptogenesis as well as the effects of recurrent seizures or chronic medications on neural systems. Indeed, our understanding of developmental malformations, mesial temporal sclerosis, and tumors has been greatly facilitated by human tissue studies. For many epilepsy syndromes animal models do not exist and human tissue studies provide the only means to learn about how these disorders affect the brain. Perhaps most exciting, however, is that new experimental methodologies to extract genomic DNA and mRNA from archival tissue samples now permits an in-depth analysis of the molecular mechanisms and genetic causes of virtually any inherited or sporadic epilepsy syndrome. With the advent of tissue microdissection an even finer experimental resolution can be gained. My laboratory has over 10 years experience with extraction and analysis of mRNA and DNA from human epilepsy tissue specimens. We have tried numerous protocols and optimization procedures to quantify mRNA expression, perform PCR, and sequence candidate genes; some have succeeded, many have failed. This chapter will provide an overview of the experimental strategies that can be implemented for tissue preservation, storage, and molecular analysis in human epilepsy. The goal will be to demonstrate how archival tissue research can provide exciting new discoveries in epilepsy pathogenesis.[1]

Background: why study genes in epilepsy?

The initial attempts at molecular analysis of human tissue were largely confined to in situ hybridization studies in particular, focusing on mesial temporal lobe epilepsy. These groundbreaking experiments provided pivotal new insights into molecular events that either heralded or followed intractable seizures. Of particular interest were experiments that defined altered expression of the family of immediate early genes such as c-fos in human epilepsy specimens.[2,3] From these results came the notion that seizures were associated with changes in gene and protein expression and furthermore suggested the exciting concept that seizures could alter gene transcription. The ideas that seizures could affect the expression of numerous genes opened a new door in epilepsy research and placed a 'molecular face' on epilepsy. Subsequent studies furthered this notion by demonstrating altered expression genes encoding a variety of candidate molecules including neurotrophins, neurotransmitter receptor subunits, and structural elements.[4–6]

More recently, the development of cDNA or oligonucleotide arrays (for a recent review, see ref. 7) has provided a high-throughput strategy to assay the differential expression of several thousand genes at once. Arrays are simply a solid support medium such as nylon or silica upon which is adhered either short cDNA sequences (oligonucleotides) that are portions of known genes or expressed sequence tags identified in existing gene databases or near full-length sequences of known genes (cDNAs). Arrays are probed with nucleic acid (either cDNA or amplified mRNA) tagged with a radioactive or a fluorescent nucleotide extracted from cells or tissues. Differential hybridization of the labeled DNA or mRNA probe to the oligonucleotide or cDNA sequence on the arrays determines the relative abundance of that gene. The array strategy permits quantification of numerous genes simultaneously so direct comparison of genes across families, functional clusters, developmental epochs, or in response to pharmacological manipulations can be made. The advent of array technology has provided a powerful strategy for evaluating changes in gene transcription in human epilepsy as well as in animal epilepsy models. An added benefit is that while arrays render a broad view of gene transcription, some conclusions can be made regarding altered expression of the encoded proteins. These data can then provide new insights into functional alterations in neurons or astrocytes that relates to epileptogenesis. Perhaps most intriguing is that for many specimens areas of tissue pathology are directly adjacent to morphologically normal tissue, thus providing a unique tissue control for gene analysis or gene sequencing (Figure 165.1).

Cataloging tissue

Most human tissue used in epilepsy research is obtained either directly from a neurosurgeon in the operating room,

