Several recent studies have compared outcomes in patients with MTS and those with other pathologies. Findings suggest that patients with temporal lobe epilepsy and associated MTS demonstrate poorer memory performance both pre- and post-surgically than patients with other pathologies including tumor, DNET, cortical dysplasia, and vascular factors.[59–61] Furthermore, patients with MTS demonstrate more limited post-surgical memory declines following temporal lobectomy than patients with other pathologies.[61–63] Patients without MTS appear to be at increased risk for post-operative decline in naming ability[64,65] as well as memory. Many of these studies, particularly those involving children, have been conducted with small sample sizes. Nevertheless, it is promising that most of the studies that have been conducted to date have reported similar results.

Functional MRI

In recent years, fMRI studies have been conducted to determine their usefulness in the lateralization and localization of seizure onset as well as the lateralization of language and memory functions.[66–70] These studies have demonstrated that fMRI is useful in demonstrating hemispheric dominance for language.[71,72] More recently, studies have reported a significant relationship between pre-operative hemispheric asymmetry on fMRI during memory tasks and post-operative memory change. Patients with greater pre-surgical activation in the ipsilateral side showed declines in memory post-surgically, whereas those with greater contralateral activation showed memory improvements.[73–76] Functional MRI has also shown to be useful in predicting naming declines following left temporal lobectomy and to be even more predictive than pre-operative naming ability in the course of neuropsychological testing.[77] Specifically, research has demonstrated that patients whose fMRI results suggested greater language lateralization to the left hemisphere show greater declines in memory following left anterior temporal lobectomy than those whose fMRI results suggested language lateralization toward the right hemisphere.[77]

PET

Studies on F-fluorodeoxyglucose-positron emission tomography (FDG-PET) have reported that patients with no or limited PET asymmetries in temporal lobe metabolism are at greater risk for a decline in verbal memory following dominant temporal resections than those with notable asymmetries. This relationship has not been observed in patients following nondominant temporal resections, however.[24]

EEG

Neuropsychological deficits have been shown to be related to the level of EEG abnormality. Specifically, patients with generalized discharges tend to perform more poorly on neuropsychological measures than patients with focal discharges or no discharges at all.[78] Furthermore, patients with more frequent epileptic discharges demonstrate greater neuropsychological deficits than patients with fewer epileptic discharges.[78]

Intracarotid amobarbital procedure

Similar to neuropsychological findings prior to and following temporal lobectomy, lesions of the left temporal lobe often result in impaired verbal memory on IAP testing and right temporal lesions often result in nonverbal memory difficulties.[79,80] Many studies over the years have investigated the intracarotid amobarbital procedure (IAP) as a predictor of post-operative outcome in patients with epilepsy. In general, IAP results have been most predictive of verbal memory changes in patients with dominant temporal lobe epilepsy, but have not fared as well as a predictor of nonverbal memory changes after nondominant resections.[46,81] Three scores derived from IAP testing have been demonstrated to predict post-operative memory change. Several studies have reported that memory performance after ipsilateral injection (indicating memory ability associated with the structures to be spared) is a significant predictor of post-operative memory outcome.[23,81] Memory performance after contralateral injection (indicating memory ability associated with the structures to be resected) has also been demonstrated to be a significant predictor of post-operative memory impairment following temporal resection.[45,46] Finally, a number of studies have suggested that IAP discrepancy, or asymmetry, scores between performance after ipsilateral and contralateral injections are useful in predicting memory impairments following temporal lobectomy.[82] IAP asymmetries have also been shown to be useful in predicting naming declines following left temporal lobectomy, with patients showing left language lateralization on IAP demonstrating the greatest naming declines following left temporal lobectomy.[77] It remains unclear as to which of these three IAP indices best predicts post-operative memory decline following temporal resection, largely due to methodological differences among studies.[83] Nevertheless, the patients at greatest risk for post-operative decline based on IAP testing alone are those who have IAP scores demonstrating intact functional adequacy, limited functional reserve, and little discrepancy between contralateral and ipsilateral injection scores.

Event related potentials and intraoperative mapping

Recently, event related potentials have been shown to predict individual post-surgical memory with high precision.[21,84] It has also been reported that decline in verbal memory following dominant temporal resection can be predicted with relatively high accuracy (e.g., 80%) using results from intraoperative mapping of language and memory areas.[28] However, more research is required to determine the reliability and validity of this procedure in the prediction of post-operative cognitive decline.

Extent of surgical resection

Several studies have reported that selective temporal surgeries typically result in fewer memory problems than standard two-thirds temporal lobectomies,[85–88] although this finding has not been universal.[89–92] Furthermore, when studied in conjunction with other predictor variables, research has suggested that the functional adequacy of the tissue to be resected is more strongly related to post-surgical memory outcome than the extent of the resection itself.[42,91]

Demographic and seizure factors

There are a number of demographic and seizure variables that have proven to be very important in the interpretation of pre-operative neuropsychological test results and the prediction of

post-operative cognitive outcome. As such, a brief discussion of these variables is provided.

Age at seizure onset/first risk

Age at seizure onset has proven to be a very powerful predictor of cognitive outcome. Patients with earlier age at seizure onset often demonstrate more significant intellectual and cognitive dysfunction than patients who develop seizures later in life and are less likely to demonstrate significant cognitive declines following epilepsy surgery.[93–99] Studies have shown that age at onset and age at first risk (i.e., age at which the first risk factor for seizures occurred) are useful predictors of memory and language, particularly naming, decline after temporal lobectomy.[100,101] Patients with later age at seizure onset often show greater declines in memory and cognitive functioning following temporal lobectomy, particularly if the dominant temporal lobe is resected.[100–102] However, it should be noted that some researchers have suggested that age at seizure onset may simply reflect the likelihood of the presence of MTS, as MTS is strongly associated with early age at seizure onset.[53]

Duration of epilepsy

It has been suggested that the duration of epilepsy is related to cognitive performance. For example, it has been reported that patients who have had seizures for many years perform more poorly on intelligence tests than patients with shorter epilepsy duration.[10,96,97,103–105] However, this finding has not been universal,[17,94,98] and some have suggested that this relationship may be driven primarily by age at seizure onset rather than duration per se.[98] Alternatively, duration of epilepsy may not show a consistent relationship with cognitive functioning due to the manner in which seizure duration is defined (e.g., confound with seizure frequency).[94,104] For example, some patients may have frequent seizures and others may go years between events. As a result, Farwell *et al.*[104] have suggested that number of years with seizures may be a more appropriate measure than number of years since seizure onset.

Seizure frequency

Seizure frequency has been demonstrated to be related to cognitive test performance. Patients with more frequent seizures have been shown to have decreased scores on cognitive measures.[106–110] This appears to be more apparent in children with uncontrolled seizures than among adults.[111,112] It has been reported that recent seizure activity can affect a patient's profile on neuropsychological testing[113]; however, number of lifetime seizures appears to be more related to cognitive abilities than the recency of seizures (e.g., past month).[94,114] Further, patients with generalized tonic clonic seizures demonstrate more cognitive impairment than patients with partial seizures,[104,105] and a history of status epilepticus is associated with greater cognitive difficulties than observed in patients with frequent generalized seizures.[114]

Age at time of surgery

The risk for poor memory outcome following temporal lobectomy appears to increase with advancing age, at least on some measures of episodic memory.[102,115] There have been several studies that have reported that older individuals are at greater risk for post-operative declines in naming and verbal memory following dominant temporal resection than younger individuals.[50,52]

Drug therapy

There is a rather extensive literature on the cognitive side effects of antiepileptic drugs (AEDs). Although most AEDs have dose-related cognitive side effects,[116] these effects vary substantially with the type and number of medications being used. For example, barbiturates have been demonstrated to have the most adverse cognitive effects, phenytoin has been shown to slow response speed, and Topiramate often affects executive functioning.[117–120] In contrast, carbamazepine appears to have relatively few cognitive side effects.[94] Patients on multiple drug therapies over a number of years are more likely to demonstrate negative cognitive effects; however, it has been noted that all of these factors are likely affected by the severity of the epilepsy.[94]

Sex

Some research has suggested that males with epilepsy are at higher risk for intellectual difficulties than females, particularly with regard to verbal cognitive abilities.[98,121,122] Other studies have demonstrated that verbal memory is more bilaterally represented in women.[123] As a result, women tend to have better post-operative memory outcomes than men.[123,124] However, a subsequent study suggested that women may perform better than men both pre- and post-operatively with no significant interaction between sex and surgery.[125] It has also been reported that atypical language dominance, as determined via IAP, is not more frequently observed in women than men.[126]

Handedness and speech dominance

Studies have found that patients who are left-handed or have atypical language dominance demonstrate greater general cognitive impairments than those who are right-handed and have typical language dominance, particularly with regard to nonverbal functions.[17,98,127,128]

Psychopathology

Several studies have investigated memory performance in patients with temporal lobe epilepsy and comorbid depression, suggesting that patients with increased depressive symptoms demonstrate reduced auditory memory scores as compared to patients with fewer depressive symptoms.[129–131] However, this finding has not been universal.[132,133] This relationship appears to be most evident in patients with left temporal lobe epilepsy.[131,134] In addition to be ing associated with preoperative memory performance, preoperative depression has also been associated with declines in general and verbal memory following left temporal lobe resection.[135] Please refer to Chapter 100 for a more detailed discussion of psychiatric risk factors for post-surgical deficits.

Genetics

Recent studies have suggested that the apolipoprotein (APOE) e4 allele, previously implicated in the memory impairment observed in Alzheimer's disease, may be a risk factor for memory and cognitive impairment in temporal lobe epilepsy as well. The ε4 allele has been associated with reduced word-list learning performance in patients with newly diagnosed

partial epilepsy[136] and well-controlled, nonlesional TLE.[137] In fact, the latter study found that patients with an e4 allele were four times more likely to perform poorly on measures of verbal memory than patients without the allele.[137] A more recent study was conducted at our center with patients who underwent temporal resections for treatment of their seizures. An interaction was observed between e4 status and duration of epilepsy such that ε4-carriers with a long duration of epilepsy demonstrated the poorest memory performance on both verbal and nonverbal measures.[138] Interestingly, this relationship was observed both before and approximately six months after temporal lobectomy with little change in test performance over time.[138]

Multivariate prediction of post-operative cognitive outcome

Although the previously discussed studies provide very important information about individual factors that are related to post-operative cognitive decline, few studies to date have considered these risk factors simultaneously. In an attempt to facilitate the clinical utility of data obtained during pre-surgical epilepsy investigations, in recent years researchers have begun to develop multivariate regression equations that can use data from multiple sources simultaneously to predict post-operative cognitive decline.

Investigations using multivariate prediction

One of the earliest multivariate investigations was conducted by Chelune and colleagues in 1993.[139] They found that memory scores following contralateral IAP injection and baseline memory scores were significant predictors of change in verbal and general memory.

In 1995, Hermann *et al.*[102] examined multiple demographic and seizure variables simultaneously to determine their ability to predict change in verbal memory performance following temporal lobectomy. Later age at seizure onset, older age at time of surgery, and higher pre-operative memory performance were significant predictors of memory decline following left temporal resection. Pre-operative memory performance and chronological age were only significant predictors for change on select memory measures following right temporal lobectomy. Age at seizure onset was not a significant predictor of memory change in the right temporal group.

Davies and colleagues[142] examined the following predictors: age at onset, chronological age, sex, FSIQ, education level, and pre-operative memory scores. They determined that verbal memory decline following anterior temporal lobectomy could best be predicted using a multiple regression equation that included age, FSIQ and pre-operative verbal memory scores.

Helmstaedter and Elger[44] used multiple regression analysis to examine pre-operative memory performance (verbal and visual), extent of temporal resection, seizure outcome following surgery, presence of MTS, onset and duration of epilepsy, seizure type, age at time of surgery, and sex as predictors of verbal memory decline following anterior temporal lobectomy. In patients who underwent left temporal resections, memory decline was associated with high pre-operative memory scores, older chronological age, long duration of epilepsy, extensive resection, pre-operative visual memory deficits, and pre-operative secondarily generalized seizures. For patients who underwent right temporal resections, post-operative verbal memory declines were associated with higher pre-operative verbal memory performance and post-operative seizure outcome. For both surgical groups, pre-operative memory performance was the most significant predictor of post-operative memory decline.

In 1997, Jokeit and colleagues investigated prediction of change in prose recall following left temporal lobectomy. They examined a total of 15 independent variables including sex, age at epilepsy onset, probable age at temporal lobe damage, age at testing, lateralized frequency of sharp waves and slow waves, seizure frequency, left and right hemisphere IAP memory performance for verbal and nonverbal information, and immediate and delayed recall performance of two prose passages. They found that pre-surgical prose recall performance, in conjunction with discriminability score of the right hemisphere from IAP, explained up to 82% of the total variance. Specifically, patients with higher pre-operative memory functioning and impaired performance following left IAP injection were at highest risk for memory loss following left temporal resection.

These authors also investigated an alternative regression model in which age of probable temporal lobe damage (i.e., age at first risk) and age at epilepsy onset were used in place of IAP results. This regression equation was less effective than the first equation, explaining only 71% of the variance. Nevertheless, when age at first risk and age at onset were used in place of IAP results, patients with late age at first risk and early age of epilepsy onset were at highest risk for decline in prose recall following surgery.

Bell and colleagues[23] used a multivariate approach to examine the utility of IAP scores in predicting post-operative memory decline in patients with left temporal lobe epilepsy and left hippocampal sclerosis. They found that three variables, when examined in combination, were predictive of verbal memory decline following left temporal lobectomy: poor IAP recognition score following ipsilateral injection, high pre-operative cognitive ability, and late age at surgery.

Chelune and Najm[141] used a multivariate approach to predict memory decline following temporal lobectomy. They examined eight potential predictor variables: patient age, age of seizure onset, sex, baseline verbal memory scores, percent recall following IAP contralateral and ipsilateral injection, ratio of right to left hippocampal volumes on MRI, and side of surgery. They found that surgery in the dominant hemisphere, absence of ipsilateral MTS, and intact baseline verbal memory performance were all independent predictors of post-operative memory decline. Approximately 42% of the patients in this study demonstrated post-surgical memory declines. Using the three significant predictor variables discussed above, 71% of the patients were accurately classified with regard to absence or presence of memory loss with a sensitivity of 63% and a specificity of 76%. To facilitate clinical utility, the authors provided odds ratios for different combinations of the three unique predictors. They also provided odds for a nonsurgical control group.

In 2003, Stroup and colleagues[45] replicated and extended the findings of Chelune and Najm[141] in a larger sample.

They examined a total of five potential risk factors: dominant temporal resection, MRI findings other than unilateral MTS, intact pre-operative immediate and delayed verbal memory function, and intact IAP memory performance following contralateral injection. All five of these risk factors were found to be independently associated with memory decline following surgery. Side of surgery and MRI findings were the variables most strongly associated with memory change following surgery. Approximately 38% of the patients in this study demonstrated post-surgical memory declines. The combination of these five predictors accurately classified 78% of the patients included in the study with a specificity of 99%.

A recent study investigated the ability of fMRI, in conjunction with several other risk factors, to predict post-operative memory decline. Richardson and colleagues[75] examined three predictor variables: pre-operative verbal memory performance, volume of the dominant hippocampus, and encoding asymmetry evidenced on fMRI. All three of these variables were demonstrated to be independent predictors of post-operative verbal memory decline, with the difference between left and right hippocampal encoding activity providing the strongest independent prediction of decline in verbal memory.

Moderator/mediator variables

The studies presented in this chapter have provided very useful information in determining which patients are at highest risk for declines in cognitive functioning following epilepsy surgery. However, the majority of these studies have not directly examined the potential mediating and/or moderating effects[142] of demographic and seizure variables in the prediction of post-operative cognitive outcome. A moderating variable is a variable (qualitative or quantitative) that affects the direction or strength of the relationship between an independent predictor variable and the dependent variable. Mediator variables, in contrast, account for the relationship between the predictor and criterion variables. In other words, "moderator variables specify when certain effects will hold, mediators speak to how or why such effects occur."[142]

Clearly, many of the studies cited have provided evidence suggesting that the relationship between predictors and post-operative cognitive change is moderated by a number of factors, including side of surgical resection,[26–30] age at seizure onset,[100,143] and pathological findings.[47,54–58] However, few of the studies on post-operative cognitive outcome have directly assessed the moderating effects of these variables and the potential moderating effects of other factors known to be related to cognitive outcome (e.g., duration of epilepsy, seizure frequency, sex) and we are unaware of any studies that have assessed the potential mediating effects of these variables.

Recent studies examining the predictive ability of neuropsychological instruments in determining seizure lateralization have underscored the importance of considering potential mediators/moderator factors. For example, the relationship between confrontation naming measures and side of surgery has been shown to be moderated by intelligence, age at seizure onset, and duration of epilepsy,[144,145] suggesting that pre-surgical confrontation naming performance is best predictive of side of surgery in only a subset of patients. One would expect that similar relationships exist between the various predictor variables discussed in this chapter and cognitive change following epilepsy surgery. Careful consideration should be given to potential mediating and moderating variables in conducting multivariate predictions of post-surgical change. Consideration of such variables can only be expected to improve the predictive power of pre-surgical data in assessing risk for post-surgical cognitive outcome by accounting for more variance in the prediction of post-operative cognitive outcome.

Summary and conclusions

Over the last couple of decades, significant progress has been made in identifying the factors that are related to post-operative cognitive decline following epilepsy surgery. Information gleaned from pre-operative investigations as well as a number of demographic and seizure variables have proven to be rather consistently related to cognitive outcome following temporal lobectomy, particularly in patients who undergo dominant temporal resections. More recently, studies have sought to combine pre-surgical data in multivariate prediction analyses to improve the accuracy of identifying those patients at highest risk for cognitive declines following surgery. Additional studies are needed to determine which combination of pre-surgical and demographic variables result in the most accurate prediction of post-operative cognitive outcome. Consideration and identification of factors that may moderate and/or mediate the relationship between predictor variables and post-surgical cognitive outcome will only serve to improve the predictive ability of our pre-surgical variables in the future.

91 Pre-surgical psychiatric evaluations: risk factors for post-surgical deficits

AM Kanner and AJ Balabanov

Introduction

Psychiatric comorbidities are a common occurrence in patients with pharmaco-resistant epilepsy who are being evaluated for epilepsy surgery and their prevalence-rates are significantly higher than those of people in the general population.[1–7] Depressive and anxiety disorders are the most commonly diagnosed disorders in adults while Attention Deficit Hyperactivity Disorders (ADHD) take the lead in children. For example, various investigators have reported lifetime prevalence rates of depressive disorders ranging between of 30–55%, while ADHD has been identified in 20–30% of children with epilepsy, particularly those with seizure disorders of temporal and frontal lobe origin.[6,7] Typically these psychiatric disorders are chronic with a waxing and waning severity. The actual prevalence rates of ADHD in adults with partial epilepsy have not been investigated, however; yet, 50–70% of nonepileptic children with ADHD are expected to continue to be symptomatic in adult life.[8] Psychotic disorders are less frequent than the three other types of conditions, their prevalence rates are two- to fourfold higher in patients with epilepsy than in the general population.[9,10]

Post-surgical psychiatric complications have been recognized for the last 40 years, often presenting as *de novo, recurrence* or *worsening* of a previous mood, anxiety and/or psychotic disorder.[11–14] Given all of these facts, it is surprising that most patients being considered for epilepsy surgery do not undergo a pre-surgical psychiatric evaluation. After all, *pre-surgical* comorbid psychiatric disorders have significant impact on epilepsy surgery at several levels; these include: (i) a potential interference with the successful completion of the pre-surgical evaluation, including the ability to make an objective informed decision to proceed with epilepsy surgery; (ii) a potential risk for post-surgical psychiatric complications; (iii) an impact on post-surgical psychosocial adjustment, including the potential to obtain gainful employment; (iv) a potential impact on post-surgical seizure outcome. In this chapter we discuss the reasons behind the need to consider a pre-surgical psychiatric evaluation in every surgical candidate and review its content in the clinical and research domains, so as to identify patients at risk for post-surgical psychiatric complications and to ensure optimal adjustment to a life without seizures. We also discuss the circumstances under which epilepsy surgery should not be considered for patients with comorbid psychiatric disorders. The information presented in this chapter is complemented by that of Chapter 144, where we review the impact of epilepsy surgery on post-surgical psychiatric, psychosocial, and seizure outcome and discusses the disclosures that need to be made to patients and families with respect to potential surgical related psychiatric complications.

Surgical candidates: a population at risk of comorbid psychiatric disorders

Mood disorders

Mood disoiders are the most common psychiatric comorbidities in patients with epilepsy.[15–18] While the higher prevalence rates are typically found among patients with refractory epilepsy (and hence, potential surgical candidates), a recent population-based study has found that almost one in three patients with epilepsy had experienced a major depressive episode in their life.[19] Primary mood disorders comprise an *heterogeneous* group of conditions with respect to their clinical manifestations, course and response to treatment. Mood disorders in epilepsy may be identical to primary mood disorders that meet diagnostic criteria suggested in the Diagnostic and Statistical Manual of Mental Disorders (DSM), be it in its third, third revised, fourth, or fourth text revision (IV-TR).[20] These include major depressive disorders, dysthymia, minor depression, bipolar disorder, and cyclothymia. Yet, a significant percentage of mood disorders fail to meet any of the DSM-IV-TR diagnostic criteria in patients with epilepsy. That is, they present with atypical manifestations. This compounds the heterogeneity of mood disorders alluded to above in these patients.

Major depressive episodes (MDE) are the more severe expression of a mood disorders. Yet, MDE can occur as part of: (i) a major depressive disorder (i.e., multiple MDE); (ii) a bipolar disorder; and (iii) a double depression, in which recurrent MDE are intermixed with dysthymic disorders. Furthermore, establishment of whether an MDE is the first one is of utmost importance as the risk of subsequent MDE is of 50%, of 70% after two and almost 100% after more than two episodes.[20–22] Ten to 15 years after an index MDE, about 80–90% of patients can be expected to have a recurrence. Furthermore, several studies have highlighted the importance of also recognizing subsyndromal forms of depression, as these are associated with a risk of developing a major depressive episode.[22] Furthermore, in the setting of any MDE, clinicians must always look for risk factors of a bipolar disorder (i.e., family history, a MDE before the age of 18, hypomanic symptom triggered by the use of antidepressants) as spontaneous manic and/or hypomanic episodes can occur several years after an initial MDE.

As stated above, atypical mood disorders are relatively frequent in patients with epilepsy. Mendez *et al.*, found that almost 50% of depressive disorders in patients with epilepsy had to be classified as Depressive Disorder Not Otherwise Specified, or Atypical Depression, according to DSM III-R criteria.[23] A review of the psychiatric literature shows that in the early part of the 20th century two German psychiatrists, Kraepelin and Bleuler had recognized a form of depression that was associated with epilepsy.[24,25] Their observations were later on confirmed by Gastaut[26] and Blumer expanded on the work of these three investigators and coined the term of *Interictal Dysphoric Disorder* (IDD) to refer to this type of mood disorder.[27] He confirmed its relatively frequent occurrence in patients with TLE, an observation that has been supported by others and our own data. The predominant clinical manifestations consist of a chronic pleomorphic picture that includes symptoms of depression, anxiety, irritability, somatic symptoms, including pain, and intermixed periods of euphoric mood. It tends to mimic a *dysthymic* disorder, given the milder severity of symptoms and their chronic course with the exception of symptom-free periods that may last several days. Blumer considered that almost one-third to one-half of patients with epilepsy seeking medical care suffer from IDD. Likewise, in a study of 97 patients with epilepsy and depressive symptoms of enough severity to require pharmacologic treatment, we found that 69 patients had a clinical presentation mimicking a dysthymic disorder.[28]

Depressive disorders usually do not occur in isolation, both in patients with and without epilepsy. Rather they tend to occur in association with anxiety disorders. For example, in a study of 174 consecutive outpatients with epilepsy from five epilepsy centers, 73% of patients that met DSM-IV diagnostic criteria for a depressive disorder also met criteria for an anxiety disorder.[29] The comorbid occurrence of anxiety and depressive disorders is of great significance as the latter increases the suicidal risk of depressed patients. This problem is more worrisome in patients with epilepsy, as these are a population with a significantly higher risk of suicidality.[30]

Anxiety disorders

Together with mood disorders, anxiety disorders are the most common psychiatric comorbidity in patients with epilepsy.[31] Population-based studies have estimated the prevalence of anxiety in epilepsy patients to range between 15 and 25%.[32,33] In the study by Jones *et al.* cited above, a DSM-IV diagnosis of a current anxiety disorder was found in 30% of patients.[29] As in the case of mood disorders, the higher prevalence rates of anxiety disorders are more often identified in pharmaco-resistant patients.

The DSM-IV-TR has included 11 types of anxiety disorders.[34] Generalized anxiety disorder, panic disorder, phobias, agoraphobia without panic disorder, and obsessive compulsive disorder are the most frequently identified in patients with epilepsy and as stated above, often as comorbidities of a mood disorder. In addition, patients with epilepsy may often exhibit episodes of anxiety that fail to meet any DSM diagnostic criteria.

Attention deficit hyperactivity disorders and behavioral disturbances

As in the case of depression and anxiety disorders, ADHD and behavioral disturbances are significantly more common among children with epilepsy than in the general population.[1,6,7] Furthermore, in a population-based study done in the Isle of Wight in Great Britain, Rutter and collaborators found behavioral disorders in 28.6% of children with uncomplicated seizures, and 58.3% of children with both seizures and additional central nervous system pathology.[35] In a separate population-based study of children with seizures, cardiac disorders, and controls, McDermott and collaborators found that children with epilepsy had more behavioral problems than either the children with cardiac disease or the controls, who presented with higher rates of hyperactive behavior (28.1% vs 12.6% in cardiac children and 4.9% in controls), headstrong or oppositional behavior (28.1% vs 18.3% of cardiac children and 8.6% of controls), and antisocial behavior (18.2% vs 11.6% of cardiac children and 8.8% of controls).[36] Children with seizure disorders of temporal and frontal lobe origin are at special risk of this disorder, and particularly those with poorly controlled seizures. Hence, potential surgical candidates! As stated above, the prevalence rate of ADHD in adults with epilepsy is yet to be established.

Psychotic disorders

These are the less frequent than mood, anxiety, and ADHD, but their prevalence rates are still significantly higher than those of the general population.[9,10] Psychotic disorders are divided into interictal, ictal, and postictal psychotic episodes (PIPE). Consideration of epilepsy surgery in patients with comorbid psychotic disorders has been the source of great controversy among epilepsy centers. In a large number of programs, the presence of a psychotic disorder constitutes a criterion for exclusion from pre-surgical evaluation; other centers, on the other hand do not ruleout a surgical option, as long as the patient is able to cooperate with the pre-surgical evaluation and understands the risks of the surgical procedure and the benefits and limitations of this type of treatment.

Interictal psychotic disorders can be indistinguishable from primary schizophreniform disorders and present with delusions, hallucinations, referential thinking, and thought disorders. However, in a significant proportion of patients with epilepsy, interictal psychosis differs from that of patients with primary schizophreniform disorders. Slater coined the term of interictal psychosis of epilepsy (IPOE) to describe certain clinical characteristics, particularly, psychotic episodes seen interictally in patients with chronic epilepsy which are remarkable for *the absence* of negative symptoms, better premorbid history, and less common deterioration of the patients' personality.[37] This form of psychosis is less severe and more responsive to therapy. The 'more benign' clinical manifestations and course of IPOE acquires additional relevance for patients with refractory epilepsy who are being considered for surgery. Indeed, it makes it more likely that these patients can cooperate during a pre-surgical evaluation.

Postictal psychosis

Postictal psychosis (PIPE) can present in the form of isolated symptoms or as a cluster of symptoms mimicking psychotic disorders and represent approximately 25% of POE. The prevalence of PIPE in the general population of patients with epilepsy is yet to be established, but has been estimated to

range between 6% and 10%.[38] We estimated the yearly incidence of postictal psychiatric disorders among patients with partial epilepsy that are undergoing V-EEG to be 7.9%.[39] The majority or 6.4% presented as PIPE. In every case, the onset of symptoms lagged by a mean period of 24 hours (range 12 to 72 hours) relative to the time of the last seizure. The mean duration of the PIPE was 69.6 hours (range: 24 to 144) and they all responded well to low doses of antipsychotic medication or benzodiazepines. Other authors have reported similar findings with respect to clinical characteristics, course and response to pharmacotherapy.[39–44]

The occurrence of PIPE in potential surgical candidates is significant as several studies have found a greater risk of bilateral independent ictal foci.[39,41,42,44] In a study of 282 consecutive patients who underwent an ATL, Christodoulou *et al.*, identified three who developed denovo PIPE post-surgically.[45] In these patients, seizures were recorded predominantly from the contralateral (nonsurgical) site or had bilateral independent seizures; none of the patients who failed surgery but continued to have seizures from the site of the surgery developed de novo postictal psychosis. In a study completed at the Rush Epilepsy Center, the occurrence of PIPE was found to predict the presence of bilateral independent ictal foci with an 89% probability.[46] By the same token, patients with recurrent PIPE are at significant risk of developing interictal psychosis. To minimize this risk, clinicians must carefully weigh the option of 'palliative' surgery, particularly to patients with mesial temporal sclerosis (MTS), provided that most seizures originate from the side of the atrophic hippocampus and the neuropsychological data are concordant with the intended surgical target.

Clearly, patients with refractory epilepsy being considered for surgery are likely to be suffering from comorbid psychiatric disorders. In the next section we review the problems behind the limited use of psychiatric evaluations in surgical candidates.

Psychiatric consultations during pre-surgical evaluations

Use of psychiatric evaluations in major epilepsy centers

How do major epilepsy centers in the USA evaluate the existence of comorbid psychiatric disorders or risk factors for post-surgical psychiatric complications? To answer this question, we investigated the use of psychiatric and neuropsychological evaluations during pre-surgical work-ups of candidates for antero-temporal lobectomy (ATL) in a survey sent to the 88 epilepsy centers belonging to the National Association of Epilepsy Centers (Kanner AM, submitted). Forty-seven centers (53%) completed the survey. The survey consisted of seven questions (see Table 91.1).

Our results revealed that only 10 centers (21%) routinely perform a psychiatric evaluation in *every* patient who is being considered for ATL. Three centers (6%) perform a psychiatric evaluation only in case of a previous psychiatric history, 16% if it is recommended by the neuropsychologist and 45% use either of the latter two criteria.

The lack of available psychiatric consultants has been 'blamed' for the failure to carry-out psychiatric evaluations in all pre-surgical patients. This 'forces' the epilepsy team to rely on neuropsychological evaluations to screen for comorbid psychiatric disorders. Thus, the second question of the survey, enquired about the *availability* and *use* of psychiatrists in each center. Among the 47 centers, only 12 (26%) had a psychiatrist in their epilepsy team. Consultations were provided by the hospital's psychiatry liaison and consultation service (LCS) in the other 35 centers: in 10 (21%) the *same* psychiatrist was always available to do the consultation while in 24 (51%) consultations were carried out by *different* psychiatrists. In one center, consultations were done by the residents but the attending did not see the patients in person.

The concern among epilepsy teams of post-surgical psychiatric complications is another variable that accounts for the diversity in the use of psychiatric consultations in these centers. The third question addresses this issue by asking the epileptologists whether they believe that psychiatric complications following ATL are frequent enough to warrant a pre-surgical psychiatric evaluation. The survey's data indicate the absence of a consensus on this issue as 21 centers (45%) considered it to be a problem, while 26 (55%) did not. Clearly, the lack of consensus in this very important question among 47 of the leading epilepsy centers in North America is indicative of an urgent need to investigate this problem in a systematic manner.

The availability of an epilepsy team psychiatrist appears to make a significant difference on the concerns of post-surgical psychiatric complications and on the use of psychiatric evaluations in every patient. Thus, 75% of centers with an epilepsy team psychiatrist voiced a concern of frequent post-surgical psychiatric complications, while this was true in one third centers in which consultations were carried out by LCS psychiatrists. Of note, there was no difference among centers where the same (30%) or different (33%) psychiatrists performed the evaluation. These data suggest that psychiatrists with special expertise in psychiatric aspects of epilepsy are more 'attuned' to potential post-surgical psychiatric complications. These data also raise the question of the quality of psychiatric evaluations performed by psychiatrists that lack special expertise in the psychiatric problems of epilepsy patients. In fact, 35 centers (75%) voiced concerns on the failure to obtain in-depth psychiatric evaluations.

As suspected, the lack of an epilepsy team psychiatrist is associated with a reliance on neuropsychological evaluations to identify comorbid psychopathology. For example, among the 24 centers that rely on a different LCS psychiatrist for their evaluations, 23 (96%) based their decisions to order a psychiatric evaluation on the basis of the recommendations of a neuropsychologist or if the patient is known to have a psychiatric history, while this is the case in eight of the ten centers (80%) who have the same LCS psychiatrist available. In contrast only four of the 12 centers (33%) with epilepsy team psychiatrist relied on these criteria.

Whether neuropsychological evaluations are adequate to identify patients at risk for post-surgical psychiatric complications is the next question. In our opinion they are not! In fact, most neuropsychological evaluations rely on screening instruments aimed at identifying psychiatric symptoms occurring during the prior 1 to 4 weeks, depending on the instrument used; thus, these instruments are likely to fail to detect any past psychiatric history that may be in remission at the time of the pre-surgical evaluation and to capture the

Table 91.1 Survey on the use of pre-surgical psychiatric evaluation

Please check the answer that best reflects the practice at your center:

1. **Patients evaluated for an antero-temporal lobectomy:**
   - **(a) Only undergo a neuropsychological evaluation.**
   - **(b) Always undergo both a neuropsychological evaluation and a psychiatric evaluation.**
   - **(c) Only undergo a psychiatric evaluation if they are known to have a psychiatric history.**
   - **(d) Only undergo a psychiatric evaluation if suggested by the neuropsychologist.**
   - **(e) Either c or d apply.**

YOUR ANSWER:

2. **When requesting a psychiatric evaluation for our patients with refractory temporal lobe epilepsy undergoing a pre-surgical evaluation:**
   - **(a) We have a psychiatrist who is part of the epilepsy team and evaluates all of these patients.**
   - **(b) We can request a consultation from the Psychiatry Consult Service, but the same psychiatrist is always (or most of the time) available to see these patients.**
   - **(c) We can request a consultation from the Psychiatry Consult Service, but there is no one psychiatrist dedicated to evaluate the epilepsy patients.**
   - **(d) We can request a consultation from the Psychiatry Consult Service, but the attending psychiatrists rarely see the patient.**

A. In the following five statements, please check ***True*** *or* ***False****, according to your opinion*.

1. **Psychiatric post-surgical complications following a temporal lobectomy are frequent enough to warrant a pre-surgical psychiatric evaluation in every patient.** *True____ False____*
2. **Neuropsychological evaluations are adequate to identify any patient at risk for post-surgical psychiatric complications.** *True___ False____*
3. **Psychiatric evaluations are only** *necessary* **for patients in whom the neuropsychologist has suggested the use of psychotropic drugs.** *True_____ False_____*
4. **In my opinion, it is difficult to find psychiatrists interested in carrying out a thorough psychiatric evaluation in our epilepsy patients.** *True____ False_____*
5. **There is a need for more psychiatrists to be trained to evaluate the psychiatric comorbidities of Epilepsy.** *True____ False_____*

complexity of the comorbid psychiatric disorders that are so common in these patients, as discussed in the previous section. Indeed, only with a comprehensive psychiatric evaluation that investigates present and *lifetime* histories can clinicians have the necessary information to formulate a correct psychiatric diagnosis, recommend the appropriate treatment and make estimations on the risk for potential post-surgical psychiatric complications. Furthermore, family psychiatric history is one of the leading risk factors of mood, anxiety and ADHD. Unfortunately, these data are rarely investigated in a neuropsychological evaluation. In short, screening instruments do not identify the complexity of such psychiatric comorbidities.

Can epileptologists and neuropsychologists rely on a *patient's self*-report of past or concurrent psychiatric history? The answer to this question is also 'no'! Indeed, it is a well established fact that most frequent psychiatric comorbidities in epilepsy patients (depression, anxiety, and ADHD) are very often unrecognized by the treating epileptologist and that only severe forms of these disorders are reported by the patients to the physicians. In addition, patients may not volunteer information on a comorbid psychiatric disorder out of misinterpretation of such disorders being 'a normal reaction' to a life with epilepsy, while some patients may hide such history out of fear that such history would disqualify them from consideration for epilepsy surgery. Failure to recognize chronic depressive disorders is illustrated in a study of 97 patients with partial epilepsy with a depressive disorder severe enough to warrant the consideration of pharmacotherapy, 60% had been symptomatic for more than one year before any treatment had been suggested.[28] Only one-third of the 97 patients had been treated within 6 months of the onset of their symptoms.

What is the reason behind a failure of most epilepsy programs to incorporate a psychiatrist in their 'team'? After all, all programs have one or more than one neuropsychologist. The answer is ironically rather simple: lack of financial resources on the part of hospital psychiatry departments to provide a full- or part-time staff psychiatrist to a single service. Indeed, a careful analysis of the 12 epilepsy centers with an epilepsy team psychiatrist reveals that the epilepsy programs pay for part of the salary of their psychiatrist. Thus, epilepsy centers that wish to have a psychiatrist in their team will have to budget a fraction of the psychiatrist's salary in their operating costs.

Psychiatric complications of epilepsy surgery

This topic is reviewed in great detail in chapter 142; we present here the most relevant points. Post-surgical psychiatric complications can be identified in up to 30–50% of patients undergoing an ATL consisting primarily of *recurrence* or *exacerbation* in severity of pre-surgical depressive and anxiety disorders, and less frequently of de novo mood disorders.[11–14,47] Most of these complications occur within the first six months after surgery and tend to remit within the first 12–24 months. However, a subset of 10–15% of patients is expected to suffer from refractory depressive and anxiety disorders.[47] De novo

post-surgical psychotic disorders are relatively rare, reported in 1–10% of series.

What should a pre-surgical psychiatric evaluation consist of?

Clearly, the evidence presented in the previous sections suggest that patients who undergo epilepsy surgery are at risk for post-surgical psychiatric complications. Accordingly, pre-surgical psychiatric evaluations must seek to obtain the following:

1. *Lifetime* and *current* psychiatric history of mood, anxiety, attention deficit disorders and psychotic disorders and to identify any evidence of a personality disorder.
2. A detailed history of the temporal relation of psychiatric symptoms to seizure occurrence (i.e., to establish if all symptomatology was interictal or if it presented as preictal or postictal episodes solely or in addition to interictal disorders).
3. A family psychiatric history, since a genetic predisposition is a pivotal factor in the development of mood, anxiety and attention deficit disorders, the most frequent psychiatric comorbidities in these patients.
4. An assessment of family dynamics, and specifically, the role played by each spouse with respect to the decision making process in economic and family-related matters as well as an assessment of whether the patient's spouse is ready to adjust to a greater independence associated with a post-surgical seizure-free state. Indeed, it is not rare for spouses to have difficulty relinquishing the role of 'care taker' which inadvertently can lead to conflict, including divorce.
5. A vocational assessment and the need for referral to a vocational rehabilitation program.

Pre-surgical evaluations in research

The data obtained in the survey presented above clearly indicates the need of systematic research on the incidence and types of post-surgical psychiatric complications, the impact of pre-surgical risk factors on post-surgical psychiatric seizure and psychosocial outcomes. To that end, any methodologically sound study must include:

1. A structured psychiatric interview aimed at identifying lifetime DSM-IV-TR psychiatric syndromes and personality disorders. Various diagnostic interviews are available and can be administered by trained research assistants. It should be remembered, however, that these interviews were developed for patients with primary psychiatric disorders and not for patients with epilepsy with psychiatric comorbidities. The limitations of using these instruments are not known at this time. Furthermore structured interviews specifically developed for patients with epilepsy will need to be elaborated in the future.

   The most frequently structured interviews include: (i) the Structured Clinical Interview for Axis I and II DSM-IV Disorders (DISC).[48] (ii) the Composite International Diagnostic Interview (CIDI);[49] (iii) the Schedule for Affective Disorders and Schizophrenia (SADS);[50] (iv)the Diagnostic Interview Schedule;[51] (v) The Mini International Neuropsychiatric Inventory (MINI).[52]

   It should be said that these psychiatric interviews need not be given in their entirety. Indeed, depending on the question at hand of the specific study, special sections of a questionnaire can be administered. For example, in the case of a study on mood and anxiety disorders, investigators can decide to administer the section of these disorders of the SCID.

   Structured interviews have been developed specifically for the identification of psychiatric syndromes in children and adolescents. The most rigorous is the SADS, adapted from the adult version for this school-age children.[53]
2. We cannot emphasize enough the need to include an instrument that investigates the family psychiatric history. The Family History Screen for Epidemiologic Studies (FHE) is an user-friendly screening instrument that can be used in research.[54]
3. Self-rating *screening* instruments are the favorite methods to acquire psychiatric data in research studies of epilepsy patients because of the logistical ease and low costs.

Unfortunately, these instruments are designed to detect symptoms and not to establish a DSM-IV diagnosis, let alone the diagnosis of psychiatric entities with all their complexities and atypical manifestations encountered in patients with epilepsy. Thus, the sole use of these instruments represents the most frequent methodological error in psychiatric research studies in epilepsy. The argument for exclusively using screening instruments is that they have been validated to identify conditions such as MDE some with acceptable levels of sensitivity and specificity and the severity of the depressive episodes. Thus, proponents of the sole use of these scales might reason, *if a patient has a score of >30 on the Beck Depression Inventory–II, what can it be, other than a MDE?* While this statement is probably correct, a MDE may be the expression of more than one type of mood disorder, each with a different prognosis and treatment strategy (see the section on mood disorders in this chapter).

As in the case of structured interviews, most of the screening instruments were developed for the screening of symptoms in patients with primary psychiatric disorders and not in patients with epilepsy. The only exception is the *Neurological Disorders Depression Inventory for Epilepsy (NDDI-E)*[55] (see below). In addition two screening instruments for the identification of symptoms of depression, the Beck Depression Inventory-II (BDI-II) and the Center for Epidemiologic Studies-Depression Scale (CES-D) have been recently validated in patients with epilepsy.[56]

Clearly, the use of screening instruments for psychiatric research in epilepsy must be *used in conjunction* with a structured psychiatric interviews designed to establish a DSM-IV-TR diagnoses; only then do these screening instruments yield meaningful data as they permit regular re-screening to measure changes in severity of symptomatology. The most frequently used screening instruments in adults include the following.

Screening of general psychiatric symptoms

Adult Self-Report Inventories-4: The Adult Self-Report Inventories are symptom inventories that can be used as a

guide for conducting clinical interviews.[57] They include the behavioral symptoms of more than two dozen psychiatric disorders described in the DSM-IV. There are parallel versions of the Adult Self-Report Inventories that are designed to obtain information from both patients and significant others. These inventories take approximately 15 to 20 minutes to complete. Items are grouped according to diagnostic categories.

Hopkins Symptom Checklist (SCL-90 Revised): The SCL-90 is used to evaluate a broad range of psychopathology. It consists of 90 items and usually can be completed in less than 30 minutes.[58] The scoring system includes nine symptom scales (somatization, obsessive-compulsive behavior, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism) and three global indexes. This scale has documented validity and has been used in many treatment studies of mood disorders and schizophrenia.

Minnesota Multiphasic Personality Inventory: It consists of a self-report personality inventory with ten clinical scales (hypochondriasis, depression, hysteria, psychopathic deviance, male-female, paranoia, psychasthenia, schizophrenia, mania, and social introversion) and three validity scales. The administration time is about 40 to 90 minutes.[59]

Depressive symptoms

Beck Depression Inventory-II (BDI): The BDI-II is the most commonly used self-rating scale for depression.[60] There are 21 items scored on a scale from 0–3 according to how the patient feels at the current time. The scale is sensitive to change and has been used in clinical drug trials. As stated above, the BDI-II has been recently tested in 205 patients with epilepsy from five epilepsy centers and was found to have a high sensitivity and specificity as a screening instrument of major depressive episode.[56]

The Center for Epidemiologic Studies-Depression Scale (CES-D): It is a composite of 20 items, rated from 0 (rarely) to 4 (most or all of the time). It can yield scores from 0–60, with scores >16 being suggestive of depressive illness. This scale has also been recently validated for its use in patients with epilepsy.[56]

Neurological Disorders Depression Inventory for Epilepsy (NDDI-E). This is a new self-rating instrument that consists of only six items but which was *specifically* developed to screen for the presence of major depressive episodes in patients with epilepsy, while minimizing the risk of overlap with adverse antiepileptic drug effects or preexisting cognitive problems.[55] Completing this instrument only takes 3 minutes or less and a score >14 is suggestive of the presence of a major depressive episode.

Anxiety symptoms

Hospital Anxiety and Depression Scale:[61] This scale is specifically developed for use in patients with medical comorbidity, and consists of 7-item self-rated subscales for both depression and anxiety.

Beck Anxiety Inventory (BAI):[62] The BAI is a 21-item self-report measure of anxiety severity. The scale consists of 21 items, each describing a common symptom of anxiety over the past week on a 4-point scale ranging from 0 (*Not at all*) to 3 (*Severely–I could barely stand it*). The items are summed to obtain a total score that can range from 0–63.

Goldberg's Depression and Anxiety Scales:[63] The instrument consists of nine questions assessing mood and anxiety over the previous month, and the full set of nine questions need to be administered only if there are positive answers to the first four. The scales are devised specifically to be used by nonpsychiatrists in clinical investigations. Scores are from 0–9.

Hamilton Anxiety Rating Scale (HAM-A or HARS):[64] This scale is a 14-item clinical interview scale (not self-reported) measuring somatic and psychic anxiety symptoms. The responses include five degrees of severity ranging from 0 (*None*) to 4 (*Frequent and severe symptomatology*). This instrument should be used with caution in patients with epilepsy, given the large number of somatic symptoms included in this scale which in patients with epilepsy can result from adverse effects of AEDs potentially yielding false positive suggestions of more severe anxiety symptomatology.

Obsessive-compulsive symptoms

Yale-Brown Obsessive Compulsive Scale (Y-BOCS): This is the most widely used scale for rating obsessive-compulsive symptoms. It includes a symptom checklist as well as a ten-item scale that is rated by clinicians. It has been shown to be a highly reliable instrument that is sensitive for measuring changes in the severity of obsessive-compulsive symptoms.[65]

Self-Report measures for children and adolescents include:

Child Symptom Inventories (CSI-4): The Child Symptom Inventories are screening instruments for the behavioral, affective, and cognitive symptoms of more than a dozen DSM-IV childhood disorders. There are Child Symptom Inventories for three different age groups: Early Childhood Inventory-4 (ages 3 to 5 years), Child Symptom Inventory-4 (ages 5 to 12 years), and Adolescent Symptom Inventory-4 (ages 12 to 18 years). There is a self-report measure for adolescent patients: Youth's Inventory-4 (ages 12 to 18 years).[66]

Child Behavior Checklist (CBCL): Developed by Thomas M. Achenbach, this scale evaluates pathologic behaviors and social competence in children ages 4 to 16 years. Forms are available for teachers, parents, and children. It is one of the most widely used scales for both clinical use and research.[67]

Children's Depression Inventory (CDI): This is a 27-item self-report questionnaire that can be given to 7- to 17-year-olds. It is currently one of the most widely used instruments for monitoring depression in children. Each question includes three statements of increasing severity.[68]

Multidimensional Anxiety Scale for Children (MASC): This is a scale for children and adolescents designed to assess symptoms of anxiety. The 39 items are scored on a scale from 0–3 as follows: 0 = never true about me; 1 = rarely true about me; 2 = sometimes true about me; 3 = often true about me.[69]

Connors' Parent/Teacher Rating Scales: This scale identifies behavior problems through parent and teacher report and particularly symptoms of ADHD. It is available in three versions: a 93-item version, a 48-item version, and a ten-item screening version. It is used in children ranging in age from 3 to 17 years.[70]

Leyton Obsessional Inventory-Child Version (LOI-CV; Short Form): This questionnaire is a 20-item inventory with 'yes/no' responses adapted from the adult version to assess obsessive-compulsive symptoms.[71]

Should patients with pre-surgical psychiatric disorders be excluded from epilepsy surgery?

The short answer is *no, as long as they can cooperate with the pre-surgical evaluation and they can understand the risks of the surgical procedures and the likelihood of achieving a seizure-free state.* As discussed in detail in chapter 142, epilepsy surgery is associated with a significant improvement of pre-surgical psychiatric disorders, including remission of depression and anxiety disorders in approximately 50% of patients.[11,13,47]

A pre-surgical psychiatric evaluation is important in these patients as it can be predictive of the risk of developing post-surgical psychiatric complications (see chapter 142). Indeed, a pre-surgical lifetime history of depression has been identified as the strongest predictor of post-surgical psychiatric complications presenting as exacerbation or recurrence of latent pre-surgical psychiatric disorders. Various studies have also identified an association between pre-surgical psychiatric disorders and a worse post-surgical seizure outcome (see chapter 142). Thus, in the setting of a pre-surgical psychiatric disorder, discontinuation of AEDs post-surgically may be discouraged to avert seizure recurrence.

The biggest controversy centers on the consideration of epilepsy surgery in patients with psychotic disorders. In general, patients with chronic psychosis are less likely to be referred to epilepsy surgical programs because of the assumption that they cannot cooperate with the pre-surgical evaluation. This assumption, however, has been proven to be erroneous time and again. Also, there has been a concern that psychotic disorders may worsen following epilepsy surgery. As stated above, IPOE is more benign than the primary schizophreniform disorders and hence poses less problems for the patient to be able to cooperate with the necessary tests of the pre-surgical evaluation. A review of the literature in Chapter 144 shows that the impact of ATL on the post-surgical course of the psychotic disorder has varied from unchanged (in a majority of cases) to improved psychotic status and/or level of functioning. For example, among 74 patients who underwent an ATL, Jensen and Larsen found 11 patients who had experienced a psychotic disorder pre-surgically.[72] The surgical procedure had no impact on the course of psychotic disorder. On the other hand, in a small series of five patients with a chronic psychotic disorder who underwent an ATL, Reutens *et al.*, reported an excellent seizure outcome in all patients and while the seizure-free state did not modify the actual psychotic disorder post-surgically, it facilitated their level of functioning.[73] Marchetti *et al.* reported a series of six patients with pre-surgical interictal psychosis who underwent an ATL.[74] Five of the six patients achieved a seizure-free outcome and there was no worsening of their psychotic disorder, with relative improvement in the mental conditions of five patients. In summary, the presence of a comorbid psychotic disorder should not be an 'automatic' reason for exclusion for epilepsy surgery.

Concluding remarks

Pre-surgical psychiatric evaluations are of the essence to ensure that any psychiatric comorbidity has been properly identified and the appropriate treatment has been started to avert or minimize the development of post-surgical psychiatric complications. While most epilepsy surgery rely on neuropsychological evaluations to screen for comorbid psychiatric disorders, there is a great risk that comorbid psychiatric disorders will go undetected and untreated. As mentioned above, the psychiatric disorders of patients with refractory epilepsy are often atypical in their presentation and screening instruments are unlikely to provide an objective picture.

Epilepsy centers need to incorporate a psychiatrist into their epilepsy team. Unfortunately, the economic barriers of today's healthcare environment limits the availability of access to psychiatrists in general and epilepsy programs may need to cover the costs of having a psychiatrists available in their team.

92 Pre-surgical neuropsychological workup in children and intellectually disabled adults with epilepsy

U Gleissner and C Helmstaedter

Introduction

Due to several factors, children and intellectually disabled adult patients are more difficult to analyze neuropsychologically than other patients with epilepsy. There are similarities between both groups – for example behavioral problems often complicate the assessment of cognitive functions in both children and intellectually disabled adults – but there are also differences. For instance, the assessment of children needs to be sensitive to the developmental increases in cognitive skills, while floor effects in intellectually disabled patients can prevent an adequate mapping of performance changes. Therefore, children and intellectually disabled patients will be addressed in separate sections. The chapter summarizes technical problems of the neuropsychological assessment in children and intellectually disabled patients and provides an overview of test issues. First, special features that must be considered in the neuropsychological assessment of children and commonly used tests will be introduced and we will discuss matters of interpretation. Then, information concerning intellectual disability in patients with epilepsy will be provided as well as methods for the pre-surgical neuropsychological assessment. The final topic for discussion will address why a localizational interpretation of the neuropsychological profile in these patients is only of minor relevance in pre-surgical diagnostics.

Neuropsychological assessment of children

The goal of neuropsychological pre-surgical testing in children and adolescents is to provide a detailed assessment of the individual's cognitive functioning that serves as a basis for estimating and judging post-operative changes. The following objectives have been summarized by Oxbury.[1]

1. Confirmation of lateralization and localization of the epileptogenic area.
2. Prediction of risk to memory and other cognitive functions as well as long-term cognitive development.
3. Educational and rehabilitation issues and potential.

As we will see, the individual fit of these goals depends on the age and developmental level of the child. The neuropsychological assessment of pediatric patients is complicated by certain methodological and interpretational difficulties related to brain development and by patient intrinsic features which include lower cooperation and a frequent occurrence of behavioral problems. An overview of special features that have to be considered in the neuropsychological assessment of children is provided in Table 92.1.

Methodological aspects

Test selection

The components of a neuropsychological evaluation assess linguistic, attentional, memory, executive, sensory, perceptual, motor and higher cognitive functions. Table 92.2 lists commonly used tests well suited for the assessment of specific cognitive domains, academic achievement and behavioral problems in children and adolescents and provides information on the age range of their norms. Please note that the table is not comprehensive. Baron[2] recently provided a broad collection of tests and normative data in child neuropsychology. Other comprehensive test surveys that are not specifically designed for children were compiled by Spreen and Strauss,[3]

Table 92.1 Special features in the neuropsychological assessment of children

Methodological aspects
Test selection should consider the following aspects:
- Applicability of tests across a larger age range
- Suitability of tests for a specific age level
- Adequacy and topicality of age norms

Observation of the patient is a valuable additional source of information.
Anamnesis of parents or another caregiver is essential.
Interpretation of test results must relate to developmental expectations.

Patient intrinsic features
Ability-achievement discrepancy is likely because of
- Lower level of cooperation and motivation particularly in younger children
- Increase of behavioral problems

Brain development
- Increased potential for reorganization/ plasticity
- Possibility of a 'growth into the deficit'
- Possibility of functional changes during development

and Lezak.[4] A very useful overview is also given in Anderson *et al.*[5] Standardized neuropsychological test batteries such as the Halstead-Reitan Neuropsychological Test Battery for Children (9–14 years)[6]; the Luria-Nebraska Neuropsychological Battery – Children's Revision (8 years and older)[7]; and the NEPSY (3–12 years)[8] ensure a comprehensive assessment and usually rely on adequate normative data. However, their fixed format lacks the flexibility needed in order to tailor the assessment to the individual patient and often not all of the subtests are reliable for assessing the specific problems of patients with focal epilepsy. Many neuropsychologists therefore prefer a 'self-made' set of tests that are proven to be sensitive for the pre- and post-operative course of focal deficits in epileptic patients. When selecting a test, one must consider that test translations and culturally-specific, adequate age norms are not available for each country and that differences in the educational system may prevent the transfer of norm data between countries. A variation of the preferred tests is therefore found in the different countries. However, also within English-speaking countries, a great variety of tests was revealed by a comparison of the assessment methods used by neuropsychologists who work with children at different epilepsy surgery centers.[1] Neuropsychological tests should be selected in such a way that they are suited for a specific age level. Most abilities improve as the child grows older and it is essential to have tests that comprise adequate age norms. On the other hand, a test should be applicable across a larger age range in order to assess the course of illness and treatment effects in the individual child.