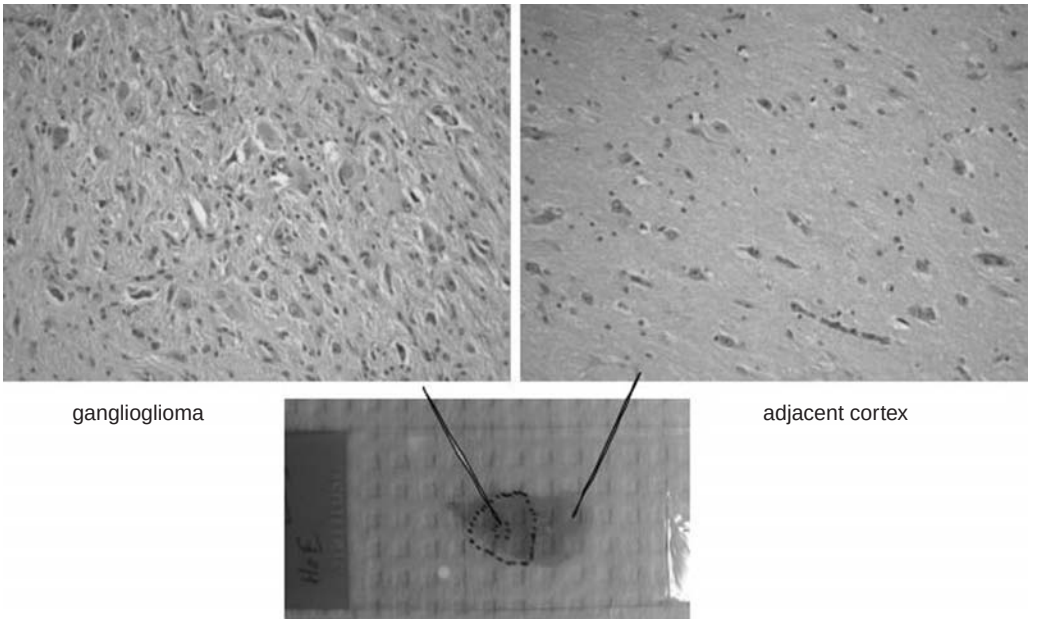

Figure 165.1 Top left, region of ganglioglioma directly adjacent to morphologically normal cortex (top right) resected from epilepsy patient for treatment of complex partial seizures. Tissue on same section (below) can be used en bloc or each region can be dissected for independent analysis (Hematoxylin and eosin stain).

through a pathologist, or from a tissue bank. In many institutions, a diagnostic pathology evaluation of resected tissue is needed prior to the use of tissue for research purposes and in general, removal of tissue directly from the operating room in a prospective paradigm requires patient consent. Retrospective collection of archival material typically does not require patient consent and is often deemed exempt from human studies institutional review. Many gene expression studies in other disorders for example cancers, have relied on tissue directly removed from the operating room. In our experience, procurement of tissue directly from the operating room can be limited by institutional review boards issues or issues relating to diagnostic accuracy in the resected specimens. For example, many pathologists will voice concerns over potentially missing low-grade neoplasms or other relevant pathological features in the tissue that is taken from the operating room. One strategy to surmount this is for investigators to use only the tissue that is needed and return the unused portion to the pathologist. Alternatively, we often have the pathologst 'sign off' on the material immediately after removal.

In view of HIPAA regulations on human research, it is of the utmost importance to maintain patient confidentiality. Unless specific phenotypic parameters are under investigation, investigators must avoid including patient identifying information in their research publications. It should be noted that birthdates, social security numbers, medical record numbers, and pathology/autopsy numbers are considered patient identifiers and thus cannot be used to label tissue in the laboratory. Nonetheless, it remains imperative to have some ability to track samples for a variety of reasons, e.g., collaboration, phenotypic analysis, request for more tissue, and thus a system should be designed for tissue identification and storage of necessary patient information. One strategy to assign each tissue sample a lab-specific number or label so that no member of the lab can identify the sample. A separate strictly confidential information database (for example, Excel) for each specimen is maintained (in duplicate) in a password protected, limited access file. Thus, an investigator can maintain tissue identity for research purposes but protect patient confidentiality. Prior to embarking on human tissue research, it is strongly suggested that investigators meet with appropriate protocol personnel at their home institutions to assure complete compliance with standards for human tissue research.

Tissue fixation and storage

A common myth is that resected tissue used for molecular analysis must be kept frozen or used immediately after removal. While it is true that frozen tissue yields high quality mRNA or DNA, paraformaldehyde or formalin fixed tissue can be used for both DNA and mRNA analysis.[8,9] Perhaps the most optimal situation for tissue analysis is to obtain both fresh, frozen, and fixed material although this may pose logistical procurement problems since specimens must typically be analyzed by a neuropathologist prior to experimental analysis. The use of fixed tissue has particular appeal since molecular analysis can be combined with tissue immunohistochemistry to define for example protein expression or to use protein expression as a phenotypic marker for cell specific mRNA analysis. In addition, it is much easier to obtain archival pathological material stored in paraffin than fresh frozen tissue.

As a general rule, frozen tissue is exquisitely sensitive to transient rise in temperature. Even 10–20°C changes can lead to mRNA and protein degradation over time. Frozen tissue should be maintained at −70°C in a frost controlled freezer. The freezer should have a backup power source with an alarm system should the internal temperature rise above −50°C. Contact persons and appropriate information should be displayed prominently near the freezer in case of emergencies.