Table 92.2 Common neuropsychological tests for the assessment of different functional domains

Function	Test	Age range
Attention	Trail-Making-Test for Children (Reitan & Wolfson, 1993)	7–13 years
	Continuous Performance Tests (Conners' Continuous Performance Test, TOVA...)	Variable
	Visual Cancellation Tests (d2-Test of attention, Cancellation of Targets Test..)	Variable
	Test of Everyday Attention for Children (Manly *et al.*, 1999)	6–15 years
Language	Clinical Evaluation of Language Fundamentals-3 (Semel *et al.*, 1995)	6 years–adult
	Children's Token Test (Di Simoni, 1978)	6–13 years
	Peabody Picture Vocabulary Test-III (Dunn & Dunn, 1981)	2.5 years–adult
	Boston Naming Test (Kaplan *et al.*, 1983)	6–12 years
	Controlled Oral Word Association Test (Gaddes & Crocket, 1975; Anderson & Lajoie, 1996)	7–13 years
Learning/Memory		
General	Wide Range Achievement of Memory and Learning (Sheslow & Adams, 1990)	5–17 years
	Rivermead Behavioural Memory Test for Children (Wilson *et al.* 1991)	5–11 years
Verbal stimuli	Rey Auditory Verbal Learning Test, several parallel forms (Rey,1964)	7–13 years
	California Verbal Learning Test for Children, one alternate form (Fridlund & Delis 1994)	5–16
	Story Recall (Christensen, 1979; Anderson & Lajoie, 1996)	7–13 years
	Digit Span (Isaacs & Vargha-Khadem 1989; Wechsler 1991; Anderson & Lajoie 1996)	6 years–adult
Nonverbal stimuli	Rey-Osterrieth Complex Figure [a]: Recall (Rey, 1941; Forrester & Geffen, 1991; Anderson & Lajoie, 1996; Kolb & Wishaw, 1996)	6 years–adult
	Corsi Block-Span (Milner, 1971; Anderson & Lajoie, 1996)	7–13 years
	Benton Visual Retention Test, three parallel forms (Benton, 1982)	8 years–adult
Visuospatial functions	Rey Osterrieth Complex Figure: Copy (Kolb & Wishaw 1990)	6–15 years
	Motor free visual perception test-3 (Colarusso & Hammill, 2002)	4 years–adult
	Block Design and Object Assembly of the Wechsler Scales (Wechsler 1991)	6 years–adult
Executive and Motor Functions	Maze Tests (Porteus, 1965, Milner 1965, Wechsler 1991)	Various
	Tower of London (Shallice 1982)	7–13 years
	Digits backwards (Isaacs & Vargha-Khadem 1989)	7–15 years
	Trail Making Test (Reitan 1969)	7–13 years
	Wisconsin Card Sorting Test (Heaton 1981; Chelune & Baer 1986)	6–12 years
	Children's Category Test (Boll T 1992)	6–13 years
	Tests for manual motor sequencing and coordination	No norms available
	Purdue Pegboard (Gardner & Broman 1979)	5–15 years
	Finger Tapping (Finlayson & Reitan, 1976)	6–14 years
Academic functions	Wide Range Achievement Test (reading, spelling, arithmetic) (Jastak & Wilkinson 1994)	5 years–adult
	Wechsler Individual Achievement Test (Wechsler 1993)	5–19 years
Behavior and Mood	Achenbach Child Behavior Checklist (Achenbach 1991)	2–18 years
	Adolescent Psychosocial Seizure Inventory (Batzel *et al.* 1991)	12–19 years
	Conners' Behavioural Rating Scales–Revised (Conners 1997)	3–17 years
	Specific scales for the assessment of depression, anxiety, autism, conduct disorder,...	Variable
Family functioning	Parenting Stress Index (Abidin 1995)	3 months–10 years

[a] Full references and more detailed descriptions of the tests can be found in refs. 2,3,and 5. The Taylor Complex Figure as a parallel form of the Rey Osterrieth Figure is probably a bit easier.

It is important, that tasks are not too complex but yield information about functioning within specific functional domains. If possible, one should favor tests that include alternate versions, since neuropsychological testing in children treated with epilepsy surgery includes retesting after surgery. This is particularly relevant for tests that evaluate learning and memory. The type of assessment and the choice of instruments depends on the age as well as the maturational and cognitive level of a child. It can thus be adequate to evaluate a 10-year–old child with moderate intellectual disability using a test developed for preschool children.

Global intellectual functioning provides a background for the interpretation of the test profile in patients with focal epilepsy who are candidates for surgical treatment. Better than functions in individual domains, intelligence provides information about intellectual disability and this can be a clue in determining the etiology. Furthermore, intelligence is still the best predictor of school achievement. A measure of intelligence should therefore be included in the neuropsychological examination, although intelligence tests are usually insensitive indicators of common but subtle neuropsychological dysfunctions in these patients and they are largely insensitive to surgical effects. Table 92.3 provides an overview of tests for the assessment of intelligence or developmental level. The Wechsler Intelligence Scales are probably the most popular measures of general intellectual ability. There are versions for preschool children (WPPSI-III) and for school children (WISC-III) and these tests have been translated in to a multitude of languages. Abbreviated forms have been developed for screening purpose.[9] For infants, the Bayley Scales of Infant Development–II are probably the most popular method for assessing the current developmental level. For those patients who speak a foreign language or for language-impaired patients (e.g., deaf-mute or aphasic patients) tests of nonverbal reasoning (e.g., CPM, SPM) or nonverbal subscales of common intelligence tests (e.g., the performance scale of WISC-III) can be applied.

Table 92.3 Tests for the assessment of intelligence or developmental level

Test	*Age range*
Bayley Scales of Infant Development II (Bayley, 1993)	1–42 months
McCarthy Scales of Children's Abilities (McCarthy, 1972)	2 ½–8 ½ years
Wechsler Preschool and Primary Scale of Intelligence (WPPSI-III, Wechsler, 2002)	2 ½–7 years 3 months
Stanford-Binet Intelligence Scale[a] (SB-IV, Thorndike *et al*., 1985)	2 yrs–adulthood
Kaufman Assessment Battery for Children[b] (KABC, Kaufman & Kaufman, 1987)	2 ½–12 ½
NEPSY (Korkman *et al*., 1998)	3–12 years
Coloured Progressive Matrices[c] (CPM, Raven 1995)	4–11 ½ years
Wechsler Intelligence Scale for Children[d] (WISC-III, Wechsler 1991)	6–16.11 years
Standard Progressive Matrices[c] (SPM, Raven 1996)	8–80 years
Kaufman Adolescent and Adult Intelligence Test[e] (KAIT, Kaufman & Kaufman 1982)	11–85 years.

[a] The SB-IV is particularly apt to assess gifted children.
[b] The KABC includes an achievement scale.
[c] The Raven's Progressive Matrices keep verbal instructions to a minimum and require nonverbal reasoning, they are relatively culturally unbiased.
[d] The WISC-III differentiates between verbal and nonverbal intelligence.
[e] The KAIT differentiates between fluid and crystallized intelligence.
Full references and more detailed descriptions of the tests found in refs. 2,3,and 4.

Interpretation of test results

In a child that is referred for the purpose of pre-surgical diagnostics, the neuropsychologist interprets the obtained data in the context of a comprehensive understanding of brain-behavior relationships. This interpretation varies depending on the age of the patient. In very young children or children with severe intellectual disability, the neuropsychological evaluation mainly aims to assess the global developmental level to set a baseline for follow-up. Answers to localization-related questions can normally not be given for those patients. In school children (6–12 years), neuropsychological patterns that exhibit specific profiles with strengths and weaknesses of localizing or lateralizing value can sometimes be recognized. Neuropsychological factors in the adolescent (> 12 years) are assumed to be very similar to those found in adults and neuropsychological patterns are often of localizing or lateralizing value. Specific deficits can be taken to strengthen or confirm or amplify other findings of the presurgical diagnostics, especially if an intracarotid amytal test has confirmed left hemisphere language dominance. General guidelines for a localizational interpretation are:

1. Selective deficits in language associated functions (e.g., expressive or receptive language, vocabulary, semantic fluency, verbal memory) point to impairments in functions of the language dominant hemisphere.
2. Selective deficits in visuospatial functions (e.g., visuoconstruction, visual perception, visual memory, mental rotation) point to impairments in functions of the nonlanguage–dominant hemisphere.
3. Predominant memory deficits are associated with temporal foci.
4. Predominant executive deficits are associated with frontal foci (see also Table 92.4).

The performance on psychological tests is reported in percentiles, standard scores or developmental/mental age scores. Mental age scores have a descriptive appeal, but it must be kept in mind that they are only on an ordinal-scale level and that the meaning of differences systematically shrink with age: a 5-year-old child functioning with a mental age of a 3-year-old might be quite impaired, while a 14-year-old functioning at a 12-year-old level might be only moderately behind. Percentile scores have an advantage over mental age scores because they maintain their meaning at different ages. However, they are also on an ordinal scale level and the unit of measure varies across the range (e.g., a 20-point difference is insignificant in the middle but very meaningful near the tail of the distribution). Standard score scales (e.g., z-, IQ-, T-Scores) report scores in standard deviation (SD) units from the

Table 92.4 Studies on cognitive functions in pediatric patients with focal epilepsy

Study	N	Measure	Results concerning group differences
Adams *et al.*[64]	16 LTLE 12 RTLE	WMS, RCFT, TROG/Grammar test, Shortened Token Test	LTLE declined in verbal memory after surgery.
Cohen *et al.*[65]	12 LTLE 12 RTLE	Comprehensive Children's Memory Scale	LTLE impaired in verbal memory. RTLE impaired in nonverbal memory.
Jambaque *et al.*[66]	14 ETLE 28 TLE; 18 IGE,	Signoret's Memory Battery Scale	LTLE lower performance in verbal tasks. RTLE defective visual memory.
Beardsworth & Zaidel[67]	13 LTLE 16 RTLE	Memory for faces	RTLE < LTLE in memory for faces.
Lendt *et al.*[47]	12 FLE 12 TLE	Verbal fluency, Mazes, VLMT, DCS-R WISC-R, Motor coordination Reaction times, Corsi Block Design Digits, Token Test, Letter cancellation	FLE more impaired in motor coordination, FLE higher IQ-level.
Culhane-Shelburne *et al.*[68]	12 FLE 15 TLE	TOVA, TOL, CVLT WRAML, Twenty Questions Test, Stroop Color-Word test, VABS	FLE deficits in planning and executive functions and mal-adaptive functioning. TLE deficits in memory.
Gleissner *et al.*[42]	26 LTLE 26 RTLE	VLMT, DCS-R	LTLE had a significant decline in verbal memory after surgery.
Hernandez *et al.*[69]	16 FLE 8 TLE 8 GEA	Purdue Pegboard, Self-ordered pointing task, motor coordination, WCST, TOL, Verbal Fluency.	FLE deficits in planning, impulse control, fluency, and motor coordination.
Hernandez *et al.*[70]	16 FLE 8 TLE 8 GEA	CVLT, CPT, WISC-III RCFT, CBCL	FLE were more impaired in attention, impulse control, working memory, perceptual organization, and behavior than the other groups.
Mabott & Smith[71]	17 LTLE 18 RTLE	CAVLT, RCFT face recognition	Significant post-operative difference in memory for faces (RTLE < LTLE).
Nolan *et al.*[72]	25 FLE, 32 TLE 13 GEA	WRAML	TLE more impaired in memory than FLE.

The table illustrates the fact that several studies observed functional deficits in children often associated with a focal epilepsy similar to those reported in adult patients. Therefore, the table is not comprehensive; it presents only a selection of studies on cognitive functions in pediatric patients with focal epilepsy. CAVLT = Children's Auditory Verbal Learning Test; CBCL = Child Behavior Checklist; CPT = Continuous Performance Test; CVLT = California Verbal Learning Test; DCS-R = Diagnosticum für Cerebralschädigungen-Revision; FLE = frontal lobe epilepsy; GEA = generalized epilepsy with absences; IGE = idiopathic generalized epilepsy; LTLE = left temporal lobe epilepsy; RAVLT = Rey Auditory Verbal Learning Test; RCFT = Rey Complex Figure Test; RTLE = right temporal lobe epilepsy; TOVA = Test of Variables of Attention; TLE = temporal lobe epilepsy; TMT = Trail Making Test; TOL = Tower of London; VABS = Vineland Adaptive Behaviour Scales; VLMT = Verbal Learning and Memory Test; WCST = Wisconsin Card Sorting Test; WISC-R = Wechsler Intelligence Scale for Children–revision; WISC-III = Wechsler Intelligence Scale for Children–third version; WMS = Wechsler Memory Scale; WRAML = Wide Range Assessment of Memory and Learning.

normative sample's mean. To understand and interpret standard scores, one must know the mean and SD of the scale on which it is based (e.g., 100 ± 15 for IQ-scores, 50 ± 10 for T-Scores). Standard scores allow for a more direct comparison of the different measures in the different age groups. A deficit is usually assumed if the test result is more than one SD below the mean. A deficit is specific if it is more than one SD below the test results in other functions. Thus, if a child exhibits memory problems, but also has difficulties in attentional, visuospatial and language functions, one would not diagnose a prominent temporal lobe dysfunction, but would rather assume diffuse functional damage. On the other hand, average verbal memory functions in an epileptic child with otherwise above average results might be considered as an indicator for a left temporal lobe dysfunction.

It should be kept in mind that neuropsychology never diagnoses epilepsy. Classifying test results into a cognitive pattern does not prove a causal relation with epilepsy. However, if a cognitive pattern with weaknesses and strengths is consistent with a focal deficit in the context of general assumptions about brain organization and if it is consistent with other, particularly functional findings (e.g. EEG, functional imaging), it is of course plausible to assume that the performance is influenced causally by the disease.

Intelligence tests usually do not localize or lateralize to specific brain regions or hemispheres. It is tempting, but not justified by empirical evidence, to interpret a difference of the verbal and performance IQ of the Wechsler Intelligence Scale for Children (WISC-III) or between the scales of simultaneous and sequential processing of the Kaufmann-Assessment Battery for Children (K-ABC) in terms of lateralization. Subtests of intelligence tests often cross multiple domains. However, if it is possible to decide the cause of a child's failure, this can provide valuable localizing information within the general context of the other tests. For instance, the 'picture arrangement' subtest of the Wechsler intelligence test requires that the child sorts cartoon pictures to make sensible stories. This can be impaired because of slow speed, a deficit in visual-motor integration, an impulsive mental style, or a comprehensional or conceptual deficit. Asking a child to tell the story helps one understand why a child fails the task. But please note that a real process approach during testing (i.e., determining what a child needs for successful performance as a means of determining which cognitive processes are not fully

operational) – although very useful in neuropsychological training and rehabilitation – cannot be applied in the field of pre- and post-operative evaluations because this would distort the results of the retest.

The observation in a face-to-face interaction provides indispensable additional information. For instance, as a basic function, an attentional problem can lower the performance in all of the other tests, but relevant attentional tasks can also be failed due to an impairment in the other processes. In practice, the psychologist will rely not only on the test results but also on his clinical observation of the child's alertness, his ability to focus on the task in hand, reactions to distracting stimuli, and the ability to sustain effort throughout time. The interpretation of performance will therefore rely not only on the profile of the test results but also on the observation of the child during the examination and on information given by the caregivers and other relevant persons (e.g., teachers).

Brain maturation

One of the main differences between an adult brain and that of child or adolescent, is that the child/adolescent brain is still engaged in significant developing processes. The enormous changes that occur, including an overproduction of dendrites and synapses and their consecutive pruning during the first years of life, are well known. The sequence in which the cortex matures shows parallels to the cognitive and behavioral development.[10] Regions subserving primary functions, such as sensory and motor systems, mature earliest. Temporal and parietal association cortices associated with basic language skills and attention mature next. Higher-order association areas, such as the prefrontal and lateral temporal cortices which integrate sensorimotor processes and modulate attention and language processes, mature last. However, it has become clear in recent years that the process of postnatal brain maturation is long and lasts at least into early adolescence. Although the total brain size is approximately 90% of its adult size by age six, the gray and white matter subcomponents of the brain continue to undergo dynamic changes throughout adolescence. Data from recent longitudinal studies which use modern imaging tools as magnetic resonance imaging (MRI), functional MRI (fMRI), and diffusion tensor imaging indicate that, while white matter volume increases in a roughly linear pattern until approximately young adulthood, gray matter has an inverted U-shaped pattern with a regional variation.[11] Developmental curves for the gray matter of the frontal and parietal lobes peaked at about age 12, the temporal lobe at about age 16, and the volume in the occipital lobe continued to increase through age 20. Ongoing maturation of the temporal lobes during adolescence is also indicated by electroencephalographic and postmortem studies.[12,13]

At least three possible implications of this immaturity for the neuropsychological evaluation of pediatric patients with epilepsy have to be discussed:

1. The function of a specific neural area may change over time. Several studies indicated that children recruit more diffuse prefrontal regions when performing executive tasks, and that the pattern of activity within brain regions with task-related activity becomes more focal or fine-tuned with age, whereas brain regions with task-unrelated activity decrease in activity with age.[14] However, similar results were obtained in adult learning studies.[15] Thus, it is likely that task-related activation of more extended or different areas in children is due to differences in training or strategy. A regional qualitative change of functions during development would not be economic and does not fit with the assumption that learning and experience guide cerebral development processes. Therefore, we regard it unlikely that functional brain organization is qualitatively fundamentally different in children.
2. Due to brain maturation, the extent of an impairment may not become obvious until the underlying brain structure is fully mature. Table 92.4 provides a selection of studies reporting neuropsychological results in children with focal frontal or temporal lobe epilepsy with functional associations similar to those reported in adults. Of course, this does not exclude the possibility that those functional deficits might strengthen when the children grow up. A deficit can also become more imposing when daily tasks become more demanding. The demands for self-organizational abilities, for instance, are relatively low at school because school provides a highly organized structure. The issue of a 'growth into the deficit' can be answered only in a longitudinal design. In their longitudinal study, Bjoernaes *et al.*[16] found some evidence that children may experience a greater decline of intellectual functioning than adults over the years of a severe epilepsy. However, the adult patients also had a significantly longer duration of epilepsy and started with a significantly lower performance at the time of the first test. There are a few single case reports about children with frontal damage, whose deficits were not apparent until they were grownup.[17] However, in the literature one gets the impression that this is the exception rather than the rule.
3. Brain damage in infants and children may produce different effects because it can alter the basic functional brain organization. When interpreting test results, it is essential to keep in mind that brain damage in infants and children can more easily alter the basic functional brain organization than in adults. The preservation of language functions seems to be particularly important for the brain. A reorganization of visuospatial functions with a suppression of language functions has not yet been described but a suppression of nonverbal functions in patients with an interhemispheric reorganization of language is a robust finding.[18,19] Language is usually thought to be lateralized by the age of 6 years. After the age of 5, the potential for language to reorganize from the left to the right hemisphere appears to decrease rapidly.[23] A high incidence of atypical (i.e., right- or bilateral) language representation in patients with early left hemisphere insult has been well documented.[18,20] Atypical language due to a damage beyond adolescence is very rare and probably reflects a genuine right hemisphere participation in language. In patients with epilepsy, it is presumed that not only lesions but also epileptic dysfunction can cause a language shift. Thus, a relatively small lesion which is not necessarily proximal to classic anterior or posterior language areas associated with epileptic activity can be sufficient for an interhemispheric transfer.[21] Characteristic features of adult patients with atypical language dominance are left-hemispheric

damage, an early onset of epilepsy, atypical hand dominance, a predominance of extratemporal lesions and a strong deficit in nonverbal memory. The same characteristics have been described also in children.[19,22,23]

The assessment of language representation can be more difficult in children than in adults. The determination of language representation by the IAT (Intracarotid Amytal Test) is more often applied in adults than in pediatric patients. The IAT temporarily inactivates one hemisphere by the injection of sodium amytal or, more recently, also with brevimytal by a catheter through the internal carotid artery. Difficulties in performing the angiographic portion of the procedure in conscious children are frequent and sedation interferes with language testing. Although IAT language testing has been successfully obtained in children as young as seven years of age,[24] children under ten years of age and intellectually disabled patients are sometimes not able to cooperate actively in the IAT situation.[25] The same is principally true for language assessment with fMRI, although there have been attempts to develop child-friendly functional magnetic resonance imaging paradigms for children too young or too impaired to execute an active task.[26] The baseline testing used to get the child familiarized with the procedure, and use of a pediatric protocol with simpler pictures and familiar words is recommended also in the IAT in order to maximize cooperation and the validity of the results. Near-infrared spectroscopy (NIRS), transcranial magnetic stimulation (TMS) and contrast transcranial Doppler sonography (CTCDS) provide interesting and valuable options for assessing language dominance in children, but these methods do not yet show a breakthrough.

It is still widely assumed that less dysfunction will result from a brain lesion if a child is younger at the time of a neurological insult, because plasticity processes can counterbalance the damage. This believe came up mainly because early hemispherectomized children often showed a respectable development and school achievement after surgery, but the general assumption is not true in light of the present data. An early cure of epilepsy can result in an impressive developmental catch-up, but early damage during the first two years of life in general is destructive for cognitive development and often results in global intellectual impairment.[27] Interhemispheric functional reorganization probably is an emergency solution for the brain. The resulting performance level for the rescued function is not unimpaired and it is not without cost as has been shown by the suppression of nonverbal functions in patients with an interhemispheric language reorganization.

Patient intrinsic difficulties

Behavioral problems

As both chronic illness and CNS disorders are risk factors for behavioral problems, the frequency of behavioral disorders is much higher for patients with epilepsy. The prevalence of behavioral problems is below 10% for the general childhood population. In pediatric patients with epilepsy, rates between 30% and 50% have been reported for behavioral problems, while rates of approximately 20% have been reported for children with other chronic physical illness not involving the central nervous system (i.e., diabetes mellitus or cardiac disease).[28] Behavioral problems include anxiety, aggression, oppositional behavior, autistic features, depression, and hyperactivity. Behavioral problems can already be observed in children with new-onset seizures.[29] Risk factors for behavior problems in childhood epilepsy include neurologic dysfunction, side-effects of antiepileptic medication, seizure variables as an early onset and a higher frequency and a stronger severity of seizures.[30,31] No significant associations have been found with the side and site of epilepsy.[32]

The family environment variables (e.g. family stress, family mastery, and extended social support) are also significant predictors of behavioral problems in childhood epilepsy.[33] Symptoms of depression, reported in approximately one-quarter of children and adolescents with epilepsy,[34] were correlated with a negative attitude toward seizures, lower satisfaction with family relationships and no internal locus of control. This points to the relevance of early educational programs that should support the family and the patient in order to reduce the risk of depression and anxiety.

Behavioral problems are diagnosed by a combination of the anamnesis of the patient and the parents, the observation of the patient during the examination and standardized questionnaires (see Table 92.3). The Child Behavior Checklist (CBCL[35]) and the Conners Behavioral Rating Scales[36] are among the most widely used instruments for assessing behavioral problems. They provide parent-, teacher-, and self-ratings. The CBCL is introduced as an example. It consists of 120 items that describe specific behavioral and emotional problems, plus two open-ended items for reporting additional problems. Also included are scales for measuring social problems, anxiety and depression, somatic complaints, attention problems, thought problems, delinquent and aggressive behavior. On a superordinate level, a score for Internalizing Problems (e.g., anxiety, depression), a score for Externalizing Problems (e.g., aggression, delinquent behavior), and a Total Problem score can be derived. The newest form (ASEBA) is for children between 1.5 and 5 years.[37] Children with epilepsy exhibit prominent problems, particularly in the scale of internalizing problems and in the subscale indicating attention problems (Figure 92.1, see also ref 29). It should be noted that for children with epilepsy, it is important to consider, that a few items describe the consequences of a chronic illness or aspects of

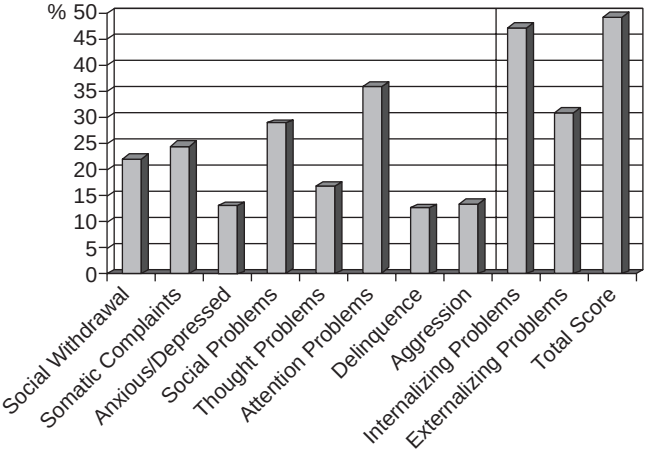

Figure 92.1 Child Behaviour Checklist : % with deviant performance (T-Scores ≥ 67 for the subscales, ≥ 60 for the superordinate scales) in our unselected clinical population of pediatric patients (in between 526 and 539).

seizure semiology rather than the behavior problems. Oostrom *et al.*[38] found that rescoring the CBCL by seven ambiguous items* reduced the percentage of patients trespassing the clinical cut-off score considerably in newly diagnosed patients while rescoring had no effect in healthy children. A recent study in pediatric epilepsy patients who were assessed pre-operatively and one year after successful surgical treatment indicated the CBCL as a valid assessment tool in children with epilepsy[73]. The parents of children with epilepsy should nevertheless be instructed that seizure should not be included in the ratings to avoid a confusion of behavior problems with seizure semiology.

Post-operatively, impressive improvements of behavioral disorders have been reported.[39,30] Post-operative behavioral improvements can often explain the positive changes in school and social life as reported by the parents despite no obvious improvements in the neuropsychological examination.

Guidelines for a valid neuropsychological assessment of children

A reliable and valid assessment implies that a child has put forth appropriate effort. Some guidelines that optimize a valid neuropsychological assessment of children are briefly outlined here; a comprehensive description is available in Baron.[2] Testing is often stressful for the child and produces anxiety especially at the beginning when the structure of the situation and the examiner are still unfamiliar. At the beginning of the test, informal conversations about a special interest or favorite activity increase the child's comfort level and allow the examiner to formulate initial clinical impressions. The purpose of testing should be explained as should information about what will happen during the session and how long it will approximately take. This will reassure the child. It should be emphasized that the child tries his best but failures are unavoidable, because some tasks are designed to push the test-taker to his limits and no child will always be correct. Children are often reassured when told that a hard item is actually intended for an older child. Praise should be given for the effort that the child made. Difficult tasks should not be given at the beginning, if it is compatible with a standardized sequence of the tests. Suitable first tests are drawings or simple verbal or motor tasks if they do not emphasize an expected weakness. A low level of cooperation and motivation can be expected particularly in children with conduct disorder, attention deficit disorder, and in younger children. In the latter, attentional persistence and tolerance to failure are limited and the children are less able to comprehend the relevance of the situation. This is probably one reason why intelligence measures during early childhood and preschool measures are far less predictive of later functioning than assessments taken during middle childhood. Highly active children require considerable structure and guidance from the examiner and it can be necessary to set firm limits for those patients. Informing the child that if the examination is not completed, there will be another visit might sufficiently motivate a defiant child to continue. If the child is extremely resistant, it might be appropriate to terminate and continue another time. It is absolutely crucial that the examiner adjusts to the individual child to optimize the child's motivation.

*The items are Nr. 13 "confused, seems to be in a fog", Nr. 17 "Daydreams", Nr 46 "Nervous movements or twitching", Nr. 80 "Stares blankly", Nr. 84 "Strange behaviour", Nr. 107 "Wets during the day", and Nr. 108 "Wets the bed".

Predictors of post-operative neuropsychological outcome in pediatric patients with epilepsy

As in adults, the location and extent of surgery in children influences the neuropsychological outcome. However, due to additional factors such as ongoing maturational changes and physiological and functional plasticity, the impact of epilepsy surgery on brain functions could depend also on the maturational stage of the child at the time of epilepsy onset and the time of surgery. Early surgery may prevent the disturbance of brain development by epileptic activity and enable the brain to recover more completely from the consequences of the surgery due to structural and functional plasticity. All in all, the available data indicate that early surgery in pediatric patients is beneficial.[40–43] It has been observed in individual patients that a cognitive decline was stopped or that development was advanced by successful seizure control after surgery.[44] However, group data on cognitive outcome after epilepsy surgery indicate that surgery is usually not followed by markedly improved intellectual development, but there seem to be fewer additional deficits induced by surgery and a better recovery than in adults.[45] With respect to temporal lobe resections, studies which have found no evidence of post-operative decline outweigh those studies revealing a loss.[46] Risk factors for a post-operative memory decline are a left-sided resection, a higher pre-operative performance, a shorter post-operative retest interval and a longer duration of epilepsy. One study investigating the cognitive outcome after frontal surgery observed improvements in measures of memory and attention. Seizure outcome was not a predictor of cognitive outcome in this study.[47]

After a hemispherectomy, the intellectual functions usually remain unchanged,[48] although more positive results could probably be obtained if the assessment of psychosocial features (e.g., level of integration in the family, at school or at work) would be assessed instead of the IQ. Etiology seems to be a relevant factor for the pre-operative level and the post-operative course.[49] Very favourable results have been obtained with regard to the post-operative cognitive development for patients with Sturge-Weber-Syndrome and an early epilepsy[74] Patients with hemimegalencephaly have a worse outcome than other etiological groups probably due to the presence of bilateral structural and epileptic anomalies.[43] An earlier age at the time of surgery has been shown to be prognostically good in patients with hemispherectomy.[43,40]

For those patients undergoing a callosotomy, behavioral improvement is one of the major surgical benefits.[50] In the series of Sauerwein *et al.*[41] only mild or moderate mental deficiency before surgery was the most reliable predictor of post-operative cognitive gains. The age at the time of surgery had an effect on the course of recovery from post-operative sequelae – patients younger than 13 years recovered more rapidly and more completely and had almost no disconnection deficits in simple tactile interhemispheric transfer tasks. All patients aged 13 years and older displayed permanent disconnection signs. Bilateral language and dissociated language dominance patterns can be considered an exclusion criteria for a callosotomy.

It should be considered that developmental gains may need longer periods to accumulate. Freitag and Tuxhorn[51] observed a significant increase in the developmental quotient after surgery for preschool children only after a follow-up interval of 2–3 years. Westerveld[52] reported that a longer post-operative retest interval (range 5–60 months) was a significant predictor for a gain in performance IQ.

Neuropsychological pre-surgical workup in intellectually disabled adult patients

Intellectual disability (ID) is found more frequently in patients with medically intractable epilepsy than in the normal population. Its prevalence has been estimated at 35% for those patients with an early onset of epilepsy.[53] It should be noted that the term 'mental retardation' has become stigmatizing and should be avoided. ID is pragmatically defined as a measured IQ of greater than two standard deviations below the mean (IQ ≤70), such that approximately 2 – 3% of the population would be defined as intellectually disabled. Further diagnostic criteria are according to DSM-IV, an onset of ID before age 18 and significant limitations in adaptive functioning in at least two skill areas (e.g., communication, home living, social/interpersonal skills).

According to the diagnostic manuals, there are four severity grades of intellectual disability (see Figure 92.2). Intelligence tests (see Table 92.2) are not suited for assessing more severe ID, since IQ test scores usually end between 10 and 50. Therefore, it is useful to also apply a measure of adaptive functioning, usually in the form of a semistructured interview with the parent or caregiver. Instruments which assess functional capacities in a wide array of domains including daily living skills, communication skills and socialization are the Vineland Adaptive Behavior Scales-II (VABS-II,)[54] and the second edition of the American Association of Intellectual disability Adaptive Behavior Scales.[55]

Pre-operative neuropsychological diagnostics refer not only to the absolute level of performance, but also to the diagnostic information given by the pattern of strengths and weaknesses in the cognitive profile. In the majority of intellectually disabled patients, many functions are equally impaired and the test results often indicate a diffuse functional impairment without a performance minimum of localizing value. More often, a performance maximum in a single function indicates relative functional integrity of a region, but this is, of course, of minor relevance from a pre-surgical diagnostic point of view. Finding tests for the assessment of specific neuropsychological functions in patients with ID is more difficult. Although most of the neuropsychological tests listed in Table 92.3; can be applied to patients with mild intellectual disability (e.g., Boston Naming Test, semantic fluency, recognition form of the Benton Visual Retention Test), the floor effects often prevent an adequate mapping of performance changes. Therefore, it might be more appropriate for the documentation of the post-operative course in patients with ID to compare raw scores rather than standard scores. Application of tests originally designed for children can be considered to quantify performance in intellectually disabled patients who can not cope with the test versions for adults. Behavioral problems are more frequent in intellectually disabled patients and can further complicate the neuropsychological examination. A health-related quality of life questionnaire (e.g., QOLIE-89)[56] should also be used, to optimize mapping of the post-operative outcome. A proxy report form can be used in those patients, who are not able to fill out the questionnaire themselves.

Patients with epilepsy and intellectual disability are often difficult to treat. Drug resistance is more frequent in patients with intellectual disabilities. In a long-term study conducted by Huttenlocher and Hapke,[57] 70% of the patients who had an IQ <70 and were studied for at least 18 years continued to have more than one seizure per year, while the rate was only 25% for those patients whose intelligence fell within the borderline or normal range. Surgical treatment could be beneficial for patients with intellectual disabilities, but intellectual disability is often associated with a bilateral or diffuse morphologic brain damage that increases the probability of a multifocal epilepsy or diffuse epileptogenic regions. However, there have also been reports of 9–30% focal lesions among intellectually disabled patients with epilepsy[58,59] and for these patients a surgical treatment is a valuable option. The assumption of a worse post-operative cognitive outcome for intellectually disabled patients due to lower compensational capacities of brain regions beyond the epileptogenic focus is not very well founded from an empirical standpoint. On the contrary, children with a low IQ can have substantial gains after surgery, that indicate a restart of development after a period of developmental stagnation or regression due to severe epilepsy.[30]

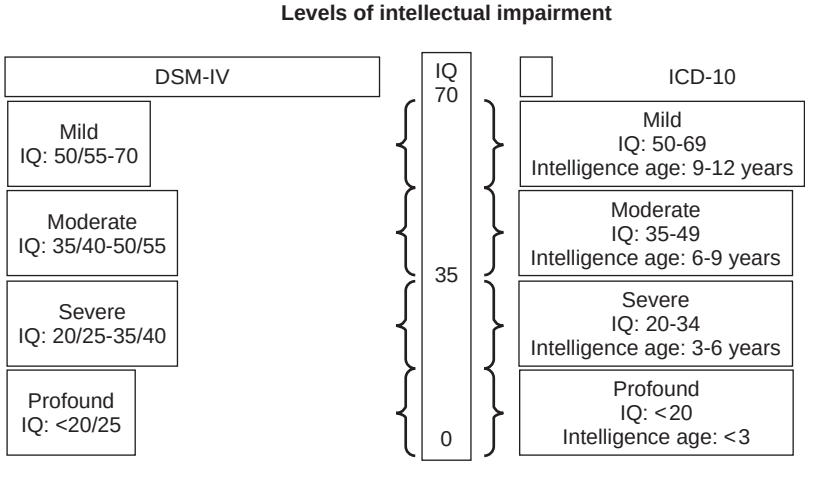

Figure 92.2 Severity grades of intellectual disability according to DSM-IV and ICD-10. Since IQ-test-scores usually end in the range of 40 – 50, it is useful to also apply a measure of adaptive functioning, e.g., the Vineland Adaptive Behavior Scales-II.

It has become clear through recent studies, that IQ alone is not a good predictor of the post-operative outcome. Bjornaes *et al.*[60] reported no significant post-operative cognitive declines in 31 patients with an IQ <70. The rate of seizure-free patients was 52% after temporal resection and 38% after extratemporal resection. A better outcome was found for those patients who underwent surgery at a younger age and displayed a shorter duration of epilepsy. In our series of 16 adult patients with an IQ <85, we observed no deteriorations in the cognitive and socioeconomic status after temporal and extratemporal focal resections.[61] The rate of seizure control was satisfactory one year after surgery (64% Engel Outcome Class I). In a large multicenter study, Chelune *et al.*[62] observed that adult patients with an IQ ≤75 were at a higher risk for continued seizures if structural lesions other than mesial temporal sclerosis were present. However, no influence of IQ was evident for the other patients. Freitag and Tuxhorn[51] recently reported in severely and profoundly retarded preschool children a complete seizure control in 46% and a worthwhile seizure reduction in another 39%.

Patients with a lower IQ often have a more severe epilepsy than those patients with normal intelligence. To further analyze the influence of the intelligence level, we matched pediatric groups with different IQ levels according to clinical and etiological criteria.[63] The comparison of intellectually disabled, learning disabled and pediatric patients of normal intelligence indicated no group differences with respect to seizure outcome and no dependency of the post-operative cognitive outcome on the pre-operative intelligence level. Behavioral improvements were observed in all groups independent of the intelligence level. As with patients of normal intelligence, the decision to operate on patients with a low level of intelligence should depend on the results of the pre-surgical workup. If the results of the neuropsychological examination indicate diffuse functional impairment, this should not hinder further steps if all other findings are consistent.

93 Wada test and epileptogenic zone

DS Dinner and T Loddenkemper

Introduction

Main purpose of the Wada test is the lateralization of language and memory function. For that purpose, an anesthetic agent, usually amobarbital, is injected into the internal carotid artery producing temporary inactivation of the ipsilateral cerebral hemisphere.

It is important to know the lateralization of language when one is considering surgery of an epileptogenic zone or lesion located close to or possibly overlapping a potential speech area, Wernicke's area or Broca's area. In terms of memory function, the Wada test was initially used to predict postoperative global amnesia following unilateral temporal lobectomy. Subsequently the Intracarotid Amobarbital Procedure (IAP) has also been used to attempt prediction of selective modality specific memory deficits after surgery. The IAP may also assist in the lateralization of the epileptogenic zone as well as to predict seizure outcome following temporal lobectomy.

History

First description for language lateralization by Juhn Wada

The effects of injection of sodium amobarbital into the common carotid artery were first observed by Juhn Wada in 1948, when he described his findings in 15 right-handed patients the following year in Japanese[1] and later translated the original report into English.[2] The IAP was subsequently used to determine language lateralization in a series of 20 patients at the Montreal Neurological Institute being evaluated for focal surgical resection in the management of intractable epilepsy.[3] They then published a larger series of 123 patients being evaluated for epilepsy surgery which was the first large series of the relationship of speech lateralization and epilepsy.[4]

Gardner, a neurosurgeon at the Cleveland Clinic, previously reported the use of a local anesthetic agent to localize language areas (Figure 93.1). He injected procaine hydrochloride directly into the cerebral cortex through burr holes in order to functionally inactivate potential language areas to assess the possibility of a reversed hemispheric lateralization of language in the right hemisphere in two left-handed patients.[5]

IAP for memory lateralization

In the 1950s there were several reports of postoperative memory difficulties following unilateral temporal resection for intractable temporal lobe epilepsy (TLE).[6,7] Scoville and Milner described three cases with persistent global amnesia with bilateral mesial temporal resection.[8] It was also noted that patients who had undergone unilateral temporal lobectomy may demonstrate similar memory deficits if there was an unsuspected lesion in the contralateral temporal lobe.[9] Their hypothesis was that significant memory deficit in patients following temporal lobectomy was due to abnormally functioning tissue in the contralateral temporal lobe. The Montreal group subsequently modified the IAP to evaluate memory function in addition to language lateralization.[10] They hypothesized that unilateral inactivation of the ipsilateral hemisphere should not affect memory function during the procedure unless there was a lesion in the contralateral hippocampus. In their initial studies, they injected 200 mg of sodium amobarbital into the common carotid artery on the side contralateral to the side of the epileptogenic lesion and found memory disturbance in 11 cases. None of the patients developed postoperative memory loss. Subsequently, injection of sodium amobarbital was performed into the internal rather than the common carotid artery, allowing a smaller dose of sodium amobarbital, 125 mg, to be administered.[11]

The IAP later came to be referred to as the Wada test and has continued to be frequently referred to as such until the present. Besides amobarbital some centers have recently used alternate anesthetic agents including methohexital,[12–14] etomidate,[15] and propofol.[16–19]

Selection criteria and indications

Many centers perform the Wada test in the majority of candidates who are seriously being considered for surgical management of their epilepsy. However, some centers restrict the use of the Wada test to left-handed patients or those who demonstrate evidence of bilateral or contralateral hemisphere damage or unexpected or confusing findings on neuropsychological testing. In the past, the Wada test has most commonly been performed in candidates for temporal lobectomy. In these patients it was used for the evaluation of language and memory function. In patients with extra-temporal lobe epilepsy, the primary indication is the evaluation of language lateralization rather than memory function.[20]

Recently, indications and selection criteria have been changed due to advent of alternative language and memory lateralization techniques,[21–23] possible problems with memory lateralization, and due to recognition of complications during this invasive procedure.[24–26]

Risk of memory deficit

Neurocognitive morbidity, especially memory deficit is a significant and relatively common adverse effect of surgical resection in patients with intractable TLE.[27–30] Resection of the speech dominant temporal lobe has been associated with postoperative impairment in the ability to learn and retain verbal material.[21–36] Similarly a decrease in nonverbal memory after nondominant temporal resection has been reported by some investigators.[31,33,37–39] However other investigators have not found memory deficits after nondominant temporal resection.[32,34,36,40,41] Chelune and colleagues at Cleveland Clinic found that the rate of reliable decrease in verbal memory after left temporal resection was nine times higher than among nonoperated patients with intractable TLE and three times higher than among patients after right temporal resection.[42] Decrease in visual memory was only slightly higher than chance and no differences were noted between right and left temporal resection cases.

Model of hipppocampal memory function

The traditional model of hippocampal memory function suggested that memory decrement after temporal lobectomy was related to the capacity or functional reserve of the contralateral temporal lobe to support memory function. Support for the functional reserve model of hippocampal function was

based on the early observations of memory deficit following temporal resection as described above. It is also the reason why the group at the Montreal Neurological Institute (MNI) modified the IAP to study memory in the hemisphere contralateral to the proposed resection. The report of three cases of persistent global amnesia following bilateral mesial temporal resection demonstrated the critical role of the hippocampi in the the acquisition and retention of memory.[8] Subsequently in 1958 there was a report from the MNI of two cases with significant memory deficit following unilateral temporal resection.[9] They hypothesized that the patients had an occult lesion in the contralateral hippocampus which was not able to support memory. Among the factors that have been demonstrated to predict a decrease in memory after surgery has been the presurgical function of the mesial structures in the hemisphere to be resected. This is referred to as the model of hippocampal functional adequacy.[43] According to this model, postsurgical decline in memory is dependant on the functional adequacy of the tissue that is to be resected. This function in turn has been related to the presence of and degree of mesial temporal sclerosis. Support for the functional adequacy model of memory deficit after temporal resection comes from studies of both structure (histological analysis of neuronal cell densities and MRI volumetric studies) and function (neuropsychologyical evaluation and IAP memory testing).

Postoperative memory changes have been associated with histologic evidence of hippocampal pathology. The greatest decrease in verbal memory occurred in patients without evidence of significant hippocampal pathology.[33,44–46]

Patients with hippocampal sclerosis have poor memory prior to surgery as compared to those without widespread neuronal loss. The patients with relatively healthy hippocampi demonstrate marked memory loss compared to those with clear evidence of sclerosis following surgery.

MRI volumetric measurements are associated with hippocampal sclerosis.[47–50] MRI volumetry has also been shown to have an inverse correlation with the degree of verbal memory deficit after temporal resection in the speech dominant hemisphere supporting the functional adequacy model.[51] There is also a relationship that has been demonstrated between the neuropsychological measures of memory function and postoperative changes after temporal lobectomy. A decrease in cognitive ability particularly verbal memory was observed following left temporal lobectomy in patients with high preoperative baseline memory scores.[28] Other authors have found that good baseline memory preoperatively is a predictor for memory decline after left temporal resection.[33,32]

Findings on pathologic and neuroimaging studies also support the association of memory results on the standard IAP with hippocampal changes. Rausch and colleagues examined the relationship between memory performance and hippocampal damage in patients with TLE.[53] They found that patients with severe neuronal loss (>80%) throughout the hippocampus generally failed the IAP memory test following contralateral injection. In patients with less severe damage, IAP memory performance was not related to the degree of hippocampal damage. Sass and co-workers reported a subfield specificity with IAP memory results related to neuronal loss only in the CA_3 and hilar regions.[54] O'Rourke and colleagues provided further evidence of subfield specificity but noted that the degree of unilateral memory impairment was related to decreased neuronal density in the hilar and dentate granular regions and not in the CA_1 or $CA_{2–3}$ regions.[55]

In patients with unilateral hippocampal atrophy on MRI, significant asymmetries of IAP memory scores have been noted.[56] This has also been confirmed on volumetric measurements, although the relationship is not one-to-one.[57] It has also been shown that memory scores relate to hippocampal but not extrahippocampal volumes in TLE.[58] Salanova and co-workers investigated the relationship between interictal hypometabolism determined by fluorodeoxyglucose positron emission tomography (PET) and memory function with the IAP in 23 patients with unilateral TLE.[59] Ninety-five percent of patients demonstrated hypometabolism on PET scan or impaired memory on the epileptogenic side. No patient had impaired memory contralateral to the hypometabolic zone. Rausch and colleagues had also earlier noted that five of six patients with severe hippocampal sclerosis had asymmetric glucose hypometabolism on PET scan.[53]

Methodology

Although the IAP was first used over 50 years ago and the test is widely accepted, there is still no standardized protocol used. However certain basic aspects are common to most protocols. A trans-femoral arterial route is used to perform the cerebral angiogram immediately prior to the IAP to evaluate the vascular anatomy and also to determine the presence of and degree of crossover-flow to the contralateral cerebral arteries which may influence the effect of the amobarbital to be injected and subsequent interpretation of the study. Anomalous vascular patterns may affect the distribution of the amobarbital and impact on the subsequent interpretation of its effects. After the angiogram the catheter is kept in the internal carotid artery usually at the C3–4 cervical spine level and its position is confirmed by fluoroscopy.[60] Immediately prior to the injection, the patient is asked to keep both arms elevated to evaluate strength and then is instructed to start counting aloud. The anesthetic agent, usually sodium amobarbital is injected by a hand-push technique over several seconds. The contralateral arm drops as hemiplegia develops and if the speech dominant hemisphere is injected, the patient also develops global aphasia and stops counting. The patient is usually mute for 2–3 minutes and then speech returns, initially dysphasic with paraphasic errors being present for a few minutes before the speech returns entirely to normal. With injection of the nondominant hemisphere, the patient may continue counting, usually with a degree of dysarthria. However, the patient may become mute and this lasts for a much shorter time, 20–30 seconds, as compared to the dominant hemisphere.

Immediately after injection, strength is first evaluated to determine if adequate hemiparesis has occurred as an indicator that the injection has been sufficient to produce ipsilateral cerebral hemisphere inactivation. The patient's level of attention is then assessed by asking him or her to follow a simple one step command, requiring a nonverbal response such as 'close your eyes'.

Language and memory function are evaluated as long as the patient continues to demonstrate hemiparesis. Memory for the items presented during the period of hemiparesis is

tested approximately 10 minutes after the time of injection when strength and language function have returned to baseline. We also monitor the effect of the anesthetic agent on the EEG as a parameter of the effect of the EEG and wait for cessation of any slow and return of the EEG activity to baseline. We inject the hemisphere ipsilateral to the epileptogenic zone first and the contralateral hemisphere the same day a short time later, 30 minutes after initial injection if amobarbital is used and 10–15 minutes if methohexital is injected.

Variations in procedure

Baseline evaluation

At many centers, as well as in our protocol at the Cleveland Clinic, a practice test is performed prior to the actual Wada test in order to obtain an evaluation of the patient's baseline memory function and also to familiarize the patient with the procedure.[60] At certain centers only hand strength may be checked to gauge the degree of hemiparesis following injection or to perform a brief language assessment.[54,61] Baseline evaluation may be done either a day earlier or shortly before the procedure. We usually perform this baseline evaluation on the day prior to the Wada test.

Drugs administered: amobarbital

Sodium amobarbital is the standard drug used. The most frequently used dosage is 125 mg, but it may vary from 60–200 mg based on the patient's weight. When using amobarbital we most frequently inject 100 mg of amobarbital and if this did not produce an adequate hemiparesis, we would inject an additional 25 mg. The drug is usually diluted in several ml of solution and is injected by hand-push technique over 3–5 seconds. In a study of 72 patients, Loring *et al.* compared patients with lower doses (125 mg or lower) versus patients studied with high doses (greater than 125 mg). The group with higher doses performed significantly poorer than the patients with lower dose.[62] It was also suggested that the higher incidence of bilateral language and at-risk amnestic patients reported at some centers may be related in part to large amobarbital doses and that using lower doses such as 75 mg can improve the efficacy of the procedure.[63] Lower doses may not always produce adequate hemiparesis or be sufficient to produce transient global amnesia,[20] whereas too high doses may produce transient periods of confusion and thus impair the ability to evaluate the effect of the amobarbital.[25] One study investigated the relationship of dosage administered and memory performance during the Wada test.[64] The authors analyzed the effects of doses varying from 45–425 mg and found that dosage was not related to any of the measures of memory used in the test or to the final pass/fail outcome.

Alternative drugs

Although amobarbital was the standard drug for many years other drugs such as methohexital, propofol and etomidate have been used.[13,18,20,65] Several years ago when there was a shortage in the supply of amobarbital we began to use methohexital which has subsequently become the agent we routinely use.[66] We inject 3 mg initilally and if there is inadequate contralateral hemiparesis we inject an additional 2 mg after a 30 second interval. Ocassionally 5 mg is routinely injected. Of interest is the technique recently described by Jones-Gotman *et al.* They use etomidate injected as a bolus and then as a constant infusion to maintain a constant anesthetic effect during the testing of memory and language function.[15]

Time of injections

Most centers inject both internal carotid arteries to evaluate language and memory function.[20] Both hemispheres are usually evaluated on the same day with a period of time between each injection. This is more efficient in terms of performing the study and also subjects the patient to only one femoral arterial puncture. However injecting both sides on one day with a relatively short interval between the two injections may have an effect on memory evaluation particularly after the second injection. When injecting the epileptogenic zone first and comparing the effect of the timing of injection on memory one study showed that memory after the second injection on the same day was not as good as compared to testing on a second day.[67] They showed that memory for both verbal and figural material after intracarotid amobarbital injection was lower when injecting both hemispheres on the same day. If injecting amobarbital we usually wait 20–30 minutes from the time of the first injection to the time of the second injection. In some centers, the injections are performed on separate days. The centers using larger doses may inject the ipsilateral and contralateral injections on separate days because of the concern of obtundation associated with larger medication doses.[27]

Side of injection

The epileptogenic hemisphere is usually injected first.[68,69] However there is some concern that the order of injection may have an effect on memory evaluation. Grote and colleagues showed that memory after second injection on the same day was not as good as mentioned above.[67] The side injected first is usually the side ipsilateral to the epileptogenic zone in most centers. This is to mimic the effect of the proposed resective surgery in intractable temporal lobe epilepsy. The side of the epileptogenic zone is injected first in case it is not possible to subsequently inject the contralateral side. The group in Berlin compared a congruent patient population (where the epileptogenic side is injected first) with a noncongruent patients (where the nonepileptogenic hemisphere is injected first).[70] This comparison found that the congruent group demonstrated poorer memory function after injection of the nonepileptogenic hemisphere compared with injection of the epileptogenic hemisphere. The authors concluded that the commonly used method of injecting the epileptogenic side first results in a poorer memory recognition by the epileptogenic hemisphere than the nonepileptogenic hemisphere.

Arousal asymmetry

The effect of the injection on arousal may be asymmetric. Decreased arousal after left hemisphere injections has been demonstrated.[71,72] The Glasgow coma scale has been used in one study to objectively measure the level of consciousness.[72] Decreased arousal in turn may decrease the apparent memory

function of the opposite hemisphere being evaluated. This effect appears to also interact with the side of the epileptogenic zone, so that patients with left temporal lobe epilepsy are more likely to demonstrate poor memory related to the right hemisphere and may 'fail' the Wada test.

In the standard IAP, Lesser *et al.* showed that the initial confusion and muteness did not interfere with the ability of patients to form new memories since the patients remembered objects presented during this period.[73] Hart and colleagues compared the ability to comprehend the semantic relatedness between a picture and a word with the ability to name and read aloud individual items following dominant side injection.[74] They found that although almost all patients had severe impairment in reading aloud or naming pictures, 53% were able to match perfectly the same visually presented words to their corresponding pictures by their meanings or associations. These results suggest that some degree of comprehension, specifically complex auditory comprehension, is preserved following the standard IAP.

Crossover of drugs

Perrine and colleagues studied the relationship of behavioral, language, and memory variables during the IAP to angiographic evidence of the degree of ipsilateral posterior cerebral artery or contralateral anterior cerebral artery filling in 42 patients.[75] Contrast medium injection at the same rate as that of the later amobarbital injection was used to control for effects of different rates of injection. They found that ACA cross-filling was not related to any behavioral measure including the level of consciousness and mutism. The degree of PCA filling correlated significantly with the level of consciousness, but this was not significant after accounting for the effects of seizure laterality, injection side, and amobarbital dosage. Specifically, neither ACA cross-flow nor PCA filling correlated significantly with memory.

Stimulus timing

The timing of presentation of items for memory testing after injection is quite variable amongst centers. We usually present items after the first nonverbal response is obtained, performing a simple one step command to insure that we have the patient's attention,[76] even in the presence of aphasia. In some centers, presentation of items is performed only after return of speech.[10,60,77] With injection of amobarbital we found an initial period of muteness, confusion and unresponsiveness especially after injection of the language dominant hemisphere.[73] However stimuli presented early during this initial period of confusion could be recalled when memory was being tested.[73] Only left sided injections in left-hemisphere language dominant patients were used in this study. The London, UK, group investigated the influence of interference with language on memory. Their hypothesis was that memory function is dependent on language ability and that injection of the language dominant hemisphere will result in an artificially lower memory score.[78] In this study, however, patients did not display a better memory for items presented after return of speech than those presented while language was impaired. Thus language recovery and memory function were found to be independent. Nevertheless, result may be material specific.

At the Medical College of Georgia, Augusta, items are presented immediately after demonstration of hemiplegia, evaluation of gaze function and execution of a simple command by the patient before return of language. This is referred to as early presentation of items. Presentation of items after some recovery of language function is referred to as late presentation of items. Hemiparesis is usually evaluated by the grip strength of the contralateral hand and loss of strength in antigravity muscles of the arm.[20] The group in Georgia demonstrated that memory for objects presented early (beginning approximately 55 seconds after amobarbital administration) differed as a function of ipsilateral versus contralateral injection at a very high level of statistical significance. Items presented late (4 minutes and 30 seconds after injection) were also related to the laterality of the seizure focus but at a lower statistical level.[79]

The duration that each stimulus is presented is also quite variable from center to center and may also influence memory performance. In one report line-drawings were presented for 10–15 seconds[75] whereas in another report objects were presented for 4–8 seconds.[79]

Hemisphere speech dominance

After the injection of the speech-dominant hemisphere there is initially a profound aphasia and the duration is dependant on the drug and dose used.[20] Although the patient is unable to read or name objects, objects that are shown or tactually handled by the patients are encoded into memory and recognized after the drug effect has worn off.[11,73,80,81] Auditory verbal stimuli given in the early postinjection period are less likely to be recalled during subsequent testing of recognition memory.[82,83] Memory for three visual stimuli, pictures of common objects, words and abstract forms were used to investigate the effect of speech dominance on memory evaluation.[84] They demonstrated that injection of left speech dominant hemisphere compared to the right nondominant hemisphere resulted in an overall increase in errors. Long term memory testing following left hemisphere injection showed that fewer errors were made in regard to pictures of common objects during the early postinjection period as compared to the later long term memory testing. Thus pictures of objects could be adequately encoded for later recall. In contrast fewer errors occurred after right hemisphere injection and selective errors seen after left hemisphere injection were not found.