A backup freezer should be identified in a nearby lab in case the power should fail to prevent loss of tissue.

In most cases, fixation for pathological preparation uses paraformaldehyde or 10% neutral buffered formalin. These protein cross linking fixatives afford excellent protein fixation but can make extraction of nucleic acids difficult. Boiun's fixative is occasionally used and combines picric acid with formalin and is very stringent. In general we avoid using Bouin's fixed tissue for nucleic acid work. Investigators may have little control over which fixative is used by pathologists, but if given a choice an alternative fixative to a crosslinking compounds is 70% ethanol with 150 mM sodium chloride which permits high yield and quality mRNA for array analysis.[10] Ethanols are denaturing fixatives and thus do not pose significant problems for nucleic acid extraction. In general for small blocks of tissue (less than 2 cm^3), a fixation period of 2–3 weeks may be effective, whereas for larger blocks or for example, whole brains or hemispheres, several weeks will be necessary. One issue that persists is whether there is a fixation time after which DNA or mRNA cannot be extracted from fixed tissue. In our experience, trial-and-error have been the norm and sometimes an initial failure to recover DNA can be overcome by manipulations of various protocols.

Tissue storage for nucleic acid work requires little else than space. DNA is perhaps the most stable biomolecule known and thus breakdown is unlikely even in fixed, paraffin-embedded tissue blocks. We have sequenced through several genes including *PTEN*, *TSC1*, and *TSC2* in genomic DNA extracted from paraffin-embedded tissue blocks stored for up to 5 years. That said, as tissue ages, DNA fragmentation may occur resulting in smaller sequence length available for analysis. DNA fragmentation becomes an issue when longer sequences are necessary to define gene mutations or polymorphisms (see below) or when using DNA to probe array platforms such as single nucleotide polymorphism (SNP) arrays. Paraffin blocks should be kept in cool, dark, dust-free boxes.

Work environment

DNA degradation is uncommon due to lab practice. In contrast to DNA analysis, mRNA work requires more care for success. The major difficulty with tissue-based mRNA experiments is overcoming mRNA breakdown by tissue and environmental RNAses. These ubiquitous enzymes are present in skin oils, expired breath, bacteria, and other benchtop contaminants and can easily degrade even large quantities of extracted mRNA. However, while RNAses have achieved an almost villainous status in some labs, we find that simply making all reagent buffers and solutions in DEPC (diethylpyrocarbonate, a potent RNAse inhibitor) treated water effectively does away with most RNAse contamination. Similarly, all glassware is autoclave sterilized and fresh plasticware is a must. Of course, all mRNA workers should wear gloves and a lab coat. For mRNA work, radiolabeling of the amplified mRNA is frequently necessary. Thus protocol approval and training of personnel by each institution's radiation safety office is mandatory.

Fresh tissue and frozen unfixed tissue is potentially infectious and thus universal precautions (gloves, eye protection, lab coat) should be implemented. While fixation of human tissue largely inactivates most pathogens, i.e., HIV, hepatitis B and C, we implement universal precautions for every day work with fixed human tissue as well. To start with, we make every attempt to ascertain HIV and hepatitis serology status in our patient samples and this data is usually available from existing tissue banks. For those working on epilepsy in association with known human pathogens, communication with institutional safety offices is requisite to insure safe practice for all lab staff. Transmissible spongiform encephalopathies are a particularly serious risk of working with human brain tissue. While it is believed that formalin fixation at least diminishes the risk of lab-related transmission of spongiform encephalopathy, the utmost care must be taken to protect lab personnel. As a general practice, gloves must be worn for *every* instance of contact with human brain tissue, whether it is during microtome sectioning, transfer of slides, or immunohistochemistry. We strongly recommend that investigator review their own institutional policies on working with human tissues and pathogens prior to embarking on human tissue research.

A final word about the work environment relates to responsibility and professionalism. Investigators working with human tissue must maintain respect for those individuals from whom tissue has been procured. While it is easy to look at blocks of tissue as 'data points' or 'sample numbers,' all human tissue specimens used in the lab are obtained following a major surgical procedure or patient death. Thus, each 2 cm^3 tissue block represents significant human suffering. This is especially important when communicating with families or support groups or grassroots funding agencies from whom these patients/tissues may be derived and lab staff should maintain appropriate respect for this fact. Of paramount importance is that the public perception of human brain tissue research can assume a 'ghoulish' overlay if not addressed in the appropriate context and with the necessary facts. Remember that the public may not realize that obtaining tissue from a tissue bank typically requires a processing fee and thus if not discussed openly, can lead to a misperception that tissue is 'for sale'. Similarly, it is vitally important that all human tissue research be approved by each institutional review board and that this approval is kept current. Imagine how the public might respond to learning of a scientist 'buying' brain tissue for 'experimentation without any approval'. Even worse, imagine how this would appear as a newspaper headline.