Stimulus type

A variety of test stimuli can be used to assess memory. Stimuli usually include actual objects, line drawings of objects, words and designs or photographs. A multicenter study including subjects from four centers studied the influence of the stimulus type in regard to memory lateralization in TLE.[85] They compared memory for actual objects and line drawings and determined that real objects were superior to line drawings in differentiating left from right TLE groups. Line drawing asymmetries incorrectly lateralized the temporal lobe memory impairment in left TLE subjects at a rate of 2.7 times greater than asymmetries based on object recognition. Similar findings were also reported by the same group in 152 pediatric patients aged 16 years and younger. In this study the use of real

objects (rather than using mixed stimuli, photographs and line drawings) discriminated the memory asymmetry better and lateralized the epileptogenic zone in a greater proportion of patients.[86]

At the University of Pennsylvania differential temporal lobe memory was demonstrated in relation to verbal versus visuospatial stimuli.[87] Patients with left temporal lobe lesions had poorer memory for verbal stimuli, whereas patients with right temporal lobe lesions performed more poorly for visual spatial stimuli during the IAP.

At our center, items are presented during the period of hemispheric inactivation, usually while the hemiparesis persists and while there is associated unilateral slowing in the EEG. Our current protocol involves three groups of items, a line drawing of an object, an object word and a function word (e.g., indeed, inspite). We previously also used abstract designs (Chinese pictograms) but dropped these from our protocol several years ago. After the initial injection and adequate hemiparesis is documented as well as adequate attention is obtained, one item of each of these three groups is then presented. Then strength of the contralateral arm and speech are re-evaluated. The next set of three items is then presented and language and motor function reassessed. The above pattern is repeated until full strength has returned. The time of presentation of items in the study is divided into three phases based on the contralateral hemiparesis. Phase one is the period from the time of injection to return of strength to grade 3/5; phase two is the period from the time strength reaches grade 3/5 until the return of baseline normal strength, grade 5/5; Phase three is the period after return to baseline or normal strength until presentation of all items is completed.

We evaluate memory for items presented 10 minutes after the injection of amobarbital providing full strength has returned and the patient's EEG has returned to baseline.[11,20,68,69,76,88–90] Since we have been injecting methohexital the duration of anesthetic effect is shorter and we are able to test memory sooner, but wait at least 5 minutes after injection.[66] We initially test memory for the items shown with spontaneous recall and then ask the patient to recognize the item shown on a flashcard, given a choice of the item and three foils.

Number of presented items

The number of stimuli that are presented in the test protocol is also quite variable at different centers. The Medical College of Georgia used eight early and five late items.[91] Harborview Medical Center in Seattle used 20 to 30 items.[92] UCLA used six items.[83] At Cleveland Clinic we initially used up to 20 items,[68,69] but now we use a maximum of 12 items.[66]

Language scoring

At our center, assessment of language lateralization is mainly based on speech arrest times. The hemisphere that displays the longest period of muteness after injection is usually defined as the language dominant hemisphere. However, if the interhemispheric time interval of speech arrest is shorter than 30 seconds, bilateral language is suspected. A protocol using different lateralization measures has been proposed by Benbadis *et al.*[93] In this paper three lateralization measures were suggested:

1. the absolute duration of the speech arrest after left and right intracarotid barbiturate injection, using a cutoff of 60 seconds;
2. the difference between speech arrest times after left and right injections using a cutoff of 30 seconds; and
3. the laterality index, definded as the difference between speech arrest times after left and right injections, divided by the sum of speech arrest times after left and right injection.

Other centers also use scoring of dysarthria and paraphasias during the language assessment.

Memory scoring

Memory score is calculated as the number of items correctly recognized as a percentage of the number shown during the period of hemiparesis, phases 1 and 2. The patient's memory score is not penalized for guessing. We inject the opposite internal carotid artery after an interval of 30 minutes from the initial injection if we are using amobarbital.[68,69,76,90] However if we use methohexital then we inject the opposite hemisphere 10–15 minutes after the first injection.

The initial major indication in evaluating memory function with the IAP was to determine the risk for postoperative global amnesia after unilateral temporal lobectomy, by determining if the patient failed the memory test with injection ipsilateral to the epileptogenic zone. In many centers memory scores of 67% or greater are classified as passing scores for the memory test and those with scores with less than 67% are classified as having failing scores on the memory test of the IAP.[53,54,68,69,76,94] A passing score of 50% or greater has also been used.[92] Additionally, a comparative method of evaluating memory with failure, defined as a retention score of at least 20% lower on one side compared to the other has also been used.[68,69] They defined failure on both sides when both scores were less than 50%, with neither score being 20% lower than the other.

Memory asymmetry scores have been devised to determine lateralization of seizure onset. This refers to inter-hemispheric differences in memory scores which may be calculated from left injection score minus the right injection score,[61] or right injection score minus left injection score.[75] An asymmetry of at least two is interpreted as indicating lateralized impairment of memory function. In addition, an IAP asymmetry ratio has been calculated by dividing the higher hemispheric score by the lower score.[95] We recently developed a scoring technique to account for patient guessing in the memory recall. In this study, memory function was based on identification of a minimum number of items (pass/fail). This number was determined by the probability to guess a series of results correctly in our multiple choice paradigm ($p < 0.05$ in binomial probability tables). For example, if the patient was tested with 12 items, a score of 8 or more would be achieved by chance or by guessing less than 5% of the time and was therefore used as the cut-off score to demonstrate functioning memory.[96,97]

Clinical applications

Prediction of language lateralization

Prediction of language lateralization has been the primary objective of the IAP. Despite obtundation language lateralization was robust and was easily confirmed on repeated intracarotid amobarbital testing.[96,97] Although language is usually unilateral, different methods to score language lateralization during the Wada test [93,98] and advances in functional imaging[99] indicate that language lateralization is not just left or right, but a continuum with different degrees of laterality. In biased epilepsy patient populations this continuum may be shifted more to the hemisphere contralateral to the lesion. Möddel *et al.* at our center analyzed 445 bilateral IAPs and found that patients without neocortical lesions on MRI are left-hemispheric-dominant for language. Right-handed patients with left-neocortical lesions were more likely right-hemispheric language-dominant or had bilateral language-dominance. Left-handed patients with left neocortical lesions were most frequently right- or bilateral dominant.[100] Due to possible bilateral language representation unilateral lack of speech arrest may not reliably predict language outcome after resection in selected cases.[101] Exclusively in patients with Rasmussen's encephalitis of the dominant hemisphere, transfer of language and subsequently change in language lateralization on Wada testing has been described up to teenage years.[96,102] This, however, does not question the validity of the Wada test language lateralization, as language itself switched in these patients.

Prediction of memory deficits

Prediction of memory deficits can be divided into prediction of global aphasia and prediction of selective memory deficits.

Predicting postoperative global amnesia following temporal lobectomy

Prediction of postoperative global amnesia after temporal lobe resection has been another objective of the IAP memory test since its introduction.[10] The majority of patients who pass the test, i.e., who have good memory after injection of the hemisphere ipsilateral to the epileptogenic zone, do not develop significant postoperative amnesia (true negatives).[10,11,77] However, there is no acceptable 'gold standard' with which to compare the results of the IAP except by producing the syndrome itself. It is not possible to know how many patients would become amnestic without operating on all of them, and there are ethical constraints to subjecting a patient determined to be at risk by the preoperative IAP results to surgery.[83] There are no true validation studies. The test is used as if its validity were beyond question.[60]

Validity of the test can only be estimated indirectly. The IAP can identify true-positives, i.e., patients who failed the test and subsequently became amnestic after unilateral temporal lobectomy. In the survey from the Palm Desert conference, six of these patients were reported.[20,103] In five of these patients, resection included mesial structures and were spared. MRI studies in one patient showed no obvious abnormality in the contralateral hippocampus.

On the other hand, there are rare instances where the IAP has missed patients at risk for postoperative amnesia (false-negatives). In the same survey,[20] six respondents reported such patients. One of these had transient amnesia, while confirmation and details of the remaining cases were unknown.[103]

There are also reports of patients who failed the IAP but underwent temporal lobectomy including the hippocampus and developed no postoperative amnesia (false-positives).[103] Loring and colleagues described ten patients who failed either the early or the late item recognition portions of their test following injection ipsilateral to the seizure focus.[91] All had satisfactory performance on other tests of hippocampal function (hippocampal stimulation or cooling) and underwent temporal lobectomy including hippocampal resection. On follow-up neuropsychological assessment, none of these patients had anterograde amnesia, although some had reduction in material-specific memory. The practical implications of these false-positive patients are that some patients may be needlessly denied surgery if only Wada memory results are taken into account and that, in those who are operated on, the hippocampus may be unnecessarily spared with poorer seizure outcome than if it was removed.[104] The methodological factors also need to be considered when analyzing false-positive cases.[105] With use of some protocols, a patient may be more likely to fail the injection ipsilateral to the proposed surgery. Rausch and colleagues found that the majority of centers reported a failure rate of greater or equal 5% and the percentage of patients showing consistent failure ipsilateral to surgery ranged from 0% to greater than 30%.[20] Also, at some centers only patients considered to be at high risk for amnesia undergo a Wada test, while other centers the test is performed on all surgical candidates.

Surgery is frequently denied to patients who fail the test or the extent of resection is modified to spare the hippocampus and the parahippocampal gyrus.[31] Other options include repeating the IAP at the same or lower dosage,[62,106,107] using information from other complementary tests such as neuropsychology or neuroimaging, and performing selective arterial amytal procedures. At the Medical College of Georgia, memory was further tested during localized hippocampal cooling during surgery [108] or by low-level electrical stimulation via depth electrodes with simultaneous memory testing,[109] but these procedures are no longer employed because of failures.[110]

McGlone and MacDonald reported changes in pass/fail rate in eight of 18 patients in whom the IAP was repeated.[107] However, in seven of these eight patients, the changes were due to extrinsic factors such as obtundation. We reviewed 15 patients with intractable TLE who underwent repeat IAP because they had poor memory scores following initial injection ipsilateral to the epileptogenic zone.[111] In these patients memory scores increased from a mean of 32.9–56.9, and this change was not related to the difference in duration of ipsilateral EEG slowing, contralateral hemiparesis or muteness, side of language dominance, age, or presence or absence of a lesion. Following temporal lobectomy none became amnestic. In another survey of 1249 consecutive IAPs at our center the IAP was repeated in 4% of patients due to unsatisfactory information on either language or memory lateralization.[96,97] Repeated memory test results were less consistent across tests, and memory lateralization was unreliable in 63% of the patients. However, these results may have been influenced by obtundation, varying dose of amobarbital, testing of both hemispheres on the same day, unblinded observers,

fluctuating cooperation of the patients and a biased sample of patients.[96,97]

In a group of patients who underwent modified surgery, sparing the hippocampus because of IAP failure Jones-Gotman found that the Wechsler Memory Scale memory scores were significantly worse before and after surgery than in patients who had passed the IAP.[104] Their results suggest that patients who fail the IAP have poorer memory and their memory remains disproportionately worse after surgery.

In summary, an accurate estimate of the usefulness of the IAP in predicting postoperative amnesia is difficult, and its validity for this purpose remains a concern. The considerable variation in patient characteristics, technique, and interpretation of results across centers is a major problem. Further studies investigating test reproducibility and the effects of methodological and patient differences are necessary.

Predicting selective memory deficits

The initial indication of the use of the Wada test in relation to memory was to predict who may be at risk to develop global amnesia after temporal lobectomy. However it was well recognized that postoperative global amnesia is rare after unilateral temporal lobectomy, and that a rather mild material-specific deficit commonly occurs.[76] Subsequently studies tried to extend the utility of the IAP memory testing to predicting more selective modality-specific deficits. Based on pre- and postoperative neuropsychological tests, decrements on verbally based tests following dominant temporal lobectomy have been found in several studies.[28,32,34,36,81,112,113] There appears to be an inverse relationship between the amount of verbal memory decrement and the preoperative level of functioning. Patients who are functioning higher preoperatively show greater decrements than those who are poorly functioning.[28] However, a similar decrement in visual memory scores has not been convincingly documented following nondominant temporal lobectomy.

In 1991 the Cleveland Clinic group reported that an absolute ipsilateral IAP memory value of <67% was not associated with a decrease in modality-specific memory after temporal lobectomy, but when ipsilateral failure was defined by a comparative method (retention score at least 20% lower after ipsilateral than contralateral injection), the results showed greater differences between groups.[69] Four patients with left temporal lobectomy who failed the IAP had a median postoperative decrease of the Wechsler Memory Scale-Revised (WMS-R) Verbal Memory Index score of 14%, while 16 patients who passed the IAP had a decrease of 7%. This difference was not statistically significant but suggested that patients with lower ipsilateral memory performances may be at greater risk for memory decline. Loring also found that memory asymmetries, but not absolute values, following left or right injection may be predictive of verbal memory decline following left temporal lobectomy.[114]

Although these studies examined material-specific postoperative deficits, they used global IAP memory scores, i.e., using a wide variety of items including objects, words, and designs. They made no attempt to correlate memory for material-specific items with material-specific postoperative scores. Rausch and Langfitt grouped their IAP items based on the amount of verbal encoding upon which they were presumed to depend.[83] An unfamiliar design was regarded as a nonverbal item, whereas a printed word was regarded as a verbal item. Their results suggested that left but not right temporal lobectomy patients who fail to remember the printed word following ipsilateral IAP have a worse postoperative verbal memory performance.

There are several studies that have investigated the importance of the contralateral injection in predicting material specific post-surgical memory changes.[42,76,91] In the study by Kneebone *et al.*,[76] 63 patients who passed their contralateral IAP subsequently underwent left temporal resection. The patients with a pass score on Wada, defined as equal or greater 68% correct recognition of early presented items when strength was <3/5, had a greater postoperative verbal memory deficit measured by the WMS-R than the patients with left temporal who failed the contralateral IAP. When the contralateral IAP recognition memory score was used as a continuous variable rather than pass/fail variable the contralateral memory IAP recognition score was significantly correlated with postoperative changes in the WMS-R verbal memory and Logical Memory. This relationship was not found in right temporal lobe patients with regard to visual memory and failure of the contralateral IAP. Similar to this Stroup also found that patients with left TLE and high memory scores on contralateral IAP were at a greater risk for postoperative verbal memory deficits.[115] This group studied the relationship of the material specific aspects of the IAP and the material specific changes in memory after surgical resection. They found that the IAP memory related to postoperative verbal memory but not to visuospatial memory change after injection ipsilateral to the epileptogenic zone when relying on the contralateral memory. This is consistent with the functional reserve model of memory.[116]

Sabsevitz investigated memory outcome in the expected asymmetry and unexpected asymmetry groups by IAP and found that patient with left temporal lobectomy and reversed IAP asymmetry have a poorer memory outcome as well as a poorer seizure control.[117] They concluded that patients with reversed Wada asymmetry were at greater risk for memory deficit after surgery. The reversed asymmetry group showed a significant decrease in the selective reminding test. This reversal may relate to two possible hypotheses. The ipsilateral hippocampus is minimally sclerotic or intact or secondly there is a reorganization of the verbal material to the right temporal lobe.

Contrary to that the group from the UCSF epilepsy center found a significant number of their patients with left TLE, 36%, had a reversed memory asymmetry and this did not predict a decline in postoperative verbal memory deficit. This may relate to the fact that they used mixed stimuli rather than real objects for memory testing. At Cleveland Clinic we found that patients with TLE who demonstrated a reversed memory asymmetry on Wada testing had a prolonged period of dysphasia after left internal carotid injection and this factor may be responsible for lowering of the right hemisphere memory scores with a subsequent reversal of memory asymmetry.[118] We concluded that reversed

memory asymmetry does not predict postoperative verbal memory change.[118]

Lateralization of the epileptogenic zone

Prediction of epileptogenic zone laterality by memory results

The IAP may also assist in lateralization of the epileptogenic zone in patients with TLE. Although the IAP was initially not used for this purpose, Milner noted that in 11 of the 12 cases with memory disturbance, injection was contralateral to the side of the epileptogenic lesion.[10] In 1981 Engel specifically proposed the use of the IAP to lateralize the epileptogenic zone in patients with TLE.[119] In 1989 Rausch subsequently demonstrated impaired memory performance on the IAP following contralateral injection which correlated strongly with the hemisphere from which the seizures were originating in 19 of 30 patients with intractable complex partial seizures.[53] None of the patients who underwent surgery failed the IAP following injection ipsilateral to the epileptogenic zone. At our institution similar results were found: in a series of 37 patients who underwent temporal lobectomy, memory was significantly lower following contralateral injection than ipsilateral injection.[68,69] The lateralizing significance of the IAP for the more epileptogenic hemisphere was greatest in patients with profound amnesia, with memory score from contralateral IAP of <33%. Additionally, the epileptogenic left temporal lobes showed worse memory function than epileptogenic right temporal lobes. Many other investigators have cnfirmed that the IAP, especially the contralateral IAP, is useful in defining the lateralization of the epileptogenic zone.[53,56,57,62,75,120–127]

Perrine studied the relationship of the IAP difference scores and the lateralization of the epileptogenic zone.[75] The IAP difference score was defined as memory score after right injection subtracted from the memory score after the left injection. This was performed for 70 patients with left-hemisphere language and TLE without an associated structural lesion. One point was added to the score after left-hemisphere injection to compensate for the effect of the dysphasia on memory. A difference score of <–1 indicated right memory better than left memory and was thought to predict a left hemisphere epileptogenic zone. A score of >1 indicated left memory better than right memory suggestive of a right-hemisphere epileptogenic zone. Scores in-between these two values was indeterminate in lateralizing the epileptogenic zone. This method classified 50 of the 70 patients (71.4%). Of these 50 patients, 100% of the right and 98.0% of the left were correctly lateralized.

The influence of timing of stimulus presentation after injection on correct lateralization of seizure foci has been studied by Loring *et al.*[128] They found that recall for items presented shortly after injection had greater lateralizing value than recall for items presented after partial return of language function.[129] In this study material-specific stimuli were used to assess the role of the IAP in lateralization of seizure foci in 45 left-hemisphere language-dominant patients with TLE. Patients with right TLE had significantly worse memory for verbally mediated stimuli (words, object drawings, colored shapes) with left as compared to right injection. Patients with left TLE had worse memory for a nonverbal stimulus (abstract design) after right injection than after left injection. They concluded that material-specific memory remains intact in the hemisphere contralateral to a seizure focus, but wider representation may occur for stimuli normally dominant for the hemisphere with the seizure focus. Other studies have shown similar results with memory for words and numbers being worse following the dominant side injection than the nondominant side injection and recognition of faces being better following left rather than right injection in patients with left TLE.[82,130,131]

Le Jeune compared three different techniques of IAP memory procedures, in defining lateralization of the epileptogenic zone [120] including the Montreal, Seattle, and Interview procedures. They found that the Montreal and interview techniques for right–left injections each significantly differentiated the patients into right and left seizure onset foci. They produced the correct lateralization in >70% in their original sample of 100 patients as well in an additional cross validation sample of 60 patients. However the Seattle method did not differentiate the patients correctly.

Pathology may influence the predictive value for the epileptogenic zone. The IAP correlated extremely well with the side of the epileptogenic zone in the group of patients with unilateral mesial temporal sclerosis (MTS) but not in the group without MTS.[132]

Determination of seizure laterality with neuropsychological test results and the IAP has been compared.[121,133] Brown found that seizure lateralization was correctly predicted by IAP in 83% and this was similar to standard neuropsychology 82%.[122] Kneebone found that the IAP was superior to the standard neuropsychology evaluation in predicting seizure laterality.[133] The results of discriminatory function analysis resulted in correct lateralization of the seizure onset in 59.3% for the WMS-R, 57.1% for the WRMT and 81.5% for the IAP. This analysis was significantly better than clinical analysis. However not all investigators have found the IAP to be superior to neuropsychological test results in defining seizure lateralization. Privitera found neuropsychology significantly more accurately.[121]

Use of intracarotid barbiturates in secondary hypersynchrony

Besides prediction of the seizure focus by calculation of memory asymmetroes, intraarterial injections of barbiturates may also serve as a tool for distinguishing independent epileptogenic zones in patients with bilateral hypersynchrony or generalized EEG patterns and a unilateral lesion on imaging.[134–136] In these cases, injection ipsilateral to the epileptogenic zone may interrupt 'generalized' of bisynchronous EEG discharges, whereas contralateral injection will only mask the injected hemisphere.

Predicting seizure outcome

All patients undergoing IAP are not operated on. Unless all patients undergo surgery, there is no 'gold standard' with which to compare the results of the IAP for correct lateralization of the epileptogenic zone. In those who are operated on, seizure freedom or significant reduction may be used as the 'gold standard'.[83,137] Rausch and Langfit studied two groups of

patients with TLE who underwent temporal lobectomy and had adequate follow-up.[83] One group underwent depth electrode evaluation, whereas in the other group, it was felt that seizure foci were well localized and depth electrode evaluation was not required. IAP memory scores were compared to the side of focus and seizure outcome. In the group of patients who underwent evaluation with depth electrodes, the IAP predicted good outcome (Engel class I and II) in at least two-thirds of cases in whom it confirmed the side of the epileptogenic zone. Similar results were seen in the other group but these were not statistically significant.

Perrine used a memory difference score calculated as right minus left hemisphere memory to predict seizure laterality and seizure outcome in 70 left-hemisphere language-dominant patients.[138] A difference score of >2, with 1 point added to the left hemisphere injection score to correct for aphasia, correctly predicted seizure laterality in 98% of patients and seizure-free outcome at 1-year follow-up in 80%.

Hamberger and colleagues proposed using the IAP to distinguish between mesial and neocortical TLE.[139] Using a memory assymetry score defined as the difference in memory scores after right and left injection, they found that the mean asymmetry scores were lower in a group of patients with neocortical TLE (<25%) than in a group with mesial TLE (≥25%).

Loring *et al.* investigated the IAP memory performance with seizure outcome following temporal lobectomy.[123] He examined the relationship of an asymmetry score to seizure outcome at 1-year follow-up in patients with no radiological evidence of structural lesions other than hippocampal sclerosis. In patients who were seizure free, asymmetry scores were greater than in patients who continued to have seizures. Patients with asymmetry scores of 3 or greater were more likely to be seizure free than patients with scores of < 3. Sperling *et al.* studied 117 patients and included concurrent factors that might affect outcome such as age at first seizure, presence or absence of tumor, and full scale intelligence quotient in their analysis.[140] They concluded that the IAP correctly predicted seizure relief independently of these factors.

At Cleveland Clinic Lancman and colleagues studied the sensitivity, specificity and the predictive value of the IAP for predicting seizure outcome after temporal lobectomy.[141] They studied 108 patients who underwent temporal lobectomy and who had at least 1-year follow-up after surgery. They found that at a 30% asymmetry of recall specificity for favorable outcome Engel class I and II was 100% (95% confidence interval). However the sensitivity was only 51% (95% confidence interval). The positive predictive value was 100% and the negative predictive value 34%. They concluded that asymmetric recall on the IAP was highly specific but not very sensitive and the positive predictive value was very high.

Sabsevitz and colleagues divided patients with left TLE undergoing resection into two groups: expected memory asymmetry where memory is better in the hemisphere contralateral to the proposed resection and the reversed asymmetry group.[117] They found patients with reversed asymmetry had a greater risk for memory difficulty as well as a poorer seizure outcome than the patients with IAP memory in the expected memory asymmetry group. All 12 patients with expected Wada memory asymmetry were seizure free at 6 months. In patients with reversed Wada memory asymmetry only four of nine patients met criteria for Engel class I.

Complications

A retrospective chart review of 447 patients undergoing the IAP at the Cleveland Clinic between 1993 and 1996 revealed four cases with clinically significant complications (0.96%). These complications consisted of a cerebral infarction, a transient femoral neuropathy, a temporo-mandibular joint dislocation and a left internal carotid artery spasm causing hemiplegia, hemisensory loss and hemianopia, which resolved within 15 minutes.[142] An additional study at our center in 677 patients covering the period from 1996 to 2002 found complications in 11.6%. During the procedure, encephalopathy (8%), seizures (1%), bleeding from the catheter insertion site (0.1%) and allergic reaction to contrast (0.1%) was seen. Interestingly, seizures were more frequently seen after methohexital than after amobarbital injections suggesting possible epileptogenic effects of methohexital.[143] After the procedure, 0.6% of patients were diagnosed with strokes, 0.6 % had transient ischemic attacks, and 0.4% had dissections of the carotid artery. Additionally, hemorrhage at the catheter insertion site and infection was seen.[25,26] Other studies also report behavioral and emotional reactions during and after the IAP.[144,145]

Conclusion

The IAP is a useful tool to determine language lateralization in selected patients undergoing epilepsy surgery. Additionally, the Wada test may also predict who is at risk for material-specific memory change particularly for verbal material after dominant temporal resection. There is preliminary evidence that IAP findings are predictive independently of other factors. Alternative speech lateralization techniques by means of functional transcranial Doppler ultrasound,[146] by functional MRI,[147,148] by PET,[149] by MEG[150,151] or by means of repetitive transcranial magnetic stimulation[152–155] have been described and may complement or even replace the Wada test for language lateralization. Additionally, memory lateralization has been attempted with alternative techniques such as functional MRI.[23,156,157] Noninvasive tests may eventually render an invasive procedure such as the IAP obsolete.[110,158,159] Although these tests may provide much of the same information as the IAP, they rely on activation of cognitive function, whereas the IAP, which is an inactivation procedure, more directly models the effect of surgery.[21,22] However, imaging techniques continue to be developed and refined. They may ultimately replace the IAP when an imaging paradigm for identification of language regions to be spared from resection, and for valid and reliable prediction of postoperative memory deficits can be established.

94 Event-related potentials in patients with epilepsy

K Usui and A Ikeda

Introduction

Monitoring and evaluation of brain activities and functions are essential before, during, and after the surgery of patients with epilepsy. The pre-surgical evaluation incorporates the selection of candidates for surgery, characterization of seizure types, identification of treatable causes, and localization of the epileptogenic zone.[1] Intraoperative monitoring is performed to obtain accurate information of the extent of resection and to assess its completeness.[2] Post-operative evaluation is conducted to assess the outcome: seizure elimination or reduction in frequency.[3]

The goal of pre-surgical evaluation of candidates for epilepsy surgery is to identify the abnormal cortical region that generates seizures and to provide necessary information to remove or disconnect the region without precipitating any significant functional impairment. A variety of noninvasive diagnostic tests are used to help localize the putative seizure focus using electrophysiological and/or imaging methods.

In electrophysiological evaluation, the electroencephalogram (EEG) is the primary resource. In noninvasive recording, the simplest recording can be conducted with a pair of electrodes attached to the surface of the human scalp and connected to a differential amplifier. EEG is the output of the amplifier which shows a pattern of variation in voltage over time. While its original role is to detect abnormal electrical activities related to epilepsy, EEG is currently also applied to objectively evaluate specific brain functions using event-related potentials (ERPs). ERPs are based on the observation that the brain activities change in response to a stimulus given from the outside world. Voltage changes, or potentials, which occur time-locked to the stimulus, constitute the ERPs. In early studies, the term 'evoked-potential' or EP was employed because the potentials were believed to reflect brain activity strictly 'evoked' by the presentation of the stimulus, or activity associated with basic sensory processes. The more neutral term 'event-related' was later introduced because it was realized that the potentials reflected more than just evoked activity. ERPs, therefore, can be described as voltage fluctuations that are associated in time with some physical or mental occurrence. These potentials can be recorded from the human scalp and extracted from the ongoing background EEG by means of filtering and signal averaging. The time-locked nature of ERP recording along with their millisecond resolution make ERPs very useful for determining the temporal sequence/location of cortical events.[4–6]

The consensus among neurologists and electrophysiologists is that the ERP reflects activity generated within the brain. However, the relationship between what is occurring within the brain and what is observed at the scalp is not transparent. ERPs recorded from the scalp are the reflection of net electrical fields associated with the activity of large populations of neurons. The electrical fields can be measured at the scalp only when the associated neuronal population have a certain common geometric configuration (which is perpendicular to the cortical surface) and are activated synchronously. Biophysical and neurophysiologic considerations strongly suggest that scalp-recorded ERP waveforms are principally a reflection of post-synaptic (dendritic) potentials, but not of axonal action potentials.[7–10]

It is certain, however, that much neuronal activity is never apparent at the scalp. In many neuronal populations, activity might not be synchronous enough to generate an electrical field that can be recorded at a distance. In addition, the electric field distribution is inevitably distorted and dampened by the layers of skull and scalp. When the noninvasive methods of evaluation are inconclusive to determine the origins of the epileptic focus or when the epileptogenic zone must be defined with high precision in relation to nearby eloquent cortex, invasive measurement of epicortical EEG or electrocorticogram (ECoG) and epicortical ERP are indicated.

Since pre-surgical evaluation includes several methods and no single technique can provide complete information on which the precise neurosurgical decision is based, the best combination of techniques for evaluation has not been defined yet. There are different opinions about the specific surgical procedures that produce the best outcomes for different types of seizures.[11]

This chapter is intended to be a concise reference for practicing epileptologists and surgeons to help determine the appropriate evaluation methods and procedures among which a variety of ERP should be included as essential techniques. Since thorough and detailed description of ERP is out of its scope, this chapter will describe benefits and limitations of both noninvasive and invasive ERP measurement in relation to the phases of evaluation.

Terminology

The ERP waveforms contain components that span a continuum between the exogenous potentials (obligatory responses determined by the physical characteristics of the eliciting

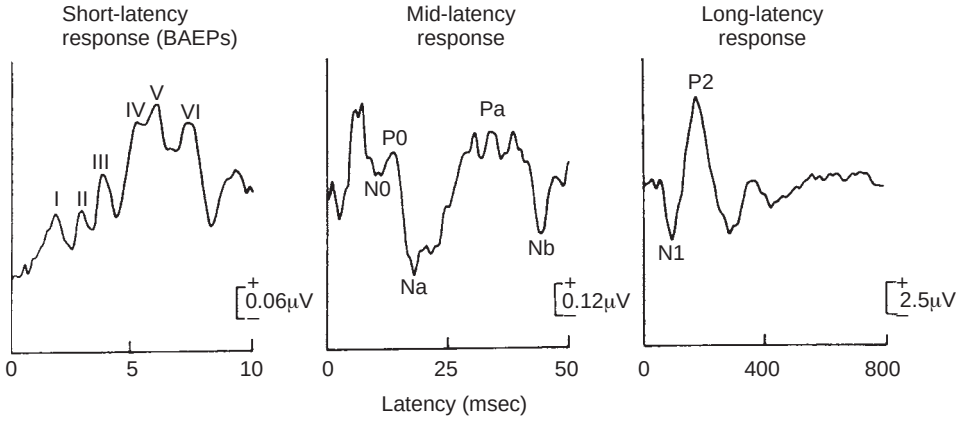

Figure 94.1 Auditory evoked potentials (AEPs) recorded from the vertex (Cz) in three sequential time periods. Early responses (also called brain stem auditory evoked potentials, BAEPs) and mid-latency components are regarded as exogenous. Long-latency components, N1/N100 and P2/P200, tend to be more endogenous (Reprinted with permission from Goodin DS, 1992.[5] Copyright 1992 Elsevier.)

event in the external world) and the endogenous potentials (manifestations of information processing in the brain that may or may not be evoked by the eliciting event). Principal factors that characterize ERP signals are their polarity and latency. Each ERP consists of a sequence of negative and positive voltage fluctuations. Each voltage fluctuation is labeled as component, and called by a name that denotes its polarity ('N' for negative and 'P' for positive) and characteristic latency after the stimulus onset. For example, P300 is a positive deflection occurring with a peak latency of 300 ms from the stimulus onset.

Potentials observed with the latency shorter than 100 ms from stimulus onset tend to be more exogenous and divided into three categories depending on their stimulus modality; visual evoked potential (VEP), auditory evoked potential (AEP) and somatosensory evoked potential (SEP). Strictly speaking, the terms EP and ERP refer to similar but not identical events. Considering the characteristics of the causes and/or origins, the potentials with latency shorter than 100 ms are usually called evoked potentials (EP) because they are believed to be 'evoked' by the presentation of the stimulus, or associated with basic sensory processes. The potentials with the latency longer than 100 ms, by contrast, are usually called event related potentials (ERP) because they tend to be more endogenous (Figure 94.1).

Numerous different components have been identified, such as N200, P300, N400, P600, CNV, and so on. Each component is evoked by a specific stimulus sequence, or paradigm, designed to produce the component. There has been much debate on each component with regard to its sensitivity to specific cognitive factors or its functional significance. In this chapter, only the components that have been investigated in relation to epilepsy will be discussed.

Noninvasive evaluation

In noninvasive pre-surgical evaluation, there are two clinical applications of ERPs. One is to use known components of ERPs to identify specific functional areas which should not be damaged by surgical procedures. Since some ERP components are confirmed to be generated in a specific functional area, the identification of the target area is more accurate with the help of ERP. The other is to use ERPs to detect functional abnormality. The abnormality may appear as changes in latency, amplitude, topography, and/or waveform of specific ERPs.

In many cases, crucial functional areas can be approximated by using anatomical landmarks.[11] In pathological brain, however, those landmarks are often distorted and the localization using them tends to be imprecise. In addition, functional areas may 'shift', which blurs the boundary of the targeted functional area.

SEPs obtained by electrical stimulation of peripheral nerves have come to be used for the localization of functional areas in an attempt to compensate for the inaccuracy of landmark study before surgery.[12] Historically, the first component of SEP, N20, was obtained by the electrical stimulation of the median nerve, and its characteristics are reported in the literature.[13–18] However, since noninvasive SEPs recorded at the scalp still do not have sufficient spatial resolution to localize the signal in a specific lobe or gyrus even with the insight obtained by invasive SEPs, the magnetic counterpart of ERP, event-related magnetic fields (ERFs), are also often used for noninvasive evaluation, which provides better spatial resolution. (Magnetoencephalography (MEG) is described in detail in another chapter of this textbook.)

In brief, MEG measures magnetic fields produced by electric current originating from synchronously activated neuronal populations using multiple channels of a superconducting quantum interference device (SQUID), a sensitive detector of magnetic flux.[19,20] Since it has as good temporal resolution as EEG and far better spatial resolution, the magnetic counterpart of N20, called N20m, is used to identify the SI cortex. Although MEG has a limitation, careful selection of target components will make ERF an efficient tool for pre-surgical evaluation.

As for the functional abnormalities, noninvasive ERPs have been used in research to identify the hemisphere from which epileptic seizures originate. In patients with temporal lobe epilepsy, P3 or P300 was recorded in pathological hemispheres

and compared with those in normal hemispheres.[21–25] The attempt to use scalp-recorded ERPs as a lateralizing tool of epileptic foci, however, has been mostly unsuccessful or at least not established as a standardized procedure. Although there is a possibility that the failure in the detection of signal difference between hemispheres might be partly due to insufficient coverage of the head with limited numbers of electrodes, the scalp-recorded ERP inherently has a limitation in separating neuronal activities between two hemispheres.

New techniques such as a topographic map[25,26] and a source localization using brain electrical source analysis procedure (BESA)[27] may broaden the applicability of scalp-recorded ERPs.

Invasive evaluation

Invasive evaluation is preferable when the highly precise identification and localization of specific functional area/areas in relation to the epileptic zone are necessary. Consideration of the type of disorder and possible surgical procedure is one of the essential factors to determine the methods for evaluation. If epileptic foci or other brain lesions that are to be resected are in the surrounding areas of the primary cortices for motor or sensory function, or crucial areas for higher cognitive function such as memory or language, pre-surgical and/or intraoperative localization of functionally important cortex is of utmost importance. Since the evaluation must provide crucial information for the decision of the extent of resection and the approach to the pathological area, noninvasive approach alone is not satisfactory in most of cases.

For invasive evaluation, surgically implanted electrodes are commonly used for a certain period of time, usually several days or two weeks, to localize seizure focus. The electrodes used for the evaluation include subdural grids or strips enmeshed in plastic, intracranial depth electrodes, foramen ovale electrodes, and others. Selection of electrodes depends on the type of seizures and the area that is most likely involved. When, for instance, signals from gray matter in deep areas are needed, depth electrodes are employed because no other electrodes provide access to that area. Subdural electrodes, by contrast, are directly implanted in the subdural space, hence they are less invasive than depth electrodes. All types of electrodes should be placed closer to the anticipated seizure foci based on the information obtained by noninvasive evaluation.

There are two main techniques in invasive procedures to investigate cortical functions; electrical cortical stimulation and epicortical ERPs. Since the former will be described in other chapters, this chapter is focused onto the latter. Compared with the noninvasive methods mentioned in the previous section, the most significant advantage of invasive ERPs is that they directly record neuronal activities occurring in the brain. Subdural electrodes monitor the activities beneath the electrodes, and depth electrodes detect the electric field from the contacted area.

Although invasive methods provide significant information that cannot be obtained by other techniques, attention has to be paid to the fact that invasive methods are not without problems. Monitoring using electrodes detects activities only in the areas where electrodes are placed. Even with the limited precision, whole-brain examination in general is conducted using scalp-based noninvasive methods.

Since invasive evaluation includes a wide variation in terms of the type of electrodes, techniques, as well as analysis and interpretation of data, which is not always straightforward, the detailed description of the whole aspect of ERPs would require an entire book. Instead of providing scant information of wide-ranging topics, this section will focus on some of the recent significant findings. The following subsections include new approaches using both subdural and depth electrodes, interpretation of memory-related component, language-related components, components associated with motor planning and with the integration of sensory information. As for the primary cortex for vision, audition and somatosensory sensation, identification is usually performed by using epicortical VEP, AEP, and SEP, respectively, details of which will be discussed in other chapters.

Temporal lobe epilepsy and invasive ERPs

Application of depth electrodes to mesial temporal lobe epilepsy

Temporal lobe epilepsy (TLE) is the most common type of partial epilepsy.[28] Mesial temporal lobe epilepsy (MTLE) occupies a large portion in TLE and is often surgically treated.[29] In most cases, the epileptogenic zone is in the medial temporal structures, including hippocampus, amygdala, and adjacent neocortex. Precise localization before resection, therefore, requires invasive evaluation that provides information from deep areas where only intracranial depth electrodes have access. Since the objective of pre-surgical invasive evaluation is not only to localize epileptic foci but also to decide the extent of resection without precipitating any significant functional impairment, ERPs are used also to identify specific functional areas.

It should be noted in practice, however, that intracranial monitoring may involve greater risk than resective surgery itself and should be used only after appropriate noninvasive monitoring has been completed so that a hypothesis of seizure onset has been formulated and a clear goal of the investigation has been defined.[11]

Identification of memory-related ERPs

Research results suggest that memory is not just a storage of information in a specific area but coordinated functions among various regions in the brain as a sophisticated neural network.[30–32] It is generally indicated that the medial temporal structures play an important role in this particular cognitive function.[33–35] Clinical observation revealed that patients with MTLE, whose medial temporal lobes are involved in epileptic activities, show some memory impairment, although the severity varies depending on the patient.[36]

Among several ERP components regarded as memory-related, two components, P300 and 'N400 and P600 complex' are associated with the temporal cortex. Hence they are significant for pre-surgical evaluation of patients with MTLE and have been investigated using various experimental paradigms.

P300 is evoked in a relatively simple task of target detection, called an 'oddball paradigm', in which subjects are requested to react only to the rare target stimuli amongst the

frequent 'standard' stimuli. The rare target stimuli provoke a potential with a peak latency at around 300 ms from the stimulus onset.[37,38]

The anatomical localization of generators of P300 has been reported using invasive recording (Figure 94.2). Multiple generators have been identified, including in the hippocampus, frontal, and parietal lobes.[39–44] In medial temporal structures, bilateral hippocampi separately generate the P300. The clinical significance of P300 in the pre-surgical evaluation is also suggested in studies using depth electrodes sited in the bilateral hippocampi. Unilateral absence or decrease in amplitude of this component was reported to be predictive of the lateralization of epileptic focus and hippocampal sclerosis.[45–47]

In the case of scalp recording, it is difficult to conclude that the scalp-recorded P300 is the summation of the generators identified in invasive recording. The major contributor of scalp-recorded P300 is probably not the hippocampus but may be in an inferior parietal region[42] or midtemporal and inferior frontal area.[44]

P300 generally represents selective attention and information processing. Such detailed functional meanings as 'context updating'[48] and 'context closure'[49] are also reported, but the interpretation is not conclusive.

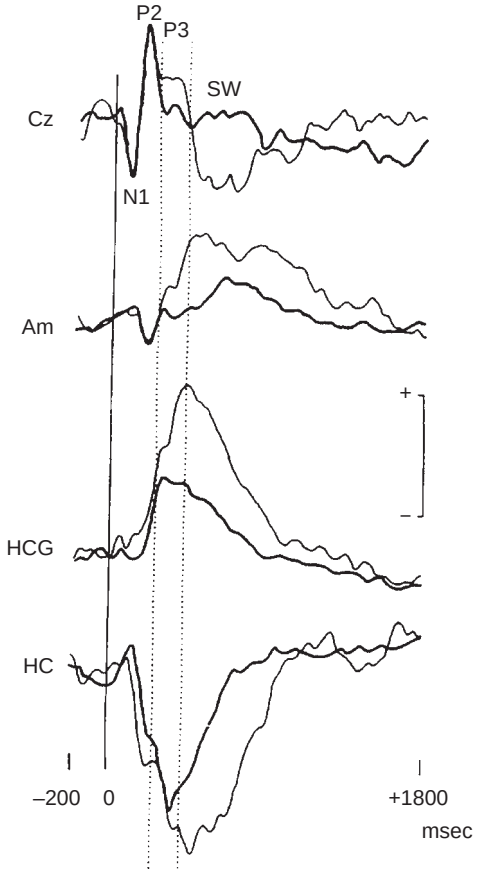

Figure 94.2 P300 recorded from scalp (Cz) and from the medial temporal structures by skin and depth electrodes, respectively. Thin lines show responses to rare stimuli and thick lines to frequent stimuli. Scalp-recorded P300 and responses from the medial structures present different waveforms. Am: amygdala; HCG: hippocampal gyrus; HC: hippocampus; SW: slow wave. (Reprinted with permission from Halgren E *et al.*, Endogenous potentials generated in the human hippocampal formation and amygdala by infrequent events. *Science* 210: 803-05.[39] Copyright 1980 AAAS.)

'N400 and P600 complex' was first recorded from depth electrodes placed in the medial temporal structures by using a paradigm to test recognition memory.[50] During the task of discriminating between novel stimuli and repeated (i.e., old one which is also in the memory) stimuli, a complex potential, consisting of a negative peak around 400 ms (N400) followed by a positive peak around 600 ms (P600) from the stimulus onset, is evoked. The complex varies in amplitude depending on the novelty of stimuli. The amplitude of N400 becomes larger in response to the novel stimuli than that are evoked by repeated stimuli. The amplitude of P600, by contrast, becomes larger in response to the repeated stimuli than that are evoked by novel stimuli. The phenomenon is called an 'old/new effect', which has been replicated in several other studies[36,51–57](Figure 94.3).

The N400 and P600 complex was indicated to have multiple generators in temporal, frontal, and parietal lobes.[58] Among these generators, ones in the medial temporal structures have been extensively investigated to assess the effect of epilepsy on this memory-related ERP component. Several researchers recorded the ERP complex from depth electrodes placed in the medial temporal structures. The results, however, varied between studies; some studies claimed that the ERP complex was sensitive to lateralize epileptic foci,[36,53,55] while others did not.[50,51]

In post-surgical states, the ERP component was also investigated. Groups of patients who had underwent left or right anterior temporal lobectomy and unoperated or normal controls performed the recognition paradigm. One study indicated that the old/new effect diminished in the patients with left-side lobectomy, while the patients with right-side lobectomy and unoperated patients showed the old/new effect.[59] There was, however, a contradictory result presented from other studies.[52]

Although the findings have contributed to the investigation of memory, the N400 and P600 and their old/new effect still need further evidence to be established as the evaluating method in epilepsy surgery.

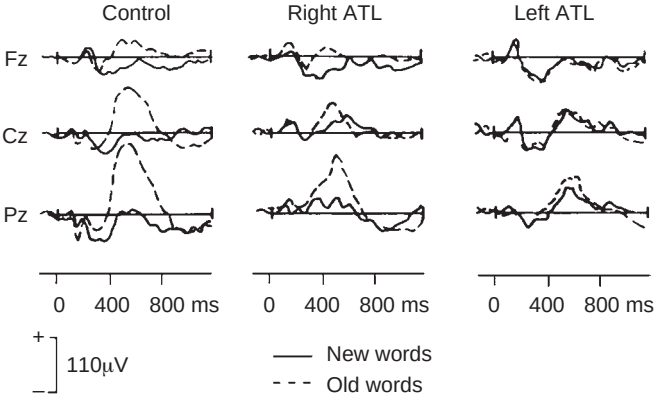

Figure 94.3 Memory-related N400/P600 complex and old/new effect. Grand-average ERPs from midline electrodes evoked by correctly recognized old and new words are shown. ERPs are presented separately for unoperated control subjects, and for subjects who had undergone right- or left-sided anterior temporal lobectomy. Old/new effects are exhibited in the ERPs of controls and right-sided patients but not in those of left-sided patients. ATL: anterior temporal lobectomy. Application of subdural electrodes to the left basal temporal area

Among cognitive functions associated with the temporal lobe, language is one of the most important together with memory. The classical approach to studying the relationship between brain lesion and behavior identified Wernicke's in the posterior superior temporal area, as well as Broca's in the inferior frontal area. In addition to these classical language areas, recent studies using electrical cortical stimulation revealed the existence of another language area in the left basal temporal area (LBTA).[60–68]

Since the evaluation of the LBTA requires probes in the subdural space, strips or grids are inserted into the space and the technique is less invasive than depth electrodes. Subdural strips are made of flexible Silastic or Teflon strips with embedded stainless steel or platinum contact disks. Different types of electrodes with up to 10 contacts or more are used.[2]

Localization of the functions in LBTA is crucial in the surgical treatment of MTLE because LBTA is sometimes involved in resection due to insufficient pre-surgical evaluation, which occasionally results in the occurrence of post-surgical language impairment, mainly anomia.[63,69] Sparing of LBTA can be beneficial in this respect.[70]

Identification of language-related functions

In the basal temporal area, two language-related ERP components are known; N200 and N400.[71–74] Both of them are reported to be evoked by visual stimuli of written language but with different cortical localization. The conditions for them to be evoked are also different.

N200 is evoked by letter strings, both words and nonwords. The component is regarded as language-specific because other visual stimuli, such as pictures of objects do not provoke the potential. N200 was recorded on the electrodes located in the posterior portion of basal temporal area.[71] The existence of this ERP component indicates that the cortical area is involved in written language processing.

Localization of the areas that exhibit N200 is not straightforward because it was recorded bilaterally both in the language-dominant and nondominant hemisphere in several studies.[71,74] The combination with other methods, such as electrical cortical stimulation, is necessary for the final decision to confirm that the cortical area from where the N200 is recorded is crucial for written language processing.

N400, the most well-known language-related component, was first reported in a study using scalp electrodes.[75] In a landmark study, Kutas and Hillyard[75] showed that the amplitude of the N400 was a measure of 'semantic incongruity' (Figure 94.4). In particular, large N400s were observed for words that violated semantic context. Further research has suggested that the N400 amplitude is inversely proportional to the expectancy of the word in a sentence ('close probability').[76] N400 amplitude appears to decrease across word positions in a sentence.

An invasive examination of language function was conducted by employing intracranial depth electrodes inserted in the medial temporal lobe[72,73] using two types of sentences visually presented word by word; one ends with a word appropriate for the context and the other with a word that makes the sentence incomprehensible. A negative field potential with a peak latency around 400 ms was evoked only by incongruous sentence-ending but not by normal ending. The field was focally distributed in the anterior medial temporal lobe (AMTL), anterior to the hippocampus and near the amygdala in both hemispheres.[72,73] The potential was named 'AMTL N400'. In the recording using subdural electrodes placed on the anterior portion of the basal temporal region just inferior and lateral to the amygdala recorded a positive potential at the same latency (which is called 'AMTL surface P400'). The spatial distribution of the potential recorded from depth and subdural electrodes indicated the generators in the neocortex near the collateral sulcus and anterior fusiform gyrus.[72,73]

Although the anatomical localization of the component is achievable, identification and/or interpretation of language

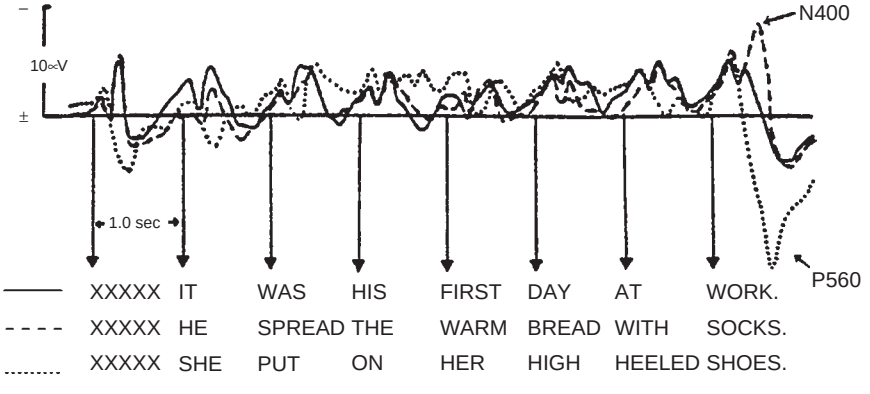

Figure 94.4 Language-related N400 recorded from midline scalp electrodes. Sentences with normal ending, with semantically incongruous ending and with physically incongruous ending are shown to subjects. Only the semantically incongruous final words evoke a large negative deflection. (Reprinted with permission from Kutas M and Hillyard SA, Reading senseless sentences: brain potentials reflect semantic incongruity. Science 207:203–205.[75] Copyright 1980 AAAS.)

function borne by each component is not conclusive. The potential was recorded bilaterally with no obvious interhemispheric difference in amplitude.[72,73] There was no report regarding the post-surgical evaluation of this ERP component, as well as the language ability of the patient, after the resection of this particular area. In pre-surgical evaluation, the existence of this ERP component and the results of electrical cortical stimulation must be compared for the final decision of the extent of the area to be resected.

Frontal lobe epilepsy and epicortical ERPs

Partial seizures of frontal origin are candidates for surgical treatment when the clinical manifestations and diagnostic evaluation localize an epileptic zone in a resectable area. Frontal resections range from localized topectomies to complete frontal lobectomies and must be carefully individualized. Identification of the primary and nonprimary motor cortices is essential to avoid motor deficits and of anterior language cortex to avoid speech difficulties.[4]

Nonprimary motor cortices

Since the primary motor area and its examination by movement-related cortical potentials (MRCPs) or Bereitschaftspotential (BP) will be discussed in another chapter, this chapter focuses on issues in nonprimary motor areas which are considered to be associated with motor planning. Previous sections discussed the ERPs observed after the stimulus onset, i.e., components that follow the events. Historically, however, a potential that precedes the event was also identified by Kornhuber and Deeke.[77] In their studies of voluntary movements, they found slow negative deflection of potentials that preceded the actual production of a voluntary hand movement.

Regarding the motor functions, another important potential in this category of 'event-preceding components' is contingent negative variation (CNV). CNV was first reported by Walter and his colleagues in 1964.[78] CNV is evoked in a paradigm using pairs of stimuli presented with an interval of one or several seconds. The first stimulus is a 'warning' stimulus (S1) served as a cue for the next 'imperative' stimulus (S2) to which subjects are required to make a movement as a response.

CNV is a slow surface-negative deflection observed between S1 and S2. A noticeable feature of CNV is that, when the interval between S1 and S2 is set to 1.5 s or longer, not one but at least two components appear.[79] Interpretation of these two components, 'early CNV' and 'late CNV', so far varies. Early CNV, or an initial portion of CNV, is claimed to be a response to S1[80,81] and an expectation of S2 to a lesser degree.[82] Late CNV, or the posterior portion, is supposed to be an anticipation of processing S2[83] and a preparation for a motor response.[77]

CNV using a conventional paradigm and S1-choice-go/no-go paradigm showed contrasting results (Figure 94.5). Early CNV consists of two subcomponents; one is a 'signal-related' potential evoked by stimuli after both S1 and S2, and the other an 'early set-related' potential recorded in the first half of the S1-S2 delay period. These constituents of early CNV are observed in both conventional and S1-choice-go/no-go paradigms. Late CNV, however, showed a contrasting result. Late CNV consists of a 'sustained set-related' potential occurring mainly in the second half of the delay period and a 'movement-related' potential. The subcomponents of late CNV are evoked only by S1-choice-paired stimuli which require motor response after S2. In addition, paired stimuli with no-go S1 in the variant paradigm did not evoke late CNV.[84,85] In the mesial frontal area, especially the presupplementary motor area (pre-SMA), decision-related potentials were also described in both S1-choice/S2-choice reaction time paradigms (Figure 94.6).

Application of subdural electrodes to frontal lobe area

Subdural EEG recording has revealed the cortical generators of CNV. In the studies using auditory stimuli, late CNV was

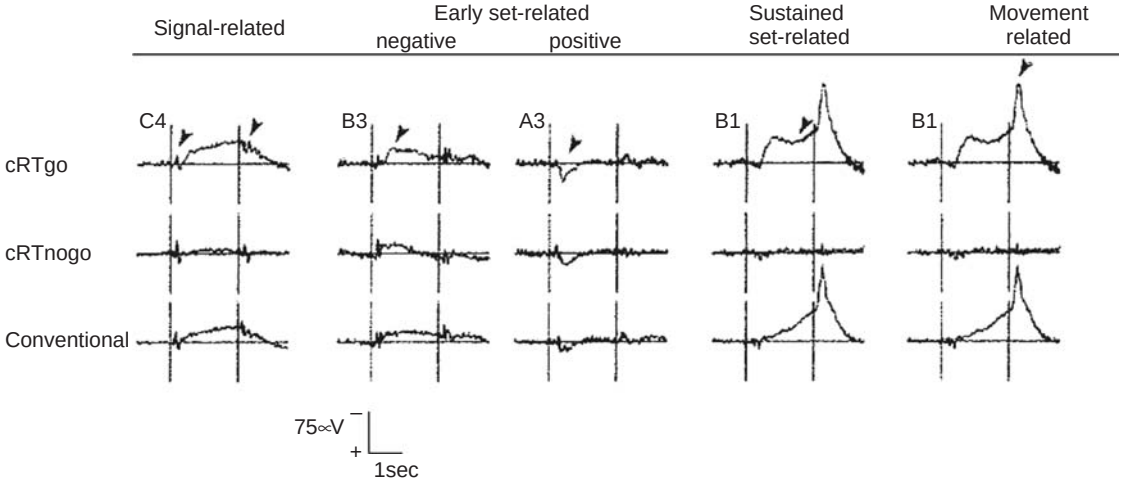

Figure 94.5 CNV recorded from subdural electrodes in two visuomotor tasks; (1) S1-Go/No-go-choice delayed reaction-time paradigm and (2) conventional S1-warning delayed reaction-time paradigm. Middle-finger extension was employed as a task response to S2 signals. The upper two rows show responses in the S1-Go/No-go-choice paradigm and the lowest shows responses in the conventional S1-warning paradigm. Arrowheads indicate each of the transient potentials occurring between S1 and S2. S1: green/red LED light; S2: yellow LED light; cRTgo: responses to choice delayed reaction to S1-Go signals; cRTnogo: responses to choice delayed reaction to S1-No-go signals. (Reprinted with permission from Matsumoto *et al.*, 2003.[85] Copyright 2003 Elsevier.)

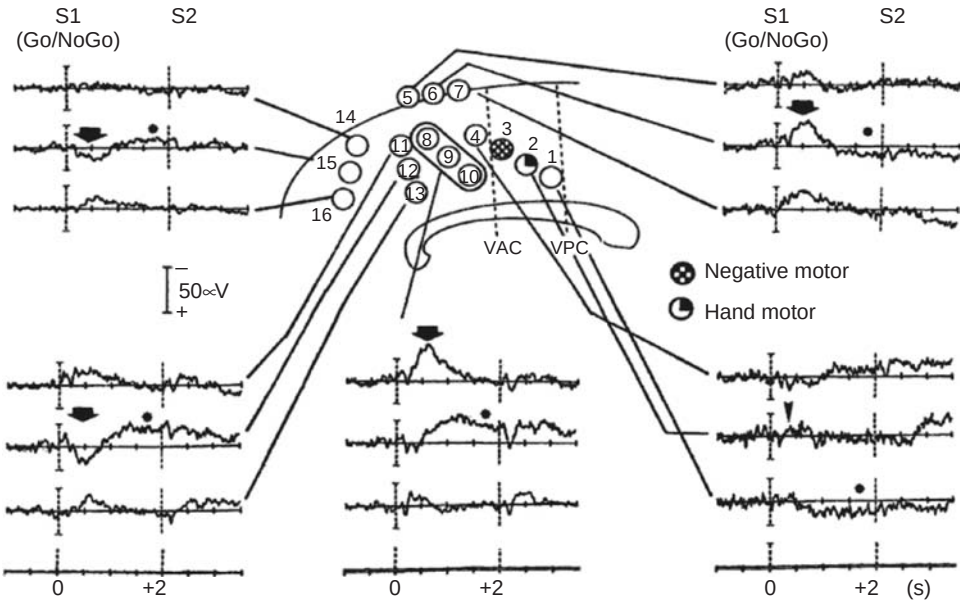

Figure 94.6 Decision-related potentials recorded from the medial frontal structures. Subdural electrodes are placed on the medial surface of the right hemisphere. In S1-Go/No-Go-choice and S2-reaction-time paradigm, transient potentials after S1 (indicated by arrows) are observed at pre-SMA, located rostal to VAC line. VAC line: a line on the anterior commissure perpendicular to AC-PC line. VPC line: a line on the posterior commissure perpendicular to AC-PC line (Reprinted with permission from Ikeda A *et al.*, 1999.[89] Copyright 1999 Oxford University Press.)

found to originate from the nonprimary motor cortices (pre-SMA, SMAproper, lateral premotor area), prefrontal area (mesial and orbitofrontal areas), and MI.[86–90]

In the 'go/no-go paradigm', the component was principally observed at the pre-SMA, starting around 200 ms and peaking at 600 ms from choice-related stimulus onset.[87] This may represent the characteristic function of cognitive motor control in pre-SMA. The generators of four components (two subcomponents of both early and late CNVs) were found to be located in a sequential manner from the rostal to the caudal part of the lateral premotor area.[85]

CNV may help to delineate the cortical functional area associated with motor planning or preparation. However, since late CNV has multiple generators including pre-SMA, SMA proper, the lateral premotor area, and MI, further delineation between the closely located, and yet distinct, structures (lateral premotor area versus MI, pre-SMA versus SMA proper) may require other methods such as electric cortical stimulation or vice versa.

Other functional areas and ERP components

Although parietal and occipital resections are performed much less commonly compared with the frontal lobe, patients with partial seizures from other extratemporal sites may also be candidates for surgical treatment when clinical manifestations and evaluation indicate an epileptic region in a resectable area. The results of resection for extratemporal epilepsy are variable depending upon patients and method of pre-surgical evaluation. Overall results are not so satisfactory for extra-temporal resections as for temporal removals. Nevertheless, extra-temporal resections including the frontoparietal and occipital regions can give excellent results.[11]

The basal aspects of the occipito-temporal area are known to be associated with face recognition.[91] Lesion studies suggested that the damage in this area causes prosopagnogia. Both invasive studies of animals and noninvasive imaging studies of humans indicated that, if the brain is intact, a specific region in this particular area selectively responds to visual stimuli of faces.

Reports using subdural electrodes placed on ventral occipitotemporal and lateral temporal cortex demonstrated that visual stimuli of faces selectively evoked a negative potential with the peak latency of around 200 ms.[92–94] The potential is recorded bilaterally. This N200 is the signal that is evoked by face recognition. Although the same peak latency, language-specific N200 that was previously discussed is totally a different one.

The inferior parietal area was found to cause asomatognosia, hemispacial neglect syndrome and visuo-spacial agnosia when damaged.[95–97] Since no noninvasive methods were applied for this particular function, there is no insight into the feasibility of electrophysiological evaluation of this cortical area by noninvasive techniques. As for invasive evaluations, by contrast, a study using subdural electrodes covering temporal and parietal area revealed that an ERP component has recorded potentials in response not to single but to cross-multiple modalities of sensory stimuli (i.e., visual, auditory and somatosensory) in a small area in the temporo-parietal junction within the inferior parietal area.[98] These findings indicate that the area is associated with multisensory integration in transforming perception into recognition.[99] If this particular area is intact, therefore, the function is supposed not to be specific to a single modality but multimodal.

Clinical role of ERPs

Since the eventual objective of pre-surgical evaluation is the precise localization of the epileptogenic zone and the identification of resectable area, a functional approach is essential

because anatomical localization by no means satisfies the necessity of exact delineation of vital cortical functions which include motor and language abilities. ERP reflects brain activation related to the preparation for, or response to, specific events. One of the advantages of invasive ERP is its high temporal and spatial resolution which localizes specific functional areas.

The utility of ERP can be increased when it is combined with other methods that would increase the accuracy of evaluation and provide sufficient data for surgical planning. Functional mapping using electrical cortical stimulation, for instance, allows accurate identification of crucial cortical areas that must be spared during resective epilepsy surgery to avoid or reduce post-operative functional deficits. On some occasions, however, ERP is solely employed without using electrical stimulation because the stimulation to the 'irritable' cortical area may induce epileptic activities.

While electrical stimulation directly stimulates the cortex with electric current, the ERPs record spontaneous cortical activities in response to peripheral sensory input. In addition, ERP recording and electrical cortical stimulation can be performed using the same set of subdural electrodes. The analysis of ERP generators, therefore, is clinically useful also as a complementary method for electrical cortical stimulation.

There has been steady progress in developing a variety of methods to address the issues of evaluation. However, none of them are perfect. Because the ERP signals are so small in amplitude or intensity, their recording requires a way to identify a very small signal from background noise. The most common technique is by averaging a large number of trials that all contain the same specific event.

Since particular areas in the brain and particular functions of cognitive processes are supposed to be activated in coordination, pre-surgical evaluation requires a combination of methods that will make information unambiguous in terms of correlation among functions of the brain, and procedures that will be determined to best fit each individual case. ERPs are a particularly powerful technique which clarifies the temporal aspects of cortical activities, which may lead to the understanding of the correlation among clinical signs. In patients with an unknown seizure origin, invasive ERPs are indispensable.

SECTION 10

Pre-surgical evaluation of eloquent cortex

95 Eloquent cortex and tracts: overview and noninvasive evaluation methods

J Reis and F Rosenow

Preoperative evaluation for epilepsy surgery not only has to consider what to take out but also what to leave in
(Ron Lesser)

Definition and concepts of eloquent cortex and tracts

Epilepsy surgery is usually an elective procedure. Whereas the complete resection of the epileptogenic zone is of major importance, this aim is limited by the sparing of eloquent cortex in order to avoid new, unacceptable deficits after epilepsy surgery. Based on the findings of clinical and pathological studies of patients with brain lesions, it has been shown that different cortical areas are crucial for different functions and that some of the regions of cortex are indispensable for a defined cortical function.[1] These areas were referred to as 'eloquent cortex'. Furthermore, a high correlation between these eloquent cortical areas whose lesions produce a permanent functional deficit and the results of electrical cortical stimulation has been shown. During electrical cortical stimulation either activation or deactivation of a certain cortical function support the determination of eloquent cortical areas, while electrical stimulation of noneloquent areas does not elicit any symptoms. Examples of such areas are primary motor cortex, primary somatosensory cortex, essential speech areas (Broca's and Wernicke's area), primary visual areas, angular gyrus and mesial temporal regions crucial for memory. Many other cortical areas can be resected without obvious consequences for the patient, although detailed neurological or neuropsychological testing may reveal subtle deficits. These cortical areas may be considered to be partially dispensable eloquent cortex, as either the loss of function is clinically not significant or the loss of function is temporary with fully recovery over time. This might include the face primary motor area, primary auditory areas, the pre-SSMA and basal temporal region.

In pre-surgical planning also the determination of eloquent afferent and efferent subcortical white matter tracts (including pyramidal tract, corpus callosum and optic radiation) is important for preservation of function as these tracts carry information from and to eloquent cortex and therefore reproducibly connect a cortical function to the central and peripheral network. The disconnection of eloquent tracts was proven to result in similar neurological deficits than resection of the eloquent cortex area itself.

In the past decade, new imaging techniques were developed that can be used to define and localize these functional and structural cortical tracts in vivo. While diffusion tensor imaging is most helpful to illustrate structural connectivity, fMRI is used to depict functional connectivity. Matching of these data with a conventional 3D-CT or MRI allows the exact transfer of this information into the surgical field by neuronavigation.

The exact identification of eloquent areas in each individual is crucial, since the classical concept of a constant localization was proven to be incorrect and the spatial localization of these areas may show large interindividual differences.[2,3] Applying Intraoperative electrical stimulation of cortex sometimes necessitates the performance of surgery in the conscious patient. This can be a severe burden both for the patient and the operating team in a procedure that lasts several hours; in addition, electrical stimulation may evoke epileptic seizures which can be harmful to the patient in this setting. Therefore, non-invasive methods for pre-operative functional assessment (e.g., TMS, fMRI, MEG) should be applied if possible, which allow individual localization of eloquent areas.

This chapter will focus on noninvasive techniques to localize eloquent cortex by MRI, SPECT, PET, fTCD, TMS, MEG, and will describe the Wada Test as the 'gold standard', although it is an invasive method, for lateralization of speech and memory.

Methods used to define eloquent cortex and tracts during pre-surgical diagnosis of epilepsy

Magnetic resonance imaging (MRI)

Magnetic resonance imaging (MRI) is the neuroimaging modality of first choice in epilepsy. It is the gold standard in identifying epileptogenic lesions and their spatial relation to neighbouring cortical structures such as the precentral gyrus, which usually harbours eloquent cortex. The results of functional imaging techniques used to identify eloquent cortex are usually coregistered with a structural MRI in order to visualize the spacial relation between lesion and eloquent cortex at the time of resection planning or resection (neuronavigation).

Functional MRI

Functional MRI (fMRI) was introduced to investigate areas of altered regional cerebral blood flow (rCBF) and oxygenation

status of haemoglobin during task performance. The most frequently used method of fMRI is blood oxygenation level-dependent (BOLD) imaging.[4] BOLD fMRI employs hemoglobin as a convenient endogenous contrast agent, relying on the magnetization difference between oxy- and desoxy-haemoglobin to create the fMRI signal[5,6] and therefore measures neuronal activity indirectly via its assumed haemodynamic correlate. The accurate interpretation of the BOLD signal depends on the characterization of the underlying neural activity that gives rise to the haemodynamic response, known as neurovascular coupling. The exact nature of this coupling remains largely unknown, with regard to both the nature and origin of the communicating signal between neurons and vessels.[7,8] Other determinants of the BOLD response include the technical setup of the MRI scanner. The best current resolution of fMRI BOLD is at the level of one cortical column, which contains about 10^5 neurons.[9] Most fMRI scanning paradigms use shorter acquisition times with a lower spatial resolution of about 8–50 mm^3 (1–3 mm^3 dimensions), containing at least 10^6 neurons. Therefore, fMRI BOLD signal is able to reflect the hemodynamic status of a cell population, even within a single voxel. Beside its common availability, other advantages of fMRI are a beneficial cost value ratio, safety of the technique without need of radiation, a high temporal resolution (at the order of 5 seconds) and a good spatial resolution.[9–11]

Functional MRI has become a useful tool to investigate eloquent cortical areas and is now commonly available for presurgical diagnostics to delineate motor and sensory cortex from the areas of planned neurosurgical resection.[12–17] Simple motor and sensory tasks used to map primary sensorimotor regions can produce strong circumscribed BOLD signal activations in healthy individuals and patients (Figure 95.2).[18–20] Lateralization of language function may also be accomplished using fMRI.[18,20–23] However, additional activations (e.g., in the supplementary motor cortices or in the ipsilateral hemisphere) have often been described in patients with lesions or motor deficits and there is less information whether these 'unexpected' BOLD signals are relevant for normal preoperative function.[24] Some of these BOLD activations may represent movement artifacts (which may be compensated by image co registration), or haemodynamic responses of large veins remote from the relevant cortical area, but draining blood from activated cortex.[25] It is not clear yet if any of the fMRI paradigms developed can lateralize and localize memory functions reliably enough, to obviate the need for a intracarotid amobarbital test in candidates for a mesial temporal lobe resection.[20,26,27]

For the pre-surgical assessment of epilepsy, specific factors have to be considered before analyzing the fMRI results: Task performance may be decreased if the epilepsy is associated with cognitive impairment. This can also be secondarily related to anticonvulsive treatment. Furthermore, BOLD signal changes may be directly correlated with overall synaptic activity and changes were found in and around cortical lesions as well as in distant cortical and subcortical structures. Spike related changes of the BOLD signal as well as changes in the (peri-)ictal state in or near the epileptogenic zone may hamper the fMRI interpretation if the epileptogenic zone is in close spatial relation to eloquent cortex.[28–30]

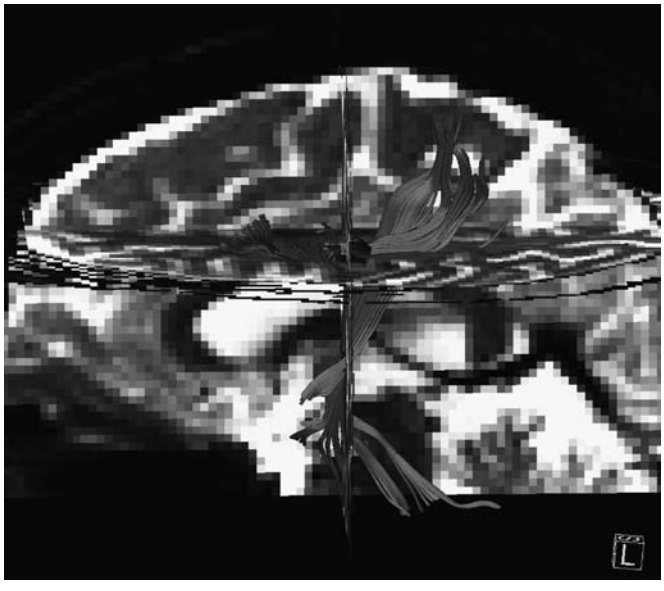

Figure 95.1 Example of pyramidal tract evaluation by diffusion tensor imaging. Images were obtained using the DTI-taskcard (Athinoula A. Martinos Center for Biomedical Imaging, Massachusetts General Hospital, Harvard-MIT Division of Health Sciences and Technology, Boston, http://www.nmr.mgh.harvard.edfu/~rpwang/siemens/dti_taskcard) developed by G. Sorensen and R.Wang). Courtesy of S. Knake Marburg.

A further limitation of the fMRI technique for investigating epilepsy patients is the duration of the whole measurement (usually about 3 hours), which may be impracticable for epilepsy patients with very frequent seizures or a reduced attention span.

Diffusion tensor imaging (DTI)

MRI contrast mechanisms are based on variable physical and chemical properties of water molecules in different tissues and, thus, each pattern reflects different physiological and/or anatomical properties of the brain. In the late 1980s to early 1990s, a new MRI contrast scheme called, 'diffusion weighed imaging (DWI)', initially used for the identification of very acute cerebral infarction, was implemented and has subsequently been used more frequently in neuroimaging.[30–32] This contrast is sensitive to the structural orientation of axons. In DWI, the water diffusion process is used as a probe to investigate brain axonal organizations based on a fact that water tends to diffuse along axons. Based on this assumption, DWI can provide information about brain white matter anatomy. However, it is far from simple to mathematically describe complex neuroanatomy based on water diffusion process. Currently one of the most widely accepted models is based on a tensor model, thus called diffusion tensor imaging (DTI) (Figure 95.1). DTI allows the visualization of localization, orientation and anisotropy of white matter tracts. The diffusion of water molecules along the main direction depends on the parallel bundled architecture of axons, the myelin shield and other microstructural factors. Within each voxel a tensor is computed to describe the diffusion anisotropy (normalized metric), and the vector of the tensor main direction corresponds to the white matter fiber direction. This vector is usually color-coded to describe the tracts position and direction.

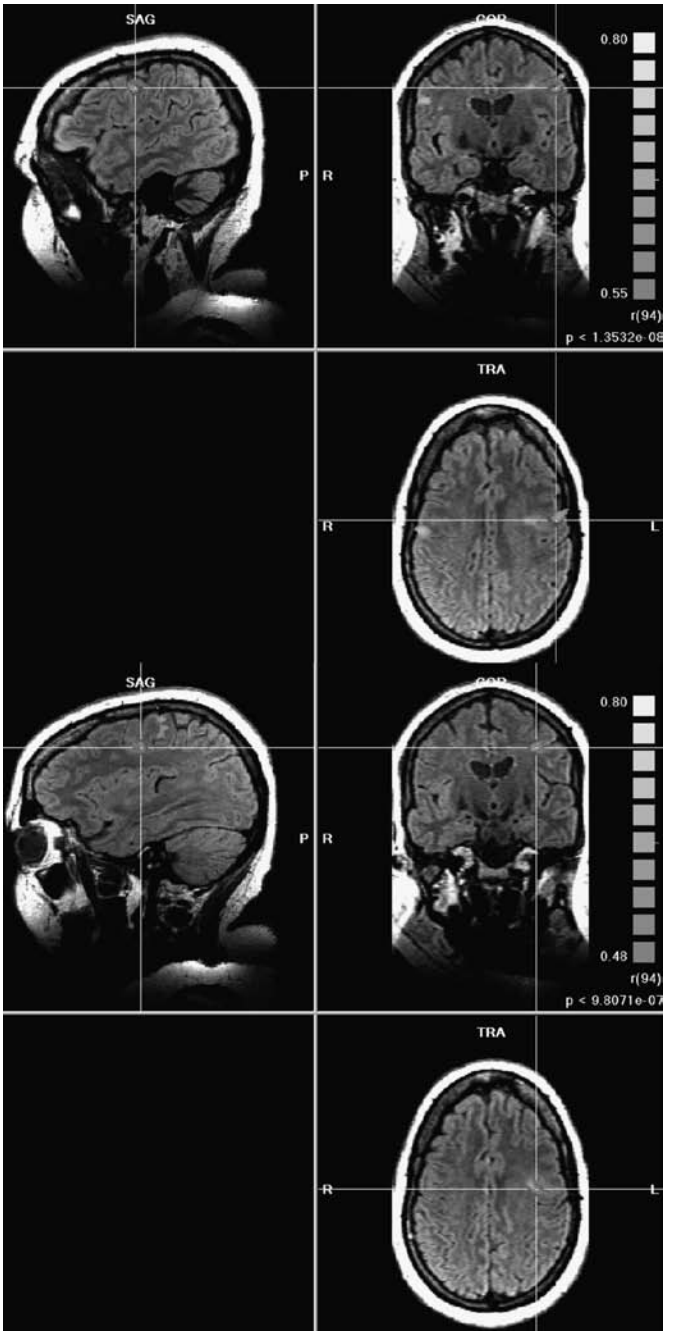

Figure 95.2 Evaluation of the tongue motor area (upper graphs) and hand motor area (lower graphs) by functional MRI.

DTI has been used to detect white matter abnormalities in epilepsy or neurodegenerative diseases.[33–35] However, as the method is based on mathematical post-processing techniques and clinical validation is lacking, DTI has to be regarded as an experimental method albeit with great potential for the localization and study of eloquent tracts in the future.

Positron emission tomography

While imaging methods such as CT or MRI isolate anatomical changes, Positron emission tomography (PET) is capable of detecting areas of specific cerebral function or altered biochemical processes even before changes in anatomy are apparent. For PET scans, short-living radioactive compounds are given intravenously to the patient. Commonly used isotopes are ^{15}O, ^{13}N, ^{11}C, and ^{18}F (^{18}F is used as a substitute for hydrogen). These radionuclides are incorporated into physiological compounds such as glucose, water, or ammonia. PET may also be used to demonstrate the binding of specific ligands to receptors, e.g., [^{11}C] flumazenil to the central benzodiazepine–$GABA_A$ receptor, or [^{11}C] diprenorphine and [^{11}C] carfentanil to opiate receptors.

The brain function studied during PET determines the used radiotracer. As increases and decreases of synaptic activity in the brain are accompanied by equivalent changes of glucose metabolism and cerebral blood flow,[36] the most frequent used PET techniques are the measurement of cerebral blood flow using labelled water ($H_2{}^{15}O$) and cerebral glucose metabolism using 2-[^{18}F]-fluoro-2 deoxy-D-glucose (FDG). Both measurements are based on the assumption that areas of high radioactivity are associated with brain activity.

For epilepsy surgery PET scanning is a useful tool which may help (i) to lateralize or localize the epileptogenic zone (usually hypometabolism during the interictal period and hypermetabolism during the ictal period in FDG-PET[37–39] and (ii) to evaluate eloquent cortex.

In comparison to the demonstration of the epileptogenic zone by measuring changes in glucose metabolism, PET scans to investigate a specific task are mainly based on changes of cerebral blood flow during 'functional activation' of brain areas. In healthy volunteers, the primary sensorimotor cortex, the visual cortex, language areas and cognitive functions have been mapped successfully with PET.[40–44]

Furthermore, the feasibility of PET for pre-surgical assessment has been shown by comparisons with direct cortical stimulation, Wada test and pre-operative outcome.[41,42,44–49] Most of these validation studies used language lateralization tasks. In one study PET showed an 88–91% positive predictive value for language lateralization compared to the Wada test.[41]

One problem with interpreting the data is that O_2-PET yields a map of all brain regions in which cerebral blood flow increases during task performance, although not all activated regions are critical to the investigated function. For example, some of the brain areas active during a language task may involve other functions such as attention and sensory or motor input. Passively visual observation of objects may produce activation in language areas and pre-motor areas comparable to naming objects.[48] Auditory activation in Wernicke's area appears identical to that in auditory cortex.[5] This problem is typically addressed by employing hierarchically-based subtraction studies, in which passive controls are subtracted from active conditions.[45,48,49] This method apparently works less well in controlling for cognitive tasks involving higher-order association areas, where activation patterns are more complex and controversial results have been reported. Thus, the choice of tasks, as well as the method of task comparison, profoundly influence the activation map, and clearly require more intensive study.

For pre-surgical epilepsy assessment PET has not become a standard procedure due to nearly universal availability of functional MRI, high costs for PET, and need of a cyclotron near the PET scanner due to the short half-life of the radiotracers (~2 min for ^{15}O, ~10 min for ^{13}N, ~20 min for ^{11}C, and ~110 min for ^{18}F). Beside this, PET is a semi-invasive procedure in that radioactive material is injected into the subject.

However, the total dose of radiation is usually small (~7 mSv, for comparison: ~0.02 mSv for a chest X-ray, ~ 8 mSv for a CT scan of the chest). Radioactivity may expose the foetus/child in pregnant or breastfeeding women, so that information gained from the PET should be considered in relation to the risk for the child.

In conclusion, PET scanning can be a useful tool to assess the epileptogenic zone as well as to determine eloquent cortex, but due to improvements of MRI in the last 10 years this has had two major consequences for the application of PET techniques to epilepsy. First, concordant MRI results may make PET data superfluous.[10]

Secondly, clinical and research PET data should always be interpreted in the light of high quality anatomical MRI to provide a structural–functional correlation. Fundamental to making these correlations has been the development of computer programs that may be used to coregister MRI and PET datasets on a pixel-by-pixel basis.[50]

Single photon emission computer tomography (SPECT)

Like PET, single photon emission computer tomography (SPECT) is a functional cerebral perfusion imaging technique. It is widely used in the noninvasive physiologic evaluation of intractable epilepsy to help define the seizure onset zone.[37,52] In comparison to the PET tracers, the SPECT radionuclides are not attached to physiological molecules. Therefore, the ^{99m}Tc-labeled lipophilic compounds hexamethylpropyleneamine oxime (HMPAO) and ^{99m}Tc-ethyl cysteinate dimer (^{99m}Tc-ECD) have been frequently and successfully used for imaging of the regional cerebral blood flow.[53] Several receptor ligands like [^{123}I] iomazenil for benzodiazepine receptors are also available. The normal adult brain shows bilaterally symmetric tracer distribution, with higher activity in temporal, parietal, and occipital (primary visual) cortices, basal ganglia, thalami, and cingulate gyrus as well as reduced activity in the white matter and interhemispheric fissures. Changes in visual stimuli such as eye opening and closing may increase or decrease, respectively, the visual cortex activity by 30%.[54] Motor and sensory stimuli have similar but asymmetric effects.[55] Auditory stimuli effects are symmetric but less impressive. Abnormal findings include focal or regional areas of decreased or increased tracer uptake. Several studies of brain SPECT during functional activation have been performed in healthy volunteers to localize eloquent cortical areas for visual stimulation,[56] motor [40,55] and sensory stimulation,[57] memory tasks,[58,59] and the investigation of complex cognitive tasks.[54,59,61] Only a few studies are available describing the presurgical determination of eloquent cortex with SPECT. In a patient with a perirolandic low grade astrocytoma the validity of SPECT in pre-surgical assessment was proven by good post-surgical outcome after tumor resection. In 17 epilepsy patients, Borbely *et al.*[62] described a 100% concordance of the results of SPECT and functional transcranial doppler sonography to determine hemispheric language dominance.[62] Finally, three studies performed SPECT and Wada test simultaneously, but the aim of the studies was not the validation of SPECT for assessment of language or memory function, but the assessment of inactivation pattern after intracarotid amobarbital injection.[63–65] The major result of one of these studies was a lack of inactivation of the hippocampus in over 60% of the patients, suggesting a lack of accuracy of the Wada test to predict the risk for pre-operative amnesia.[64]

In comparison to PET, SPECT is less expensive and more frequently available than PET. Notwithstanding, SPECT still has the disadvantage of the use of radioactive tracers. While the PET tracers decay within minutes, the SPECT tracers have a longer half-life (up to 8 hours) and can therefore be used for patient-friendly accomplishment of functional tasks outside the scanner. As a consequence, the number of achieved images per scan is limited and images after a second tracer injection might be falsified by remaining activity generated by the previous injection.

While SPECT is not routinely used for the assessment of eloquent cortex, the ictal/interictal SPECT is widely used to determine the seizure onset zone in epilepsy patients.

Magnetoencephalography (MEG)

Magnetoencephalography (MEG) is the measurement of the magnetic fields produced by electrical activity in the brain. The magnetic fields are analyzed by an equivalent-current dipole model to determine the location of the sources, e.g., epileptic discharges. The source locations can then be overlaid onto (functional) MRI images, a technique called magnetic source imaging (MSI).[37,66–68] These overlays can be used to show the spatial relation between MEG spike sources and a lesion or eloquent cortex revealed by MRI. Because the magnetic signals emitted by the brain are in the order of a few femtotesla (1 fT = 10^{-15} T), shielding from external magnetic signals, including the Earth's magnetic field, is necessary [66] and extremely sensitive devices based on superconductive technology are required for recording.[69] Modern whole scalp array systems have roughly 300 channels situated around the head to pick up intracranial activity. The MEG signals themselves derive through electromagnetic induction from the net effect of ionic currents flowing in the dendrites of neurons during synaptic transmission and in the axons during action potentials. These net currents can be thought of as current dipoles which are defined to have an associated position, orientation, and magnitude, but no spatial extent. According to the right-hand rule, a current dipole gives rise to a magnetic field that flows around the axis of its vector component. From the measured field distribution it is possible to calculate an inverse solution to determine the brain area where a set of neurons is synchronously active.

Clinical application of MEG in pre-surgical diagnostics represents a new modality for the localization of interictal epileptiform activity and seizures in patients with focal epilepsy.[67,70–73] The MEG spikes and seizure patterns have been shown to provide more accurate localization than surface EEG as they are not attenuated by skull and scalp. A comparison of MEG, MRI and EEG in pre-surgical localization of the epileptogenic zone showed that MEG was superior to both surface and intracranial EEG.[74]

Furthermore, the correct identification of eloquent areas, most frequently in respect to the sensorimotor system, has been reported.[68,71,72,75–78] Studying event related fields (ERF), the equivalent of evoked potentials, stimuli are presented in a time-locked mode to localize the primary sensory cortices. MEG and MSI have been established and validated for all primary sensory

modalities. As the temporal resolution of the MEG is within the millisecond range it is also possible to distinguish between early and late components of the ERF, which is crucial to separate activation of primary sensory and association cortex.[78–81] For the primary and secondary somatosensory cortex (SI, SII) MEG revealed a somatotopic organization of this areas after tactile stimulation in healthy and patients with perirolandic tumors.[82,83] The primary auditory cortex in the temporal lobe was localized by auditory evoked fields[84,85] and this was also validated for patients with intracranial lesions.[86] For the visual evoked fields, precise localization has been shown in healthy and patients with visual field deficits.[80] Additionally, motor-related fields were recorded to localize the hand area of the primary motor cortex.[77,78]

The reliability, validity and accuracy of language-localization by MEG as determined during simple language tasks was high[76,77] and a high correlation has been shown between the results of the MEG and the Wada-test (87–96% concordance).[76,88,89] The MEG findings were also in accordance with electrocortical stimulation results, even when atypical language representation was present.[90–92] Retest-reliability was investigated over several months and was found to be high.[93] Furthermore, MEG has been used to validate one imaging method with the other.[78,94,95]

In summary, MEG is a reliable, validated diagnostic tool to investigate eloquent cortical areas. With its high spatial and temporal resolution it bears several advantages compared to other imaging methods.

Transcranial magnetic stimulation (TMS)

Transcranial magnetic stimulation (TMS) was first introduced by Anthony Barker and allows investigating the central motor pathway in a non-invasive and painless fashion.[96] TMS is based on Faraday's principles of electromagnetic induction. A pulse of current flowing through a coil of wire generates a magnetic field. If the magnitude of this magnetic field changes in time, then it will induce a secondary current in a nearby conductor. The rate of change of the field determines the magnitude of the induced current. For TMS a stimulating coil is held over a subject's head and a brief current is passed through it. This induces a magnetic field, which passes through the subject's scalp and skull with negligible attenuation (but exponentially decaying by the square of the distance). This time-varying magnetic field induces a current in the subject's brain, which stimulates the neural tissue. During time different stimulation protocols have been introduced. For example single pulse TMS evoked effects are similar to stimulating a peripheral nerve with a conventional electric stimulator. To date, single-pulse TMS appears to be completely safe when applied to healthy individuals. It is also possible to apply a train of pulses at rates of up to 50 Hz (repetitive TMS, rTMS). This procedure can cause seizures even in healthy subjects, therefore safety guidelines must be followed.[97]

TMS mapping of cortical motor representation

The scalp positions whose stimulation elicits responses in a target muscle can be reliably and reproducibly mapped by single-pulse TMS, using a focal figure-of-eight shaped coil.[98–100] TMS mapping provides several measures of the somatotopical cortical representation of the target muscle, such as the map area, the optimal position for stimulation, or the center of gravity of the map.[101] Magnetic resonance imaging (MRI) showed that the coil position that produces the largest MEP is located in M1.[102] The spatial validity of TMS-based mapping of the motor cortex has also been demonstrated by comparing the maps with the results of direct transcranial electrical stimulation (TES) of the exposed cortical surface in patients undergoing a neurosurgical intervention. Furthermore, the functional reorganization of the motor cortical maps after a central or peripheral lesion was investigated with TMS in patients with hemispherectomy,[103] spinal cord lesions,[104] limb amputation,[105] transient anaesthesia of limbs and fingers[106,107] and prolonged immobilization.[108] Aside from case reports,[109,110] TMS mapping has not been systematically used to define eloquent perirolandic cortex in pre-surgical epilepsy candidates. Recent advances in neuroimaging now allow coregistration of the position of the stimulating coil (TMS) and (functional) MRI data.[111,112] This multimodal approach could provide a valuable tool for pre-surgical planning in epileptic patients.

TMS and language lateralization

In addition to single- or double-pulse TMS, diagnostic use of focal rTMS was reported for the production of speech arrest or for determination of language laterality.[113,114] rTMS of the left fronto-temporal region led to a speech arrest in right-handed patients. The results of the rTMS intervention correlated with the results of the Wada test which showed left-hemispheric language dominance in all subjects.[113,114] In contrast, Michelucci *et al.*[115] revealed negative results in 50% of their patients and Epstein *et al.* showed that in one third of the epilepsy surgery candidates, 4–8 Hz rTMS effects did not correlate with the Wada test (apparent bilateral or right hemisphere lateralization).[116] One problem with these studies is that high-intensity rTMS could produce speech arrest by an effect on either the language processing or the jaw and mouth motor areas. Presumably, subthreshold stimulation over sites anterior to the rolandic area, which can dissociate the language components of speech from the motor ones,[117] should increase the specificity of rTMS to assess language laterality. A second problem of rTMS is discomfort or pain at the site of stimulation, depending on stimulation frequency (usually ranging from 8–30 Hz) and stimulation intensity (60–100% of the maximal stimulator output).[113,115] In conclusion, due to a lower sensitivity of the test and the frequently reported discomfort of the stimulation rTMS has not become a standard procedure to determine language laterality.

Functional transcranial Doppler sonography (fTCD)

Transcranial Doppler sonography has been widely used in clinical practice to detect intracranial stenosis of cerebral arteries. Additionally, the characterization of cerebral blood flow changes in relation to functional activation of brain areas was implemented as functional TCD.

Functional TCD, like fMRI, is based on the principle of neurovascular coupling assuming that neuronal activation increases cerebral perfusion in the corresponding brain area. The fTCD device measures the resulting cerebral blood flow velocity (CBFV) modulation in the corresponding larger intracranial arteries (M1-2, A1, P1-2); usually the medial cerebral arteries are investigated, and a difference between two different physical

stages (rest and activation task) is calculated. As CBFV increases bilaterally during task performance, a statistical procedure is used to calculate functional laterality indices which incorporate the difference between the relative CBFV changes in the right and left MCA over time of the task performance.[118,119]

During the last 10 years fTCD became a widely accepted tool to investigate changes in cerebral blood flow velocity (CBFV) during cognitive tasks.[19,119–125] In respect of the presurgical evaluation of eloquent cortex, lateralization of language has been most frequently investigated by fTCD.[23,121,123–126] While 'reading', 'silent word generation' and 'mental calculation' all increased the rCBF in the MCA bilaterally, a significant lateralization was only present in the word generation paradigm.[127] In patients, the results of language lateralization with fTCD using a word generation task matched with Wada test results in 100 %.[124,126] Furthermore, a 95% correlation between the results of fMRI and fTCD during a word generation task was shown for healthy volunteers.[22] Motor function (e.g., elbow and hand movement) was investigated in few studies.[128,129] The results have provided evidence that fTCD is capable to reveal a hemispheric lateralization of these functions.[21]

According to the CBFV modulation in intracranial arteries, fTCD has a poor spatial resolution, and provides only indirect information about the processes activated intracerebrally. Only statistical differences between two different physical stages (rest and activation) are evaluated. Therefore, the coactivation of several brain areas, that are not implicitly preconditioning performance of a specific task, has to be considered. Further restriction for fTCD is given by a lack of a temporal bone window in 10–20% of the subjects, ruling out recording of the Doppler signal.[130] Advantages of fTCD are the noninvasiveness, the high temporal resolution by continuous measurement of information about CBFV changes in relation to a cognitive task, the usefulness in children, disabled and patients with reduced IQ.[126]

Wada test, intracarotid amobarbital procedure

The intracarotid amobarbital procedure was first reported by Wada in 1949 for language lateralization and modified by Milner *et al.* in 1960 by including a memory task.[131,132] Since the early 1960s the Wada test is the gold standard to predict pre-operative amnesia, memory decline and language disability in pre-surgical evaluation of temporal lobe epilepsy patients. Nevertheless, for right-handed patients with right temporal lobe epilepsy, that do not have ictal or postictal aphasia as documented by video-EEG-monitoring is considered to be unessential in some centers.

The Wada test uses the functional inactivation of a single hemisphere by injection of sodium amobarbital into the ipsilateral internal carotid artery; during this temporary deficit, the language and memory abilities of the active contralateral hemisphere can be assessed in isolation. Usually, both hemispheres are tested successively with about 30 minutes waiting between injections. For the interpretation of the results it is necessary to keep in mind, that the intracarotid amobarbital procedure is only a lateralizing, but not a localizing procedure. Comparability of the results is limited, as different methodologies are used across centers (e.g. different dose of amobarbital, use of EEG, preinjection, delay between injection and testing). Especially the criteria used to test language and memory ability often varies between centers. There is a general consensus that over 90% of right-handed individuals show left hemispheric language dominance.[132] Thus, language can often be reliably lateralized by the Wada test.[20,124,126]

Results of memory testing may also be able to predict the likelihood of pre-operative memory dysfunction, though the significance is controversial. Several SPECT studies have shown that – due to the fact that vascular distribution does not supply the posterior three fourths of the hippocampus – the ipsilateral hippocampus is often not inactivated directly during the amobarbital procedure injecting the internal carotid artery,[63,64,133] and therefore interhemispheric comparison of memory dominance may be limited. Other studies suggested that perfusion of the hippocampus is not necessary for valid memory testing.

Due to its invasiveness the Wada test carries risks. On the one hand the cerebral angiography has a mean overall rate of 1.6% for neurological complications, ranging from 0.4–12.2% transient deficits, and permanent deficits in up to 5.4%.[134] The relative risk of death was reported to be 1.7%.[138] On the other hand the risk of misinterpretation of test results has to be considered prior to surgery.[139,140] The need to replace the Wada test with less invasive techniques of proven reliability has long been recognized. Several attempts have been made to substitute the Wada test in determining hemispheric language lateralization by noninvasive techniques such as fMRI,[18] functional transcranial Doppler sonography (fTCD),[124] PET,[43] SPECT,[144] magnetoencephalography,[124] or transcranial magnetic stimulation.[116] For example, fMRI showed comparable results for language lateralization (>90% concordance.[20] Furthermore, results of language lateralization in functional transcranial Doppler sonography (fTCD) matched with Wada test results (100%) with the advantage to be noninvasive and easy to use even in children, patients with low IQ and nonnative speakers.[126]

Summary and conclusion

During the last decade, several noninvasive techniques like fMRI, PET, SPECT, MEG, TMS, and fTCD have been investigated in respect of their validity to localize functional eloquent cortex (Table 95.1). Furthermore, the comparability of these results with the results of the Wada test as a gold standard has been addressed by several studies and a convenient consistency of results were found for fMRI, PET, SPECT, and fTCD. Therefore, it appears likely that the use of single or combined noninvasive evaluation methods could further limit the use of invasive methods such as the Wada test and invasive EEG recordings in the future. DTI may become a clinical tool to identify eloquent tracts.

Table 95.1 Summary of noninvasive methods to evaluate eloquent cortex and tracts

	fMRI, DTI	PET	SPECT	MEG	TMS	fTCD	IAP
Method of action	Functional imaging, based on BOLD effect, water diffusion	Functional imaging, cerebral blood flow, metabolism, radioactivity	Functional imaging, cerebral blood flow, radioactivity	Electromagnetic induction, evaluation of magnetic dipole sources	Magnetic stimulation of cortex, functional activation/inactivation (rTMS)	Functional evaluation of cerebral blood flow velocity changes	Pharmacological inactivation of cortical function by short acting barbiturate (amytal, brevimytal)
Availability (+ to +++)	++ (fMRI) + (DTI)	+	++	+	+++	++	+++
Spatial resolution	High	Medium	Medium	High	Med	Low	Low
Temporal resolution	fMRI medium, DTI low	High	High	High	High	High	Low
Advantages	Safe, painless, convenient to use	Biochemical image, even without anatomical changes	Available, biochemical image, even without anatomical changes	Very high resolution, evaluated reliability	Available, easy to use	Painless, convenient to use, useful in children, disabled, low IQ.	Inactivation paradigm, predicting pre-operative status
Disadvantages/ Limits	Task-related coactivation, bilateral activation, long duration of fMRI	Short-living radiotracer, radioactivity, false positive results in biochemical dysbalanced patients, limited detection of grey matter lesions	Short-living radiotracer, radioactivity, low special resolution	Special equipment, magnetic shielding, high costs, interference-sensitive	Risk of seizure induction (rTMS), need of clinical evaluation, poor reliability, discomfort	Lack of temporal bone window; only lateralizing tool, no localization	Invasive test, only lateralizing tool, no localization

96 Noninvasive tests to define lateralization or localization of the motor area

R Matsumoto and H Shibasaki

Introduction

In the field of functional neurosurgery including epilepsy surgery, the areas of 'eloquent cortex' must be identified in order to minimize the risk of irreversible neurological deficits. Electrical cortical stimulation, first performed by Bartholow in 1874[1] and later developed intraoperatively by the Montreal group in the early 20th century,[2] has become a gold standard method to explore various cortical functions. The development of chronic intracranial encephalographic recordings with subdurally placed electrodes allowed extensive extraoperative functional cortical mapping of the brain.[3] This technique, however, is unable to be applied to the wide area of the brain due to the limited coverage with intracranial electrodes, and thus the region of implantation should be determined based on the noninvasive presurgical evaluation of the epileptic focus and functional cortical areas.

Owing to advancement of the anatomical and functional neuroimaging techniques that were originally developed to study normal brain functions in the early 1990s, a variety of mapping techniques are currently available for noninvasive evaluation of 'eloquent cortex'. In this chapter, we will focus on the mapping of the motor areas and introduce the state-of-the-art of available techniques.

Anatomical imaging of the motor cortex

Nomenclature of the motor cortex

The motor cortex is an agranular sector of the frontal lobe which occupies the caudal part of the frontal lobe and has been subdivided into two regions by Brodmann,[4] the primary motor cortex (MI), area 4 (BA4) and the nonprimary or premotor cortex, area 6 (BA6). According to recent proposals based upon comparison with the nonhuman primate findings,[5–9] the premotor cortex consists of the premotor dorsal (PMd) and ventral (PMv) areas in the lateral convexity and the supplementary motor area (SMA) in the medial wall (Figure 96.1). PMd is defined as BA6a-β and the dorsal part of BA6a-α, and PMv as the ventral part of BA6a-α and BA44. The boundary between PMd and PMv is physiologically set at the frontal eye field that is situated immediately rostral to the border of the face and hand portions of the motor strip.[10] The anatomical border between PMd and PMv, however, has not been established. Medially, the premotor area BA6, namely SMA, is located above the cingulate sulcus and is subdivided into the rostral (pre-SMA) and caudal (SMA proper) parts. The vertical anterior-commissural (VAC) line[11] is regarded as a landmark to differentiate between pre-SMA and SMA proper.[6]

The 'eloquent' motor cortex corresponds to the two motor homunculi described by Penfield.[2] One lies along the precentral gyrus with the face lying mostly ventrally and the foot most-medially, and the other situated in the medial frontal cortex along the rostro-caudal axis with the face lying mostly rostrally and the foot mostly caudally. These areas are determined by the positive motor response by electrical cortical stimulation, and thus mostly constitute the origin of spinal projection from the motor cortex. These positive motor areas likely correspond to the monkey motor execution areas with direct spinal projection, that is, the primary motor area and the caudal part of the premotor areas (caudal PMd, caudal PMv and SMA proper). Indeed, in humans these motor execution areas along the precentral gyrus cytoarchitecturally consist of BA4 and BA6a-α to a varied degree[12] (see Figure 96.1). In this sense, it is plausible to refer to them together as 'the precentral motor area' instead of 'the primary motor area (MI)' usually employed in the field of functional neurosurgery.

Identification of the motor cortex

Morphological identification of the central sulcus and the so-called 'hand knob' is the initial and most important step to identify the motor cortex. Three methods have been well-described to locate the central sulcus by means of structural MRI.

1. Lateral axial method[13]; identification of the intersection of the superior frontal sulcus with the precentral sulcus. The central sulcus is a sulcus immediately posterior to the precentral sulcus (Figure 96.2a).
2. Medial sagittal method[14]; identification of the ramus marginalis of the cingulate sulcus that reaches the midline cortical surface. The marginal ramus is located just behind the central sulcus (Figure 96.2b).
3. Lateral sagittal method[15]; identifying the course of the anterior horizontal and ascending branches of the sylvian fissure and the precentral sulcus. In the sagittal plane, the

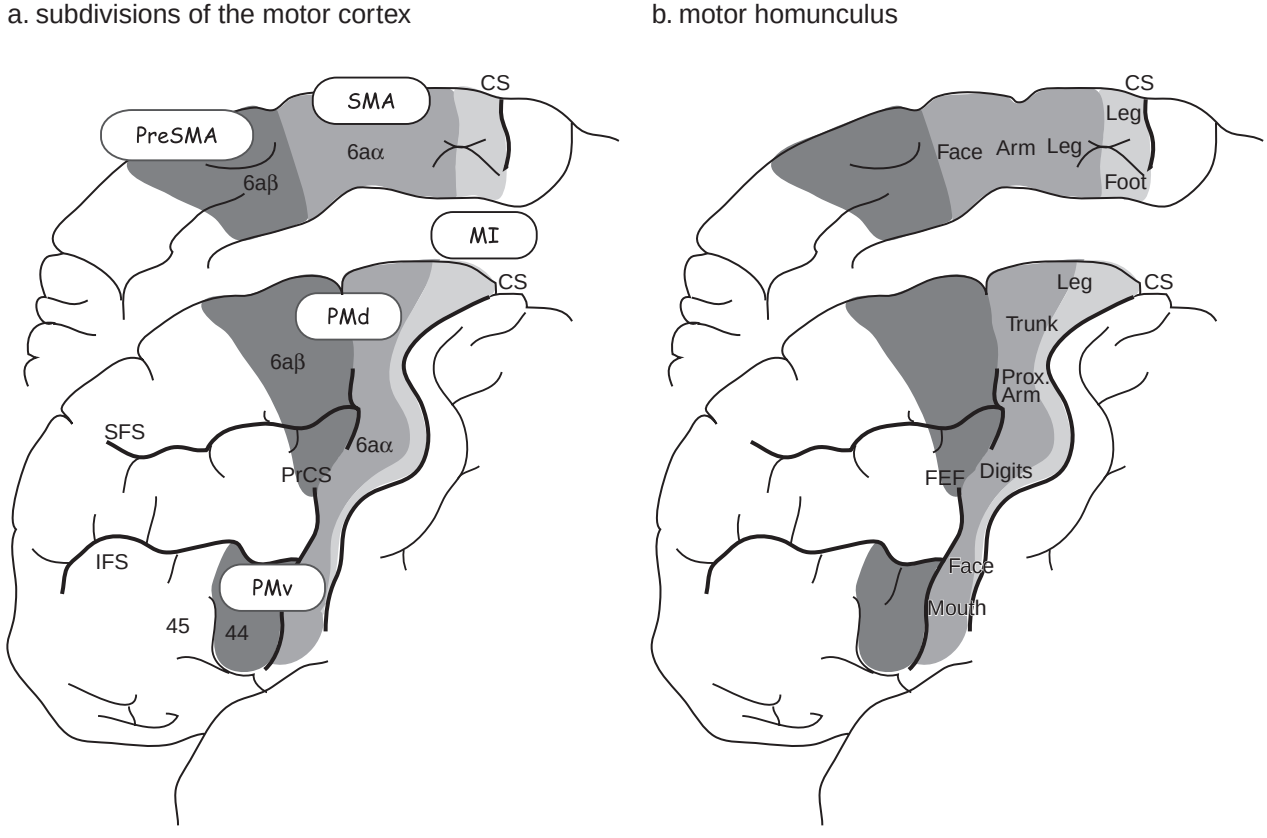

Figure 96.1 Diagram showing the human motor cortex. (a) Subdivisions of the motor cortex. Boundaries are based on recent proposals.[5–10] Note that the crown part of the precentral gyrus consists of Brodmann's area 6a-α(premotor area) and 4 (primary motor area) to a various degree; area 4 is situated more broadly in the leg area than the face area. SMA; supplementary motor area proper, pre-SMA; presupplementary motor area, PMd; premotor dorsal area, PMv; premotor ventral area, MI; primary motor area. (b) Motor homunculus. Two motor homunculi are present – one along the precentral gyrus and the other in the medial premotor area (SMA). The former motor strip consists of a mixture of area 6 and 4, and thus is better termed as 'the precentral motor strip' than the classical terminology of 'the primary motor area'.

zigzag shaped inferior frontal sulcus usually intersects with the precentral sulcus. The central sulcus is located immediately behind the precentral sulcus. The central sulcus typically does not unite with the sylvian fissure. Instead, in most cases, the lower end of the central sulcus is closed and detached from the sylvian fissure by the fusion of the lower ends of the pre- and postcentral gyri, which forms an arc of tissue, concave superiorly, called the subcentral gyrus. This fusion, closing off the central sulcus, also serves as the landmark (Figure 96.2c).

The relatively high variability of the central and surrounding sulcus pattern occasionally makes central sulcus identification difficult. With detailed MR and cadaver specimen analysis, Yoursey *et al.*[16] reported that a knob-like structure is a very consistent landmark to identify the precentral hand motor area in the precentral gyrus. This 'hand-knob' structure in the axial plane was defined as a knob-like, broad-based, posterolaterally directed structure of the precentral gyrus. It usually has an inverted omega shape and sometimes a horizontal epsilon shape with a mean diameter of 1.4 cm. On average it is located about 23 mm from the midline, just caudal to the junction of the superior frontal sulcus with the precentral sulcus and 19 mm from the lateral surface. It appears as a posteriorly directed hook when viewed on the sagittal plane. This anatomical knob-like structure corresponds well to the fMRI activation area by the hand movement.

Above the aforementioned methods, the omega-shaped knob of the central sulcus in the hand region seems to be especially useful for identification of the central sulcus; highlighting it in the 3D-MRIs would probably provide a useful starting point for intra- or extraoperative search for motor cortex, even without additional functional information (Figure 96.2d). Subsequently the other premotor areas can be located anatomically using landmarks such as the precentral sulcus, VAC line and cingulate sulcus. It is clinically important to note that no established methods currently exist to differentiate the foot portion of SMA proper from that of the primary motor area (BA4) in the medial frontal area.

Identification of the pyramidal tract

Until very recently, the knowledge of white matter pathways in humans has come from 'impoverished' dissection of the postmortem brain or from the extrapolation from the nonhuman primate invasive tracer studies. As for the pyramidal tract that constitutes an important part of the motor execution system, only a part of the tract could be traced by structural MRI (e.g., pedunculus cerebri, internal capsule). The fiber pathway in the deep white matter or corona radiata has not

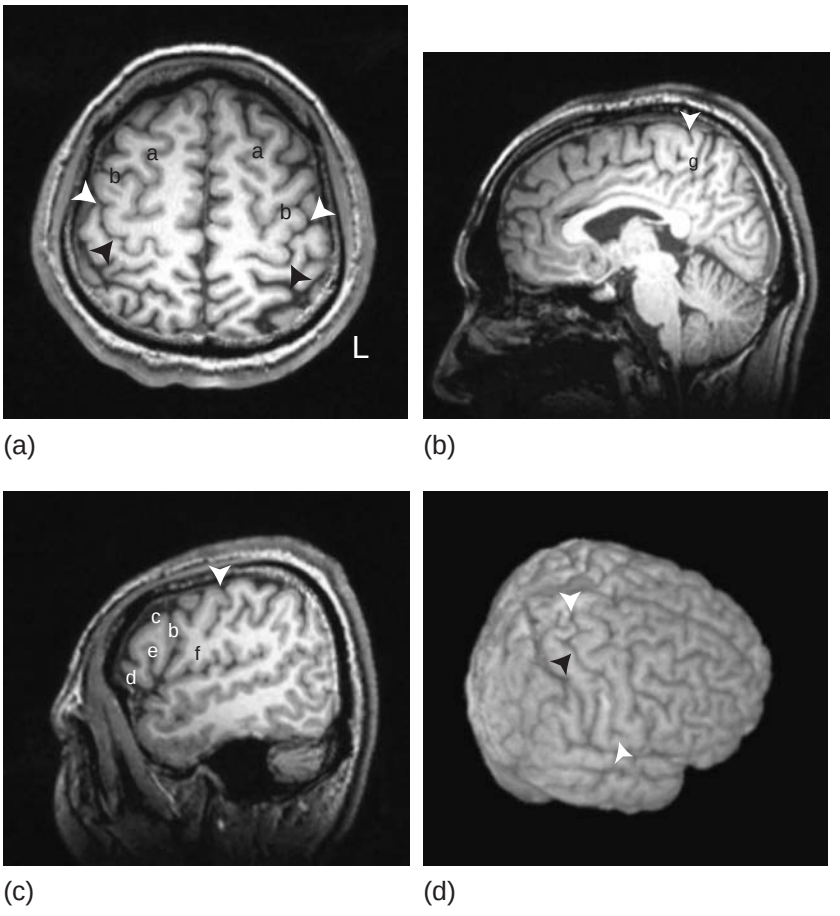

Figure 96.2 Identification of the central sulcus. (a) Lateral axial method. (b) Medial sagittal method. (c) Lateral sagittal method. (d) 3D MRI. MPRAGE sequence was taken and reconstructed into 3D image using MRIcro software (www.mricro.com). white arrowhead: central sulcus, black arrowhead: hand knob structure, a: superior frontal sulcus, b: precentral sulcus, c: inferior frontal sulcus, d: anterior horizontal ramus of the sylvian fissure, e: anterior ascending ramus of the sylvian fissure, f: subcentral gyrus, g: marginal ramus of the cingulate sulcus.

been visualized until very recently by a novel method of the diffusion weighted MR imaging (DWI).

DWI is a magnetic resonance imaging technique that is sensitive to mobility in the intravoxel water molecules and characterizes the local diffusion properties of water in tissue at a millimeter scale.[17] In tissue with a high degree of directional organization, the self diffusion of water is hindered more in some directions than others. With diffusion measurements in several noncolinear directions, the diffusion tensor imaging (DTI) computes the tensor matrix with principal diffusion direction at each voxel and enables fiber tracking of the major white matter fiber trajectories. DTI studies have enabled 'in *vivo* dissections' of major white matter tracts in normal subjects,[18,19] and its clinical application for tracing the pyramidal tract has progressed in the past few years (Figure 96.3). DTI, however, has limitation and should be used clinically with caution. The major limitation of DTI is that it can only resolve a single fiber orientation within each imaging voxel owing to the constraints of the tensor model. Therefore, DTI cannot resolve fiber crossing, bending, or twisting within an individual voxel. Because of this feature, the attempts to locate the pyramidal tracts have been more successful for those arising from the precentral hand and foot area than the face area. The white matter beneath the hand motor area contains the predominant unidirectional pyramidal tract fibers while that beneath the face area does less so, mixed with association fibers

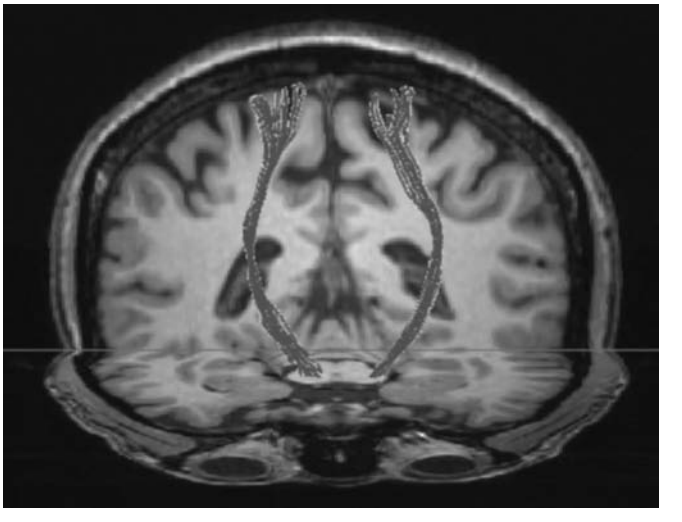

Figure 96.3 The pyramidal tracts revealed by diffusion tensor imaging (DTI). Diffusion-weighted images were taken in 12 noncolinear directions, and DTI was performed using DTIstudio version 2.40 software (H. Jiang, S. Mori; Department of Radiology, Johns Hopkins University).[19] Two ROIs were segmented on axial b=0 images for fiber tracking; the first ROI at bilateral cerebral peduncles, and the second ROI at bilateral precentral gyrus at the level of the hand knob. Results of fiber tractography are superimposed on MPRAGE. (Note that the majority of fibres were traced between the cerebral peduncle and the foot/arm motor area).