Extraction of genomic DNA

Analysis of genomic DNA provides a unique opportunity to study gene sequence in human tissue. For example, in monogenic disorders, if the genotype of a particular patient is unknown, it can be determined by direct sequencing of the candidate gene in genomic DNA from a tissue specimen (Figure 165.2). We have accomplished this for several genes in a variety of disorders such as hemimegalencephaly or tuberous sclerosis complex.[9] Of course, unless a lab is certified, results cannot be communicated to the patient or family member, nor can it be used for clinical practice, decision making, or counseling. However, reliable and reproducible results can be determined with published DNA sequence primers for most genes.

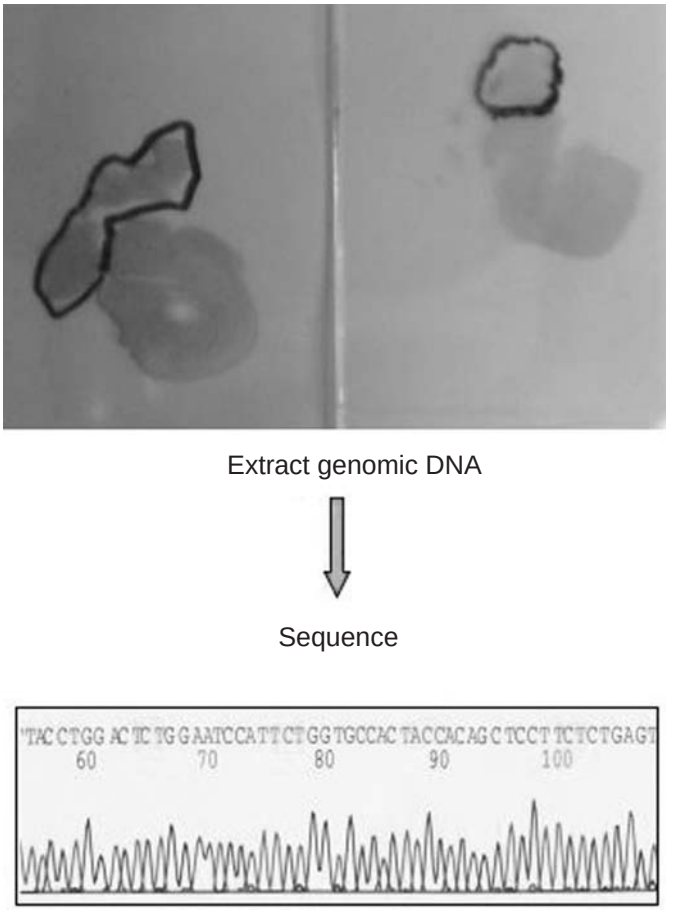

Figure 165.2 Specimen of mesial temporal lobe. Genomic DNA can be extracted from subregions defined by immunostaining (top left, glial fibrillary acidic protein)or morphology (hematoxylin and eosin, top right) and then sequenced to target select sequences.

There are several commercially available kits for DNA extraction. Initial steps in extraction include a Proteinase K step to reverse fixation and permit more effective DNA harvesting. Following Proteinase K, the tissue is treated with Tween or a similar detergent compound. DNA can be extracted with several commercially available kits. The quality of extracted DNA is then assessed by optical density (OD) measurement to determine concentration and purity as well as agarose gel analysis to determine the size of extracted products. An important issue is the quality of extracted DNA since older or poorly fixed samples may yield fragmented or degraded DNA that will be difficult to sequence. Poor quality DNA will appear as an excess of low molecular weight species on the gel. DNA extracted from paraffin embedded tissue can be used for PCR amplification, DNA sequencing and as a probe for DNA arrays including SNP arrays.