(e.g., superior longitudinal fasciculus) orienting in different directions. Nevertheless, this technique for the first time provided noninvasive evaluation of the pyramidal tract in the clinical settings.[20,21] Several theories have been proposed to solve the problem of intravoxel fiber crossing with or without tensor estimation, and further advancement will probably bring us the more precise and detailed analysis of the pyramidal tract and other motor-related pathways in the near future.[22,23]

Functional imaging of the motor cortex

The location of the motor cortex can be approximated using a priori knowledge of cortical anatomy as mentioned above, but considerable variations occur among individuals. In addition, the presence of local pathology can distort cerebral anatomy, making precise localization of the functional cortex difficult. This is not only the case with tumors but also with malformations of cortical development (MCD) that are currently recognized as one of the major etiologies of intractable partial epilepsy. Noninvasive techniques such as functional MRI (fMRI), magnetic source imaging and transcranial magnetic stimulation (TMS) can identify motor functions, if present, within or aside the dysgenic cortex as well as assess possible reorganization in the contralesional hemisphere, which is usually not explored during the invasive presurgical evaluation of patients.

Functional MRI

The basis of fMRI is that deoxyhemoglobin acts as an endogenous paramagnetic contrast agent. Therefore, changes in its local concentration lead to an alternation in the T2*-weighted MR image signal.[24] The physiological basis underlying the increase in signal intensity detected on fMRI is that, during neuronal activation, increase in the oxygen consumption by the neuronal group is accompanied by functionally induced increases in oxygenated blood flow and volume which becomes excessive for the required amount of oxygen consumption. This causes a decrease in the capillary and venular deoxyhemoglobin concentrations, producing a focal increase in the T2*-weighted MR signal. In other words, fMRI measures the blood O_2 level-dependent (BOLD) contrasts as the result of brain activity, and activation maps are derived from the BOLD images.

In order to investigate the accuracy of functional motor mapping by fMRI, several studies compared the results of fMRI activation with those of intraoperative electrical cortical stimulation in patients who harbored tumors close to or involving the precentral motor area. As for the precentral motor area, correlation between fMRI findings and the results of direct electrical cortical stimulation is high, ranging from 82–100%.[25–28] Although the correlation is relatively 'high', it does not necessarily mean that the area of fMRI activation is identical to that of the positive motor response elicited by electrical cortical stimulation. The following points are important to note for the interpretation of results.

1. fMRI is an indirect indicator of cerebral activation, because it measures changes in regional cerebral blood flow and not neuronal activity itself such as accomplished by magnetoencephalography.
2. Changes in blood oxygenation are characterized by a spatial and temporal dispersion that may cause errors in the accurate localization of activated areas (e.g., nonparenchymal deoxyhemoglobin changes in intraparenchymal capillaries or sulcal veins).
3. The area of fMRI activation does not necessarily define the 'eloquent motor cortex' which has a direct corticospinal output. Usually the activation involves the postcentral as well as precentral gyrus, even with simple abduction of the index finger.[29] The postcentral gyrus activation is most likely due to activation of somatosensory reafferents by positional changes of the hand and fingers during the performance of the motor task. In addition, even relatively simple movements (e.g., sequential finger tapping) elicit activation of the nonprimary motor areas (e.g., SMA or lateral premotor areas) as well as the parietal areas forming the premotor-parietal circuits[30] (Figure 96.4a).

Comparison of the fMRI findings and the results of direct electrical cortical stimulation in another motor homunculus at SMA is relatively scarce. Hanakawa *et al.*[30] reported such comparison and showed general, but not complete, agreement between the two modalities (Figure 96.4b).

With regard to the pathology, several fMRI studies have demonstrated that MCD can show various degrees of participation in motor functions ranging from corticospinal 'primary' motor control and putative participation as 'nonprimary' motor areas to absence of evidence for any functional participation.[31,32] The findings are consistent with the direct cortical stimulation study that showed variable motor functions in focal cortical dysplasia according to the degree of FLAIR signal abnormalities.[33]

Transcranial magnetic stimulation

TMS provides a noninvasive means of stimulating the cortex.[34] TMS is based on the principle of electromagnetic induction. The brief discharge of a capacitor induces a primary current within the stimulus coil. This primary current generates a magnetic field that passes painlessly through the scalp and skull nearly unattenuated and induces a secondary current within the conductive brain tissue. It is generally agreed that excitation of corticospinal neurons occurs within the cortex transsynaptically or, under some conditions, in the most superficial subcortical white matter.[35,36] In contrast to fMRI which visualizes both primary and nonprimary motor areas, TMS therefore can electrically stimulate the cortex and identify the positive motor areas having a direct corticospinal projection. In other words, elicitation of short-latency responses in a target muscle demonstrates the presence of monosynaptic corticospinal projections originating from the stimulated site. Using the figure-of-eight coil that can focally apply the current over the underlying cortex, motor representations that activate muscles at different joints of the upper extremity can be distinguished on the scalp and are shown to fall in the predicted somatotopic pattern.[37]

For functional motor mapping in patients with possible functional plasticity, TMS can identify the hemispheric specialization and laterality of corticospinal projections.

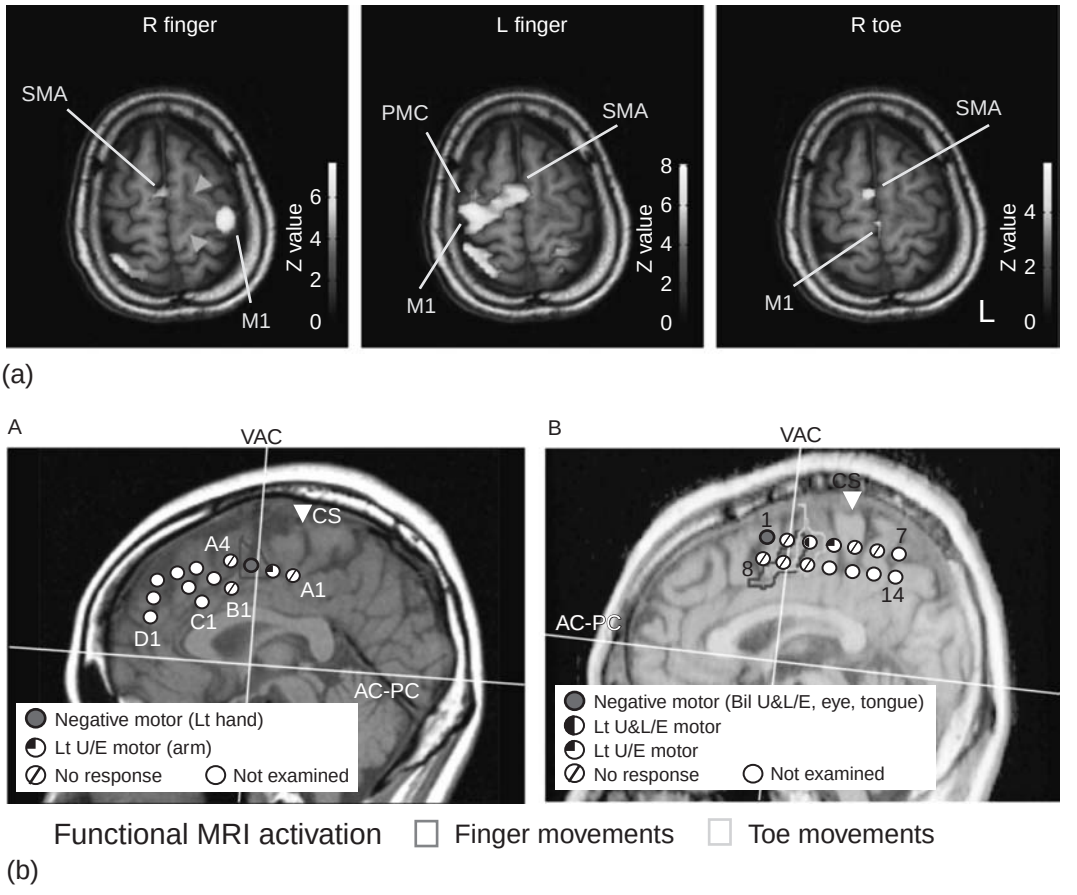

Figure 96.4 Comprehensive motor mapping by fMRI and electrical cortical stimulation. (a) Functional MRI activation in a patient with focal cortical dysplasia in the left superior frontal gyrus (green arrowheads), overlaid onto an axial slice of structural MRI. Simple limb movement task (finger tapping and toe movement) activates the lateral premotor cortex (PMC), the primary motor area (MI), the supplementary motor area (SMA) and the superior parietal lobule. Note the area of MI activation also involves the primary somatosensory area in the postcentral gyrus. Modified from reference 30 with permission. (b) The combined motor mapping by fMRI and electrical cortical stimulation for epilepsy patients with gliosis in the right medial frontal gyrus (A) and astrocytoma in the right superior and middle frontal gyri (B). The activated area of the functional MRI is shown in task-specific colors: finger-tapping task (magenta), and toe movement task (yellow). Icons indicate the cortical stimulation mapping, which are generally, but not completely, consistent with the functional MRI mapping. VAC: the line vertical to the anterior commissure-posterior commissure line (AC-PC) through the AC, CS: central sulcus, Rt: right, Lt: left, Bil: bilateral, U/E: upper extremity, L/E: lower extremity. Modified from ref. 30 with permission. (See Color plates.)

For example, in patients with polymicrogyri or schizencephalies, stimulation of the ipsilesional hemisphere may elicit normal MEP response in the contralateral hand muscle. Alternatively, stimulation of the contra-lesional hemisphere might show bilateral MEP responses suggesting the functional reorganization of both the contra- and ipsi-lateral corticospinal tracts originating from the normal hemisphere.[32]

Recent advances in frameless stereotactic surgery have refined current TMS mapping techniques by combining MRI with TMS using a 3D digitizer to measure the position of the stimulating coil and coregister this position on to a MRI data set. This 'stereotactic TMS system' combines the anatomical accuracy of structural MRI with the functional motor TMS map and provides accurate representation of the cerebral cortex immediately underlying the position of the stimulating coil on the scalp. By means of such a stereotactic TMS system, several studies attempted to locate the precentral hand area by combing TMS and fMRI.[38–40] These studies consistently reported discrepancies between fMRI and TMS maps with the maximum of fMRI activation 4~22 mm caudal to the TMS center of gravity (CoG). One plausible explanation is the presence of a somatosensory component in the BOLD activity during the hand movements. This is supported by the findings of Niyazov *et al.*[29] that maximum fMRI activation during imagined hand movements was located about 1 cm rostral to that during executed movements and corresponded well with the cortical projection area identified by the TMS mapping (Figure 96.5). In this study, all projected TMS CoGs lied within the precentral gyrus and on average slightly anterior to the hand knob. In summary, combined with the structural MRI, the stereotactic TMS mapping is capable of 'localizing' the precentral motor area and assessing the possible functional reorganization due to the underlying pathology.

Regarding the safety issue of TMS, single-pulse TMS apprears to be relatively safe even in patients with epilepsy. Even though the attempts to stimulate the epileptic focus with TMS have been made extensively in 1990s to improve and shorten the presurgical video-EEG monitoring of ictal events (see Tassinari *et al.*[41] and Ziemann *et al.*[42] for review), so far only one patient has been reported in whom seizures were

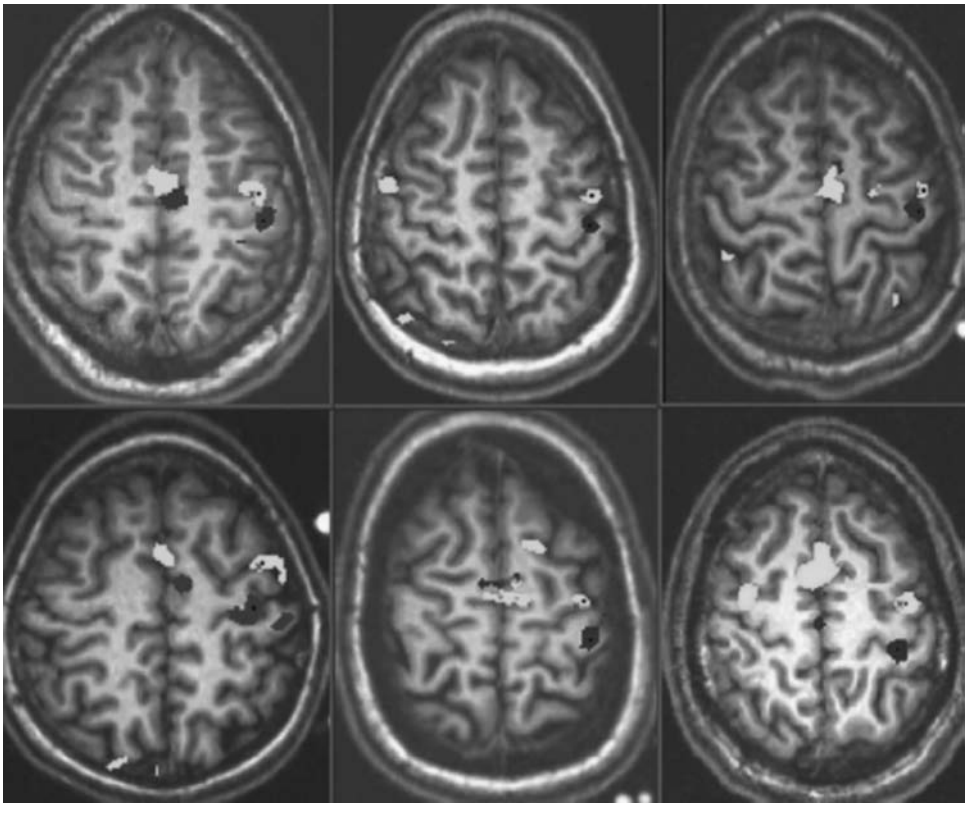

Figure 96.5 Comparison between the fMRI and TMS motor mapping. Blue and yellow activations correspond to the BOLD maps during executed hand movements and imagined hand movements, respectively. Red crosses represent the TMS CoG cortical projection points. Note that all projected TMS CoGs lie within the precentral gyrus and on average slightly anterior to the hand knob. The cortical projected area well corresponds to the fMRI activation for the imagined hand movements. From ref. 29 with permission. (See Color plates.)

triggered reproducibly and promptly by focal single-pulse TMS.[43] This patient had partial epilepsy arising from a documented epileptic focus in the left SMA, and the stimulation of SMA with an angulated figure-of-eight coil placed over the interhemispheric fissure reproducibly triggered the habitual seizure. Thus, careful observation is needed when the epileptic focus is situated close to the motor area.

Magnetic source imaging

With the development of the whole-head multichannel measurement system in 1990s, magnetoencephalography (MEG) has become one of the noninvasive useful tools to locate the motor area. In contrast to fMRI, MEG can record neural electromagnetic activity directly. Moreover, MEG has some advantage in evaluation of sources of brain activity over the more widely-used high-resolution EEG. Local changes in conductivity due to different tissues, for example burr holes from the previous operations, do not significantly affect magnetic fields, whereas electric potentials are clearly distorted.

To date, the following three methods seem to be clinically useful in localizing the motor or sensorimotor cortex; movement-related cortical field (MRCF), cortico-muscular (MEG-EMG) coherence, and somatosensory evoked field (SEF). MRCF usually starts about 1 sec before the movement onset, and it has contralateral predominance from the beginning as compared with Bereitschaftspotential in EEG which is a widely-distributed negative slow shift maximum at the vertex area, starting 3–4 sec before the movement onset.[44] The premovement magnetic fields presumably reflect neural activities originating only from the precentral motor areas, because those from the bilateral SMAs are relatively distant from the sensors and generate two tangentially oriented dipoles of opposite direction that cancel each other. Therefore, MRCF could be used to locate the precentral motor area although the recording of the slow components is occasionally hampered by patient's motion due to the relatively longer recording time (e.g., ~15 min for each muscle) compared with other methods.

Cortico-muscular coherence is evaluated by using correlograms beteeen spontaneous MEG and surface electromyograms (EMGs). The task usually employed is a sustained muscle contraction over 3–5 min for each muscle in the forearm and leg. The 15–30 Hz rhythmic activity of the motor cortex is coherent with the EMG during isometric muscle contraction, indicating that rhythmic cortical activity drives the descending motor commands at a similar rhythmicity.[45,46] In normal subjects, the generation sites of cortical MEG signals coherent with the surface EMG from the activated muscles indicate crude somatotopical organization in the precentral motor strip.[47] Makela *et al.*[48] applied this method to patients with brain tumors located in the vicinity of the sensorimotor region, and showed its efficacy in eight out of 12 patients (Figure 96.6).

The sources of SEFs to electrical stimulation of peripheral nerves accurately identify the posterior wall of the central sulcus with clear somatotopical representations of different

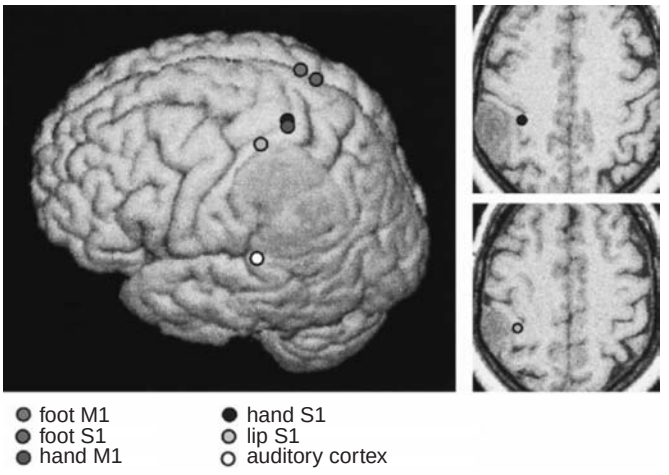

Figure 96.6 The equivalent current sources of SEFs to median nerve (shown as hand S1), tibial nerve (foot S1) and lip (lip S1) stimulation, auditory evoked field (auditory cortex), and MEG-EMG coherences for right wrist (hand M1) and ankle (foot M1) extensions are displayed on the 3D surface rendering of the brain. Sources of SEFs to median nerve and lip stimulation are displayed on two horizontal MRI sections. Note the distortion of functional cortical anatomy by the slowly growing tumor. From ref. 48 with permission. (See Color plates.)

body parts (for a review, see Hari and Forss).[49] Several literatures reported efficacy of SEF in locating the central sulcus in the functional neurosurgery.[50,51] In the aforementioned study of Makela *et al.*, the dipole analysis of SEF correctly identified the central sulcus in all patients, while useful corroborative information was obtained from anatomical landmarks in 11 and from cortico-muscular coherence in eight patients (Figure 96.6).

As reviewed in this chapter, MEG is generally useful for noninvasive mapping of the precentral motor area or the central sulcus. It is, however, important to note that the absence of MEG response does not necessarily imply the absence of function. This is because MEG detects almost exclusively tangentially oriented current source,[52] thus mostly picking up neural activity arising from the sulcal part of the cortex. Therefore, it is highly possible that some neural activation localized in the crown part of the cortex fails to be identified by MEG. Moreover, MEG is not suitable for the measurement of neuronal activities arising deep in the brain (e.g., SMA) because of the significant decay of the electromagnetic flux before reaching the MEG sensors.

Conclusion

Evoked potentials such as somatosensory evoked potentials and movement-related cortical potentials were the only methods available to 'lateralize' the sensorimotor cortex in the past. The recent advance in various technologies has provided clinically applicable means to 'localize' the motor cortex noninvasively. Because each method has its advantage as well as disadvantage, one should understand limitations of each technique for clinical use. Nevertheless, noninvasive functional mapping methods, when combined with the structural MRI analysis, will provide an important opportunity to assess, before surgery, location of the motor cortex and its possible functional reorganization due to the underlying pathology. This noninvasive approach greatly helps epileptologists and neurosurgeons to guide the placement of invasive intracranial electrodes. For the precise information for surgery, however, functional motor mapping data thus obtained should be confirmed by the gold standard of electrical cortical stimulation.

97 Noninvasive tests to define lateralization or localization of memory

EB Geller and C Santschi

Introduction

In the 1950s it became apparent that bilateral temporal resection could cause severe anterograde amnesia, such as in the well-described case of H.M.[1] Additionally, unilateral temporal lobectomy patients who developed similar deficits were found to have contralateral hippocampal damage on later autopsy.[1,2] In an effort to better predict the risk of post-operative memory decline, Brenda Milner and the team at the Montreal Neurological Institute devised memory protocols to add to the intracarotid amobarbital test (IAT), already in use at the time for language lateralization. The notion was that patients at risk for amnesia following unilateral mesial temporal excision would incur a transient amnesia after administration of sodium amobarbital to inactivate the hemisphere ipsilateral to the proposed surgery. The IAT has been widely adopted among epilepsy surgery centers. Unfortunately, variations in technique have led to the lack of standardization and difficulty comparing results from different centers.

The task before us is to predict most effectively the risk of acquired memory deficits before performing epilepsy surgery, specifically temporal lobectomy. While the combined assessment of memory and language lateralization has come to be known as the intracarotid amobarbital test (IAT) or simply the 'Wada test,' this chapter will focus on data regarding the IAT test for prediction of postoperative memory deficits. IAT memory deficits have also been used as a predictor of seizure outcome. In addition, we will review newer, noninvasive tests of brain function that may add to or eventually replace the invasiveness of the IAT. While these newer techniques have provided insights into the functional neuroanatomy of memory, for the most part they have not been validated against post-surgical outcomes and are not yet ready to replace the IAT.

Throughout this chapter, we will use the term 'ipsilateral' to refer to the hemisphere determined to have the epileptic focus or that is operated, and 'contralateral' to the normal or unoperated hemisphere.

Chelune[3] has discussed a major theoretical issue involved in preoperative memory assessment, contrasting two models of memory function. One model has suggested that good memory function of the unoperated hemisphere will preserve memory after temporal lobectomy (the 'functional reserve hypothesis'). This model was in fact the basis for the initial use of the IAT. The 'functional adequacy hypothesis' suggests that preoperative memory is more related to the intrinsic abilities of the operated hemisphere, with better preoperative function creating a higher risk of postoperative decline. These models are an important framework for evaluating the IAT literature, and we will refer back to these concepts in the following discussion.

Methodological issues in IAT memory testing

The preoperative IAT evaluation of memory functions has been widely accepted and extensively utilized for over three decades as part of the pre-surgical evaluation of patients with intractable epilepsy expected to undergo temporal lobe resection. The original technique of intracarotid amobarbital injection was developed by Dr. Juhn Wada in 1949,[4] and the further development of the 'Wada test' has been reviewed by Snyder and Harris.[5]

Since no official standards or normative data exist governing the procedure, substantial methodological variability exists among centers employing this technique. The literature reports significant variations in IAT methods across centers and over time. This lack of consensus has been emphasized in several multicenter surveys of IAT protocol.[6]

Methodological variations exist in both the administration of amobarbital, as well as in the memory evaluation procedure. Administration variables include the dose of amobarbital (typically 80–120 mg per dose), the rate and method of injection (by hand or machine), which side is injected first, and whether EEG is recorded during the procedure. Memory evaluation variables include the number and types of test items, use of a baseline training procedure, and the timing of presentation, recall or recognition testing post injection. Scoring procedures have included evaluation of absolute scores, calculation of laterality indices, and have variably corrected for false positive recall. Other interindividual factors that may affect test results include cerebral perfusion patterns, duration of drug effect, and effects of antiepileptic medication on cognition.

Historically, a major methodological concern focused on the validity of the procedure itself. Given the invasive nature of the IAT, it is not surprising that few studies have been published regarding test-retest reliability, and those available are reviews of repeated procedures done for clinical rather than research purposes. McGlone and MacDonald reviewed

data on 10 patients who underwent 18 repeat injections in the same hemisphere.[7] There were major changes in memory results in eight of 18 injections; seven of these were attributed to difficulties with one injection. In eight cases with technically satisfactory first injections, seven had identical memory classification on repeat. They also examined 70 patients who had repeat bilateral injections, and found no evidence for a practice effect. Lodenkamper *et al.*[8] found 53 of 1190 patients (4%) had undergone a second IAT at the Cleveland Clinic, and only 3 (0.24%) had a third IAT. Language lateralization was always replicated, but memory results were inconsistent in 63% of patients.

Few studies have tried to assess whether the IAT protocol is truly predictive of global amnesia. McGlone *et al.*[9] used a four item adaptation of an IAT memory protocol, without drug injection, in patients with amnesia. Two with global amnesia failed, but 12 of 13 classified as having severe amnesia had good recall. Although this raises the possibility of poor predictive value for the IAT, it may be that using fewer items than the real IAT may have been too easy. Carswell *et al.* also found that amnestic patients failed their IAT memory protocol.[10]

Although IAT memory testing was presumed to assess hippocampal function, the question has been whether intracarotid anesthesia inactivates the mesial temporal lobe, which is served primarily by the posterior rather than anterior cerebral circulation. For this reason, the technique of selective posterior cerebral artery amobarbital injection was developed.[11] Urbach *et al.* used SPECT studies with HMPAO injected simultaneous with amobarbital to show that the selective posterior cerebral artery infusion is distributed to the entire hippocampus, as well as the occipital lobe and sometimes thalamus.[12]

Studies using SPECT agents co-injected with sodium amobarbital have shown a variable distribution of inactivation, typically more limited in area than the angiographic perfusion and involving the mesial temporal lobe in only a minority of patients.[13,14] This may possibly contribute to false negative results.[15] McMackin *et al.*[16] revisited this issue by performing the IAT in 10 patients with intracranial electrodes, and injecting HMPAO intravenously *after* amobarbital injection so as to assess the areas of functional inactivation, not merely the vascular distribution of the amobarbital. They found that the posterior hippocampus demonstrated significant hypoperfusion on SPECT as well as delta activity in the depth electrodes. This finding supports intracarotid amobarbital injection as a valid test of mesial temporal function.

Thus, although SPECT studies have not added clinical utility to the IAT, they have delineated and validated the physiological changes occurring during the IAT, and eliminated the theoretical need for the more difficult posterior cerebral artery injection.

Administration variables

Many of the IAT administration variables are not always amenable to strict control in the clinical setting, and have therefore been difficult to systematically analyze. One of the more studied methodological issues has been the timing of injections. Grote *et al.*[17] compared memory scores in patients who had received injections on the same day versus two consecutive days. They found better memory scores (approximately 1 point on a 0 – 9 scale) after the second injection when the language-dominant hemisphere was injected on a subsequent day than on the same day. This may have been due to persistent amobarbital effect; they used 125 – 150 mg for each injection, while some centers use less and may not encounter this effect. Grote *et al.* suggest using a correction factor if the dominant hemisphere is injected second on the same day. While there may be medical reasons to prefer both injections with a single catheterization, these authors note that the change in their protocol to same day injections had been caused by changes in insurance reimbursement, indicating the importance of non-scientific factors in medical practice.

Memory evaluation variables

Although no standardized protocol has been adopted for memory testing, most centers have utilized an approach modified from the original Montreal procedure in which discrete items are presented during the period of anesthetization and recall is tested after the drug effects have worn off. Memory is then assessed in a recognition paradigm which includes use of foil items, i.e., items not shown during the initial presentation. Failures to recognize items are scored as errors.

Loring *et al.*, in a large multicenter study, found that using real objects for memory testing is more accurate than line drawings in predicting the side of surgery.[6]

Loring *et al.* found that asymmetric memory was more predictive of verbal memory decline after left temporal lobectomy than absolute scores.[18] They also showed that asymmetric recall of items presented early after amobarbital injection may have greater lateralizing value than later items.[19] While there may be concern that memory for such early items may be confounded by confusion or inattention due to the injection, Lesser *et al.*[20] showed that many patients could recognize at least two thirds of the items presented during the confusional state.

Dodrill and Ojemann[21] compared three different memory protocols in 159 patients. They alternated items from the original Montreal protocol (five objects) with their own Seattle protocol (object naming, followed by reading a sentence, then recalling the object). After recovery from amobarbital, they performed the Interview procedure, in which patients are questioned about five aspects of their performance during the testing. There was little agreement among the three procedures. The Seattle procedure correctly predicted postoperative memory outcome in 76%, which was statistically significant, while the Montreal protocol (48%) and the interview procedure (52%) had no predictive value. The authors felt that the Seattle protocol was superior due to emphasis on verbal memory and testing of recall during rather than after drug effect, although there is dependence on speech recovery when injecting the language dominant side. They thought the Interview procedure suffered from potential interference by drug-induced neglect.

Interindividual variables

Finally, further limitations of IAT memory testing may be due to individual subject variables including age, cognitive status and medication regimen, affecting the patient's ability to comply with the testing procedure.

Children have been subjected to the IAT, but may not respond as adults do. Willams and Rausch[22] found that children

under 13 years old were less likely to pass the IAT when an epileptogenic left hemisphere was injected, although language lateralization was possible.

Antiepileptic medication may also potentially affect IAT results. McCabe *et al.* reported a patient who performed poorly on neuropsychological testing and IAT memory performance while on topiramate, an antiepileptic drug known to cause verbal and memory problems.[23] The patient's scores improved when tested on another drug regimen.

Memory outcome after epilepsy surgery can also be affected by subjective factors. Patients may mistake other cognitive impairment (e.g., verbal deficits) as a memory problem, depression may worsen perception of memory, and personality may also play a role.[24]

IAT for prediction of memory outcome after temporal lobectomy

Studies evaluating IAT efficacy in predicting memory performance postoperatively can be categorized into those which evaluate the IAT predictions against postoperative performance directly, and those which compare IAT performance with predictions of another noninvasive technique.

Direct IAT predictive studies

Avoidance of severe amnesia was the initial aim of the IAT. In 2003, Kapur and Prevett found only nine cases of amnesia after unilateral temporal lobectomy in the English literature, indicating that it is a rare occurrence despite likely underreporting.[25] IAT results were predictive of amnesia in the three cases in which they were available.

Wyllie *et al.*[26] used the Cleveland Clinic IAT protocol that included objects, drawings, pictures, and written and spoken words. Failure (<67% recall) after ipsilateral injection did not predict material-specific memory deficits postoperatively. There was better but not significant correlation using a >20% recall asymmetry. In a later study from the same center, Kneebone *et al.*[27] compared 32 left to 31 right temporal lobectomy patients. Left TLE patients who passed (≥ 68% recall) contralateral IAT injection had a greater decrement in verbal memory, but there was no similar decrement in visual memory for the right TLE patients. This suggested the functional adequacy model is relevant, but more for verbal than visual memory.

Chiaravalloti and Glosser[28] examined the value of the IAT in predicting material-specific memory outcome after temporal lobectomy in 70 left hemisphere language dominant patients. They found that total recognition memory scores and word memory scores were predictive of verbal memory decline, using either the injection ipsilateral to the epileptic focus or an asymmetry score. However, the visual test items were not predictive of visuospatial memory decline. Wieser *et al.*[29] found that the verbal memory performance after selective anterior choroidal artery injections of amobarbital was statistically identical to that found after left anterior temporal lobectomy, but visual memory was underestimated.

Jokeit *et al.*[30] compared a variety of prognostic variables in 27 left temporal lobectomy patients. Good preoperative verbal memory on neuropsychological testing and IAT recall after right hemisphere injection were the best predictors of memory decrement.

Stroup *et al.*[31] created a multivariate model based on the functional adequacy hypothesis to predict verbal memory decline, using five preoperative variables that had been shown to be useful in univariate studies. The variables used were: (1) whether the side of resection was language-dominant or not (based on IAT results); (2) presence or absence of exclusively unilateral mesial temporal sclerosis on clinical reading of the MRI; (3) IAT total memory score after injection of the hemisphere contralateral to the seizure focus (only objects and picture items were used); and preoperative verbal memory scores on (4) immediate and (5) delayed recall testing. Verbal memory scores were assessed using the California Verbal Learning Test and the Logical Memory subtests on the Wechsler Memory Scale-Revised. Using 132 subjects, they found that each of the variables was independently predictive of post-operative verbal memory decline, and they developed an equation to predict the risk of memory decline in individual patients based on these measures. When ipsilateral injection memory scores or asymmetry scores were included, they did not add to the predictive value of the IAT, supporting the functional adequacy hypothesis. This paper supports the continued use of the IAT (at least using this protocol) as an independent component of memory risk assessment for temporal lobectomy.

Sabsevitz *et al.*[32] compared 12 left temporal lobectomy patients with the expected memory asymmetry on IAT with nine who had a reversed asymmetry. Those with reversed asymmetry had poorer verbal memory outcome and worse seizure control.

Other studies have supported the functional reserve hypothesis. Bell *et al.*[33] found that right hemisphere memory on IAT was predictive of verbal memory decline in 22 patients with left temporal lobe epilepsy.

IAT comparison with other functional techniques

Positron emission tomography using fluoro-deoxyglucose (FDG-PET) is often used to evaluate focal dysfunction in epilepsy surgery candidates.[34] FDG-PET hypometabolism in the left hemisphere, particularly the lateral temporal lobe, correlates with lower verbal IQ and verbal memory scores.[35] FDG-PET has also been compared to the IAT as a measure of temporal lobe dysfunction. Salanova *et al.*[36] found 86% (20/23) patients had hypometabolism of the epileptogenic side, but only 13 of these 20 had ipsilateral memory impairment on IAT. Overall, 95% of the patients (22/23) had abnormality on FDG-PET or IAT, suggesting that while the tests are often in agreement, they provide complementary information. Griffith *et al.*[37] found left anterior temporal lobectomy patients with no or mild FDG-PET temporal lobe metabolic asymmetry had significantly greater verbal memory decline than those with moderate to severe hypometabolism, suggesting that FDG-PET may provide additional prognostic information regarding memory. IAT results were not included in this study.

Joo *et al.*[38] compared 36 patients with bilateral FDG-PET hypometabolism to 59 with unilateral hypometabolism, who were evaluated for temporal lobectomy. They found that IAT memory scores in those with bilateral hypometabolism compared to the unilateral group were more likely to be

symmetric (48% vs. 16%). When the score was asymmetric, the bilateral patients were more likely to have a reversed asymmetry (i.e., the ipsilateral side having better memory than the contralateral side) (31% vs. 3%). Overall, the mean memory score in the ipsilateral (operated) hemisphere was lower in the bilateral hypometabolism group (51 ± 20.9%) than the unilateral group (63 ± 24.5%). However, there was no significant change from preoperative neuropsychological scores after surgery in the two groups, except in four patients with left TLE and reversed asymmetry on the Wada, who did have significant worsening of postoperative memory. Although this study seems to suggest that the IAT was not useful in prediction of postoperative memory, only 26 of the 36 bilateral hypometabolism patients had surgery, and it is likely those most at risk of memory deficits were excluded.

Across studies and protocols, there is significant concern for the group of patients who 'fail' the IAT memory component bilaterally. This result raises concern for severe postoperative amnesia and such patients may be denied surgery. Bautista *et al.*[39] found that patients with bilaterally poor memory had no significant change in memory after nonlanguage dominant temporal resection, but that dominant resections caused similar verbal memory decline compared to those with dominant resections and unilaterally poor memory or bilaterally intact memory. This study again emphasizes the major cognitive risk of temporal lobectomy is verbal memory loss in language-dominant resections, no matter what the IAT results, and that temporal lobectomy might be possible in selected patients with bilaterally poor memory.

IAT memory for prediction of seizure outcome

Given that memory deficits suggest temporal lobe dysfunction, some researchers have evaluated the IAT memory results as another possible predictor of postoperative seizure outcome. Several studies have confirmed that the IAT memory results correlate with hippocampal neuronal loss histologically, using an IAT protocol including words, pictures and objects.[40–42]

Wyllie *et al.*[43] also showed that memory failure on IAT occurred in 80% of patients after injection of the contralateral side, versus 20% failure after ipsilateral injection.

Sperling *et al.*[44] evaluated memory results of the IAT in 117 patients who underwent temporal lobectomy. When the IAT showed worse memory in the operated hemisphere seizure outcome was better. The degree of difference was not predictive, nor was the absolute score in the operated hemisphere. Loring *et al.*[45] found similar results using a different IAT protocol, but in contrast they found that an asymmetry of three or more recalled items (out of eight) predicted better seizure outcome.

Kirsch *et al.*[46] assessed patients with an unexpected memory asymmetry (UA) on the IAT. UA was found in 36% of left-sided and 8% of right-sided surgeries. UA patients had worse seizure outcomes after right temporal lobectomy than those with the expected asymmetry, but there was no difference in the left temporal lobectomy group, in contrast to Sabsevitz *et al.*[32] as noted above. They did not find a difference in postoperative verbal memory for any group. A potential problem with this study was the use of verbal memory items, in which inactivation of language function may have confounded true memory assessment of the nondominant hemisphere. Even still, this study suggests that patients should not be denied surgery exclusively based on the results of Wada memory scores.

Alternatives to amobarbital for hemispheric anesthesia

Recurrent shortages of amobarbital have led some investigators to explore other agents for intra-carotid hemispheric anesthesia. While the acute effects of the agents are detailed in the studies cited below, they have not yet been validated against postoperative memory outcomes.

Sodium methohexital (SM) has been studied by several centers.[47] Compared to amobarbital, SM has a more rapid offset of action as assessed by clinical and EEG effects.[47] Buchtel *et al.*[48] used SM in 173 Wada procedures on 86 epilepsy surgery candidates, and compared it to their experience with amobarbital. The behavioral effects of the drugs were similar, but EEG recovery took only 4.8 minutes after SM compared to 7.8 minutes for amobarbital. They compensated for the briefer duration of action by performing two injections on each side, one for language testing and one for memory testing. We have had the opportunity to try SM in several patients and were impressed with the rapid recovery from drug effect. It is possible that using SM might reduce the same-day injection effects described Grote *et al.*[17]

Takayama *et al.*[49] evaluated propofol as an alternative to amobarbital for the Wada test, because of difficulty obtaining amobarbital in Japan. Propofol is an anesthetic agent with rapid onset and offset of action that is often used for intravenous conscious sedation as well as treatment of status epilepticus. They compared 55 patients tested with amobarbital to 12 tested with propofol. They found similar rates of satisfactory contralateral hemiplegia and ability to lateralize language and memory function. Time to full recovery of motor function was similar, but the propofol group had a somewhat longer time for speech recovery on the language-dominant side. In a later study the same group explored adverse effects of propofol in a larger group.[50] They tested 58 patients, including 32 with tumors, 13 with partial epilepsy, and 13 with arteriovenous malformations (AVM). Propofol was prepared as a 1 mg/mL solution in 10 mL of normal saline. Doses ranged from 5–32 mg to produce transient hemiplegia, with an average of about 20 mg across patient groups. They found a 33% rate of adverse reactions. Reactions included eye pain, shivering, face contortion, lacrimation, laughing and apathy (grade 1); confusion, involuntary movements, and head and eye version (grade 2), and increased muscle tone with twitching and rhythmic movements or tonic posturing (grade 3). The grade 1 and 2 reactions disappeared in 5 minutes and did not interfere with cognitive testing, but the grade 3 reactions faded more gradually, and were more likely to prevent valid cognitive assessment. Grade 3 reactions were more common in patients over age 55, with AVM, and with propofol doses >20 mg.

Jones-Gotman *et al.* evaluated etomidate, another anesthetic, in what they called the etomidate speech and memory test ('eSAM').[51] They assessed 16 epilepsy surgery candidates.

They injected a 2 mg bolus of etomidate via the internal carotid artery, followed by infusion at 6 mL/hour (0.003–0.004/mg/kg/minute). Infusion was continued until all cognitive tests were completed. Recognition was tested after clinical and EEG changes had returned to baseline, about 4 minutes. They found contralateral hemiplegia and ipsilateral EEG slowing in all injections. Side effects were frequent but mild; 46% of injections caused an upper extremity tremor, usually mild. Although similar in effect to the IAT, the eSAM allowed a more reliable period of cognitive testing due to continuous infusion. There is concern etomidate can cause adrenal suppression, seen in higher doses and in critically ill patients.[51,52]

Alternatives to the IAT

Because of the limitations of the IAT discussed above, noninvasive methods have been sought to replace it in the pre-surgical workup. Functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), and transcranial magnetic stimulation (TMS) have been studied as tests of preoperative memory function. Each offers the advantages of being noninvasive and easily repeatable. It should be possible to better establish the validity of these tests in predicting postoperative memory deficits than it has been with the IAT. Their experimental nature would ethically allow their research use in a consecutive series of epilepsy surgery patients without the data influencing the surgical decision, as the IAT must. Each of these procedures has given insight into the functional neuroanatomy of memory, but they have yet to be established as reliable predictors in epilepsy surgery. The following section discusses the progress so far.

Functional MRI (fMRI)

Functional MRI is based on the finding that increased neuronal activity creates greater local blood flow, and changes in flow can be detected using the difference in MRI signal properties of hemoglobin and deoxyhemoglobin.[53] Images are obtained during two or more activation or rest states, and active areas are indicated by subtraction and statistical techniques. Assessment of hippocampal function may be difficult due to imaging difficulties in this region.[53] Functional imaging depends on detecting a difference between resting and activated states, which is more difficult in the hippocampus because memory is never truly 'at rest'.[53] Progress in fMRI for replacing the IAT was recently reviewed in detail by Gaillard[53] and Klöppel and Büchel.[54] In general, fMRI differs from the IAT in several ways. IAT is a regional inactivation procedure, which is performed rapidly and hard to reproduce. Behavioral abnormalities or sedation during testing can confound results. FMRI is an activation procedure, which may show areas *involved* in a function but cannot distinguish which are *essential* for that function.[54]

A number of studies have shown differences in fMRI activation by memory paradigms between controls and temporal lobe epilepsy patients. For example, Dupont *et al.* found that delayed verbal recall created weaker activation in left temporal lobe epilepsy patients than in controls.[55]

A small study of seven pre-surgical patients showed fMRI activations lateralized language consistent with IAT results (four left hemisphere dominant, three right hemisphere dominant).[56]

Verbal memory was assessed using learning and retrieval of a word list in seven patients with left mesial temporal sclerosis compared with normal controls.[57] All patients had left language dominance on the IAT. The patients showed significant differences in fMRI activation in both the encoding and retrieval states. They had less activation in the occipitoparietal and parahippocampal regions when encoding than the controls. During retrieval, the patients had much more extensive activation of the left lateral prefrontal region. Surgical results were not reported.

Deblaere *et al.* did a detailed comparison of their IAT protocol to memory activation using fMRI.[58] They found bilateral fMRI activation in the anterior/mesial temporal lobes in eight normal volunteers. The 18 pre-surgical patients studied included seven with a left-sided focus, nine with right-sided focus, and two determined only after depth electrode recordings. The IAT showed failure of the ipsilateral (epileptogenic) side in 7/16, bilateral passing for 9/16, while one patient passed the only injection in the ipsilateral side (i.e., testing the contralateral side), and one patient had a technically invalid test. Activation in the fMRI paradigm involved the hippocampus, parahippocampus, and fusiform gyrus, as well as other areas including thalamus and lateral temporal neocortex. Fifteen of the 18 patients had lateralized fMRI activation, and three had bilateral activation. The lateralized activations were higher in the contralateral (normal) hemisphere. Comparison of the fMRI and IAT results showed significant correlation only for the right TLE patients, not for those with left TLE. This was likely due to the differences between the two test protocols in memory modality. Their IAT protocol included 11 memory items, of which five were written words and seven were pictures, while the fMRI protocol included only five images and no words. This result lends support to the lateralization of modality-specific memory, and the importance of using appropriate testing paradigms in assessing patients. Further refinement of this fMRI memory protocol may indeed lead to a useful test that could replace the IAT.

Aldenkamp *et al.* used fMRI activated by language and memory items similar to those presented in an IAT, to assess which structures are activated by these procedures in normal volunteers.[59] Complex visual items, which could be encoded both verbally and visually, produced activation during encoding symmetrically in the bilateral hippocampus, parahippocampal and fusiform gyri, whereas recall produced activation more restricted to the posterior hippocampus as well as extratemporal (occipital and frontal) regions. They concluded that such memory items are useful and valid for activating both mesial temporal lobes during the IAT. This finding supports the validity of using complex visual items in the IAT even for assessment of the language dominant temporal lobe, as in the multicenter study of Loring *et al.*,[6] rather than combining visual and verbal items.

Deblarere *et al.*[60] created a semirandom fMRI memory paradigm, to try to incorporate more event-related type activations, which are harder to detect but show more anterior hippocampal activation than block design paradigms. This protocol produced agreement with the IAT laterality only in right temporal lobe epilepsy patients, not left-sided patients,

which they felt was due to more verbally-oriented items on the IAT protocol. Surgical outcomes were not reported.

Richardson *et al.*[61] more formally addressed the ability of fMRI memory testing to predict verbal memory outcome in left temporal lobectomy patients. They studied ten patients, and compared preoperative neuropsychological testing (List Learning and Story Recall subtests of the Adult Memory and Information Processing Battery), hippocampal volumetrics, and fMRI activation to postoperative List Learning and Story Recall scores. The fMRI memory testing was performed by presentation of 255 words. Subjects were asked to press a button to indicate if the word was 'living' or 'not living', and were not asked to memorize the items. Ninety minutes later a surprise recognition memory test was performed. The fMRI responses recorded during the encoding phase were categorized as to whether the items were later recalled, a left-right hippocampal activation difference was determined, and a recognition rate was calculated. While all these preoperative variables had some predictive value for postoperative memory, the fMRI asymmetry showed the highest correlation with memory outcome, with greater activation on the left predicting worse verbal memory outcome ($p=0.00027$). On an individual basis, fMRI showed 100% sensitivity, specificity and positive predictive value for >1 standard deviation decline in delayed list recall, with 40% specificity and 63% positive predictive value for immediate list recall and story recall. This study, while promising, was performed only in a small group of selected patients and needs to be repeated in a larger population. The authors also did not compare the fMRI results to IAT results, even though the stated intention was to develop a noninvasive replacement for the IAT. Even so, this study does provide an excellent start in developing protocols that are predictive of postoperative memory and could potentially displace the Wada test.

Rabin *et al.*[62] also developed an fMRI memory protocol to predict post-surgical memory outcome in 35 temporal lobectomy patients. They used 60 complex visual scenes, presented in ten scene blocks over 40 seconds each, and recognition was tested using 60 foils intermixed. Activation in a mesial temporal region of interest was symmetric in 30 controls, but asymmetric in patients. The degree of activation ipsilateral to the operated side was significantly inversely correlated with memory outcome, lending support to the functional adequacy hypothesis, while the contralateral activation was not correlated. However, the correlations were too weak to allow sensitivity and specificity predictions at the individual patient level, and further refinement in the procedure is needed. The authors did compare fMRI results to IAT memory results in 27 patients, finding only a mild correlation of asymmetry ratios on fMRI and Wada.

Janzsky *et al.*[63] used an introspective recall task during fMRI in 16 patients who underwent right temporal lobectomy. Reduced fMRI activation in the right temporal lobe correlated with better memory outcome after surgery, again supporting the functional adequacy model. IAT was not done in these patients.

Strange *et al.*[64] showed that there are different hippocampal fMRI responses to intentional learning versus passive encoding, suggesting that the different memory paradigms tested so far may produce varied results and be hard to compare directly.

Hwang and Golby,[65] in a recent review of fMRI and memory, note that fMRI is an activation procedure, which illuminates brain regions that may be involved in a task, but not those that are essential for the task. Inactivation procedures such as the IAT may still provide critical information for surgical outcomes. Additionally fMRI presents technical challenges in data acquisition and image processing, relying heavily on statistical analysis. These factors create time and personnel demands that may make clinical testing more cumbersome.

Transcranial magnetic stimulation (TMS)

Transcranial magnetic stimulation (TMS) uses an external magnetic coil to noninvasively produce electrical currents in underlying cortex, thereby interfering with local cortical function. It has been used to study the distribution as well as relative timing of cortical processes. It is noninvasive, generally comfortable and can be performed repeatedly. TMS has been used to investigate memory function in temporal lobe epilepsy patients.[66] In a review of the literature up to 1998, Grafman and Wasserman[67] concluded that TMS could produce a 'modest, but reversible, negative effect on all components of memory' depending on stimulation parameters. As yet there has not been sufficient research into TMS and temporal lobectomy outcomes to comment on its potential utility.

Magnetoencephalography (MEG)

Magnetoencephalography (MEG) records the extracranial magnetic fluctuations produced by neuronal electrical currents. Like EEG, MEG offers the advantage of high temporal signal resolution (millisecond range), but unlike EEG it can localize the dipole activity source on the subject's own MRI scan. MEG has already shown utility in epilepsy surgery evaluations, for mapping both focal epileptiform activity as well as noninvasively localizing somatosensory, motor, auditory, and possibly language cortex.[68]

MEG has been used to probe the neurophysiology of memory in a number of studies, some of which are relevant to eventually incorporating MEG into pre-surgical memory evaluations. For example, Tesche and Karhu used MEG to probe stimulus-induced hippocampal activity related to a working memory (digit span) task.[69] With a stimulus-averaged evoked potential technique, they found that the memory task reset hippocampal theta (4 – 7 Hz) oscillations bilaterally, after the probe in the left hippocampus and prior to the probe (anticipation) in the right hippocampus. Kaiser *et al.* showed increased gamma-band activity in the left frontotemporal region during a verbal working memory task in normal controls.[70] Papanicolaou *et al.* found modality-specific MEG responses in the hippocampi, with verbal stimuli preferentially activating the left side and visual stimuli the right.[71] Breier *et al.* demonstrated excellent correlation between IAT language lateralization and lateralized MEG activations using IAT-type stimuli, however memory was not compared.[72]

Conclusions

The IAT has many flaws. It is invasive and expensive. IAT results may be unreliable and hard to replicate, and variations

in methodology make comparisons among centers difficult. Despite these drawbacks, the IAT has gained wide acceptance and has persisted for decades. The variability in the literature has led to significant controversy about the ultimate value of the IAT, however. Dodrill has argued that 'there is no convincing evidence that the Wada test is of any practical value, and especially so when its predictive capability is compared with other easily obtained variables,'[73] while Goldstein and Gilliam have suggested that the IAT may be deferred in right TLE patients.[74] Some of this controversy is related to the different IAT procedures used. It appears that the Medical College of Georgia procedure may be the most reliable.[6,18,19,45] Although this procedure uses real objects rather than verbal items, the Rabin *et al.*[62] fMRI study noted above showed that complex visual items activate the mesial temporal lobes symmetrically in controls and asymmetrically in TLE patients, lending support to using objects for assessing both temporal lobes. The use of objects also avoids the interference of drug-induced language deficits on memory testing.

It appears likely that the IAT can predict severe global amnesia, although such cases are rare. Its greatest utility may be in helping to predict risk of verbal memory decrement in language-dominant temporal lobectomy cases. We agree with Loring and Meador[75] that the IAT should not be scored as pass/fail, but should be interpreted in the context of other preoperative testing to suggest little, moderate or significant risk to memory.

Newer technology may eventually replace the IAT for both language and memory testing, with fMRI showing special promise so far. The research nature of these tests should allow their prospective scientific validation in a way that is no longer possible with the IAT. In order to truly replace the IAT, it will important for such techniques to be standardized as simply as possible for routine clinical use.

SECTION 11

The epileptogenic zone

98 The epileptogenic zone: general principles

KM Klein and F Rosenow

Definition

The area of cortex that is indispensable for the generation of epileptic seizures is called the epileptogenic zone.[1–5] The goal in epilepsy surgery is to completely remove the epileptogenic zone while sparing the eloquent cortex. Unfortunately, there is currently no way to measure the extension of the epileptogenic zone directly. In patients who became seizure free after epilepsy surgery we can, by definition, conclude that the epileptogenic zone has been included in the resection. However, there is the possibility that the epileptogenic zone was much smaller than the resection and, therefore, a much smaller resection would also have led to seizure freedom.

By definition total removal or disconnection of the epileptogenic zone is necessary and sufficient to render a patient seizure free. The epileptogenic zone is a theoretical concept which would require permanent seizure freedom even after all antiepileptic medication was tapered. For practical purposes we would suggest to consider 1 year of postoperative seizure freedom even with the patient still on antiepileptic medication sufficient to conclude that the epileptogenic zone was removed completely/sufficiently, even though a proportion of patients will loose seizure freedom subsequently.

Relationship between the other zones of cortex and the epileptogenic zone

In order to generate an appropriate hypothesis regarding the localization of the epileptogenic zone one has to combine information about the localization of the other cortical zones which can be measured (ictal onset zone, irritative zone, epileptogenic lesion, ictal symptomatogenic zone, and functional deficit zone). When the localization of these zones is concordant there is a high possibility that a resection of this area includes the epileptogenic zone, and leads to seizure freedom.

Typically the epileptogenic zone consists of the *actual and the potential seizure onset zones*. The *actual seizure onset zone* is the area of cortex from which the seizures currently recorded arise. Even after complete resection of this area seizures may persist because neighboring or distant cortex that previously did not generate seizures starts generating seizures. In other words, this *potential seizure onset zone* reaches the threshold for seizure generation only after the actual seizure onset zone is resected.[4] This process may take time and can serve as a concept to explain that the rates of seizure freedom usually decrease over time in surgical case series.[6,7] Unfortunately, there is no way to measure these potential seizure onset zones prior to surgery.

A number further issues need consideration: a) using extracranial electrodes one has to keep in mind that at least about 6 cm^2 of cortex have to discharge simultaneously to allow detection of seizure activity.[8] When initially only small areas of cortex are involved and the seizure activity shows fast propagation, the onset zone of the recorded seizure may be more extensive or even be located differently to the real seizure onset zone. When using subdural electrodes one needs to consider that only a small part of the gyral cortex is covered and that the real seizure onset zone may frequently not be covered by the electrodes. In this situation a propagated seizure pattern might be mistaken for a focal or regional seizure onset occurring under the subdural electrodes.[3]

The location of the seizure onset zone measured with ictal SPECT depends on the time of injection. The seizure may have significantly propagated when the isotope reaches the cortex. Therefore, the epileptogenic zone may be smaller or larger than the recorded seizure onset zone.

The *irritative zone* which is the area of cortex that generates interictal epileptiform discharges must not necessarily be part of the epileptogenic zone.[1,9,10] Patients with temporal lobe tumors, for example, can achieve seizure freedom after resection of the tumor despite preoperative spikes in both temporal regions.[11,12] Furthermore, some patients with tuberous sclerosis, infantile spasms and multiregional spikes may become seizure free after focal resections.[13–15] On the other hand, in patients with mesial temporal lobe epilepsy caused by hippocampal sclerosis contralateral spikes are negative predictors for postoperative seizure freedom.[16]

In most cases the *epileptogenic lesion* is part of the epileptogenic zone. Complete resection of the epileptogenic lesion is correlated with a higher percentage of seizure freedom (Van Ness, 1992).[17] However, depending on the type of the epileptogenic lesion complete resection does not always cause seizure freedom. Brain tumors and cavernomas typically induce a perilesional epileptogenic rim restricted to the directly surrounding cortex.[4,18] In these cases the epileptogenic zone comprises the lesion and the directly surrounding tissue. Therefore, a topectomy is often followed by seizure freedom. On the other hand, in patients with cortical dysplasia frequently only a fraction of the dysplasia is visible on MRI.[19]

Consequently, the epileptogenic zone often comprises much more cortex than the lesion shown in MRI. Moreover, the complete epileptogenic lesion must not necessarily be included in the epileptogenic zone. This has been noticed in patients who became seizure free after epilepsy surgery despite only partial resection of the lesion because of its location in the eloquent cortex.[20]

The *symptomatogenic zone* gives additional information regarding the location of the epileptogenic zone. Depending on the semiology the information may be lateralizing and/or localizing.[21] In most cases the ictal symptoms did not start before a significant propagation of the seizure activity has occurred. Consequently, there is frequently no overlap between the symptomatogenic zone and the epileptogenic zone. Nevertheless, the epileptogenic zone is typically located close to the symptomatogenic zone. For example, a highly localizing somatosensory aura at the beginning of a seizure provides evidence that the epileptogenic zone is located in the vicinity of the corresponding primary sensory area.

The *functional deficit zone* which is defined as the area of cortex that is functionally abnormal in the interictal period is of limited value in the localization of the epileptogenic zone. Good correlation with the other zones supports the hypothesis of the location of the epileptogenic zone. Clear differences in the location often lead to additional tests such as invasive monitoring.[4] However, there may be disturbances of brain function at considerable distance from the epileptogenic zone. A typical example is seen in patients with pure mesial temporal lobe epilepsy due to hippocampal sclerosis where the epileptogenic zone is usually limited to the mesial temporal region. In these patients the FDG-PET often shows extensive hypometabolic regions outside the mesial temporal and even outside the temporal structures.[22]

In most cases some degree of discrepancy between the above-mentioned zones exists. Depending on the type of epilepsy, some zones are more and others less predictive for the epileptogenic zone. If there is no adequate explanation for the discrepancies of the different zones additional tests such as high resolution MRI, ictal SPECT, PET or invasive monitoring need to be performed. However, as invasive recordings are limited by their cortical coverage, a clear hypothesis regarding the location of the seizure onset zone should exist to make a well-founded decision about the placement of the intracranial electrodes.

The French and Italian concept of the epileptogenic zone

In the French and Italian school of epilepsy surgery there is a rather different concept of the epileptogenic zone. The epileptogenic zone is considered as a complex structure composed of separate pacemaker, relay and subrelay areas essential for producing ictal symptoms and signs.[23–25] According to this definition the contemporary presurgical diagnosis in France and Italy more frequently makes use of depth electrodes to define the more extensive epileptogenic zone[25] and tends to larger resections and more extensive disconnections.[4] Although there is detailed anecdotal evidence in the literature which supports this hypothesis[25] no systematic study has been performed to verify this concept.[4]

Conclusion

The epileptogenic zone is a theoretical concept. There is currently no diagnostic modality that could measure the epileptogenic zone directly. Furthermore, certain pathophysiological changes could act as an epileptogenic zone in one patient whereas another patient with the same pathophysiological changes never develops seizures. This may be due to a different seizure threshold of the remaining cortex presumably influenced by genetic factors. In order to develop future techniques to measure the epileptogenic zone directly we have to comprise genetic susceptibility factors influencing the seizure threshold.

99 Future methods for the direct assessment of the epileptogenic zone

J Engel Jr

Introduction

At the second Palm Desert conference, held in February 1992, Lüders, Engel, and Munari[1] proposed that the localization of epileptogenic tissue for surgical resection could be defined on the basis of six different types of abnormalities (Table 99.1). Five of these: (1) the irritative zone, the area generating spontaneous EEG spikes; (2) the ictal onset zone; (3) the structural epileptogenic lesion; (4) the symptomatogenic zone, the area responsible for initial ictal manifestations; and (5) the functional deficit zone, can usually be easily measured, but none of these alone accurately define the epileptogenic zone, the area necessary and sufficient for spontaneous seizure generation. The goal of the pre-surgical evaluation is to identify the location and extent of the epileptogenic zone, because its removal or disconnection is necessary to achieve a seizure free outcome. Under the best of circumstances, the dimensions of the epileptogenic zone are merely approximated based on delineation of the other five abnormalities, using standardized electrophysiological and neuroimaging procedures, as well as observation of clinical seizures, the neurologic examination, and neurocognitive testing. A reliable, cost-effective means of directly identifying the epileptogenic zone would greatly facilitate surgical treatment. Unlike most medical disorders, there is currently no reliable surrogate marker for epilepsy that identifies either epileptogenesis or epileptogenicity.

In March 2000, a White House-initiated conference co-sponsored by the National Institutes of Health and the American Epilepsy Society established benchmarks for epilepsy research as a guide for researchers. The intention was to highlight the most important realizable objectives for the next decade, in order to better understand the mechanisms of epilepsy and to apply this knowledge toward the development of new treatments and cures.[2] The first benchmark (IA1) is to 'successfully develop a noninvasive dynamic imaging system or physiological monitoring system that reliably identifies an epileptogenic region in at least one form of human epilepsy.' The search for such a surrogate marker of epileptogenesis and epileptogenicity, therefore, has become a top priority; if found, it could be used to identify which patients would develop epilepsy after an epileptogenic insult; to assess the effectiveness of antiepileptogenic interventions (drugs or devices) in patients with active epilepsy without the need to wait for another seizure to occur; to screen potential antiepileptic compounds in animal models; and, most important for the purpose of this chapter, to delineate the epileptogenic zone for surgical resection.

Surrogate markers of epileptogenesis and epileptogenicity

Interictal EEG spikes

Although accurate delineation of the epileptogenic zone has been a goal of epilepsy surgery teams for over 100 years, very little research, until recently, has gone into the search for reliable surrogate markers of epileptogenesis and epileptogenicity. Interictal EEG spikes have for many years been considered the hallmark of the epileptogenic region, but it is well known that these interictal electrographic phenomena are often falsely localizing. On scalp EEG, they commonly occur bilaterally when the epileptogenic zone is unilateral. Intraoperative spike mapping during electrocorticography was commonly used in the past as an aid to tailored cortical resections, but has now been largely abandoned because these transients usually have a much wider distribution than the area responsible for seizure generation. The concept of *red spikes* and *green spikes* was introduced several decades ago by Theodore Rasmussen, a prominent neurosurgeon at the Montreal Neurological Institute, who noted that there must be some spikes that identify the epileptogenic zone, but that electrophysiologists are not able to recognize them. There have been many unsuccessful attempts to distinguish red from green spikes based on aspects of spike morphology such as rise time, sharpness, and after coming slow waves, as well as patterns of recurrence such as frequency, and response to suppression by drugs such as methohexital.

More recent studies have identified high frequency (150–500 Hz) oscillations, termed 'Fast Ripples,' superimposed on interictal spikes that appear to be unique to structures capable of generating spontaneous seizures in patients with mesial temporal lobe epilepsy, and also in animal models of this disorder (Figure 99.1).[3–13] It remains to be seen whether similar oscillations can identify the epileptogenic zone in neocortex. Nevertheless, at present, FR offer the most promising opportunity to develop a surrogate marker of epileptogenicity and epileptogenesis, but these events can only be seen with microelectrode recordings directly from the brain. Although it may be possible to utilize FR to delineate the epileptogenic zone intraoperatively, they would be more useful clinically if they could be measured noninvasively.

Table 99.1 Definition of abnormal brain areas

	Definition	Measures
Irritative zone	Area of cortex that generates interictal spikes	Electrophysiological (invasive and noninvasive)
Ictal onset zone	Area of cortex where seizures are generated (including areas of early propagation under certain circumstances)	Electrophysiological (invasive and noninvasive)
Epileptogenic lesion	Structural abnormality of the brain that is the direct cause of the epileptic seizures	Structural imaging and tissue pathology
Symptomatogenic zone	Portion of the brain that produces the initial clinical symptomatology	Behavioral observation and patient report
Functional deficit zone	Cortical area of nonepileptic dysfunction	Neurologic examination, neuropsychological testing, EEG, PET, SPECT
Epileptogenic zone	The area of brain that is necessary and sufficient for initiating seizures and whose removal or disconnection is necessary for abolition of seizures	Theoretical concept

From Lüders *et al*.[1] with permission.

Magnetoencephalography (MEG) has the ability to detect neocortical high frequency oscillations in the range of FR;[14] however, so far, it has not been possible to use MEG to identify such fast oscillations deep within the brain, as would be necessary to visualize these mesial temporal limbic events.

It is quite likely that the neuronal mechanisms responsible for interictal spikes associated with FR are substantially different from mechanisms responsible for interictal spikes that do not contain FR, e.g., spikes that are either projected or originate in areas incapable of generating spontaneous seizures. Therefore, the metabolic signature of FR-containing interictal spikes could be sufficiently unique to allow them to be identified noninvasively with EEG spike-triggered functional MRI (fMRI) averaging.[15]

Neuronal excitability

Electrophysiological approaches have been used to directly assess neuronal excitability of epileptogenic tissue, either intraoperatively during electrocorticography, or extraoperatively during chronic invasive monitoring. The epileptogenic hippocampus displays characteristic responses to paired-pulse stimulation, a technique that measures changes in neuronal excitability induced by a test pulse. The normal hippocampus displays paired-pulse facilitation on stimulation of the perforant path, its major afferent input from entorhinal cortex; that is, the test pulse causes a response to a subsequent stimulation to be increased. This effect is in part due to accumulation of calcium within presynaptic terminals following the first pulse, which increases the amount of neurotransmitter released in response to the second. Both animal and human epileptic hippocampus demonstrate paired-pulse suppression on perforant path stimulation, which can persist for hundreds of milliseconds; that is, the response to the second pulse is decreased (Figure 99.2).[16] This is believed to reflect enhanced inhibition induced by the initial response, either as a reflection of a homeostatic protective mechanism, or perhaps as an epileptogenic abnormality responsible in part for hypersynchronization. Paired-pulse facilitation is seen, however, with direct stimulation of hippocampal association pathways, indicating that the excitatory and inhibitory disturbances within this epileptogenic structure are quite complex.[16,17] Similar approaches to assessing neuronal excitability in neocortex have not met with consistent results. Recently, however, single-pulse electrical stimulation with intracranial electrodes in the frontal lobe have revealed delayed and repetitive responses that could be indicative of epileptogenicity.[18]

As with FR, electrophysiological indicators of neuronal excitability are so far only applicable to intraoperative and intracranial electrode recording situations. These concepts, however, could be more widely applicable if they could be measured noninvasively. Transcranial magnetic stimulation (TMS) is currently being investigated as a possible diagnostic, as well as therapeutic, tool for epilepsy at a number of laboratories. TMS, particularly paired-pulse stimulation, can be used to measure cortical excitability, as a potential surrogate marker of epileptogenicity.[19,20] It is conceivable that such TMS measures could eventually be employed as a noninvasive means to localize the epileptogenic zone.

Neuroimaging

Another potential surrogate marker of epileptogenicity and epileptogenesis is the positron emission tomography (PET) tracer alpha methyl tryptophan (AMT).[21,22] In patients with tuberous sclerosis who have multiple tubers and epileptic seizures, AMT PET preferentially accumulates in the tuber responsible for generating spontaneous seizures (Figure 99.3). Similar findings have now been published for mesial temporal lobe epileptogenic regions.[23] It is believed that AMT, a serotonin precursor, detects the presence of increased activity in the kynurenine pathway, which may play an important role in epileptogenicity.

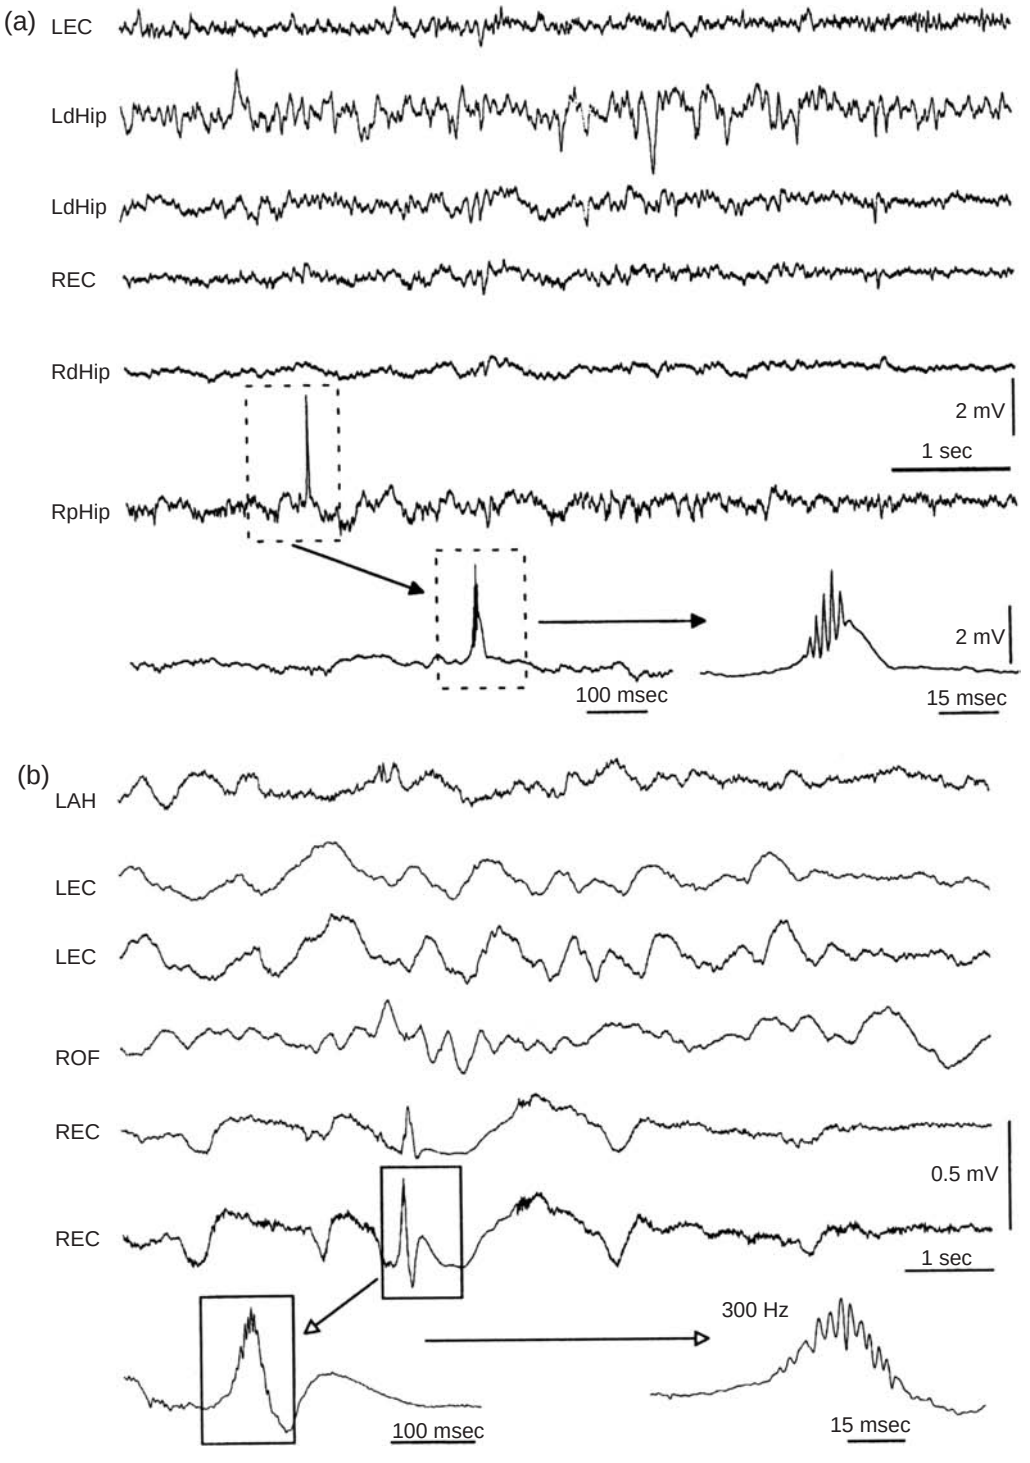

Figure 99.1 (a) Example of KA-rat EEG with interictal spike with superimposed fast ripples. Abbreviations: LEC and REC left and right entorhinal cortex; LdHip and RdHip left and right dorsal hippocampus; LpHip and RpHip left and right posterior hippocampus. (b) Interictal spike with superimposed fast ripples in the entorhinal cortex of a patient with mesial temporal lobe epilepsy. Arrows indicate extension of electrical activity in the box. Abbreviations: LAH – left anterior hippocampus; ROF – right orbitofrontal cortex; LEC and REC – left and right entorhinal cortex (two microelectrodes in each side). From Engel *et al*.[17] with permission.

The 5-HT1A receptor ligands [18F]FCWAY[24] and [18F]MPPF[25] show decreased binding in epileptic hippocampus, but it is not yet clear whether this reflects dynamic disturbances rather than static dysfunction similar to that demonstrated with fluorodeoxyglucose (FDG) PET.[26]

A potentially exciting new development for MRI is the use of magnetized nanoparticles (MNPs), extremely small magnetized particles that are visible on MRI, and that can theoretically be attached to virtually any bioactive molecule.[27–29] MNPs could potentially be used to measure such localized alterations as neurotransmitter activities that reflect brain excitation and inhibition, cerebral metabolism, immune responses, and antiepileptic drug (AED) distribution with extremely high spatial resolution. The latter is of interest in view of recent

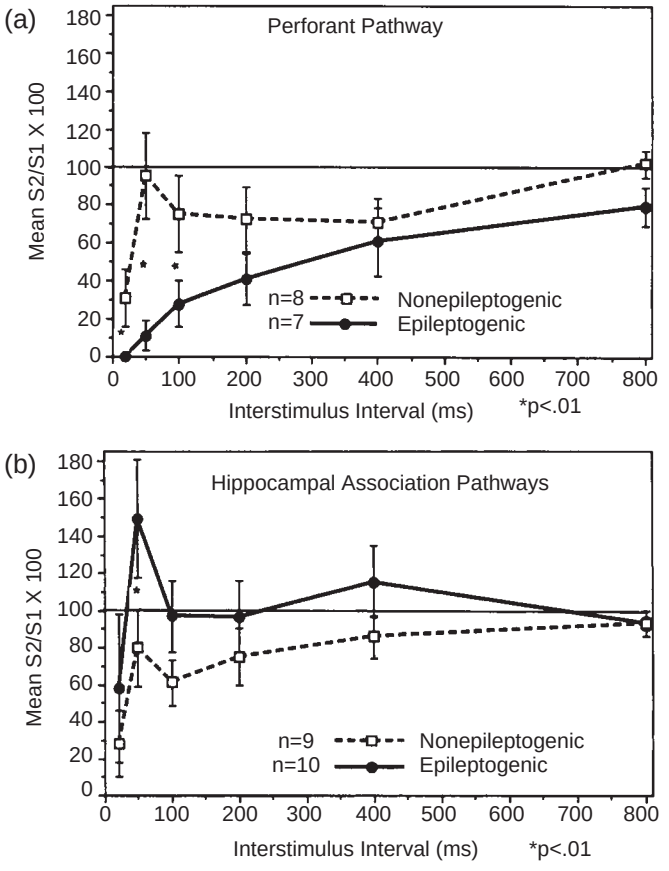

Figure 99.2 Mean differences in paired pulse excitability plotted for perforant path and intrinsic associational pathways of the hippocampus based on pPSP amplitude measurement. (a) Shows that mean suppression for the epileptogenic perforant path was profound up to 100 ms, while the nonepileptogenic perforant path showed significantly less suppression, particularly at 50 ms. The graph in (b) shows that the mean excitability of nonepileptogenic intrinsic associational hippocampal pathways was not significantly different than found in the nonepileptogenic perforant path (a), while the mean epileptogenic intrinsic hippocampal S2 response seen in (b) was significantly facilitated at ISI 50 ms. Although the epileptogenic associational pathways showed greater excitability at all interstimulus intervals than either the nonepileptogenic intrinsic hippocampal pathway or the epileptogenic perforant pathway, these differences were not significant, except at 50 ms (P <.01). From Wilson *et al*.[16] with permission.

evidence that the epileptogenic zone might be identified by lower AED levels due to up-regulation of blood-brain barrier efflux transporters.[30] The potential for application of this new technology to visualize surrogate markers of epileptogenesis and epileptogenicity is enormous.

Optical intrinsic signal (OIS) imaging is an invasive technique for measuring localized changes in cerebral activity.[31,32] Several investigators are applying this technique to animal models of epilepsy, and it has been used in patients during surgery. Research on OIS could yield results in future that would make it a potential surrogate marker of epileptogenicity, particularly if noninvasive measurements through the skull eventually become possible.

Gene expression

Microarray technology is now being widely employed to examine alterations in the profile of genetic expression in animal and human brain regions that could correlate with specific epileptic abnormalities. Individual gene expression can be up-regulated or down-regulated as a feature of the dynamic processes that cause, or result from, epileptogenic disturbances. The sum total of these alterations in individual gene expression make up a profile, or genetic fingerprint, which could possibly serve as a surrogate marker of epileptogenicity or epileptogenesis. If such genetic fingerprints are identified, it might be possible to construct tracers that would allow them to be visualized noninvasively with PET, or with MNP-MRI.

The future of pre-surgical evaluation

Because the field is moving so rapidly, it is premature to speculate on what pre-surgical evaluation might look like a decade or two in the future. Ideally, it should be based on a simple surrogate marker of epileptogenicity that would, noninvasively and interictally, identify the location and extent of the epileptogenic zone in three dimensions in the whole brain. This is much more likely to require a neuroimaging approach than a purely electrophysiological one, although advances in three-dimensional source localization, particularly with MEG, could permit the latter to be a valuable contributor to this analysis. As with the current pre-surgical evaluation, two or more different measures utilizing independent methodologies would be essential to ensure a high degree of reliability. None of these measures, however, would be concerned with delineating the irritative zone, ictal onset zone, structural epileptogenic lesion, symptomatogenic zone, or functional deficit zone. All would be direct measures of the epileptogenic zone.

The most promising candidate for a surrogate marker of the epileptogenic zone to date would be some mechanisms for identifying neuronal tissue generating FR. This could be achieved with MEG MRI fusion, or with EEG-fMRI averaging. Confirmatory tests would then involve a biochemical marker such as AMT, or perhaps a tracer based on gene expression profiles, that could be used with PET, or conjugated with a MNP to make it visible on MRI. Other confirmatory tests of the epileptogenic zone might be achieved through TMS measures of neuronal excitability and noninvasive approaches to image OIS.

Although the holy grail of this futuristic view of pre-surgical evaluation depends upon *noninvasive* measures of surrogate markers of epileptogenicity, the concept of the surrogate marker is that it measures the *potential* for seizure generation and, therefore, is present all the time, not just during seizures. Even if measurements of surrogate markers continue to require invasive monitoring, they could be carried out intraoperatively and obviate the need for ictal recording. This alone would greatly reduce the cost, and to some extent the risk, of pre-surgical evaluation. Such intraoperative invasive monitoring, however, would not likely achieve the same potential for three-dimensional localization as MEG and neuroimaging.

Continued basic animal, as well as human, research into mechanisms of epileptogenesis and epileptogenicity will not

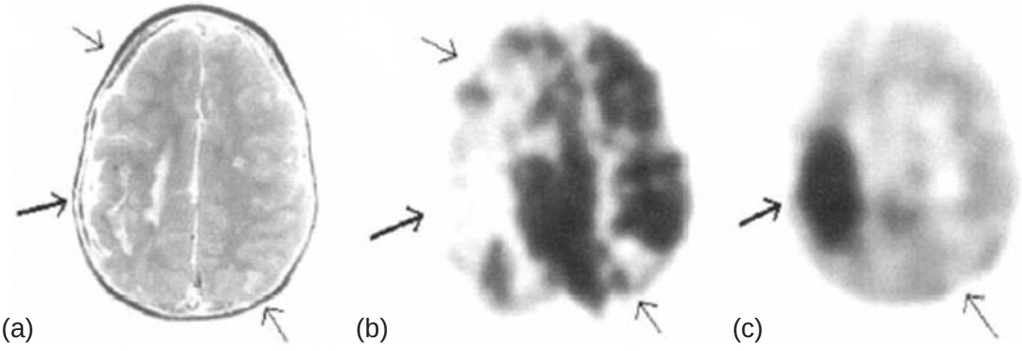

Figure 99.3 Magnetic resonance imaging (MRI) and positron emission tomographic (PET) scans in an 8-year-old girl (Patient 1) with tuberous sclerosis complex and intractable epilepsy. (a) MRI scan showing large tuber in the right central/parietal region (bold arrow) as well as other smaller lesions (thin arrows). (b) The glucose metabolism PET scan shows cortical hypometabolism in the same regions as the lesions seen on MRI (arrows). (c) α-[^{11}C]methyl-L-tryptophan ([^{11}C]AMT) standardized uptake value images display decreased tracer uptake in the location of small tubers compared with adjacent nonlesional cortex (thin arrow). The large right central tuber (bold arrow) shows a 110% increase in [^{11}C]AMT uptake. The left side of the image is the right side of the brain. From Chugani *et al*.[21] with permission.

only provide targets for novel treatments, but also for construction of surrogate markers that can delineate the epileptogenic zone. The latter should be a high priority, especially given that surgical resection of the epileptogenic zone remains the only curative treatment for epilepsy.

SECTION 12

The patient management meeting

100 The patient management conference

M Carreño and HO Lüders

Introduction

All patients with intractable epilepsy who are being considered for epilepsy surgery should be discussed at the patient management conference. During pre-surgical evaluation, a considerable amount of information regarding a particular patient is gathered. At the Epilepsy Monitoring Unit, a detailed seizure history is taken, prolonged interictal and ictal EEG is recorded, EEG tracings and seizure semiology are carefully analyzed, and valuable information about seizure onset zone can be obtained.

Anatomic and functional neuroimaging techniques are also essential during pre-surgical evaluation, and should always include a high resolution MRI to detect possible epileptogenic lesions. In some cases, interictal SPECT and PET and ictal SPECT (specially if co-registered with MRI), may be necessary to localize the functional deficit and seizure onset zone respectively.

A thorough neuropsychological examination is also mandatory, as it may help to localize the functional deficit zone and, more importantly, to predict possible functional deficits after the planned cortical resection. Psychiatric evaluation is also routinely performed at our institution. It is very useful to detect and treat psychiatric comorbidity frequently associated to epilepsy and to assess psychosocial issues that may be relevant for the surgical management.

When the results of all these tests are available, the physician taking care of the patient (neurologist or epileptologist) should present the patient at the management conference. The conference brings together the different members of the epilepsy surgery team: epileptologists, neurophysiologists, neurosurgeons, neuroradiologists, nuclear medicine doctors, psychiatrists, neuropsychologists and nurses. Epilepsy surgery requires multidisciplinary collaboration, and the patient management conference permits review of all the data regarding a particular patient, interpretation of the results of the different tests in light of each other and exchange of opinions; it facilitates a consensus decision about surgical candidacy, surgical technique and possible risks the patient and his family should be counselled about. (Table 100.1)

The conference should be held at regular intervals, preferably in a standarized way, so several patients can be discussed in one session. A brief summary including seizure history, results of video-EEG monitoring, MRI, and functional neuroimaging tests, together with neuropsychological and psychiatric evaluation, is useful to introduce the different members of the team and guide the discussion.

The conference is also an excellent educational opportunity for students, residents and fellows; and multidisciplinary case discussions, especially of the difficult cases, is always a source of ideas for future clinical and basic research.

History

Every case discussion at the patient management conference should start with presentation of a detailed but summarized seizure history, including age at seizure onset, different types of seizures, seizure semiology, seizure frequency, and seizure duration. Handedness and any relevant findings in the neurological exam should be mentioned. Family history, risk factors for epilepsy, and possible etiologies should be discussed, together with medical treatments received in the past, their length, and side effects. At this point medical intractability should be clear. It is important to discuss also other medical conditions which may be relevant for the management of the patient. Most of these aspects may be adequately summarized in the five dimension epilepsy classification.

Video-EEG

Results of the prolonged video-EEG evaluation should be presented, either by the epileptologist taking care of the patient or by the epileptologist who was in charge of the patient when he was admitted to the Epilepsy Monitoring Unit. The epileptologist should discuss the following information: interictal nonepileptiform and epileptiform abnormalities (frequency and distribution), number of seizures recorded, seizure semiology, and ictal EEG. It is important to mention also the time interval between clinical onset and EEG onset, as the interpretation about location of seizure onset zone may vary depending on this time difference. Although information about interictal and ictal EEG is included in the final report of prolonged video-EEG, we usually display the actual tracings so they can be viewed and discussed by the different epileptologists and neurophysiologists attending the meeting. This can be done easily with the digital video equipments. We also find very useful to project digital videos to illustrate each seizure type. It is a good opportunity to discuss seizure semiology, postictal deficits and also to teach residents and fellows.

After the clinical history and the video-EEG evaluation have been presented, there should be a hypothesis about

Table 100.1 Patient management conference

Date:

cortical regions involved in seizure generation. This hypothesis should be compared with the results of neuroimaging tests and neuropsychological studies which are presented later on.

Neuroimaging

Anatomic neuroimaging

An essential exam during pre-surgical evaluation of a patient with medically intractable seizures is a high-resolution MRI, which includes all the specific sequences which are specially relevant to view epileptogenic lesions such as malformations of cortical development. The written report of a given MRI may have been done by a general neuroradiologist, but is important that a neurorradiologist with experience and an interest in epilepsy is present at the conference to review the digital images; special attention must be paid to the cortical regions which may be involved in seizure generation according to the clinical and video-EEG data. It is not uncommon that subtle abnormalities, considered 'nonspecific' when the MRI was initially reviewed, are reinterpreted as 'significant' during the meeting. The epileptologists and the neurosurgeon may also ask the neuroradiologist about the proximity of the epileptogenic lesion to eloquent brain areas, which may be relevant for the surgical planning.

Functional neuroimaging

Results of interictal and ictal SPECT should be presented by a specialist in nuclear medicine, as well as the PET scan if this was done during pre-surgical evaluation. In the case of ictal SPECT, it is very important for a correct interpretation to mention when the raidioisotope was injected respect to EEG seizure onset. Once again, the findings in MRI may help to consider clinically relevant subtle abnormalities which could have been dismissed otherwise.

Functional MRI (fMRI) is a technique increasingly used to localize eloquent cortex, especially motor and language areas. In some institutions, it is replacing Wada test to lateralize language dominance. Results of fMRI, if done, should be presented at this point.

Neuropsychological evaluation

Results of neuropsychological evaluation which should be presented at the conference include overall evaluation of intellectual function and assessment of memory. This information helps to lateralize and localize the functional deficit zone, but is most valuable for predicting possible functional deficits after surgery (mainly memory loss).

If performed, results of the Wada test should be presented also. In our institution, Wada test is not routinely performed in every patient. It is used mainly to lateralize language dominance when surgery close to potential language areas is planned. It is also used to assess risk of memory loss when planning resection of possibly dominant mesial temporal structures or when the MRI shows bilateral damage (for example, bilateral mesial temporal sclerosis) or there are signs of bilateral temporal dysfunction in the neuropsychological tests. Any incidence during the Wada procedure should be mentioned, especially those that may obscure the interpretation of the results, for example excessive sedation or incomplete paresis after the injection. Findings suggesting bilateral dependent or independent language should be discussed at length, because of their relevance in the management of the patient.

If a temporal resection is being considered, the neuropsychologists should give their opinion about specific risks of memory loss according to the results of the pre-surgical evaluation.

Psychiatric evaluation

All patients admitted to our Epilepsy Monitoring Unit undergo psychosocial and psychiatric evaluation. The psychosocial evaluation helps to understand the family, social and work environment of the patient, and the impact of persistent seizures in his quality of life. It helps also to clarify the patient and family's expectations about surgery, see if these are realistic and estimate the possible impact of the patient's personality and family and social support in surgical outcome. Psychosocial evaluation is essential to assess if the patient is able to fully understand risks and possible benefits of surgical procedure and give his/her informed consent.

We strongly believe also that psychiatric evaluation should be a routine part of pre-surgical process, given the high incidence of psychiatric disorders among people with epilepsy, its impact in the perceived quality of life of the patient, and its possible role in surgical outcome regarding quality of life. The psychiatrist involved in the epilepsy team should present the data regarding psychiatric comorbidity, suggested treatment, and possible evolution of the psychiatric disorder after epilepsy surgery.

Discussion of management issues

Once the different aspects of pre-surgical evaluation have been presented and the details discussed by the different specialists, the members of the team should be asked their opinion about further management of the patient. The main question to answer is: is the patient a surgical candidate? To be a surgical candidate, the patient must have medically intractable epilepsy; the seizures must be arising from one well-localized region that can be removed without inacceptable neurological deficits. If the answer is yes, the patient is a surgical candidate, and the best surgical procedure to achieve seizure freedom without neurological deficits should be discussed. The neurosurgeon should give his or her opinion about the planned cortical resection and specific surgical risks. Other risks involved in the planned resection, such as memory loss in case of temporal resections can also be discussed at this point, together with the patient's willingness to accept them.

If the members of the team feel that the suspected epileptogenic region has not been adequately localized but otherwise think there is a reasonable chance that the patient finally becomes a surgical candidate, more invasive studies including intracranial electrodes may be suggested. A clear hypothesis about location of epileptogenic zone to guide the placement of electrodes is essential to proceed. The areas to be studied with intracranial electrodes should be detailed, with the neurosurgeon having an active part in the surgical planning.

If the patient is not considered a candidate for resective surgery, other options could be mentioned, including vagal nerve stimulator placement and ketogenic diet.

The management discussion assists the neurologist/epileptologist and the neurosurgeon in their final decision regarding surgical candidacy of one particular patient, and reassures patients and families because all specialists involved and other epileptologists have participated in the consensus.

Case presentation

Case 1

J.M.G is a 24-year-old young right-handed young man. He was the product of a normal pregnancy and delivery, and had a normal psychomotor development. At the age of 18 months he had an uncomplicated febrile seizure, but otherwise he had no other risk factors for epilepsy. Seizures started at the age of 5 years, 3 days after chicken pox vaccination. Seizures consisted of repetitive, high amplitude movements of the four limbs, with lack of response, lasting approximately 2–3 minutes and occurring mainly during sleep, but also during wakefulness. According to the family, he recovered quickly, without postictal confusion or aphasia. Seizure frequency was 1–2 per day when he first was referred to us. The previous month he had been admitted to a local hospital because of increased seizure frequency without obvious precipitants (up to 100 seizures per day) The longest seizure-free period had been two years. Previous treatments included carbamazepine, valproic acid, levetiracetam, vigabatrin, gabapentin, phenytoin, phenobarbital, and lamotrigine.

When he was referred to our unit he was treated with oxcarbazepine (1800 mg per day), topiramate (500 mg per day), and clobazam (10 mg per day).

He studied until he was 16, but at that point he stopped going to school because of repetitive seizures. He was unemployed when he was referred to us.

He was admitted to the Epilepsy Monitoring Unit in November 2004. Interictal EEG showed continuous slowing in the theta range over the left fronto-central region, ocassionally rhythmic, together with bursts of generalized slowing lasting 2–3 seconds and seen every 5–10 minutes. Frequent polyspikes were seen either bifrontally, with a maximum over the left frontal region (FP1>F3>F5>Fp2>Fz), or more localized over the left frontopolar area (FP1>F5>F3). The frequency was once every 30–60 seconds during awake and once every 5–10 seconds during sleep (Figures 100.1 and 100.2). In addition, bursts of bifrontal, max left (FP1>F3>F5) paroxysmal fast activity, of 3–5 seconds duration, were seen during sleep, once every 10 minutes approximately.

Thirty seizures were recorded during EMU stay, mainly during stage I and stage II sleep. Seizure semiology was very similar in all seizures: the patient suddenly woke up, sat up in bed and displayed high amplitude movements of trunk and arms (as if he was trying to reach for objects) and repeated vocalizations, with lack of response. Seizures' duration ranged between 30–60 seconds. The patient recovered quickly, without postictal confusion. He was amnestic for all that happened during the seizures. Ictal EEG showed a generalized electrodecremental pattern, followed by fast paroxysmal activity (15 Hz/10 mV) over the left frontal region (max Fp1>F3>F5>Fp2>Fz). After 4–8 seconds, this activity evolved to a higher voltage theta rhythm (5–7 Hz/40-60 mV) which was lateralized over the left hemisphere, soon obscured by muscle artifact. After the seizures, focal continuous slowing was evident over the left frontal region.

Injection of radioisotope for ictal SPECT happened 22 seconds after seizure EEG onset. MRI showed a dysplastic lesion over the medial part of the left superior frontal gyrus and the polar portion of the orbital region, compatible with cortical dysplasia (Figure 100.2): Ictal SPECT co-registered with MRI showed increased perfusion over the more anterior and mesial part of the malformation of cortical development (Figure 100.3).

Neuropsychological study showed intellectual level in the low-medium range. There was some psychomotor slowing in fine visuomanual coordination tasks and execution of movement sequences, together with slowing and fluctuations in verbal learning ability.

Psychiatric evaluation showed mildly depressed mood without obvious need for antidepressant drugs.

All physicians attending the conference agreed that the patient had medically intractable left frontal epilepsy with hypermotor seizures due to cortical dysplasia over the left frontal region (Figure 100.4). It was clear that the patient had medically intractable epilepsy and that his seizures were significantly interfering with his daily life. The neurorradiologist and the neurosurgeon were asked about the proximity of the lesion to the expected location of Broca's area. Both concluded that the lesion was outside this area, and the neurosurgeon concluded he could safely resect the abnormal region on MRI.

The patient and his family were informed about the procedure, possible benefits, and risks of surgery. He was given an approximately 60% chance of seizure cessation. The malformation was resected. Pathology showed heterotopic neurons

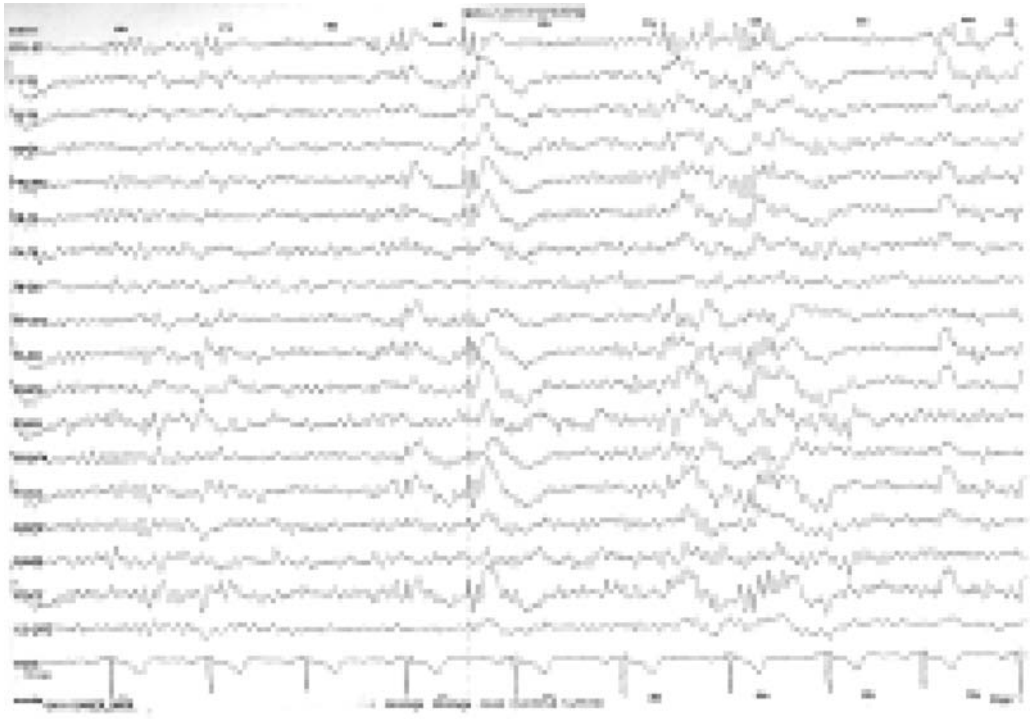

Figure 100.1 Repetitive frontopolar spikes.

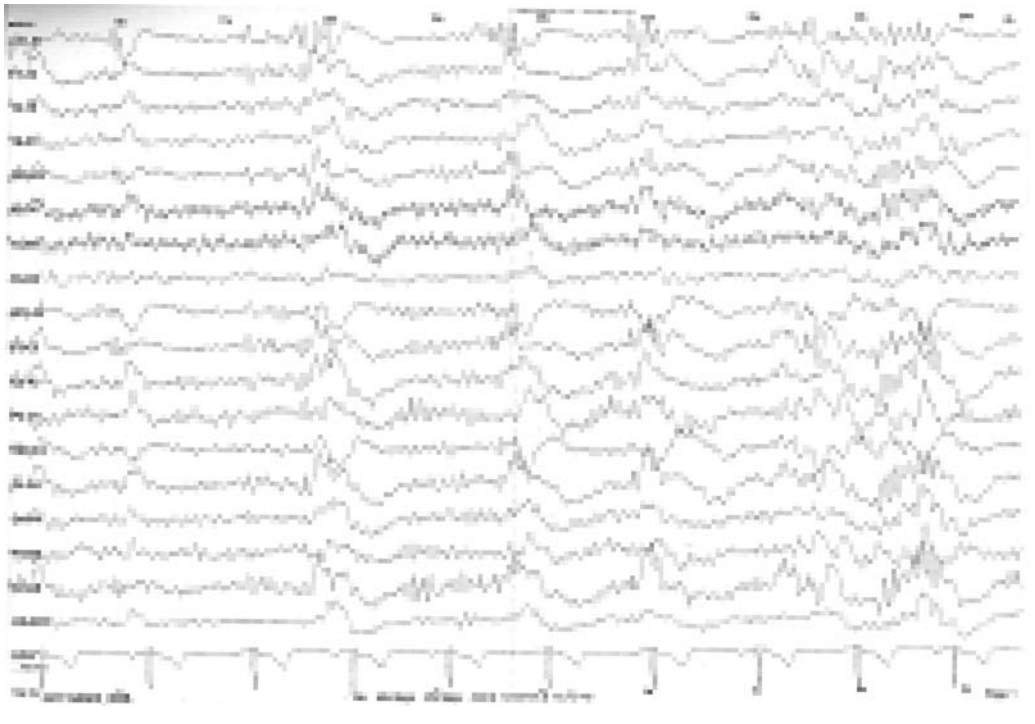

Figure 100.2 Repetitive frontopolar spikes.

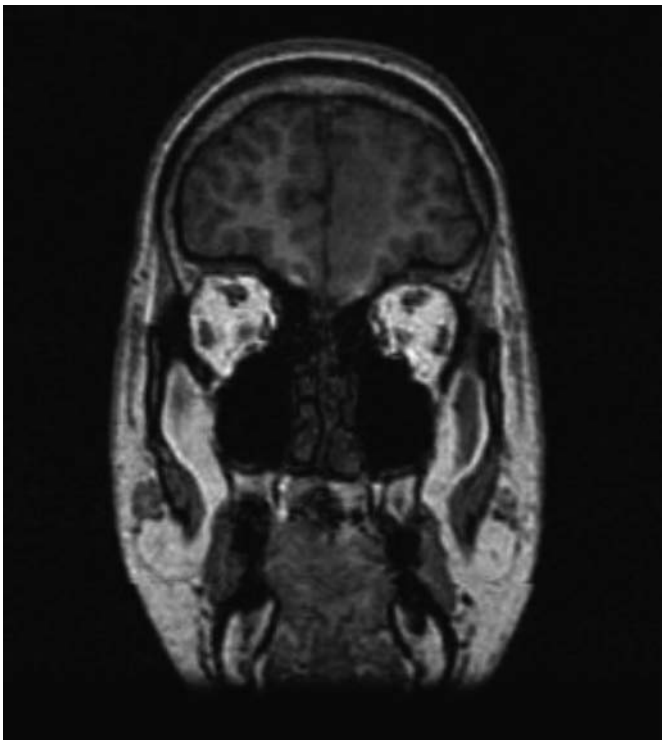

Figure 100.3 Coronal T1-W image showing malformation of cortical development over the left mesial frontal region.

and balloon cells. The patient has been seizure free since surgery. There was a temporary behavior abnormality (the patient was apathetic, with lack of inititative, and unwilling to get up and move) for 6 or 7 days after surgery. This seemed to resolve after discharge, and he has currently returned to his normal life.

Case 2

B.P.A. is a 32-year-old left-handed woman with seizures since the age of 27. She had no significant risk factors or family history of epilepsy. Seizures were characterized by an aura described as 'nervousness, together with a warm rising sensation'. Rarely she felt an auditory aura (beep in her ears, which she could not further localize). The aura was followed by a change in facial expression and clenching of both fists, without clear oral or manual automatisms. There was partial loss of awareness. At times, however, she was able to follow simple commands at the beginning of the seizure and the family stated that she was able to speak intelligibly during seizures, although sometimes the content of the sentences was inappropiate. Seizures lasted 1–2 minutes and thereafter she was slightly confused for another 4 minutes. She had never had a secondarily generalized seizure.

Seizure frequency was initially one every 10 days, but had progressively increased in spite of treatment with antiepileptic drugs. Seizures happened on a daily basis when she was first referred to us. She had failed treatment with carbamazepine, topiramate, and lamotrigine. She currently was treated with oxcarbazepine (1200 mg per day) and clobazam (20 mg per day).

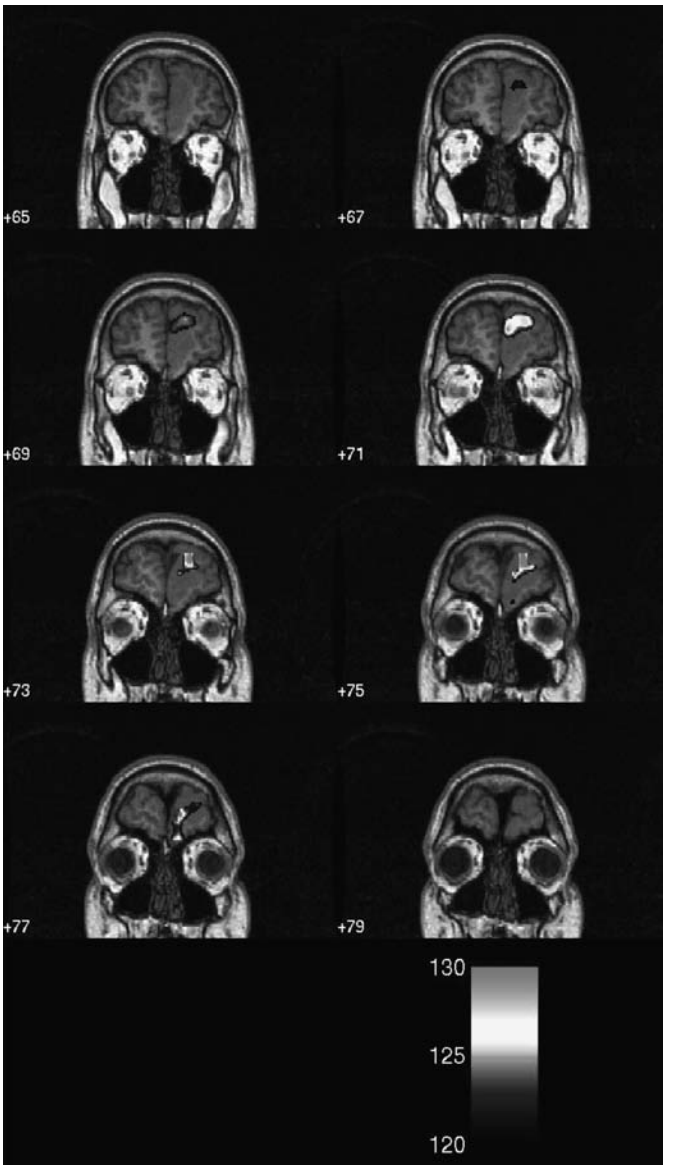

Figure 100.4 SISCOM showing hyperperfusion over the cortical dysplasia in the left mesial frontal region.

She was admitted to the Epilepsy Monitoring Unit in 2004. Right temporal sharp waves were seen, with a maxium over the middle temporal region (T4>FT8>FT10), once every 5 minutes (Figure 100.5). In addition there were left anteriotemporal sharp waves (max FT9>F9>T7, TP7), seen less frequently (once every 20 minutes of recording) (Figure 100.6). Five seizures were recorded, which were characterized by changing in facial expression, loss of awareness, and subtle oral automatisms, with ictal speech. There was no postical dysphasia. Seizures were nonlateralized on surface EEG, being characterized by irregular theta slowing over both temporal regions (Figure 100.7). Isotope for ictal SPECT was injected after 40 seconds of EEG onset.

The MRI showed a lesion in the white matter of the right temporal lobe compatible with cavernoma (Figure 100.8). There were no alterations in morphology or signal intensity of both hippocampi. Gradient sequence did not identify signs of bleeding in any other locations. Ictal SPECT co-registered with MRI showed increased focal perfusion over the mesial and basal region of both temporal regions, more pronounced on the left side (Figure 100.9).

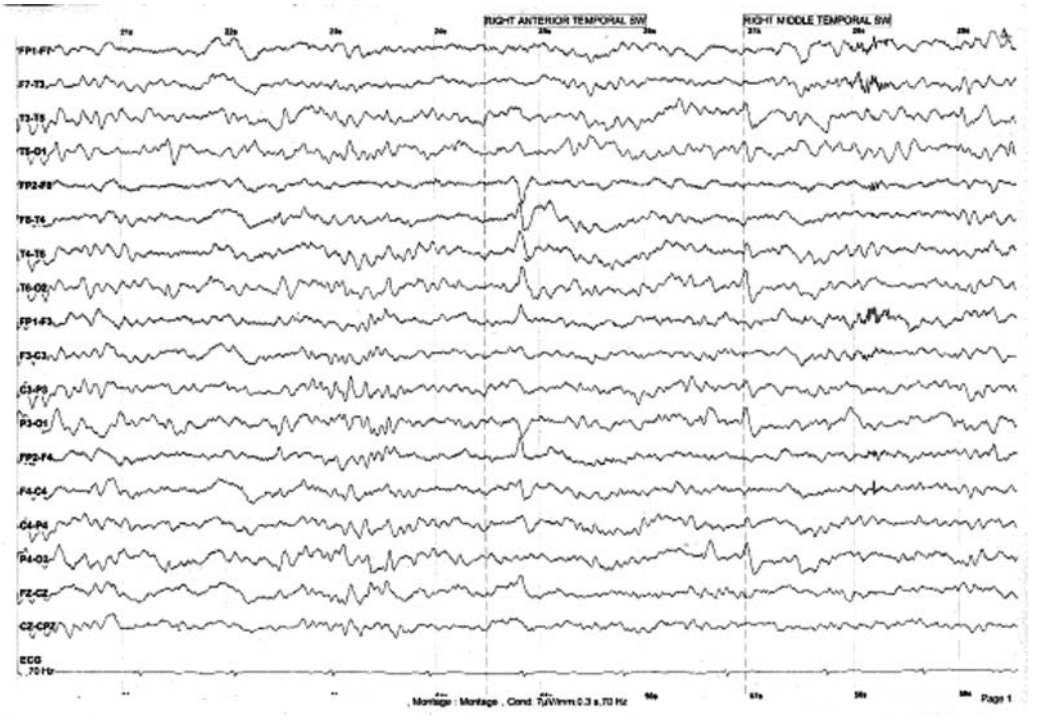

Figure 100.5 Right anterior and middle temporal sharp waves.

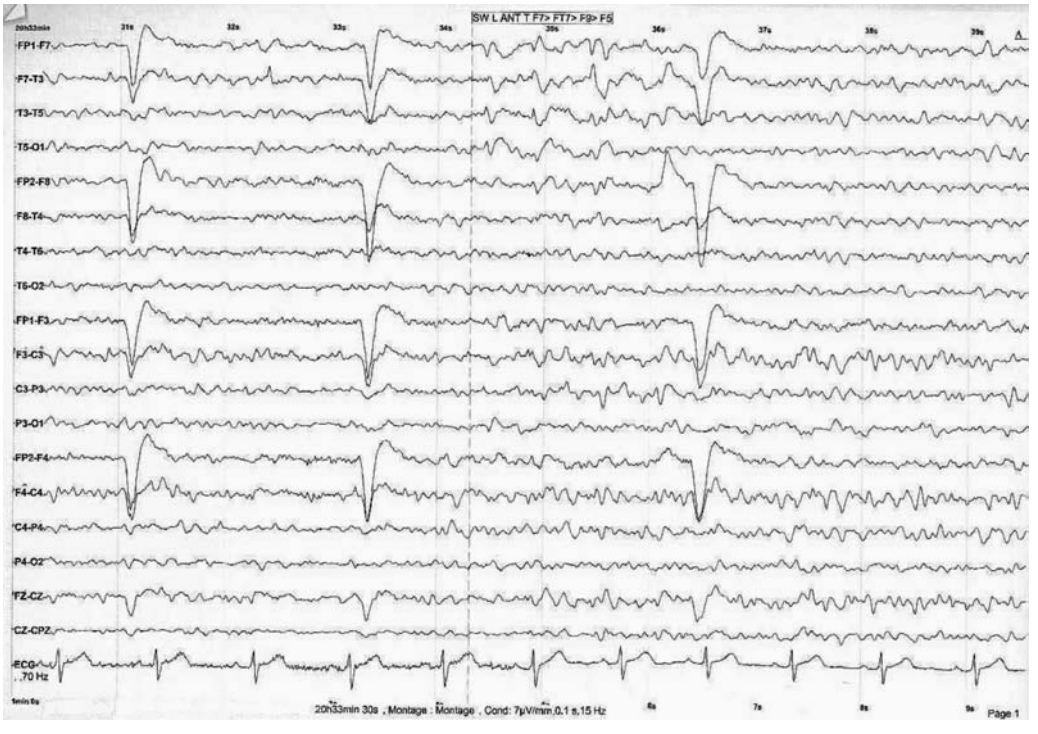

Figure 100.6 Left anterior temporal sharp waves.

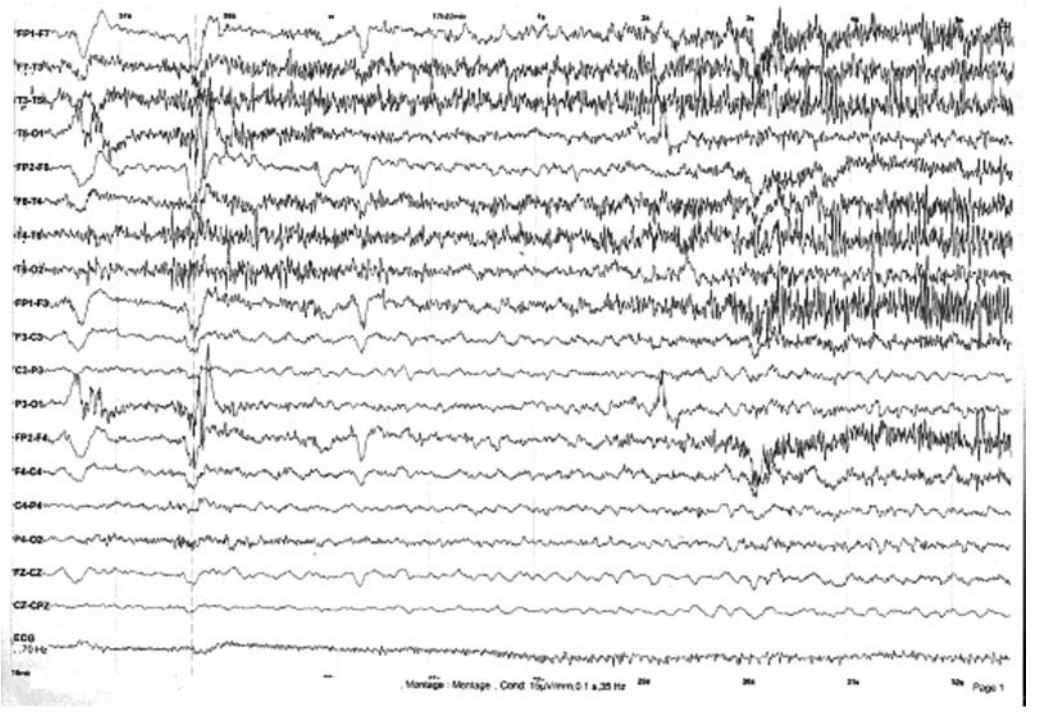

Figure 100.7 Ictal surface EEG. Nonlateralized theta.