Analysis of mRNA in tissue specimens

The analysis of mRNA from fixed human tissue sections[11] provides a unique opportunity to define differential gene expression that may be pivotal in understanding the molecular pathogenesis of human epilepsy. For years, the analysis of gene expression was confined to in situ hybridization studies. The advent of cDNA and oligonucleotide arrays has provided a new strategy to define changes in the coordinate expression of numerous genes in a single experiment. While it is widely believed that gene expression analysis must be performed in fresh or frozen tissue, recent evidence suggests that mRNA analysis can be reliably performed in fixed paraffin embedded tissue. Furthermore, recent advances in microdissection technologies make it feasible to analyze differential expression in select brain regions or even within individual cell types.

The stability of mRNA can be quite variable from sample to sample and often there is degradation due to tissue RNAses. There is reasonable evidence suggesting that mRNA extracted from fresh or frozen tissue may be of superior quality when compared with mRNA extracted from fixed tissue samples. Isolation of mRNA from frozen tissue can be accomplished using one of several available commercial kits. We have used the TRIzol reagent which permits extraction of DNA, total RNA, and protein. The generation of mRNA from total RNA (mRNA, ribosomal RNA, and tRNA) requires annealing an oligo-dT primer to the poly A tail present on all mRNA followed by reverse transcription into cDNA. The cDNA can then be labeled with a radiotag or fluorchrome so it can be used as a probe for cDNA arrays. Alternatively, most commercial labs or university based nucleic acid core facilities will extract polyA mRNA and then generate a labeled cRNA probe for arrays.

In contrast, the extraction of mRNA from fixed tissue specimens requires a bit more technical expertise. A technology devised in the late 1980s known as in situ transcription (IST) provides a reliable strategy to generate cDNA from fixed tissue section mRNA (Figure 165.3).[12] During IST, cDNA is directly synthesized on a tissue section by annealing an oligo-dT(24) primer to tissue mRNA poly A tail overnight at room temperature. IST provided the necessary groundwork to later develop

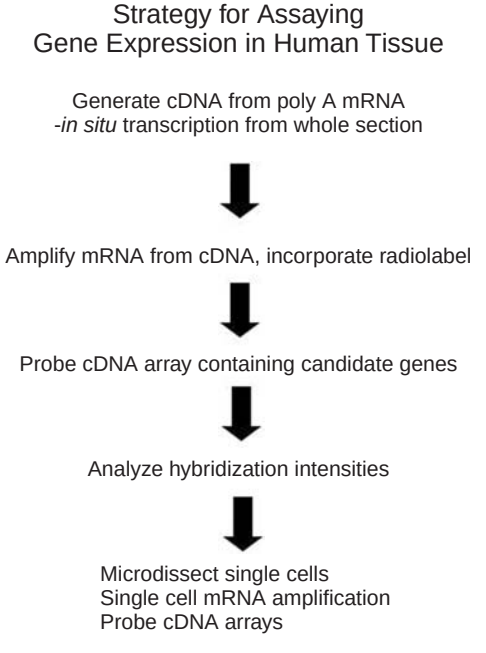

Figure 165.3 Overview of mRNA isolation and amplification strategy for fixed tissue specimens.

the technique of mRNA amplification so that mRNA in single cells could be analyzed. Coupled to the oligo-dT primer, is a promoter sequence for RNA polymerase that will be used in subsequent steps for mRNA synthesis. cDNA synthesized in IST reaction buffer (10 mM HEPES buffer pH 7.4, 120 mM KCl, 1 mM $MgCl_2$, 250 μM dATP, dCTP, dGTP, TTP) with avian myeloblastosis reverse transcriptase (AMVRT). Sections are washed in 0.5X SSC buffer. The cDNA can then be directly extracted from the section with sodium hydroxide and potassium acetate. The extracted cDNA from whole sections can be labeled with a radioactive or fluorescent tag to probe cDNA arrays. Alternatively, the extracted cDNA can be used to isolate or quantify mRNA by RT-PCR.

More recently, technologies have been developed to quantify mRNA in single cells.[8,11,13–15] This approach has in many ways revolutionized our ability to understand gene transcription in numerous disease states, i.e., epilepsy, Alzheimer's disease, Parkinson's disease, and HIV, and especially those with cell specific pathology. Single cell mRNA can be obtained from cells in culture, i.e., dissociated or tissue slice, or from fixed paraffin embedded tissue sections. For live cells, mRNA analysis can be combined with electrophysiology to provide a comprehensive view of cell function from gene expression to changes in cell firing. In live cells, a patch electrode can be used to aspirate the cytoplasm and transfer the contents into a microfuge tube for further reactions. In fixed cells in culture or tissue sections, single cell mRNA analysis provides an opportunity to analyze gene expression in a population of phenotypically defined cells, whether by protein expression using immunohistochemistry, or by cell morphology. Recent studies have demonstrated that mRNA can be extracted from single cells undergoing apoptosis identified by TUNEL.[16,17] Single cells may be microdissected from sections using a joystick driven microscalpel or by laser capture (Figure 165.4). Successful quantification of single cell mRNA has been achieved using the microscalpel technique whereas mRNA analysis in laser captured cells requires that a number of cells be harvested.