Wada test showed right hemisphere dominance for language (she became mute after right carotid injection, while she continued to talk after left injection), with good functional memory reserve on the left side.

Neuropsychological study showed intellectual level in the normal range, with a subtle deficit in verbal fluency tasks (mainly with semantic clues), a slightly inferior than expected performance in naming and a slow verbal learning curve. No alterations in memory were seen. All these subtle difficulties suggested an initial involvement of dominant temporal structures. Psychiatric evaluation showed mild depression.

During the patient management conference it was concluded that the patient had medically intractable temporal lobe epilepsy, probably secondary to cavernous angioma located on the right temporal neocortex. However there was some concern that the seizure onset zone had not been adequately lateralized during the pre-surgical evaluation (the pattern on surface EEG was bitemporal, and also the ictal SPECT co-registered with MRI suggested a bitemporal ictal onset). In addition, ictal speech suggested seizure onset in the nondominant hemisphere which was discordant with the findings in the Wada test. After discussing risks and benefits, it was concluded that the patient would be offered video-EEG with placement of foramen ovale electrodes (FOE) to better lateralize the seizure onset zone. The possibility that seizure onset could not be accurately recorded with the FO electrodes if arising from the temporal neocortex was also discussed. The patient agreed to the semi-invasive evaluation. Interictal EEG showed abundant epileptiform activity over the contacts which were closest to the mesial structures on the right side (Figure 100.10). Seizure onset was also in the right temporal mesial region (Figure 100.11).

The patient was discussed again in another patient management conference and the best surgical technique was discussed. Everybody agreed that she should have a lesionectomy, leaving the right hippocampus in place, in view of its normal apperance in MRI, to avoid memory loss.

The patient underwent resection of the cavernoma in April 2005. She has been seizure free since then. Neuropsychological evaluation has shown no memory decline.

SECTION 13

Surgical techniques for placement of intracranial electrodes

101 Anesthesia for epilepsy surgery

M Lotto and A Schubert

Introduction

Epilepsy surgery adds a level of complexity to the anesthetic care of the neurosurgical patient. Anesthetic selection significantly impacts surgical procedures which require intraoperative mapping of the epileptic foci or identification of eloquent tissue during resection of epileptogenic tissue. Designing an anesthetic that can produce varying depths of patient sedation and the patient participation necessary for speech and motor mapping requires forethought, skill and occasionally luck. In addition, anesthetic agents have a wide variation and sometimes confusing profile of proconvulsant and anticonvulsant effects that must be taken into consideration. There are also significant pharmacologic interactions between anticonvulsant medications and anesthetic drugs. Developing an anesthetic care plan that facilitates the patient's best interests and the intraoperative goals of the surgeon and neurophysiologist requires intimate knowledge of the pharmacology of the patient's antiepileptic medications and the anesthetic agents. Good communication between the anesthesiologist, surgeon and neurophysiologist is critical in achieving patient safety and a successful procedure. This chapter presents an overview of the anesthetic care of the epileptic patient undergoing epilepsy surgery, with a focus on the pharmacology of common anesthetic agents and how these drugs impact both epileptic surgical procedures and perioperative events in epileptic patients.

Pharmacology of anesthetic agents

Given the modification of neuronal transmission generated by anesthetic agents, it is not surprising that these drugs can have significant effects on CNS excitation events. However, the literature describing the pro- versus anticonvulsant effects of many anesthetic agents can be confusing and seemingly contradictory. One may produce reports which implicate the same drug in both precipitation and termination of seizure activity.[1,2] The mechanisms behind the conflicting convulsant effects of these agents are not completely understood. However, several authors attempted explanation by proposing that the ratio of affected inhibitory or excitatory neurons in both the cortical and subcortical brain structures varies with depth of sedation. EEG recording supports altering activation and inhibition of the cerebral cortex with administration of anesthetic agents. During light sedation reveals cortical activation with higher frequency beta activity which then progresses to slow wave activity as sedative/anesthetic depth increases.[3]

Some of the confusion may also be attributed to the method of documentation of epileptic activity used in the case reports of anesthetic drug related seizure activity. Several induction agents, such as propofol and thiopental, have been demonstrated to induce myoclonic activity not associated with EEG excitatory activity[4]; while others agents (etomidate, methohexital) have been shown to generate both myoclonus and EEG documented epileptiform activity in patients.[5]

Sedative hypnotic agents

As a group, these agents have the greatest variation and most confusing profile as far as effects on epileptogenic activity. Most of the agents can generate neuroexcitatory effects when used at low doses, and neurodepressive effects when used at higher doses. Motor stimulatory phenomena, such as myoclonus, opisthotonus, and tonic clonic activity may occur with varying frequency in both epileptic and nonepileptic patients during induction with these agents, however, only a few actually produce cortical electrical activity suggestive of seizures.

Methohexital, etomidate and ketamine are known to activate EEG seizure activity when administered to patients with a history of epilepsy.[6,7] Motor activity may not occur with the induction of abnormal spike wave activity. Both etomidate and methohexital have been used to assist with activation of ictal foci during intraoperative electrocorticography.[8,9] These agents may also generate nonepileptic myoclonic activity during induction which can be mistaken for epileptic convulsions.

Etomidate has a dichotomous effect on seizure thresholds, producing EEG confirmed epileptic activity when used as an induction agent in epileptic patients, as well as producing burst suppression and breaking status epilepticus when administered in higher doses.[10,11] Ketamine appears to have a dose dependent threshold for seizure generation, with most reported cases of clinical seizure activity occurring when doses greater than 4 mg/kg are administered.[12]

Despite an early report of seizure induction with propofol injection, propofol has demonstrated a good safety record and low epileptogenic potential when used in patients undergoing epilepsy surgery. The anticonvulsant properties of propofol are fairly well established, although the antiepileptic effect may be shorter acting after discontinuation of propofol than thiopental.[13,14] The short acting antiepileptic nature of propofol can be useful for sedation during epileptic procedures, generating fewer seizures in between monitoring periods than neurolept anesthesia.[15] However, propofol has also been observed to decrease the frequency of epileptogenic spikes and to quiet existing seizure foci, particularly in the lateral and

mesial temporal areas.[16] In addition, propofol may generate beta EEG activity obscuring spike wave activity for up to 20 minutes following discontinuation of the infusion.[17,18] See Figure 101.1. Therefore, propofol infusions should be discontinued 20–30 minutes prior to electrocorticography (ECoG) monitoring to facilitate successful location of the ictal foci.[19]

Barbiturates and benzodiazepines have substantiated anticonvulsive properties and are recommended for treatment of refractory status epilepticus.[20]

Volatile inhalational agents and N_2O

The epileptogenic potential of isoflurane, desflurane, and halothane appears low, and there have been no reported seizures when used in isolation.[21] However, there are rare reports of myoclonic activity with a normal EEG. Convulsions with spike and wave activity on EEG have been reported with combinations of isoflurane and N_2O.[22,23] Although N_2O has been associated with seizure generation when used to supplement other agents, it appears to be fairly inert in both the development and treatment of seizure activity in humans.[24] Both N_2O and isoflurane have been used for many years at multiple institutions with a good safety record in epileptic patients.

Enflurane, used either with or without nitrous oxide, has been the most frequent offender with reports of intraoperative and postoperative myoclonus and EEG demonstrated epileptiform activity in both epileptic and nonepileptic patient populations.[7,8,24–27] The incidence of EEG spike wave production with enflurane appears to be dose dependent. The end tidal concentration that triggers maximum epileptiform activity is reduced during hypocapnia. Enflurane has fallen out of favor as new inhalational agents have become available and it is currently rarely used clinically in the United States. Enflurane should be avoided in patients with a history of epilepsy, unless the desired effect is triggering seizures during ECoG. Sevoflurane, but not desflurane has been reported to generate convulsions as well as electrical spike waves in both epileptic and nonepileptic patients.[21,28] Similar to enflurane, the frequency of spike wave activity with sevoflurane increases with dose escalation and hyperventilation.

Analgesics

The effects of opioids on seizure threshold vary with opioid drug class. Synthetic opioids such as alfentanil, fentanyl, sufentanil, and the more recently introduced remifentanil are commonly used in neurosurgical anesthesia due to the short duration of action and ability to minimize cortical effects through continuous infusion. Synthetic opioids have been reported to have some proepileptic properties; however, the potency of seizure production is unclear. Bolus doses of synthetic opioids, such as alfentanil and remifentanil have been demonstrated to increase spike wave activity in the interictal foci of patients undergoing intraoperative EcoG.[29,30] In fact, bolus doses of these agents may be useful in ECoG to facilitate location of the ictal cortex through stimulation of spike wave phenomenon with concomitant depression of background EEG. Fentanyl has been associated with epileptiform electrical activity in subcortical nonictal cortical tissue, therefore the author prefers to avoid the dosing range in which epileptogenic properties have been observed (17–25 μg/kg).[31] The clinical history of the use of synthetic opioids in large numbers of epileptic patients undergoing ablative procedures suggest that synthetic opioids can be used safely in this patient population without significant increase in the risk of perioperative seizures.

The neurostimulatory effects of the long-lived meperidine metabolite, normeperidine have been well documented. Normeperidine can accumulate with chronic oral or parenteral administration of the drug. The normeperidine metabolite is renally excreted and can accumulate to neurotoxic doses more rapidly in patients with renal insufficiency.[32] Convulsions may occur in both epileptic and nonepileptic patients receiving repeated administration of meperidine. Concurrent administration of meperidine with anticonvulsants may increase the first pass metabolism of meperidine to normeperidine, making it a significant risk for epileptic patients treated with anticonvulsant medications.[33]

Morphine and hydromorphone used at clinically relevant doses do not appear to have significant proconvulsant activity.[24]

Muscle relaxants

Chronic anticonvulsant therapy with phenytoin and/or carbamazepine can result in reduction of the duration of effect of nondepolarizing neuromuscular blockers, including pancuronium, vecuronium, rocuronium, atracurium, and cis-atracurium.[34–36] The etiology of the phenomenon was initially contributed to induction of hepatic enzymes leading to faster breakdown of muscle relaxant agents. However, the resistance to nonhepatically metabolized agents such as atracurium and cis-atracurium suggest additional effects on metabolism and possible competitive interactions between neuromuscular blockade and anticonvulsants at the neuromuscular junction.[37]

Anesthetic goals

Goals of anesthetic management

In providing perioperative care for the patient undergoing epilepsy surgery, the anesthesiologist aims to give a continuum of critical care throughout the perioperative period. Intraoperatively, the common goals of neurosurgical anesthesia apply, including adequate brain relaxation for surgical manipulation, good systemic blood pressure control, and timely emergence from anesthesia to allow for early postoperative neurologic examination of the patient. Procedures requiring seizure induction for epileptic foci monitoring require avoidance of inducing a prolonged epileptogenic event or patient injury during an intraoperative tonic clonic event. In treating unintentional seizure activity the anesthesiologist weighs the therapeutic goals of seizure control against the potential for oversedation or interference with critical electrocortical monitoring.

Preoperative evaluation and preparation

Seizure history

The nature and manifestations of the patient's seizures should be inquired about preoperatively. Epileptic activity can occasionally be difficult to discriminate from psychomotor behavior sometimes displayed during emergence delirium. Familiarity with the patient's seizure pattern promotes recognition and awareness of perioperative seizures. In all cases, the anesthesiologist should maintain a high degree of suspicion for an epileptic etiology in a patient who has prolonged emergence, poor responsiveness, or repetitive motor movements in the postoperative period.

Associated medical conditions

Most patients presenting for epilepsy surgery are relatively young and fit from the cardiovascular and respiratory standpoint. Any patient with a significant end organ dysfunction or complex past medical history should have a comprehensive preoperative anesthetic evaluation prior to surgery. Open craniotomy is considered a moderate risk procedure (indicating a less than 5% risk of cardiac events) with regards to its taxing effects on the cardiovascular system of the patient.[38]

Several rare medical conditions associated with epilepsy may present significant challenges to the anesthesiologist. Patients with neurofibromatosis may have intracranial tumors, airway compromise from tumors involving the respiratory tract or from cranial nerve involvement. Pulmonary status may be compromised from chronic aspiration syndrome, pulmonary fibrosis, and pulmonary hypertension.

Medication history

Medication history is important for preoperative laboratory test selection and predicting intraoperative drug interactions. Antiepileptic agents have been demonstrated to have significant impact on the dose response curve for both nondepolarizing muscle blockers and opioids. Both phenytoin and carbamazepine are associated with resistance to nondepolarizing neuromuscular blockade[37] and elevated liver function tests. The direct relationship between the number of anticonvulsants a patient receives, and the dose of fentanyl required for intraoperative anesthetic maintenance[39] further suggests that anticonvulsant therapy predisposes resistance to opioids. Elevations in hepatic enzymes are prevalent (gamma-glutamyl transpeptidase is elevated in 75% and alanine aminotransferase in 25% of patients receiving anticonvulsant therapy).[40]

Asymptomatic laboratory abnormalities should not cause cancellation of the surgery, since elevated liver function tests are almost always a predictable result of anticonvulsant therapy. Sedation and lethargy are common side effects of many antiepileptic agents including newer therapies such as Lamotriqine and oxcarbazepine and may potentiate the central nervous system (CNS) depressant effects of anesthetics. Carbamazepine may cause a severe depression of the hemopoietic system and cardiac toxicity in rare cases. This drug's metabolism is materially slowed by erythromycin and cimetidine, drugs which may be administered during the perioperative period. Valproic acid therapy results in dose related thrombocytopenia and platelet dysfunction.[41] A bleeding time obtained preoperatively is indicated to assess the potential for increased perioperative bleeding. Phenobarbital, phenytoin, or valproic acid may theoretically increase the possibility of halothane hepatitis since they induce its hepatic metabolism.[42]

Recent craniotomy

Small case series suggest significant pneumocephalus may be seen in post-craniotomy patients for up to 1 month after surgery.[43] Avoidance of nitrous oxide in patients who have had recent placement of intracranial electrodes would thus be prudent.

Psychologic preparation

Preoperative consultation and discussion of expectations has a significant impact on the anxiety of the patient undergoing neurological surgery. Planned intraoperative corticography or awake craniotomy should always be preceded by a realistic description of what the patient will experience including expected discomforts, level of cooperation and tasks that will be performed for speech and memory testing, and the possibility of events that may require rapid interventions including conversion to general anesthesia. It is important that the anesthesiologist develop an excellent rapport with the patient during the preoperative period. The interview should include

an assessment of the patient's ability to cooperate during a planned awake procedure. Patients who are too young, are mentally impaired, have personality disorders, behavioral problems, or difficult airways should not be considered for 'awake' craniotomy. The age cut-off utilized at the authors' institution is variable based on the adolescent's maturity. Children under 14, however, rarely tolerate this procedure awake.

Because intraoperative electrocorticography commonly requires significant reduction in the dose of sedative hypnotic agents for adequate EEG monitoring, patients should be prepared for the possibility of intraoperative awareness even when this procedure is performed under a general endotracheal anesthetic technique. The patient should be reassured that this experience is usually described as a painless awareness of voices or other sensations. Patients and their families need to understand that this is expected and that other risks such as perioperative seizure, nausea, vomiting, and airway compromise exist.

Intraoperative anesthetic approach

Diagnostic surgical procedures for intractable epilepsy

Placement of epidural ('peg') electrodes requires multiple burr holes and can be a lengthy procedure depending on the number of electrodes to be placed. 'Depth' electrodes exploring subcortical regions of the brain require stereotactic placement. The procedure is usually uneventful and not associated with significant bleeding. A general anesthetic is most frequently used at the authors' institution. Unless otherwise indicated for medical co-morbidity, only routine noninvasive monitoring is employed.

Implantation of subdural grid electrodes requires a full craniotomy. In our institution, this procedure does not generally involve EEG recording or stimulation as this is done postoperatively in the epilepsy monitoring unit. Therefore, we employ a standard anesthetic technique without special consideration for suppression of EEG components. As with any full craniotomy procedure, significant bleeding may occur from dural sinuses. This requires good IV access (two large-gauge IVs) and an arterial cannula. The anesthetic regimen should be constructed to allow rapid emergence for timely neurologic assessment. The electrode plates to be implanted are quite bulky and require brain shrinkage with mannitol and hyperventilation. One should be aware, hyperventilation to facilitate surgical exposure may precipitate seizure activity. It should be used only as necessary, with increased reliance on ancillary measures such as mannitol and/or loop diuretics. Furthermore, patients with complex partial seizures may have reduced CO_2 reactivity of cerebral blood flow when compared to normal controls.[44]

Resection of epileptogenic brain regions under general anesthesia

The anesthetic goals for these surgeries will depend upon the need to use intraoperative ECoG for seizure foci localization. Resection of epileptic foci under general anesthesia without the use of ECoG has goals similar to those of most open craniotomy procedures. These goals are to ensure lack of awareness, immobility and hemodynamic stability, to facilitate brain relaxation, ensure rapid emergence so that neurologic status can be assessed and to avoid perioperative seizures. Benzodiazepine premedication can be given if EEG recording is not planned. Multiple studies have investigated the potential benefits of one anesthetic technique over another for providing hemodynamic stability, good brain relaxation and rapid emergence for evaluation of the patient's neurologic examination. Many anesthetic combinations have been used with success. Recent studies suggest total intravenous anesthesia (TIVA) with propofol may have the benefit of providing lower intracranial pressures and better brain relaxation when compared to isoflurane or sevoflurane administered at >0.5 minimum alveolar concentration (MAC) in patients undergoing craniotomy with intracranial mass lesions.[45] However, these benefits may be less clinically significant when lower MAC doses of volatile agent are used.[46] Use of the ultra-short acting opioid remifentanil more consistently allow for rapid emergence and early neurologic examination than other opioids.[47–50] Remifentanil has also been associated with better brain relaxation than fentanyl; however, this has not been a consistent finding in comparison studies.[51–52] No prospective studies have been adequately powered to determine the impact of anesthetic technique on neurologic outcome after craniotomy.

Additional goals for anticipated use of intraoperative ECoG include avoidance of drugs that will interfere with monitoring of seizure spikes and preventing unwanted generalization of interictal spike wave activity. Barbiturate and benzodiazepine premedication should be avoided as seizure threshold may be elevated, making EEG recording of epileptogenic activity more difficult. Antihistamines can activate seizure foci in these patients and should likewise be avoided as premedicants. Despite an isolated report of N_2O-related diminution of epileptic foci during intraoperative electrocorticography,[44] N_2O can be used for these procedures. The use of low concentrations of isoflurane, sevoflurane (for induction of pediatric patients) or desflurane is permissible, provided these agents can be eliminated well before the onset of corticography. When no potent inhaled anesthetics are in use, scopolamine or droperidol can be substituted to prevent intraoperative recall with virtually no effect on the EEG. Alternatively, narcotic dosing is increased. Mild to moderate hypocapnia ($PaCO_2$ = 30–35 mmHg), however, is often necessary to assist in brain volume control and brain relaxation.

Isoflurane may decrease the frequency and spatial distribution of epileptogenic spikes, although it is unclear whether this effect persists at low concentrations.[53] An intubation dose of short-acting barbiturate during induction is not contraindicated, but should be avoided later in the case, as should intravenous lidocaine.

If cortical motor area stimulation is necessary, particular attention to the management of neuromuscular blockade and anesthetic dosing is appropriate. As a general rule, neuromuscular blockade must be minimal to allow motor stimulation. If moderate residual neuromuscular block persists, a small dose of anticholinesterase can be administered to achieve complete reversal.

Occasionally, intraoperative EEG recording fails to reveal seizure spikes. After consultations with a surgeon and an electroencephalographer, doses of methohexital (10–50 mg increments),[8,25] alfentanil (50 μg/kg)[26] or etomidate (0.2 mg/kg)[7]

may be administered to help activate dormant foci. However, controversy exists over the correlation of seizure spikes elicited with these drugs to pathologic epileptogenic foci.

Awake craniotomy for epilepsy surgery

Awake craniotomy for resection of seizure focus is performed when tissue resection requires mapping of eloquent cortical tissue located proximal to the ictal foci. The technique may also be used to avoid anesthetic related interference with intraoperative ECoG. The anesthetic technique for awake craniotomy is more aptly described as variable depth anesthesia with periods of wakefulness. Various institutions and anesthetists have reported on favored techniques for 'Awake' craniotomies including periods of general anesthesia using a laryngeal mask airway or endotracheal intubation, or deep sedation with discontinuation of anesthesia for the period of speech or memory testing.[54,55] Despite the development of multiple approaches to the problem, the awake craniotomy remains one of the more challenging anesthetics to provide and no method is without its pitfalls and limitations. Factors which support a successful procedure include: selection of a patient appropriate for the procedure, preoperative psychologic preparation of the patient, positioning which will be comfortable for the patient for an extended period of time, and a short surgical duration. There is no prospective data to suggest one approach is preferable to another. The following techniques represent the favored technique of the authors. Regardless of the anesthetic technique used, excellent scalp local anesthesia is required for patient comfort. Escalating the patient's sedation to supplement an inadequate scalp block should be avoided as this will needlessly increase the risk of airway obstruction and oversedation during cognitive testing. Girvin described the technique which is utilized for local scalp anesthesia during craniotomy.[17,27]

Patients are best placed in the full lateral position to allow adequate access to the airway and avoid back or pressure point pain after prolonged positioning. The authors common approach to positioning these patients is to administer bolus doses of short acting sedation titrated to patient comfort levels (propofol 10–20 mg) during the placement of the local block and Mayfield head holder (if used) then allowing the patient to become conscious enough to cooperate in finding the most comfortable head and body position for the procedure. Although some surgeons choose to use a pin-type head holder to minimize head movement, the holder is not attached to the bed but is placed on a foam doughnut for comfort. Sudden movement is certainly undesirable during craniotomy, but it must be an anticipated event during awake craniotomy even with the best anesthetic technique. Patients may have confusion while emerging for the testing portion of the procedures and seizures may occur from mapping or from the patients' underlying condition. Immobilization of the head may be dangerous in these situations. Excellent access to the patient's face and extremities is required. The drapes need to be appropriately tented to allow a clear view of the patient's face for both patient safety and adequate sensorimotor and speech and memory testing. Pillows are placed between the patient's legs, between the back and the back support and in front of the patient allowing them to 'hug' the pillow. Potential pressure points are padded with foam or soft blankets. Drapes are carefully taped out of the way to allow good access to the face. Figure 101.2 demonstrates a configuration for operating room setup which the authors have found useful to facilitate the process.

The development of short acting, rapidly titratable intravenous agents has made total intravenous anesthetic (TIVA) a more popular choice over the traditional neurolept anesthesia for the awake craniotomy procedure.[56] Until recently the authors used a combination of propofol (75–150 μg/kg/min) and alfentanil (0.25–0.75 μg/kg/min) or fentanyl (0.5–1 μg/kg/hr). These agents were then discontinued

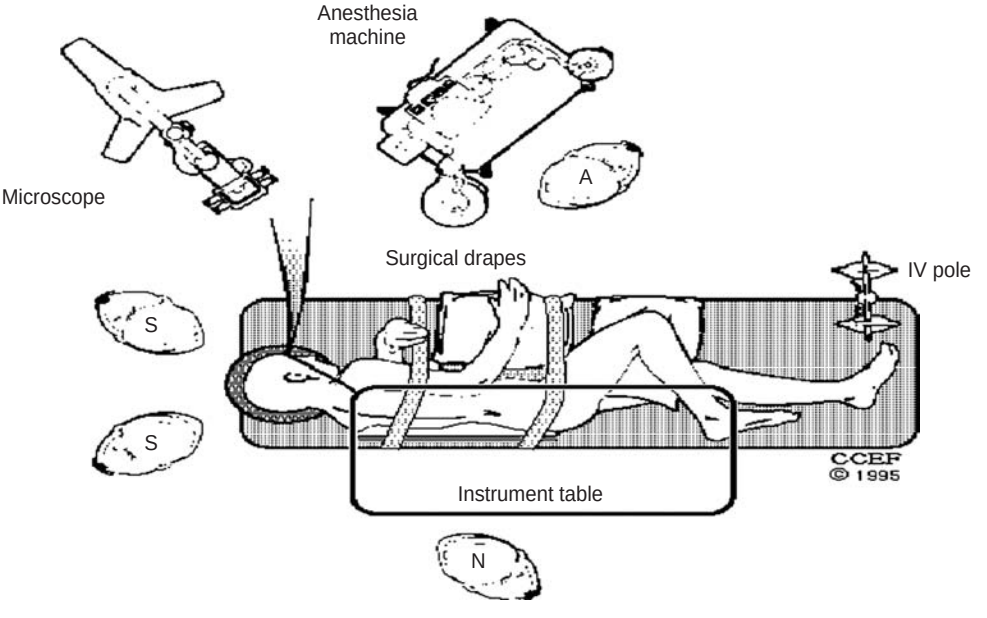

Figure 101.2 Operating room setup for right-sided craniotomy performed for the awake patient. Note the arrangement of the surgical drapes, which ensures access to the patient's face. 15–20 minutes prior to the testing period. During testing, the authors preferred to reduce, but not eliminate the opioid infusion to maintain an analgesic background.

For the last several years a newer anesthetic agent, dexmedetomidine has gained some favor due to its unique property of inducing a sedation more akin to natural sleep with minimal respiratory effects.[57] Dexmedetomidine is given as a loading dose of 1 mcg/kg over 10 minutes and then infused at 0.6 mcg/kg/hr for the remainder of the procedure. A second agent is often required for adequate sedation during cranial flap opening and then discontinued for the testing period. The authors prefer to use a low-dose propofol infusion (25–75 mcg/ kg/min) that can be titrated to the desired sedation depth to supplement dexmedetomidine. Other authors have reported good experience with remifentanil combined with dexmedetomidine.[58] Propofol is discontinued 15–20 minutes prior to intraoperative stimulation of motor, and speech areas to allow adequate time for patient emergence. Experience with dexmedetomidine has demonstrated that some patients require more intense effort to be roused from dexmedetomidine sedation (a physical stimulus such as sternal rub and calling of their name). However, once roused and engaged, the patient remains able to cooperate with cognitive testing. At least one institution has reported difficulty with cognitive testing in patients receiving dexmedetomidine during Wada testing. It is possible the excessive sedation was due to the use of additional sedative agents, such as benzodiazepines in combination with dexmedetomidine. Dexmedetomidine is known to have a significant second drug effect and the sedative effect will be greater when used in combination with other sedative agents.[59]

Frequently, surgical resection proceeds while the patient completes verbal tasks or reads from a large-print book (speech area assessment) or squeezes the tester's hand (motor area assessment). Resection is stopped or modified at the first sign of speech difficulty or weakness. During cortical stimulation, the patient may be distressed by strange sensations and involuntary movements. Reassurance and comforting words go a long way, but occasionally mild sedation is also provided. More seriously, a seizure may be precipitated which requires prompt termination as well as assurance of a patent airway and adequate ventilation.

Following the completion of the cognitive testing, sedation is then again deepened to the point of unresponsiveness as necessary.

Adverse events

Sedation techniques for 'awake' craniotomy are associated with a significant incidence of complications, which can be managed safely under the management and close scrutiny of the experienced anesthesiologist. The traditional neurolept sedation regimen was associated with a 16% rate of convulsions, an 8% incidence of nausea and vomiting and at least a 2% rate of conversion to general anesthesia.[54] Contrary to neuroleptanalgesia, propofol sedation techniques are almost completely devoid of intraoperative seizure risk. Yet, transient respiratory depression is much more prevalent with propofol compared to neurolept or dexmedetomidine-based techniques, where it is virtually absent.[54]

Seizure activity (especially with direct cortical stimulation) can be treated with propofol (0.75–1.25 mg/kg), or thiopental (1.0–1.5 mg/kg) depending on the need for subsequent EEG recording. At the end of the procedure, benzodiazepines and phenytoin may also be used.

Cerebral hemispherectomy

On occasion, the seizure foci are so diffuse as to require resection of substantial portions of an entire cerebral hemisphere. Frequently, this procedure is performed in children and can be associated with significant morbidity and mortality, related to massive blood loss, electrolyte and metabolic disturbances, coagulopathy, cerebral hemorrhage, and seizures. Hemispherectomy requires a very large craniectomy, which increases the chance of bleeding and tearing of dural sinuses. Air embolism also has been reported and may lead to serious morbidity. Recently, three different surgical techniques (anatomical, functional, and lateral) for hemispherectomy were compared. Lateral hemispherectomy was associated with the lowest intraoperative blood loss, the shortest intensive care stay, and the lowest complication rate. Functional hemispherectomy had the highest rate of reoperation, while patients undergoing anatomical hemispherectomy had the longest hospital stays, greatest requirement for CSF diversion and highest postoperative fever. Patients with cortical dysplasia had the largest intraoperative blood loss.[60]

Continuous monitoring of blood pressure by arterial catheter is required, as is central venous access and monitoring of cardiac filling pressure. Brian *et al.*[61] report a series of ten patients, ages 3 months to 12 years, whose intraoperative blood replacement amounted to 1.5 blood volumes, on average. Seven of ten patients developed a coagulopathy intraoperatively, requiring administration of platelets and/or fresh frozen plasma. Progressive hypokalemia requiring replacement occurred in 40%. Hypothermia and metabolic acidosis was observed in 50%. Urine output was a poor indicator of volume status because of frequent massive glycosuria. Zuckerberg *et al.*[62] report several children under 5 years who developed severe decreases in cardiac index, bradycardia, increased systemic vascular resistance (SVR), and an alveolar to arterial gradient suggestive of neurogenic pulmonary edema after hemispherectomy with extensive subcortical resection. Removal of the endotracheal tube at the conclusion of the case is fraught with the danger and should be carefully reconsidered in each patient. Postoperative hemodynamic instability is common and the airway may be compromised by seizure activity. Early postoperative recovery is best accomplished in an intensive care environment. As has been reported in adults,[63] children undergoing major brain resection become hypercoagulable as early as during dural closure.[64] While the clinical significance of this finding is debated, thrombotic complications should be anticipated.

Emergence and postoperative management

The incidence of complications after intracranial neurosurgery remains substantial.[65] Nausea and vomiting occur in 30–50%,

the incidence of neurologic deterioration is 8–10%, of which approximately one-half is permanent. Respiratory morbidity occurs in 3–8%, while cardiovascular complications were found in 5–19% of patients. While epilepsy patients are generally healthy from the cardiovascular perspective, seizures, impaired mental function and the effect of large craniotomy procedures with substantive brain resection can combine to put patients at significant postoperative risk.

Because of preoperative tapering of anticonvulsants and perioperative drug interactions, patients may be at higher risk of developing postoperative seizures.

Anticonvulsant blood levels need to be checked frequently and doses adjusted accordingly to continue appropriate maintenance of anticonvulsant therapy postoperatively. When a seizure occurs, adequacy of oxygenation and ventilation must be assured by appropriate measures to secure airway patency. The first step should be ventilation with 100% oxygen via bag/mask. If necessary, the airway is secured by tracheal intubation. In adults, the seizure may be stopped with a small (1–2 mg/kg) dose of thiopental, lorazepam 2–5 mg, diazepam 5–10 mg administered over 2–3 minutes, or midazolam 2–4 mg. If seizure activity recurs, phenytoin is begun at 50 mg/minute to a total dose of 20 mg/kg, assuming the patient has not previously been treated with phenytoin. Intractable status epilepticus is treated with general anesthesia using isoflurane, barbiturates, or propofol.

Antiepileptic medications are associated with drowsiness and lethargy. It is our clinical experience that epilepsy patients emerge from anesthesia more slowly than neurologically normal individuals. Intraoperative loading of phenytoin for treatment of seizures may increase the risk of delayed emergence from general anesthesia. This tendency can be exacerbated in epilepsy patients with mental handicaps who are also on therapy with the anticonvulsants mentioned. During the course of aggressive medical therapy and in the postoperative period, phenytoin and carbamazepine blood levels may increase into the toxic range.[66]

Intracranial bleeding occurs in a small percentage of patients, so that neurological status must be closely and continuously monitored during recovery. Coughing and systemic hypertension should be avoided and promptly treated so as not to precipitate or aggravate intracranial bleeding. Prophylactic administration of antinauseants is effective[67] and advisable. Other postoperative neurologic complications of temporal lobe surgery include memory and visual field deficits. Patients with temporary subdural grid electrode implants may suffer cerebral edema[68] occasionally necessitating emergency re-exploration.

102 Placement of subdural grids

F Salazar and WE Bingaman

Brief history

It is often said that the history of epilepsy surgery began on 25 May 1886, when Victor Horsley operated on a patient of John H. Jackson at the National Hospital for the Paralyzed and Epileptic at Queen's Square in London. This patient was a man of 22 years with focal motor seizures that were caused by a depressed skull fracture, the consequence of a trauma he had suffered 15 years earlier.[1]

The first cortical electrical stimulation studies in humans can be traced back to work done by Robert Bartholow in Ohio. In 1874, he had in his care a patient with a large cranial defect exposing her cerebral hemispheres. Needles were inserted into the dura mater and, upon closing the circuit, right arm and leg muscular contractions were observed.[2] In 1893, Krause performed the first documented case of intraoperative electrical stimulation of the human cerebral cortex to determine locations of cerebral function and epileptogenic foci as a guide to cortical resection.[2]

The first intraoperative electrocorticogram was produced by Foerster and Altenburger in 1934. By the early 1950s, direct electrical activity measurement from the human cerebral cortex during surgery was extensively used and considered an indispensable technique in the evaluation of surgical candidates to define the irritative zone[2]. However, chronic intracranial recordings were not reported until 1939 when Penfield used epidural single contact electrodes in a patient with an old left temporo parietal fracture and whose pneumoencephalography disclosed diffuse cerebral atrophy[3]. The use of subdural grid arrays became more popular after several publications during the 1980s demonstrated their safety and efficacy[4–6]. Before that time most invasive techniques involved epidural electrodes or intraoperative recordings.

Materials and design

Subdural electrode grids consist of stainless steel or platinum contacts embedded in a thin matrix of biologically inert but flexible material such as Silastic® or Teflon®. By design, each contact and its connecting wire are electrically isolated so as to provide precise anatomic localization of seizure foci.[7,8] These wires extend to insulated cables that attach to an extracranial amplifier. The shape and size of each subdural electrode grid varies from simple strips, consisting of a single row with usually four to eleven contacts to rectangular or square arrays of 16 to 64 electrodes. The distance between electrodes is approximately 10 mm. The diameter of the electrode contact varies between 2 and 5 mm. It is very important that the material in which the electrodes are embedded is flexible and thin permitting the array to adopt the shape of the brain it is covering.[9] The embedding material should be clear in order to facilitate its placement over specific brain areas and also to define the relationship of the contacts with the underlying vessels and other anatomical landmarks such as sulci and gyri. Minimizing the total volume of the electrode array is essential to avoid increased intracranial pressure from mass effect.

Variability in shape and size of the electrodes permits tailoring their use to the specific clinical situation. Custom designed arrays of subdural electrodes have been configured for placement in specific anatomical locations. For example, to record from interhemispheric brain regions, rows of electrodes arranged in curvilinear fashion were designed to follow the average curvature of the corpus callosum. The plate is designed with contacts on both sides to record from the ipsilateral mesial cortex and the contralateral mesial region through the falx.[7]

Indications and advantages

Epilepsy surgery is based on the principle that resection of an epileptogenic focus can result in seizure freedom. The epileptogenic zone is defined as the area of brain necessary and sufficient to generate seizures.[9] Accordingly, accurate localization of the epileptogenic zone and its relationship to eloquent cortex is crucial for the success of epilepsy surgery.[10–18] In certain clinical situations, invasive electrode recordings allow for accurate localization of the epileptogenic zone and mapping of functional cortical regions.

The most common indications for intracranial electrodes include lateralization or localization of epilepsy and localization of functional/eloquent cortical information. In the first case, preoperative noninvasive studies and semiology often suggest focal epilepsy but scalp electroencephalography (EEG) is unable to adequately localize or lateralize the epileptogenic zone.[14,19] Subdural grids have particular advantages: they can be in place long enough to record both spontaneous seizures and interictal activity during various stages of arousal, and they have applicability for mapping of cerebral function extraoperatively.[9,20,23] These characteristics allow tailored cortical resections around areas of higher function while minimizing

Table 102.1 Major indications for implantation of subdural grids

Determination of extent and distribution of the epileptogenic zone.

- Normal imaging data.
- Epileptogenic zone that is more widespread than the structural lesion.
- Absolute noncongruence of preoperative data.

the risk of permanent neurological deterioration.[21,22] Intraoperative electrocorticography, as compared with chronically implanted subdural grids, is a limited option because it only provides information restricted to interictal activity. When used in patients under general anesthesia, it is believed that anesthetic agents may influence EEG activity by altering the thresholds of after discharges and motor responses creating a misleading electroencephalographic picture. Additionally, intraoperative functional mapping often requires a cooperative patient that can tolerate being awake during surgery under local anesthesia. This is particularly difficult in the pediatric population.

Indications for invasive video-EEG monitoring can be divided in two overlapping groups (see Table 102.1[11–15]).

Disadvantages and limitations

Disadvantages of subdural invasive monitoring include increased surgical risks, financial costs, and limitations in the ability to access deep cortical regions. It requires two surgical procedures, the first to implant the electrodes and the second for removal of electrodes followed by resection of the epileptogenic zone. The amount of cerebral cortex exposed is often extensive requiring larger craniotomies and increasing the risk for complications. Implantation of a foreign body in the brain has increased potential of causing intracranial mass effect and infection. Additionally, hospital cost and length of stay are increased. Because of these factors, invasive monitoring should not be routinely undertaken as an 'exploratory procedure' to identify a focal epilepsy (the noninvasive preoperative evaluation should identify a focal epilepsy and approximate location of the epileptogenic zone). Subdural grids should be used if it is believed that their use will alter the ultimate surgical strategy and outcome. An attempt must be made to place adequate electrodes so that the predicted site of seizure origin and its boundaries are sampled.

Limitations in both the area and regions of cortex to be covered exist. In specific cortical areas such as the interhemispheric, basal temporal, and basal frontal surfaces the grids are placed without direct visualization. This makes precise cortical coverage difficult and more risky. The use of intraoperative stereotaxis can improve the accuracy by displaying the grid's implanted position on the 3D reconstruction of the cortical surface. This allows the surgeon to adjust grid position intraoperatively. The relatively common presence of bridging veins in these regions is a limiting factor for safe implantation of grids. Additionally, in the interhemispheric region it is common to find adhesions that makes grid placement difficult. Finally, subdural grid coverage of the mesial temporal lobe structures is not optimal since the grids/strips are placed in the subtemporal region without direct visualization and likely record from the parahippocampal gyrus and not the hippocampus directly.[24]

Other limitations of subdural grid implantation are the number of available channels for recording with the EEG system in the hospital. Some systems can handle only 64 channels unlike other systems record up to 200 channels thus allowing the implantation of more electrodes over wider cortical areas. Despite this, only limited coverage of cortical regions can be sampled and preoperative surgical planning is necessary to maximize the chances of covering the ictal onset zone with the electrodes.

Surgical technique

Video of subdural grids placement (DVD)

Placement of subdural grid electrodes is carried out by means of a standard neurosurgical craniotomy under general anesthesia.[20] Our preference is to use mannitol (0.5–1.0 gr/kg), hyperventilation, and optimal head positioning at the beginning of skin incision in order to obtain adequate brain relaxation and sufficient subural space for placement of the plates. Before prepping, the skin incision should be planned to allow adequate brain exposure and room to tunnel the electrode wires. Localization can be performed with simple craniometric measurement in accompaniment of magnetic resonance imaging (MRI), or frameless navigation can be used as a localizing aid.[25] The scalp and bone flaps should be of generous proportions, exposing areas of cortex needing coverage and taking into account the requirements of any definitive surgical procedure.[26] The use of stereotactic navigation and direct inspection of cortex and identification of gyri allows optimal grid placement according to the preoperative plan. The goal of surgery is to maximize the chance of fully documenting seizure foci and to be able to identify functionally important cortex by brain mapping techniques. Thus, the location of electrodes is a synthesis of the preoperative information and the surgical limitations on the amount of cortex that can or needs to be covered.[27]

Once the brain is exposed, the plates are inserted with smooth bayonet forceps, directing them towards the desired cortical region using a steady stream of irrigation allowing it to slide smoothly over the surface of the brain and preventing trauma. The grids can be 'slid' beyond the edges of the craniotomy to cover adjacent areas, including basal temporal, basal frontal and interhemispheric regions. Areas of resistance may include bridging cortical veins or adhesions that should be avoided to prevent hemorrhage. Whenever possible the electrodes should be placed under direct visualization to prevent this complication. Occasionally, when large plates are used over the convexity, there is a tendency for them to buckle. This can be overcome by dividing the grid along lines of electrodes to give a better fit over the brain. If the grids are cut to a smaller size to fit in the region of interest, edges should be carefully trimmed to avoid electrode injury and cortical laceration.[28]

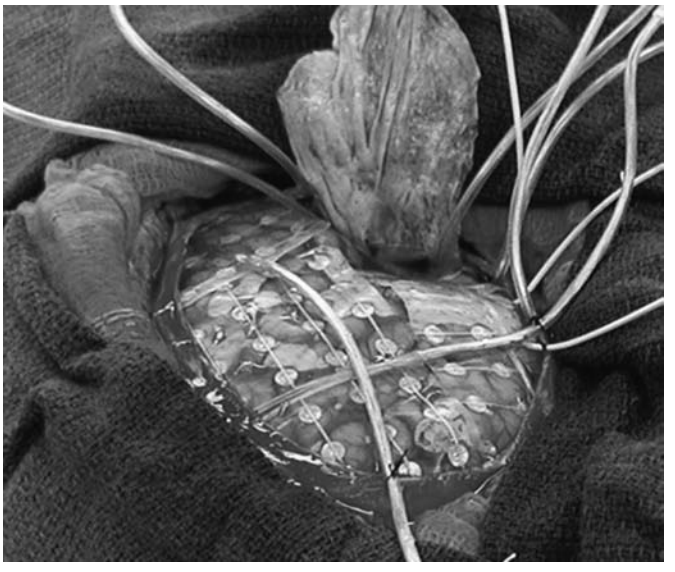

Figure 102.1 Intraoperative photography showing subdural grid electrodes after implantation before closing the dura.

Care must also be taken to ensure that the edges of large grids do not compress and impede the outflow of major draining vessels such as the vein of Labbe or Trolard as they enter the dural venous sinuses.[29] Care should be taken when implanting electrodes in patients with mass lesions, in reoperations (there are usually adhesions of the dura to the cortex), and in areas of encephalomalacia (grids may be difficult to secure). Prior to closure the electrode positions should be confirmed with the neurologist. Once in place, the electrode cables are secured to the dura with suture. A digital photograph of the brain is taken; this provides a reference between gyral anatomy and electrode placement that cannot be obtained with three dimensional reconstructed scans (Figure 102.1). A watertight dural closure around the electrode cables reduces the possibility of cerebrospinal fluid leakage. Hitch stiches are used to reduce the risk of extradural bleeding. The leads should exit without kinking in the bone edges. Electrode leads are tunneled a minimum of 10 cm from the craniotomy margin and attached to the skin with a purse-string suture. The bone flap is replaced and secured to minimize the risk of electrode movement during seizures. It is important to appropriately identify each plate and record the intended position in the patient's chart.

Computer software has been developed to aid the surgeon intraoperatively in the placement of the subdural grids. A standard preoperative stereotactic volume acquisition MRI with scalp fiducial markers in place is obtained, and co registered to the patient intraoperatively after positioning with rigid head fixation. The pointing tool is then used to register the positions of as many exposed electrodes as possible, and using specialized computer software the grid is displayed as pseudocolored spheres on the volume surface reconstruction of the brain. This allows the surgeon to have immediate intraoperative feedback demonstrating the anatomic position of the subdural grid.[30,31]

Postoperative management

The patient is sent to a neurosurgical intensive care unit (ICU) for the first postoperative night. The next day the patient is transferred to the Epilepsy Monitoring Unit where the electrodes are connected for continuous digital EEG recording along with video imaging. Intravenous antibiotics are prescribed throughout the entire monitoring period. Following removal of the subdural grids at least one of the plates is sent for culture (even in the absence of signs of infection). In cases of positive cultures, antibiotics are continued based on these results and the clinical condition of the patient. Corticosteroid therapy is administered during the first 48 hours after surgery to reduce cerebral swelling and help with postoperative pain. In some patients severe headache can develop after surgery requiring use of intravenous analgesics. Postoperatively, any change in the level of consciousness or neurological function is evaluated with computed tomography (CT) scanning. The period of implantation is variable with a range between 9–26 days and an average of 12 days.[21] In general, patients with extra temporal seizure foci require more recorded seizures than patients with temporal foci.

Traditionally, the method of localizing implanted electrodes is based on a skull X-ray after implantation and from this an electrode map is drawn on a standard hard-copy template of the brain. In this map, electrodes involved in interictal epileptiform activity, ictal onset, and spread patterns can be marked along with the functional brain map obtained during cortical stimulation and evoked potentials (Figure 102.2). The main limitation of this method is the difficulty correlating the electrode positions to precise sulcal and gyral cortical surface anatomy. The clinical value of subdural electrodes can be further enhanced by postimplantation MRI co-registration and 3D visualization of the electrode position in relation to the cortical surface on the MRI.[32] This allows a more precise understanding of the anatomic relationships between the ictal onset zone, eloquent cortex, and the underlying brain anatomy. For this, a stereotactic computed tomography (CT) scan is obtained immediately postimplantation to verify electrode location and to supplement drawings or photographs made intraoperatively. The preoperative MRI is fused with the postoperative CT scan in order to obtain a 3D reconstruction of the brain and the relationship of the grids with the particular anatomy of the patient.[33] Postoperative MRI is avoided because of safety concerns as it has been shown that the oscillating magnetic field can induce electrical currents in any metallic implants and potentially cause heating and/or electrical damage to the brain cortex.[34] Unfortunately, CT scan images show extensive streak artifact which is especially pronounced with alloy grids. Although MRI imaging allows for better visualization of the electrodes, the risk of possible complications outweigh the benefits.[8]

Upon return to the operating room, the surgeon must be careful to avoid movement of the subdural grids as they are exposed. Once exposed, the cortical resection takes place using the grids as a reference with the interictal, ictal, and functional cortex information. Additionally, stereotactic navigation can be used to further correlate electrode position based on post implantation CT.[35]

Complications

Subdural monitoring with grid electrodes has historically been shown to have low permanent morbidity (0–3%) compared

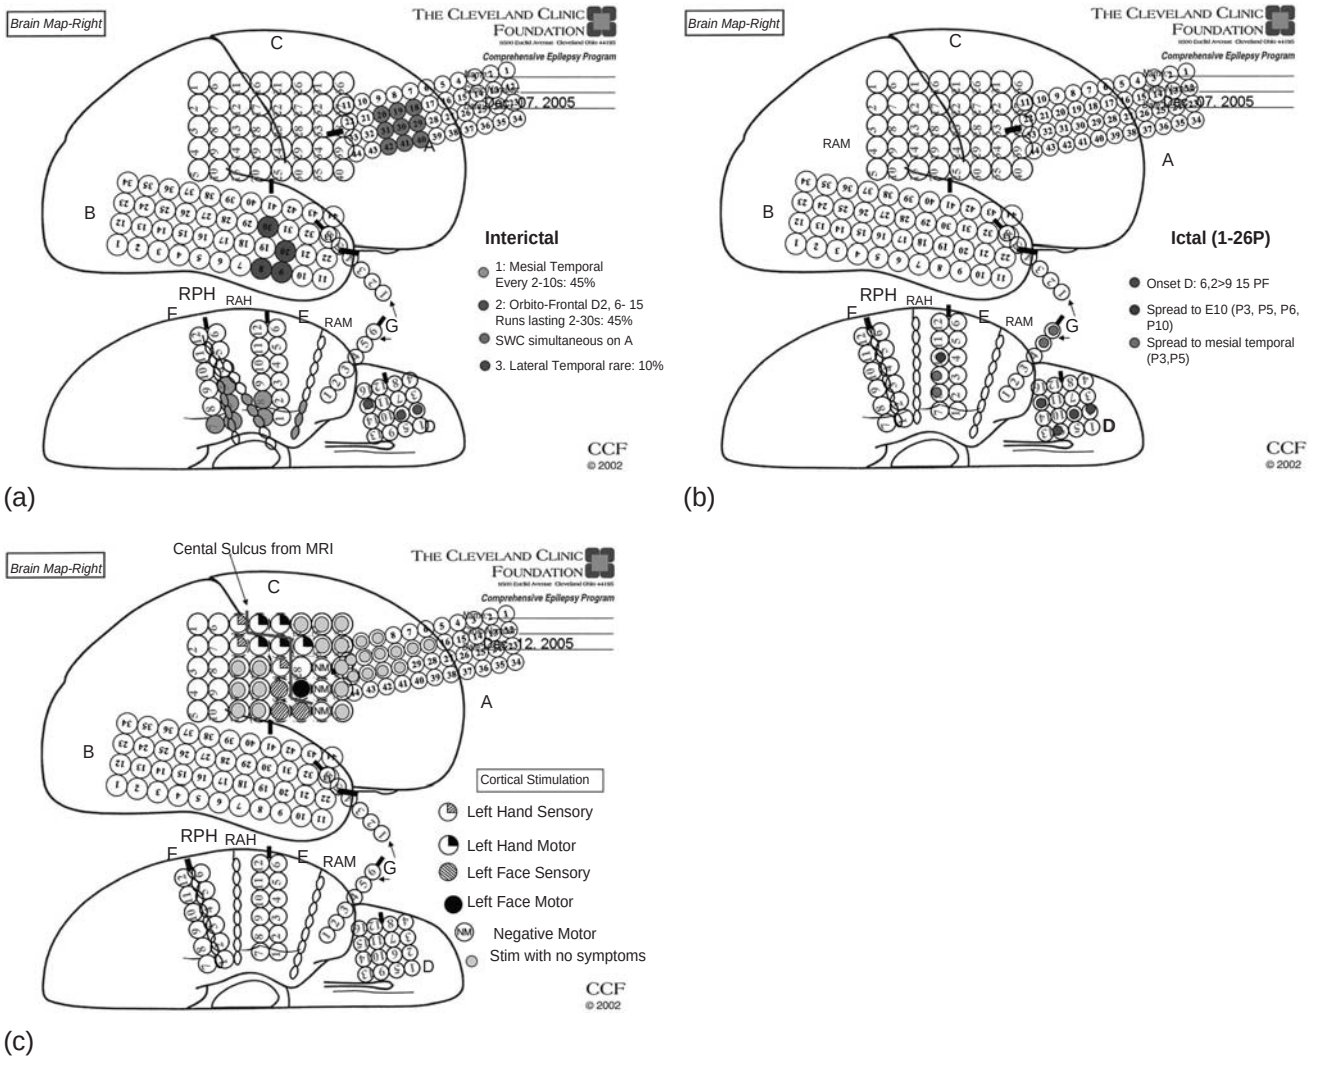

Figure 102.2 (a) Brain map showing the relative position of the subdural and intracerebral electrodes and the recorded interictal activity. (b) Brain map showing the relative position of the grids and the recorded seizure activity of its electrodes. (c) Brain map showing the cortical stimulation map.

with depth electrodes (3–6%) since, as mentioned previously, there is no intraparenchymal passage.[36] Adverse events caused by subdural grid implantation can be categorized as either surgical or neurological. For purposes of this chapter, emphasis is placed on the surgical and neurological complications related to the implantation of the grids separate from the resective stage. Resections performed after the monitoring period can also cause neurological complications, either transient or permanent. These sequelae can be variable depending on the amount of cortex resected, and are predicted based on the information obtained during the stimulation period. Risk factors for complications are: greater number of implanted electrodes, longer duration of monitoring, dominant side grid insertion, and earlier age at time of monitoring.[37]

One of the most common complications is cerebrospinal fluid leakage. Transient cerebrospinal fluid (CSF) leakage through the electrode exit site has been reported to be between 13 and 31% of the patients despite careful watertight dural closures, adequate subcutaneous tunneling, and tight skin closure.[29,38,39] This occurs most frequently after motor seizures or bouts of vomiting. Our current practice is to check the dressing regularly for any signs of cerebro spinal fluid leakage, to suture any active leak at the bedside, and to apply topical sterile skin adhesive, though the clinical utility of this practice is unknown. Use of a lumbar drain has been reported to significantly reduce the incidence of CSF leak,[40] although not routinely used at our institution due to concern of downward cerebral herniation.

Infectious complications are also reported in several invasive monitoring series. Postoperative wound infections after clean neurosurgical procedures have been quoted to range from 0.6–11%. Meningitis has been reported in 0.34–2% of patients.[41] Considering these percentages, a 6–8% rate of infection is not unrealistic for a procedure that leaves several foreign bodies implanted with cables exiting the scalp for seven or more days. Factors that have been reported to increase the incidence of infection are greater number of electrodes, exiting cables, or exit sites. The duration of recording following implantation is also found to correlate significantly with infection rate; duration exceeding 14 days is more likely to result in an infectious complication.[38] This can occur acutely during the monitoring period or chronically after

removal of the grids. During the invasive video-EEG evaluation period, wound infection, meningitis or epidural abscess can appear. Except for cases with superficial localized wound infection, the grids should be removed and aggressive intravenous antibiotic treatment initiated immediately. Subsequently, the treatment plan is modified based on culture results and clinical response. Osteomyelitis is a rare complication that has been described in 3% of the patients;[29] it usually is a late infection, occurring weeks or months after the initial surgery that requires removal of the bone flap and treatment with intravenous antibiotics. Brain abscess has also been described as a potential complication, but its incidence is very low.[42] Bacteria that have been isolated in patients with clinically relevant infections have included different species of *Staphylococcus, Streptococcus, Bacillus,* and *Diptheroid* mainly.[37]

Cerebral edema and intracranial mass effect is a potentially serious complication. Factors that favor its development are patients with multiple plates, presence of intracranial mass lesions, and pediatric patients.[37] Its precise incidence is not well defined because many times the only manifestation is headache with or without nausea that is successfully treated with analgesics and antiemetics. Severe cases leading to somnolence or stupor, focal neurological deficit, brain shift, or impending herniation are infrequent and require immediate removal of the electrodes. Large duraplasties and hinging the bone with sutures have been reported to prevent clinically significant cerebral edema in some patients. Also, some centers report on leaving the bone flap out during the monitoring period to avoid this complication.[43]

One of the most concerning complications with invasive monitoring is intracranial hemorrhage. As opposed to depth electrodes, intracerebral bleeding is a rare occurrence during placement of subdural grids. It is related more to venous occlusion or laceration of cortex caused by the edges of the plates. Subdural hematomas can be more frequently encountered and its incidence has been described around 8%; they can lie between the cortex and grids or superficial to the electrodes.[42,44,45] These could be a cause of deficient recording, may induce seizures or change the epileptiform activity, and also can contribute to intracranial mass effect and neurological deterioration.

As a result of the requirement for large craniotomies and two surgical procedures these patients have a significant risk for blood loss during surgery and may require blood transfusion. This is more frequently observed in patients with interhemispheric electrodes implanted where its location in relationship to venous structures enhances the risk of bleeding.

Accidental removal or displacement of grids is a potential complication that can be seen more commonly in patients with severe motor seizures or during periods of postictal confusion were the exiting cables can be pulled. If there is any suspicion of displacement, an immediate skull X-ray and a CT scan should be performed in order to evaluate movement of the grids or possible hemorrhage.

When the information obtained during the monitoring demonstrates that the ictal onset zone is at the edge of a grid or is suspected to be in an area not covered by the grids, repositioning of the plates may be necessary in order to obtain adequate coverage of the area of interest. In selected patients where invasive monitoring fails to identify the site of seizure origin, reinvestigation can sometimes achieve localization of the seizure onset and allow a successful surgical treatment.[46–48]

Due to the relatively prolonged period of reduced activity in these patients, other serious complications such as deep venous thrombosis, pulmonary embolism, pneumonia, and other sequelae of immobility can develop. Appropriate diagnostic and therapeutic measures should be initiated.