Following aspiration or microdissection, single cell mRNA amplification is performed in a microfuge tube with reagents that are commercially available (Figure 165.5). In the initial step, the oligo-dT-T7 promoter primer is hybridized to the dissected cell followed by cDNA synthesis with reverse transcriptase. cDNA synthesis is performed (oligo-dT(24)-T7 primer, 10 mM HEPES buffer pH 7.4, 120 mM KCl, 1 mM $MgCl_2$, 250 μM dATP, dCTP, dGTP, TTP with AMVRT) and then double-stranded template cDNA is generated with T4 DNA polymerase I (Boehringer-Mannheim). The double-stranded DNA is phenol:chloroform extracted and ethanol precipitated prior to use as a template for mRNA amplification. mRNA is amplified from the double-stranded cDNA template with T7 RNA polymerase. Unlike extraction of mRNA from whole tissue sections or from tissue homogenates, single-cell mRNA analysis requires an amplification step to generate sufficient quantities of mRNA for experimental analysis. It is imperative that the amplification kinetics be linear so that there is equal amplification of both low- and high-abundance mRNA in each cell. If not, then there may be an under- or over-representation of a particular mRNA based on its relative level of expression. The use of T7RNA polymerase, driven by a T7 promoter provides for linear synthesis of mRNA from double-stranded cDNA. Because the enzyme has high affinity for its promoter, each double-stranded DNA can be primed repetitively as a template for mRNA synthesis, culminating in an amplification of the copy number for any given mRNA. The reactions necessary for mRNA synthesis from cDNA are repeated, resulting in a 10^6-fold amplification of single cell mRNAs. Amplified mRNA serves as a template for a second round of cDNA synthesis with AMVRT and dNTPs, that is primed with N(6) random hexamers (Boehringer-Mannheim). cDNA generated from amplified mRNA is made double-stranded and serves as template for a second mRNA amplification incorporating ^{32}PCTP. Radiolabeled mRNA incorporating ^{32}PCTP is used to probe cDNA arrays.

Candidate gene expression analysis and cDNA arrays

In our lab, we have successfully probed arrays with nucleic acid extracted from human epilepsy specimens. These array

B, dissection of single immunolabeled cells from epilepsy tissue specimen. C, RT-PCR amplification of distinct genes from single microdissected cells in B.

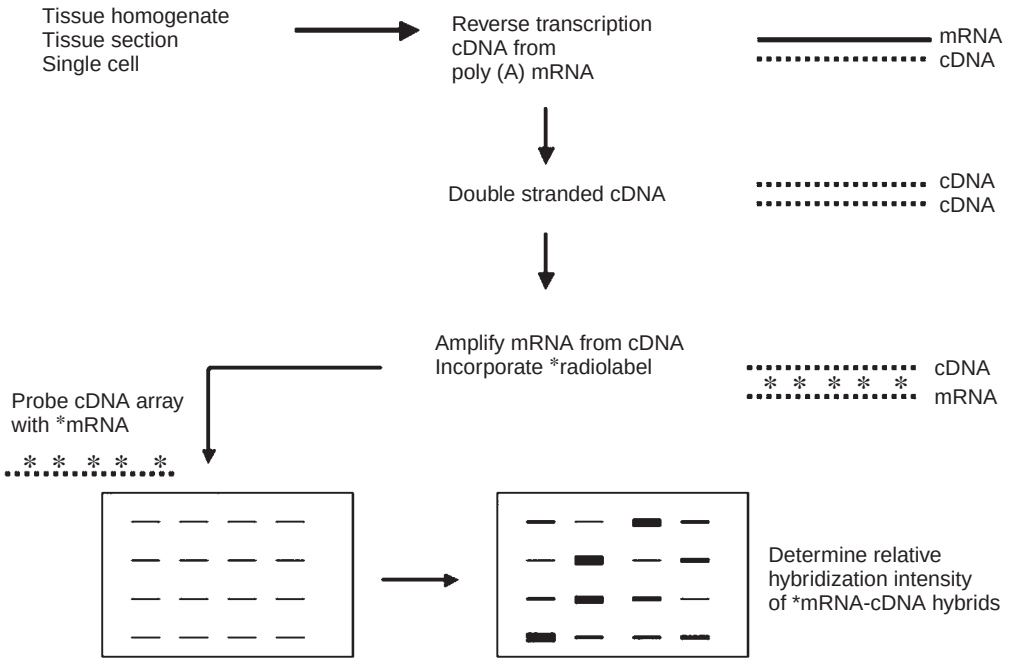

Figure 165.5 Schematic depiction of mRNA amplification procedure from human tissue specimens. On bottom right, different sized lines depict differential hybridization intensity of tissue mRNAs to cDNAs on the arrays (see also Figure 170.6).

platforms have lab-generated macroarrays (containing about 50 cDNAs),[19] small-scale commercial cDNA macroarrays (about 100 cDNAs),[9] and commercial arrays containing several thousand genes of interest. Lab-generated and some commercial arrays contain linearized, full-length plasmid cDNAs encoding genes of interest which are obtained by PCR or through collaborative efforts (Figure 165.6). The cDNAs are UV-crosslinked to the membrane. Analysis of larger scale commercial arrays such as those from Affymetrix or Agilent is not feasible with single cell mRNA and requires that mRNA amplified from multiple single cells or a tissue homogenate be used as a probe. As a general rule, arrays are screened in duplicate. 'Housekeeping genes' such as β-actin or GAPDH are included as to serve as positive hybridization controls. pBlueScript (PBS) and pUC18 plasmid cDNAs are used to define background levels of hybridization on each array platform. In our lab, a small arrays are hybridized with the radiolabeled mRNA probes for 24 hours in 6X SSPE buffer, 5X Denhardt's solution, 50% formamide, 0.1%SDS, and salmon sperm DNA 200 μg/ml at 42°C and then washed in 2X SSC.[18,19] Probed cDNA arrays are apposed to film or phosphorimage cassette to visualize the hybridization (Figure 165.6).

Troubleshooting

Often investigators new to nucleic acid work will try a protocol for mRNA extraction only to meet with failure and then frustration at repeated attempts. RNA work can be tricky and even experienced labs may have difficulty. First, make certain that the work environment is RNAse free and that all reagents, plasticware, and glassware are sterile and RNAse free. Wash all glass in DEPC-treated water and make as many reagents as possible in DEPC-treated water. Most commercially obtained enzymes are RNA free as are buffers and NTPs/dNTPs.

A second possibility is that there has been degradation of the mRNA in the tissue sample. This problem can be assessed in several ways. First, try to amplify mRNA from a whole tissue block to be sure that there is enough initial template for the polyA to bind the oligo-dT. Following the amplification and radiolabeling step, run an aliquot of the RNA on a 1% agarose denaturing gel, blot it, and appose it to film to determine if there is any mRNA. Alternatively, attempt to PCR amplify a high abundance message from the synthesized double-stranded cDNA compared with a known control sample. Finally, the tissue section can be stained with acridine orange, a fluorescent dye that labels single-stranded nucleic acids in cells (like mRNA). Cellular mRNA should glow a bright orange whereas DNA appears bright green.

If it appears that there is adequate mRNA for amplification, try to modify the reaction protocol. For example, fixed tissue sections can be treated with triethanolamine or 0.1N NAOH prior to oligo-dT hybridization. Alternatively, increase the concentration and exposure time for the Proteinase K and further diminish crosslinking fixation. The initial reverse transcription time can be increased to 24 hours to enhance cDNA synthesis. Similarly, the RNA polymerase step can be lengthened to 8 hours. If these measures are not helpful, it may be prudent to visit a lab that regularly performs mRNA analysis in human tissue. A full protocol is available on request from my laboratory.

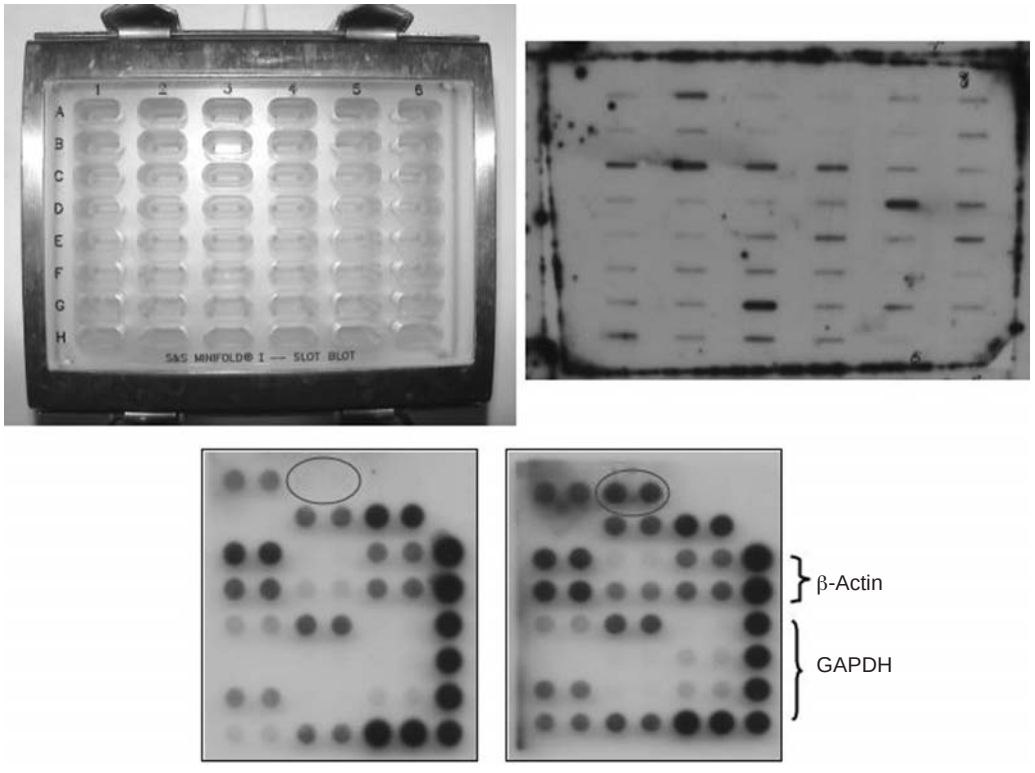

Figure 165.6 Candidate cDNA arrays used for gene expression analysis. Top left, plexiglass 'slot blot' apparatus. A single cDNA is placed in each well or slot that overlies a piece of nylon membrane. The membrane is dried and the cDNAs are UV-crosslinked to the membrane. When probed with radiolabeled mRNA, there is differential hybridization to select candidate cDNAs (top right; compare with schematic in Figure 170.5). Bottom, commercial cDNA arrays containing candidate cDNAs. Left, control tissue hybridization and right, array probed with cDNA from hemimegalencephaly specimen. Note differential hybridization of one gene pair (oval). Two genes, β-actin and GAPDH, are included on the array as 'housekeeping' genes to assess overall hybridization levels.

TEXTBOOK OF EPILEPSY SURGERY

EDITED BY HANS O LÜDERS

With twenty-two definitive sections and over one-hundred and sixty chapters, *Textbook of Epilepsy Surgery* brings together a substantial review of the latest advances in the surgical management of epilepsy.

Every section has been written by leading authorities in their field and includes such topics as the new neuroimaging techniques, more aggressive surgical approaches in cases with catastrophic epilepsies, better understanding of epileptogenic mechanisms in etiologically different types of epilepsy, new surgical techniques and strategies, neuronavigation systems, and improved statistics of surgical outcome in different epilepsy types.

This fully comprehensive textbook is an invaluable tool and reference source for neurologists, neurosurgeons, epilepsy specialists, and those interested in epilepsy and its surgical treatment.

Sections include:
• History of surgery and related fields • Epilepsies remediable by epilepsy surgery • Pre-surgical evaluation: general principles • The symptomatogenic zone • The irritative zone • The ictal onset zone • The epileptic lesion • The functional deficit zone • Pre-surgical evaluation of eloquent cortex • The epileptogenic zone • The patient management meeting • Surgical techniques for placement of intracranial electrodes • Cortical mapping and electrocorticography • Resective surgical procedures for epilepsy • Non-resective surgical procedures and electrical or magnetic stimulation for epilepsy treatment • Surgical outcome • Post-surgical management • Neuropathology and research related to epilepsy surgery • Surgical failures: re-operation • Case presentations

Professor Hans O Lüders MD PhD Director, Epilepsy Center, Neurological Institute, University Hospitals of Cleveland, Case Western Medical Center, Cleveland, OH, USA.