Outcomes

In evaluating outcomes after application of subdural grids, several important factors should be mentioned. First, it has been reported that patients selected for intracranial monitoring with subdural grids are less likely to have excellent outcomes because of their inherent complexity (non concordant preoperative data, non lesional MRI, and/or close relationship with eloquent cortex).[49–53] Second, this population of patients is heterogeneous and the analysis process itself is dynamic and changes over time. Third, in many cases, the invasive monitoring is a combination of subdural grids and strips, depth electrodes, and scalp electrodes which makes comparison of techniques difficult.[54,55] Another important variable is the amount of resection performed: resection of the ictal onset zone plus interictal epileptiform abnormalities, only the ictal onset zone, or limited resection of the ictal onset zone. The area of resection is often limited by the presence of eloquent cortex or by dominant draining veins.

Because of these factors, reported outcomes after subdural grid evaluation are difficult to interpret. In a recent Cleveland Clinic series of patients with normal preoperative MRI no differences in outcome were identified with or without the use of subdural grids, but the authors suggest that the invasive testing helped to devise a surgical strategy and allowed surgical treatment to patients who would not otherwise been candidates.[56]

Despite adequate and prolonged invasive monitoring with subdural grids, up to 10% of the patients are found not to be candidates for surgical resections. In most of these cases, the epileptogenic zone is overlapping with eloquent cortex that if resected will cause severe permanent neurological deficit. At other times, it is found that the ictal onset zone is widespread or cannot be localized thus impeding surgical treatment.

Conclusions

Subdural grid placement is a useful technique that helps to localize areas of epileptogenicity and to map functional brain cortex in order to aid in the planning of cortical resections for the treatment of medically resistant epilepsy in patients whom otherwise will not be candidates for surgical intervention or patients with increased risk of neurological deficit.

Despite its usefulness, it is a costly and risky procedure that should be limited to highly selected patients with severe refractory epilepsy and should be attempted in tertiary centers with the appropriate experience in video-EEG monitoring and by a surgeon with experience in these techniques.

103 Placement of depth electrodes

L Mulligan, K Vives, and D Spencer

Background

The first step to eradicating chronic seizures is to accurately identify the seizure focus. Although imaging has improved dramatically in recent years, there are still patients whose seizure focus defies noninvasive localization as described earlier in this text, and who must proceed to intracranial electrode evaluation. Intracranial recordings can be done by a variety of means, including subdural grid and strip electrodes, epidural electrodes, and depth electrodes. Depth electrodes, electrodes that actually enter the substance of the brain and pass to deep structures, were first used for the evaluation of epilepsy in 1950 and then more consistently in the United States since the early 1970s.[1] They are still used now either alone or, more commonly, in concert with subdural strip electrodes (SDSEs) and subdural grid electrodes (SDG) for chronic recording for as long as a month if necessary to capture an adequate number of ictal events. The electrodes are also useful for recording interictal activity and studying the pattern of seizure spread. Depth electrodes offer the advantage of being able to record from deep structures (i.e., the hippocampus, hypothalamus, deep frontal lobes) where there is inadequate coverage provided by subdural electrodes. They can also be used to record activity from the neocortex through which they pass, though the sampling area is quite limited. Similarly, they can be stimulated to map for function, although are usually far less useful than subdural strip or grid electrodes for that purpose.

Materials

Over the years, the structure and materials for depth electrodes have evolved substantially. While the early electrodes were rigid, most electrodes implanted currently are flexible (Figure 103.1), usually with a semi-rigid stylet to help prevent errant placement. They are often implanted through a guide cannula to further improve the accuracy of placement. The electrodes, usually 1–1.5 mm in diameter, come in a variety of configurations with arrays of 4–10 individual contacts with spacing from 5–10 mm between the center of each. The most commonly used material now for the contacts is platinum, though stainless steel, nickel-chromium and gold have all been used.[2] Silver and copper are toxic to brain tissue and cannot be employed. The outer casing is usually polyurethane which houses the individual wires for each contact. The electrodes can also be configured to allow for the performance of microdialysis, useful for research applications.

Planning

There are several common scenarios where depth electrodes prove useful (Table 103.1), however, the frequency and extent of their use varies from institution to institution. Their use in focal versus survey studies, temporal versus frontal studies and in re-operative cases will be discussed below. The special cases of sampling from other deep structures will also be discussed.

Temporal lobe studies

Patients that have temporal lobe epilepsy confirmed on scalp-EEG with MRI findings of mesial temporal sclerosis, appropriate semiology, and concordant PET and neuropsychological data do not require invasive monitoring. Those patients can usually go directly to resection with a high degree of success. Patients that do require invasive monitoring fall into one of several categories. The most common scenario is a patient that appears to have apparent temporal lobe epilepsy but has a normal MRI or discordant phase I and II evaluation data that do not confirm location or laterality or imply bilaterality. In that instance, one reasonable approach would be to place depth electrodes in both hippocampi and subdural, subtemporal strips around both temporal lobes. This can be performed through 2–4 burr holes or small troughs. The depth electrodes can be placed in one of two principle orientations: either longitudinally or orthogonally. Longitudinal electrodes are passed posteriorly to anteriorly starting from a paramedian occipital start point and traversing the long axis of the hippocampus. Orthogonally placed electrodes are passed perpendicularly to the cortical surface via the middle or inferior temporal gyrus into the mesial structures. These orthogonal approaches are typically designed utilizing one anterior electrode placed into the pes/amygdala area and another into the body of the hippocampus. Either method can be combined with subdural strip or grid electrodes and the purpose of the intracranial study largely determines the best approach.

Two other common scenarios involving the temporal lobe are (1) patients that are suspected to have extrahippocampal temporal lobe epilepsy or (2) patients with well lateralized epilepsy, but the lobar location of the seizure is still in question and the medial temporal lobe remains suspect. In these cases, a detailed study is usually designed to find the extent of the epileptogenic zone and its relationship to critically functional cortex. A large grid is often used over the cortex in combination with subdural strips and depth electrodes (Figure 103.2). This type of study usually requires a large craniotomy.

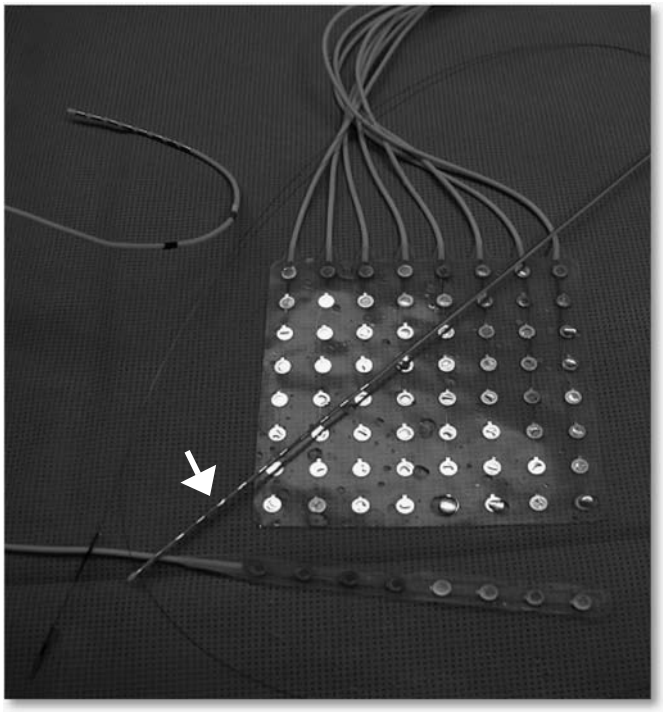

Figure 103.1 Intracranial electrodes. Arrow – depth electrode with microdialysis membrane.

Rather than making an additional burrhole to pass the electrodes from an occipital approach, depth electrodes are typically passed in an orthogonal orientation often by making a small hole in the grid though which the electrode(s) can be passed. Multiple electrodes can be passed into different portions of the amygdala and hippocampus to further refine localization as described above.

Extratemporal epilepsy

Another common category is patients with nonlesional extratemporal epilepsy. The placement of depth electrodes in these patients is usually done in order to sample areas where subdural strip coverage is either difficult or unreliable. In patients with frontal lobe epilepsy where there is a high suspicion that the medial frontal lobe is involved, interhemispheric subdural strip coverage is typically planned. Due to draining veins, these strips typically cannot reliably be placed without directly exposing and dissecting the interhemispheric fissure. In other patients, the suspicion of medial frontal onset may be lower, but a limited sampling of the interhemispheric ares is indicated; in this situation, depth electrode coverage of the anterior cingulate and supplementary area can be utilized (Figure 103.3). Care is taken to avoid primary motor and language cortices when planning the entrance sites – often coregistration of preoperative fMRI can be utilized to further define these areas. Subdural strip coverage of the orbitofrontal and fronto-polar areas is also unreliable. Depth electrodes can easily be used to provide coverage of these areas as well (Figure 103.4). Fortunately, medial occipital coverage can typically be gained by directing posterior subtemporal strips posterior to the collusum and pineal area.

Table 103.1 Common scenarios where depth electrodes prove useful

Study type	Structures sampled
Temporal lobe studies	Hippocampus and amygdala
Frontal lobe studies	Anterior cingulate, orbitofrontal and supplementary motor areas
Reoperative studies	Areas where adhesions prevent subdural strip monitoring
Deep lesions	Hypothalamic hamartoma, periventricular gray heterotopias

Deep structures

Several groups have reported successfully recording both ictal and interictal activity from hypothalamic hamartomas[3,4] and from periventricular gray matter heterotopias.[5,6] An example of this type of case is illustrated in Figure 103.5. The technique and placement of electrodes in this situation is not different that in others. Gray matter heterotopias may also be an indication that the overlying cortex may be abnormal thus making subdural cortical recordings in these corresponding areas, important. Likewise, it is often the case that depth electrode recording can supplement surface recordings in cases of large cortical dysplastic lesions, even those that come to the surface.

Technique

There are several viable techniques for inserting depth electrodes: framed stereotaxis, frameless neuronavigation, freehand passage, and endoscopically assisted. Framed stereotaxis is certainly the time-honored standard. Any number of systems are useful, including the Brown-Roberts-Wells (BRW), the Cosman-Roberts-Wells (CRW), the Leksell frame and others. Pillay *et al.* studied the accuracy of the BRW and CRW systems and found them to be consistently within 2 mm of the target.[7] Similarly, Ross *et al.*[8] reported 100% accuracy of electrode placement with the Leksell frame using MRI. Framed stereotaxis is particularly useful for bilateral survey studies. It allows for the placement of bilateral longitudinal hippocampal electrodes without the need for repositioning.

To perform a framed placement of hippocampal depth electrodes, the frame is usually placed the morning of surgery under local anesthesia and possibly light sedation. The patient is then scanned usually with fine cut MRI often using SPGR sequencing. MRI gives a more detailed anatomical image than CT and allows better visualization of blood vessels along the proposed trajectory, but CT has also been shown to be a viable alternative. CT theoretically introduces less error and is more rapidly acquired. Van Roost *et al.*[1] placed 212 longitudinal hippocampal depth electrodes using CT guided framed stereotaxis followed by postoperative MRI for evaluation of placement. They found that 97% of hippocampal head contacts and 96% of hippocampal body contacts were in or

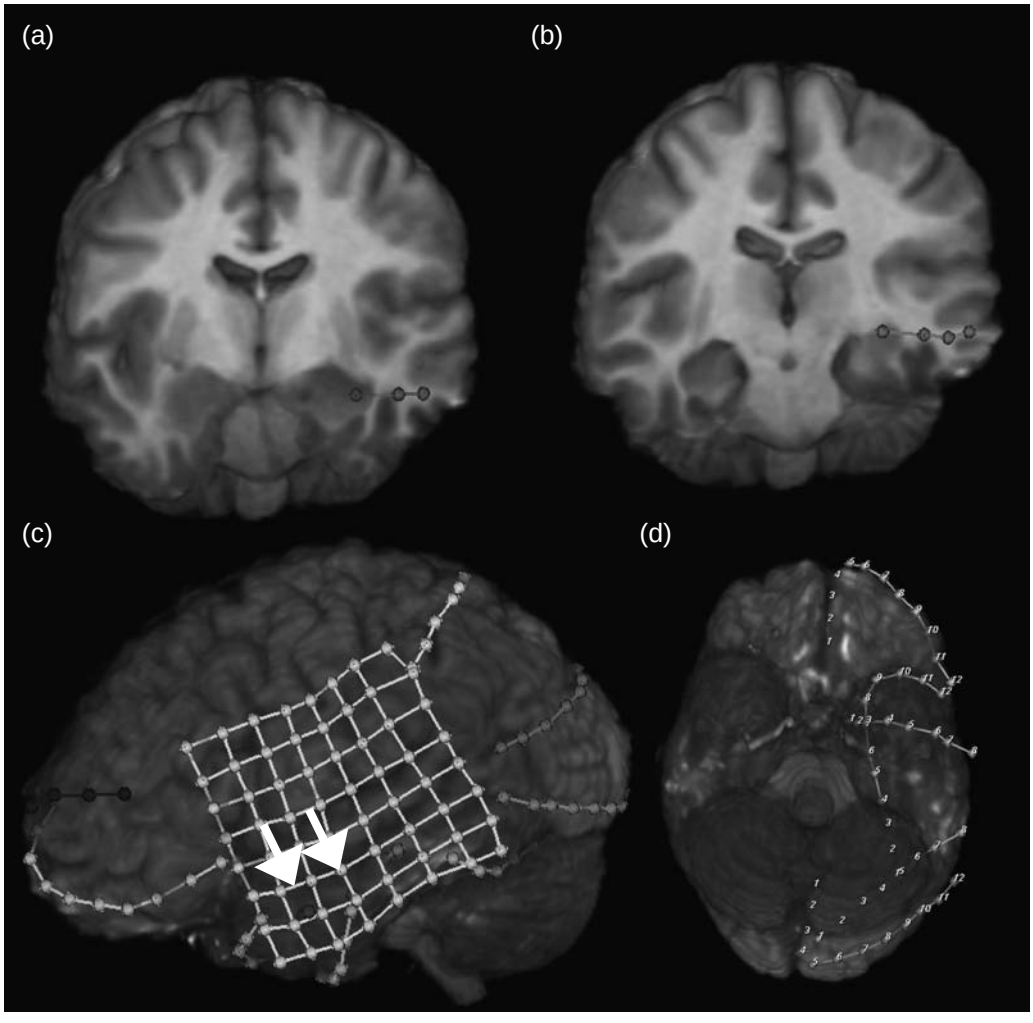

Figure 103.2 Reconstructions of electrode positions superimposed on preoperative MRI scans. A – anterior medial temporal depth electrode. B – posterior medial temporal depth electrode. immediately abutting the target.[1] Others have performed fusion of the two modalities in an effort maintain the excellent detail afforded by MRI while reducing any error introduced by magnetic reasonance.[9]

Once the scan is obtained, the patient is taken to the operating suite and the surgical planning can be performed on a navigation system. Great care is taken to define a trajectory that avoids major blood vessels and brings as many contacts as possible through the length of the hippocampus and into the amgydala. A 10-contact electrode is often chosen for this purpose. A burr hole is recommended, rather than a twist-drill hole, so that surface vessels can be identified and avoided. A rigid cannula is usually passed along the proposed trajectory, sometimes several millimeters short of the final target, and then the electrode is passed through that with its stylet still in place. Once it has reached target, the cannula and the stylet are removed and the electrode can then be tunnel several centimeters from the insertion site and secured with a stitch to the scalp. Once the depth electrodes are placed, burr holes can be made in the temporal areas to pass subdural strip electrodes. If only depth and strip electrodes are inserted, those can actually be removed at the bedside upon completion of monitoring without returning to the operating room.

Frameless systems can be employed with some minor customized adaptations to perform the same procedures. Mehta *et al.*[10] and Murphy *et al.*[11] both report on their experience with commercially available systems. Longitudinal and orthogonal electrode placement was performed and found to be accurate. Mehta *et al.*[10] showed with postoperative imaging that the electrodes were on average 3 mm from the intented target site, but only 0.4 mm ±0.9 mm from the anatomic structure of interest. Not surprisingly, they also found the orthogonal electrodes to have a lesser degree of error than the longitudinally oriented electrodes. Frameless navigation is particularly useful for detailed studies when orthogonal electrodes are to be placed can be placed through the grid at to target various locations within the amygdala and hippocampus. Using a stabilizing arm, the electrodes can be passed through a cannula in nearly identical fashion to a framed system. If the depth electrodes are passed through a large subdural grid, the electrode is typically secured to the grid and the patient must return to the operating room for their removal. Frameless navigation offers a great deal more flexibility in the design of a cranial flap as there is no frame to hinder the approach. There are several other benefits as well. First, the scanning can be done the day before the surgical procedure. Imaging can be

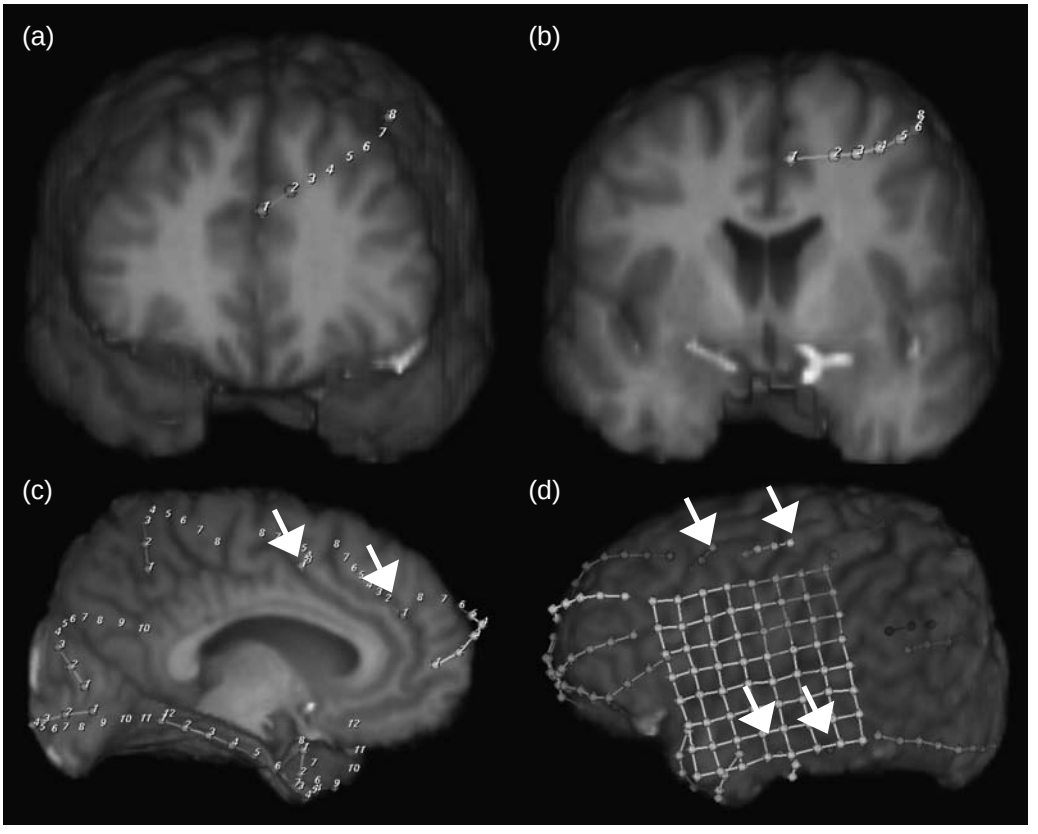

Figure 103.3 Reconstructions of electrodes trajectories for medial frontal monitoring. A – coronal reconstruction of a left anterior cingulate (AC) depth electrode. B – coronal reconstruction of a supplementary motor area (SMA) depth electrode. C – interhemispheric reconstruction of the above mentioned electrodes. Arrows point to the SMA and AC depths. acquired and a surgical plan devised prior to taking the patient to the operating room. This allows for a rapid start of the case on the day of surgery. Furthermore, application of the frame can be quite distressing to the patient and this step is obviated.

Freehand application of orthogonal depth electrodes has also been reported with acceptable accuracy. Davies *et al.*[2] placed 15 electrodes in 12 patients and found that their average closest contact was 0.8 mm from target, with 11⁄15 actually being in or abutting the hippocampus and all were capable of capturing ictal events. It is not a viable technique, however, for longitudinal placement and theoretically has a higher risk of hemorrhage as vessels along the trajectory cannot be accounted for. It does, however, reduce operative time and the need for additional imaging.

Finally, Song *et al.*[12] describe a combination of frameless navigation and neuroendoscopy for the placement of longitudinal hippocampal depth electrodes. Using frameless stereotaxis, a trajectory is developed for introduction of the endoscope into the atrium of the lateral ventricle. Then, under endoscopic visualization, the electrode is passed into the temporal horn along the hippocampus, without actual penetration of the tissue. Plain film radiography is used intraoperatively to

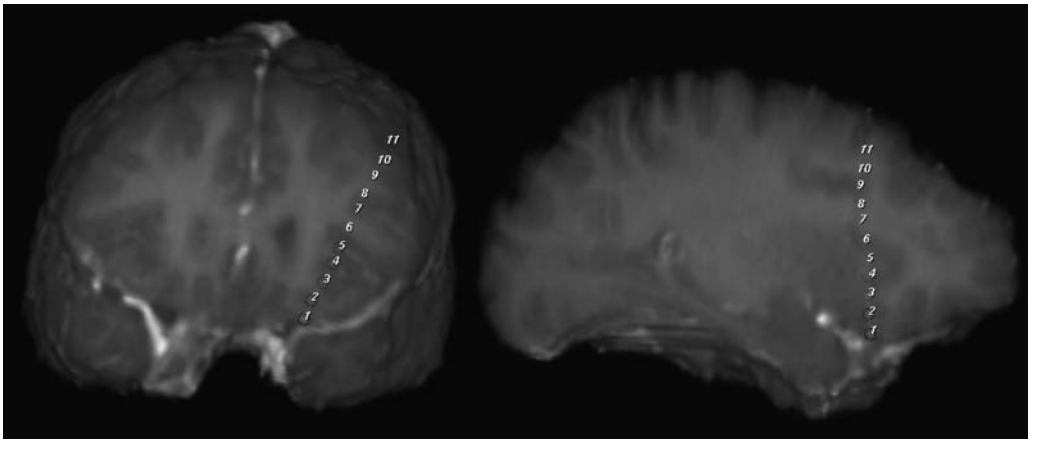

Figure 103.4 Coronal and sagittal reconstructions of an orbitofrontal depth electrode.

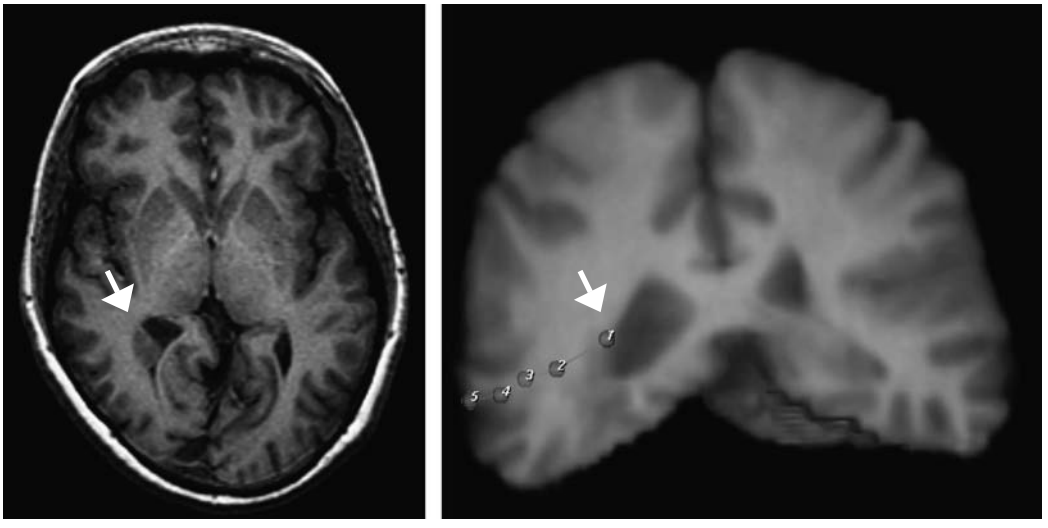

Figure 103.5 Use of depth electrode monitoring of a periventricular heterotopia. A – axial T1 weighted MR with arrow pointing to the heterotopia. B – reconstruction of the path of the depth electrode used to monitor electrographic activity.

verify an appropriate trajectory. CSF pulsations do not appear to degrade the recordings. Because the electrode does not actually traverse tissue, this method offers the advantage that the non-resected hippocampus is not injured. Although the clinical significance is not known, it certainly confers a theoretical advantage.

Once the electrodes are placed, they are tunneled several centimeters and secured by a suture to the scalp. Purse string sutures are also placed around each electrode to decrease the leakage of CSF. A generous head wrap is applied and the patient is taken to the ICU for overnight observation. Postoperative imaging is usually obtained the next day to document the actual location of the electrodes. Post placement imaging is routinely performed to assess the accuracy of the electrode placement. While plain film can certainly demonstrate at least gross localization, MRI yields the most detailed information and lends itself to three dimensional reconstruction programs. Davis *et al.*[13] performed a study to verify the safety of MRI with respect to the scanning of electrodes made from stainless steel, platinum, and nickel-chromium alloy. Placement of 143 depths, 688 subdural strips, and 38 subdural grids was evaluated on a 1.5 T MRI unit. T1, T2, and spoiled-gradient sequences were obtained and no patient had an adverse neurological event.

The patient is typically maintained on antibiotics only for 24 hours and steroids are tapered off over 3–4 days. On postoperative day 1, the patient is transferred to the epilepsy monitoring unit to continue recording.

The above discussion was directed mostly at the placement of depth electrodes into the hippocampus. Depth electrodes can be used in a number of different locations including in perilesional areas, deep frontal lobes, the hypothalamus, the thalamus, and the subthalamic nucleus. The technique for insertion remains essentially the same just with different targeting. Most experience with these alternative locations, especially the deeper locations is with framed systems.

As with any surgery, the decision to proceed must weigh the potential gains versus the potential risks. The overall risk associated with depth electrode placement is 1–4% with most risk falling into one of two categories: hemorrhage or infection. In preparation for surgery, aspirin and nonsteroidal anti-inflammatory medications are stopped and for patients on valproic acid, a bleeding time is assessed. If it is prolonged, the medicine is stopped, due to its documented adverse influence of platelet function. Specific surgical technique may also reduce the risk of hemorrhage. Using a burr hole where the cortical vessels can be adequately visualized and coagulated is safer than using a small twist-drill hole. Improved intraoperative imaging and guidance is beneficial as well. The entire tract along which the electrode is to be placed can be assessed for the presence of vessels. Additionally, limiting the number of electrodes to that which is truly essential reduces the numbers of passes through the brain and thus reduces the risk of hemorrhage as well. The risk of hemorrhage with permanent sequela ranges from 0–0.8% and hemorrhages without permanent deficit occurred approximately 0–4%.[9]

With regard to infection, the rate is approximately 0–4%.[9] Some institutions prophylax their patients with intravenous or oral antibiotics for the duration of implantation. However, there is not convincing data to support that practice,[14] so many simply perform standard perioperative dosing, and discontinue antibiotics after twenty four hours. Another technique that reduces infection is ensuring that each lead is individually tunneled several centimeters from the incision and a purse string suture is placed around the lead to minimize CSF leak. Most infections can be successfully treated with removal of the leads coupled with intraventous antibiotics. Cerebritis and abscesses are extremely rare. Of note, two cases of Jakob-Creutzfeld have been reported, so electrodes should not be reused.

Some controversy does exist about the ability of depth electrodes to provide information that subdural strip electrodes cannot. Spencer *et al.*[15,16] noted that 168 of 181 temporal lobe seizures presented in the hippocampal depth electrode in advance of presentation in the subdural strip, sometimes by as much as 70 seconds. It was further noted, however,

that 21 of 105 events captured with the hippocampal electrode, never appeared in the SDSEs. Twelve of those events were simple partial seizures, but even nine complex partial events were missed. Based on that they reported that depth electrodes were approximately 20% more sensitive that subdural strip electrodes in detecting mesial temporal seizures.[15] Seizures from patients with bilateral strip and depth electrodes were also analyzed for spread pattern and it was noted that the pattern of spread never showed epileptiform activity in the contralateral neocortex prior to the ipsilateral neocortex, thus in their data, the SDSE never provided falsely lateralizing data.[15–18] Ultimately, they felt a combination of subdural strip and depth electrodes were most effective as the sdse were useful in detecting the uncommon patient with neocortical temporal lobe or extratemporal lobe epilepsy and they were useful for studying spread patterns that are sometimes prognostically relevant. Sperling and O'Connor[19] did report rare instances of falsely lateralizing data from SDSEs when compared to depth electrodes.

Davies *et al.*[2] however, found that although the depth electrode may detect mesial temporal seizures slightly earlier by 2–3 seconds, that no novel information was gleaned from the depths and that every seizure did appear in the SDSE.[2] Eisenshenck, *et al.*[20] noted that false localization did occur between depth subdural electrodes in approximately 15% of seizure events, but was seen when the subdural electrodes were placed suboptimally and specifically, lateral to the collateral sulcus. With regard to SDSE placement, Cohen-Gadol and Spencer[21] note that a newer technique for placement may provide more accurate information. Instead of placing the strips subtemporally perpendicular to the long axis of the lobe, placement is in the anterior-posterior axis around the temporal pole just underneath the lesser wing of the sphenoid. This passage provides extensive mesial coverage. It has yet to be confirmed that this SDSE provides sufficiently similar data to hippocampal depth electrodes to be used in their place.

To justify the use of invasive monitoring, there has to be a substantial number of patients that have localizable seizure foci and that ultimately go on to have excellent seizure control following resection. Ross *et al.*[8] reported on their results over three years comparing their temporal lobe epilepsy patients that did and did not require invasive monitoring. They found of 50 patients on whom they performed invasive monitoring with combined depth and subdural electrodes, 37 were found to be good candidates for temporal lobectomy, 36 underwent the surgery, and 69% were seizure free following resection. In comparing that to their patient population who underwent lobectomy without invasive monitoring, 70% of that group was seizure free. So the results of resection were nearly identical and because of intracranial monitoring, they were able to offer resection and ultimately seizure control to a substantially larger group of patients.

Although most studies comparing subdural and depth electrodes involve the mesial temporal structures, there are case reports of extratemporal lobe epilepsy where depths were critical for detection. Privitera *et al.*[22] report the case of a patient with MRI occult focal cortical dysplasia that was not detected by subdural electrodes that was subsequently detected by depth electrodes. The patient was found to have an epileptogenic area approximately 2 cm below the sensory cortex with depth electrodes that did not demonstrate abnormalities on the overlying subdural electrodes. Following resection of the area detected by the depth electrode, the patient experienced a 95% reduction in seizures.

More recently, depth electrodes have been used in less conventional ways. With interest in deep brain stimulation for epilepsy management increasing, depth electrodes have found new used. Dinner *et al.*[23] performed a study on four patients by implanting bilateral subthalamic nucleus (STN) depth electrodes and simultaneously recording scalp and STN activity. They found that activity, both interictal and ictal, recorded from scalp EEG was also represented in the ipsilateral STN which may ultimately lead to novel treatment options.

Future

Currently, depth electrodes, or perhaps more properly probes, sample the electrical activity of structures with the brain or are also used for microdialysis in order to examine the concentrations of substances in the CSF. Centers are looking at a number of different devices to add to these probes to gather other types of information about the tissue of interest. Probes for pH, oxygenation, calcium and enzyme-linked probes for a number of different molecules are either being designed or are being used in investigations. Additionally, research is being done to provide 'smart' electrodes that house their own pre-amplifiers, analog to digital converters, wireless broadcast mechanisms and power sources. Phase 3 studies are also underway for implantable devices that continuously sample EEG activity and provide electrical stimulation to interrupt seizure activity through both subdural strips and depth electrodes (Neuropace, La Jolla, CA). Until an efficient means becomes available to monitor the electrical, magenetic and/or chemical changes in 3D space from a remote location, it is likely that depth electrodes will continue to play an instrumental role in the investigation of patients with epilepsy.

104 Stereoelectroencephalography

D Hoffmann, GL Russo, and M Cossu

Historical aspects of stereoelectroencephalography (SEEG)

The first successful attempts to record intracerebral electrical activity date back to the first half of the past century. In those decades, during which the technique of intraoperative recording from the cerebral cortex in epileptic patients had been developed by Penfield and Jasper,[1] intracerebral electrodes began to be placed with the aim to record from subcortical structures, mainly in order to elucidate the role of basal nuclei in 'petit mal'[2,3] as well as to investigate cases with presumed 'centrencephalic' seizures.[4,5] In several studies electrodes were placed using a rough 'free hand' technique, which resulted in largely imprecise targeting of intracerebral structures.[6–8] Furthermore, despite a trend towards chronic recording was progressively developing, the primary goal of inserting intracerebral electrodes was to record interictal stationary spike discharges, in this way depending on the same concepts established for intraoperative electrocorticography.

Some new essential issues were addressed by two crucial methodological landmarks in the development of presurgical evaluation of epileptic patients, namely the employment of stereotactic approaches for the targeting of intracranial structures and the introduction of the concept of Epileptogenic Zone (EZ).

Stereotactic devices for use in humans were designed in 1947 by Spiegel and Wycis,[9] and their employment in recording from deep brain structures is reported since 1950.[10] Stereotactic placement of intracerebral electrodes gained popularity and it was reported for the evaluation of temporal lobe epilepsy in the early 1960s.[11] Meanwhile, in the Neurosurgical Unit of the Saint-Anne Hospital in Paris, France, stereotactic investigations of epileptic patients with intracerebral electrodes were inspired to a newly elaborated concept: epileptic seizures were regarded to as a dynamic process, with a spatial-temporal, often multidirectional, organization, which is best defined referring to a 3-dimensional arrangement.[12–15] The site of origin and of primary organization of this dynamic process in focal epilepsies, whose surgical removal results in control of seizures, was defined as the EZ.

With these premises, the Saint-Anne group developed the methodology of stereoelectroencephalography (SEEG),[16,17] which enabled to address the complex requirements of defining in the 3D space and time the organization of the ictal discharges by tailored 'explorations' (arrangements of intracerebral electrodes). These were aimed to the verification of a previously formulated coherent hypothesis as to localization of the EZ, based upon available anatomo-electro-clinical findings peculiar of each single case (see also Chapter 78, Kahane-Francione). For these purposes, several needs should be satisfied: the electro-clinical definition of epilepsies must rely on the recording of spontaneous seizures, and not be limited to recording of static interictal electrical abnormalities; the structures presumed to be involved in the ictal electrical onset and in the primary and secondary organization of the ictal discharge should be previously defined, included in the plan of exploration and surgically reached with the precision of the stereotactic technique; unlike the early studies with intracerebral electrodes, a primary role was assigned to the exploration of cortical structures, since the dynamic organization of the ictal discharges was presumed to follow cortical trajectories. For this latter purpose, owing to the interindividual variability of cortical anatomy, the stereotactic localization of different cortical areas required an approach based on a statistically built up proportional reference system which used the intercommissural line, as identified by contrast ventriculography, as the baseline landmark. This approach enabled to incorporate the anatomy of each single patient into a flexible anamorphotic reference system.[18] Furthermore, stereotactic and stereoscopic tele-angiography provided excellent definition of the gyral and sulcal anatomy of the brain,[19,20] and allowed to plan avascular trajectories for electrode placement through a double grid mounted on the custom-made Talairach's frame.[21]

Since the pioneering experience of the Paris group, the development of modern neuroradiology and of image-fusion techniques have progressively increased the safety of the methodology and the accuracy of stereotactic targeting of intracerebral structures.[22,23] Nevertheless, the baseline concepts of a single 'stereotactic environment', where electrophysiological, morphological and functional information may be imported and entered in a dynamic process of correlation to define the 3-dimensional organization of an epileptic discharge, are still topical in the current era of SEEG and they have been relevant for the development of modern epilepsy surgery and stereotactic neurosurgery.[24–26]

Indications

In our centers, approximately 40% of resective surgical procedures in patients with drug-resistant focal epilepsy have been performed so far after chronic intracranial EEG monitoring with stereotactically implanted intracerebral electrodes (SEEG). Nevertheless, this proportion is progressively decreasing, and in the last two years it has dropped to less than 35%. This is the result of the growing experience of the teams

dedicated to selection of patients and of the refinement of available diagnostic tools, mainly in the field of neuro-imaging, which enabled to reduce the indications to invasive diagnostic procedures.

From a general point of view, invasive recordings are indicated whenever the non-invasive investigations fail to correctly localize the epileptogenic zone. This is the result of a varying degree of incoherence among anatomical, electrical and clinical findings, which is peculiar for every given patient. Although this means that indications to a SEEG exploration are usually customized to the requirements of single cases, a retrospective analysis of our experience allows to group the indications into different patterns of anatomo-electro-clinical incoherence that configure the need for invasive monitoring.[27] This issue is extensively detailed in Chapter 76 by Kahane–Francione.

Planning

General principles

The available noninvasive anatomo-electro-clinical data are reviewed to formulate a coherent hypothesis of localization of the EZ and to plan a consistent tailored strategy of exploration. This decisional process requires a good experience in the interpretation of electro-clinical patterns of focal seizures, as well as a detailed knowledge of the functional anatomy of the brain, including that of both intra- and interhemispheric connections. Furthermore, one has to take into account the intrinsic peculiarities of multilead intracerebral electrodes, which, despite a limited coverage of the cortical surface compared to subdural strips or grids, enable an accurate sampling of the structures encountered along its trajectory, from the entry site to the final impact point. In this way, the investigation may include lateral and mesial surface of the different lobes, fissural and deep-seated cortices, as well as different kinds of lesions (Figure 104.1).

The implantation strategy should be addressed to record from the regions considered the most likely origin of the discharge (including the lesion, if present) as well as from all the structures possibly involved in the organization of the discharge through the more common pathways of propagation, as suggested by available electro-clinical findings. Furthermore, one should arrange the exploration taking into consideration also possible alternative hypothesis of localization, with number and sites of additional electrodes consistent with the likelihood of these hypothesis. The aim to obtain all the possible information from the SEEG exploration should not be pursued at the expense of an excessive number of electrodes. The possible involvement of eloquent regions in the ictal discharge requires their judicious coverage, with the twofold goal to assess their role in the seizure organization and to define the boundaries of a safe surgical resection.

Patterns of explorations

The SEEG methodology emphasizes a tailored strategy of exploration, which results from the anatomo-electro-clinical features of every case, therefore rejecting a standardized arrangement of electrodes. Nevertheless, a posteriori, a number of typical patterns of coverage are clearly recognizable, and some illustrative examples of the more frequent of them will be herein detailed.

Cases of temporal lobe epilepsy with consistent anatomo-electro-clinical findings are usually operated on after noninvasive investigations. SEEG recordings may be required in patients in whom the supposed epileptogenic area, though probably involving the temporal lobe, is suspected to extend also to extratemporal areas (so called 'temporal plus' epilepsies).[28] In these cases, the main implantation patterns point to disclose a preferential spread of the discharge to the insulo-opercular complex,[29,30] to the temporo-parieto-occipital junction (Figure 104.2), or to the anterior frontal cortex. Sampling of extratemporal areas must be wide enough to provide

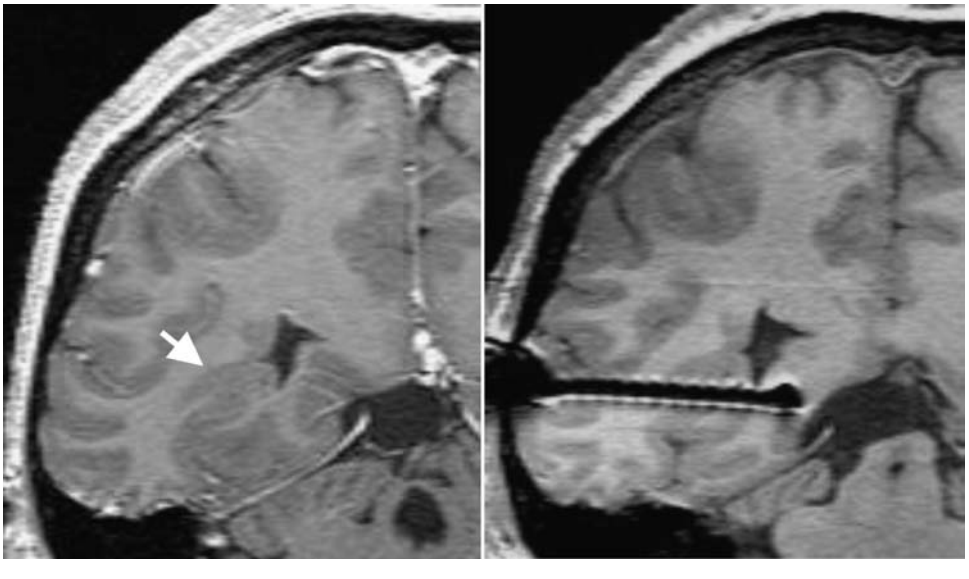

Figure 104.1 Left: pre-implant Gadolinium-enhanced T1-weighted coronal slice showing a nodular heterotopia at the right temporo-occipital junction (arrow). Right: T1-weighted 3D post-implantation MRI, coronal slice at the same level, showing an intracerebral electrode sampling the lateral cortex, the lesion and the cortex mesial to ventricular trigone. The electrode artifact generated in this sequence (as well as in the MRIs appearing in the following figures) is three-fold thick (2.5 mm) compared with the actual thickness of the electrode (0.8 mm). Single contacts on the length of the electrode are easily recognizable.

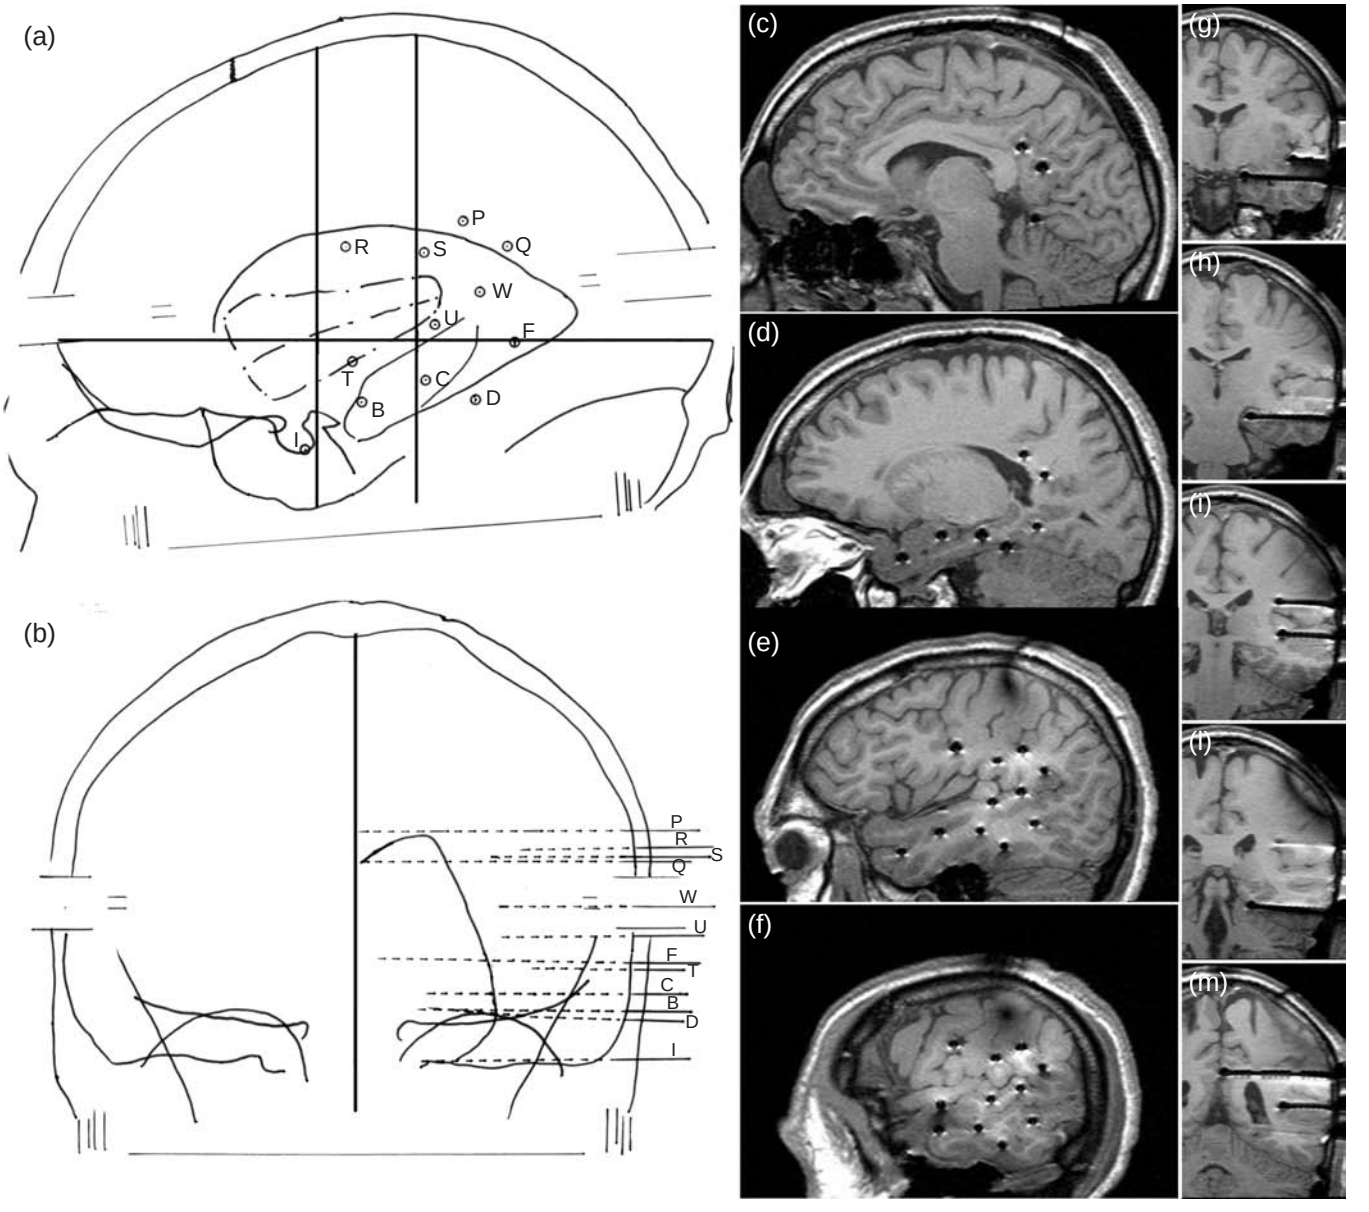

Figure 104.2 Lateral (A) and antero-posterior (B) views of the stereotactic sketch, according to the bicommissural reference system, of a left inferior temporal-parietal SEEG exploration. Electrodes are indicated with either circled dots or dashed lines labelled by upper case letters. C-F: T1-weighted 3D post-implantation MRI, where the arrangement of electrodes is shown in some sagittal slices. G–M: same MRI, coronal slices.

information also to identify a possible extratemporal origin of the seizures that could not have been anticipated with certainty according to scalp EEG and clinical findings.

Owing to the large volume of the frontal lobe, one can expect that a high number of electrodes is required for an adequate coverage of this region. In most patients, however, taking into account ictal clinical data and the related surface EEG expression, such a very large sampling can be avoided, and the exploration is focused on (but not restricted to) a more limited portion of the frontal lobe. The suspicion of an orbito-frontal epilepsy, for instance, often requires to investigate both the gyrus rectus and the orbital cortex (using oblique electrodes that also evaluate the frontal pole), the lateral fronto-basal cortex, the anterior cingulate gyrus (including Brodmann areas 32 and 24), and the anterior portion of the temporal lobe (Figure 104.3). In the same way, seizures that are thought to arise from the mesial wall of the premotor cortex are evaluated by targeting at least the rostral and caudal part of the supplementary motor area (SMA), the pre-SMA, different portions of the cingulate gyrus, as well as the primary motor cortex, mainly for functional mapping purposes (Figure 104.4). Proceeding this way, hypothesis-based sampling often allows localization of the seizure onset zone in the frontal lobe, and in some cases may allow to identify very small epileptogenic regions.[31] Occasionally, frontal lobe explorations may be bilateral, but almost always very asymmetric, because the question of the 'affected side' is usually addressed to before placement of electrodes.

Rolandic electrodes are placed when MRI shows anatomical abnormalities within or close to this region and/or when its involvement in the EZ may be suspected, with the aim to evaluate the rolandic participation to the ictal discharge and to obtain a functional mapping by intracerebral electrical stimulations. This is not infrequently required when seizures

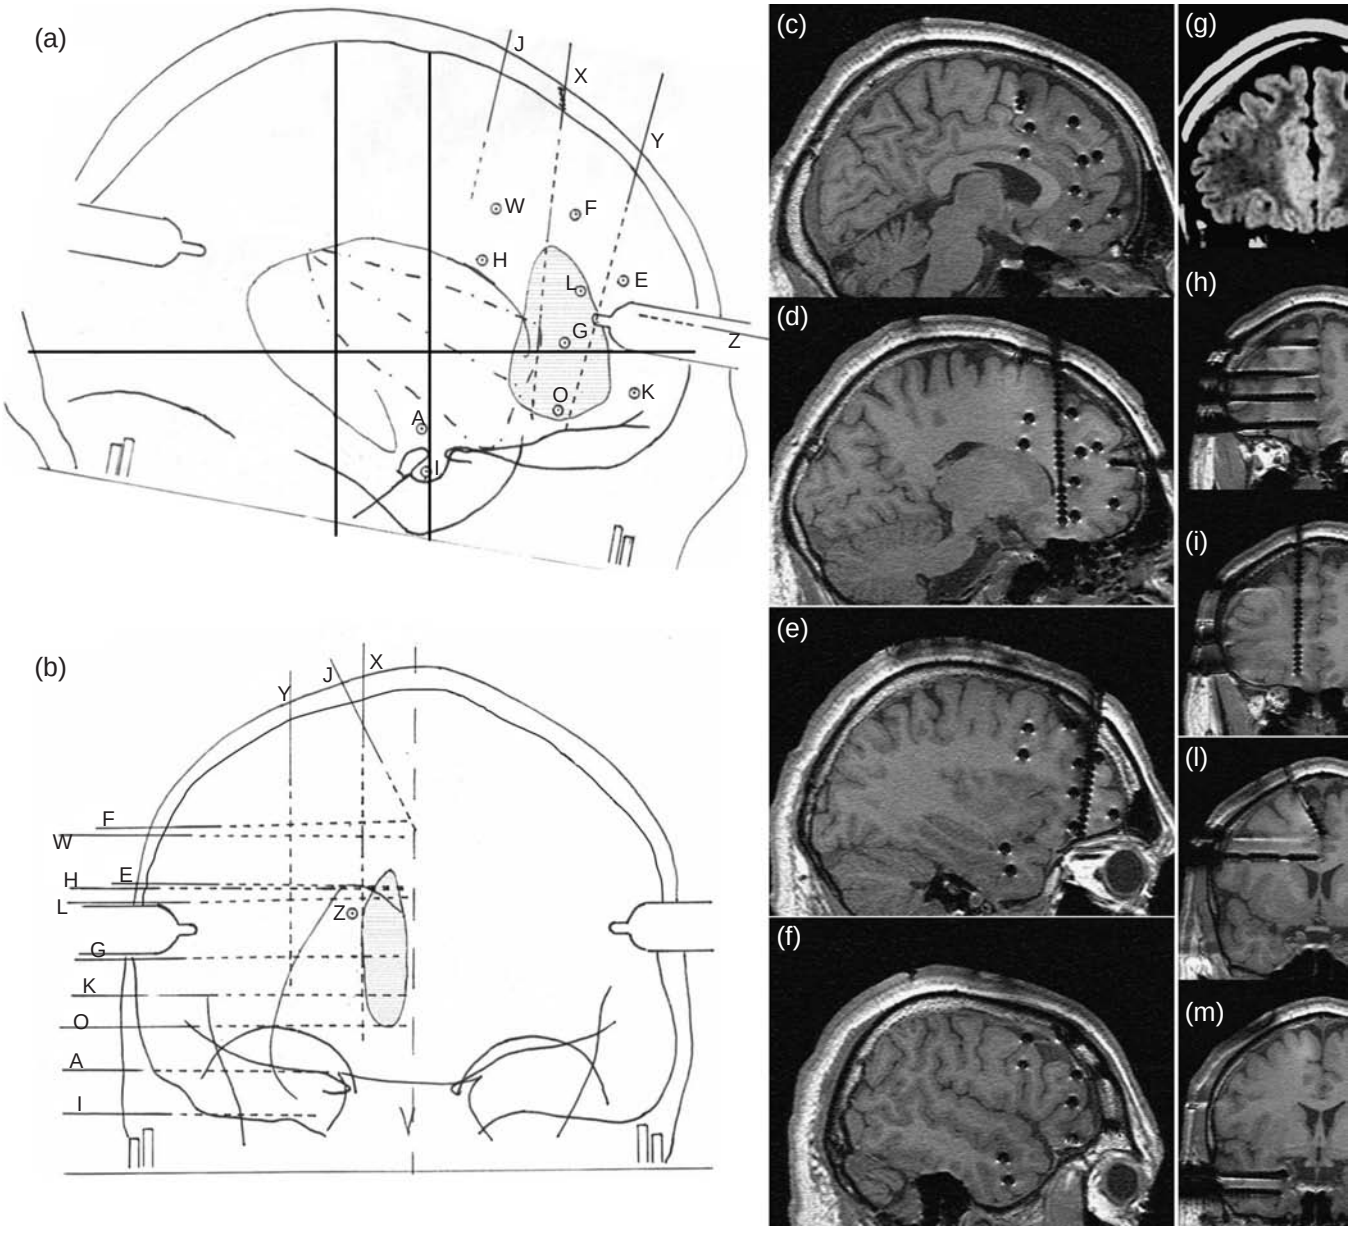

Figure 104.3 Lateral (a) and antero-posterior (b) views of the stereotactic sketch, according to the bicommissural reference system, of a right fronto-orbital and anterior temporal SEEG exploration. Electrodes are indicated with either circled dots or dashed lines labelled by upper case letters. The contoured and shaded area corresponds to a focal cortical dysplasia detected at MRI, incorporated into the stereotactic space by co-registering the 3D MRI to the stereotactic angiography. c–f: T1-weighted 3D post-implantation MRI, where the arrangement of electrodes is shown in some sagittal slices. g: pre-implant coronal T2-weighted FLAIR MRI image, showing the hyperintense dysplastic lesion on the mesial aspect of the anterior portion of right frontal lobe. h–m: coronal slices of post-implantation 3D MRI. Box h shows sampling of the lesion by the internal contacts of electrodes 'L', 'G' and 'O' (see the stereotactic scheme).

are suspected to start in the frontal or parietal lobes and to propagate subsequently to the perirolandic areas. In the central region, intracerebral electrodes are particularly helpful to sample the depth of the rolandic fissure, as well as the descending motor and ascending sensory pathways.

In the posterior quadrant of the hemisphere, placement of electrodes limited to a single lobe is extremely uncommon, due to the frequent simultaneous involvement of several occipital, parietal and posterior temporal structures, as well as to the possible multidirectional spread of the discharges to supra- and infra-sylvian regions. However, though multidirectional, posterior discharges often show a preferential spreading pattern that has to be adequately assessed by employing implantation strategies which mainly focus on parietal, occipital and temporal areas (Figure 104.5).

Technical aspects

Stereotactic neuroradiology

In all patients a cerebral stereotactic stereoscopic teleangiogram,[20] by injection of the appropriate vessels through catheterization of the femoral artery, is obtained after placement of the Talairach frame by transosseous pins and under general anesthesia.

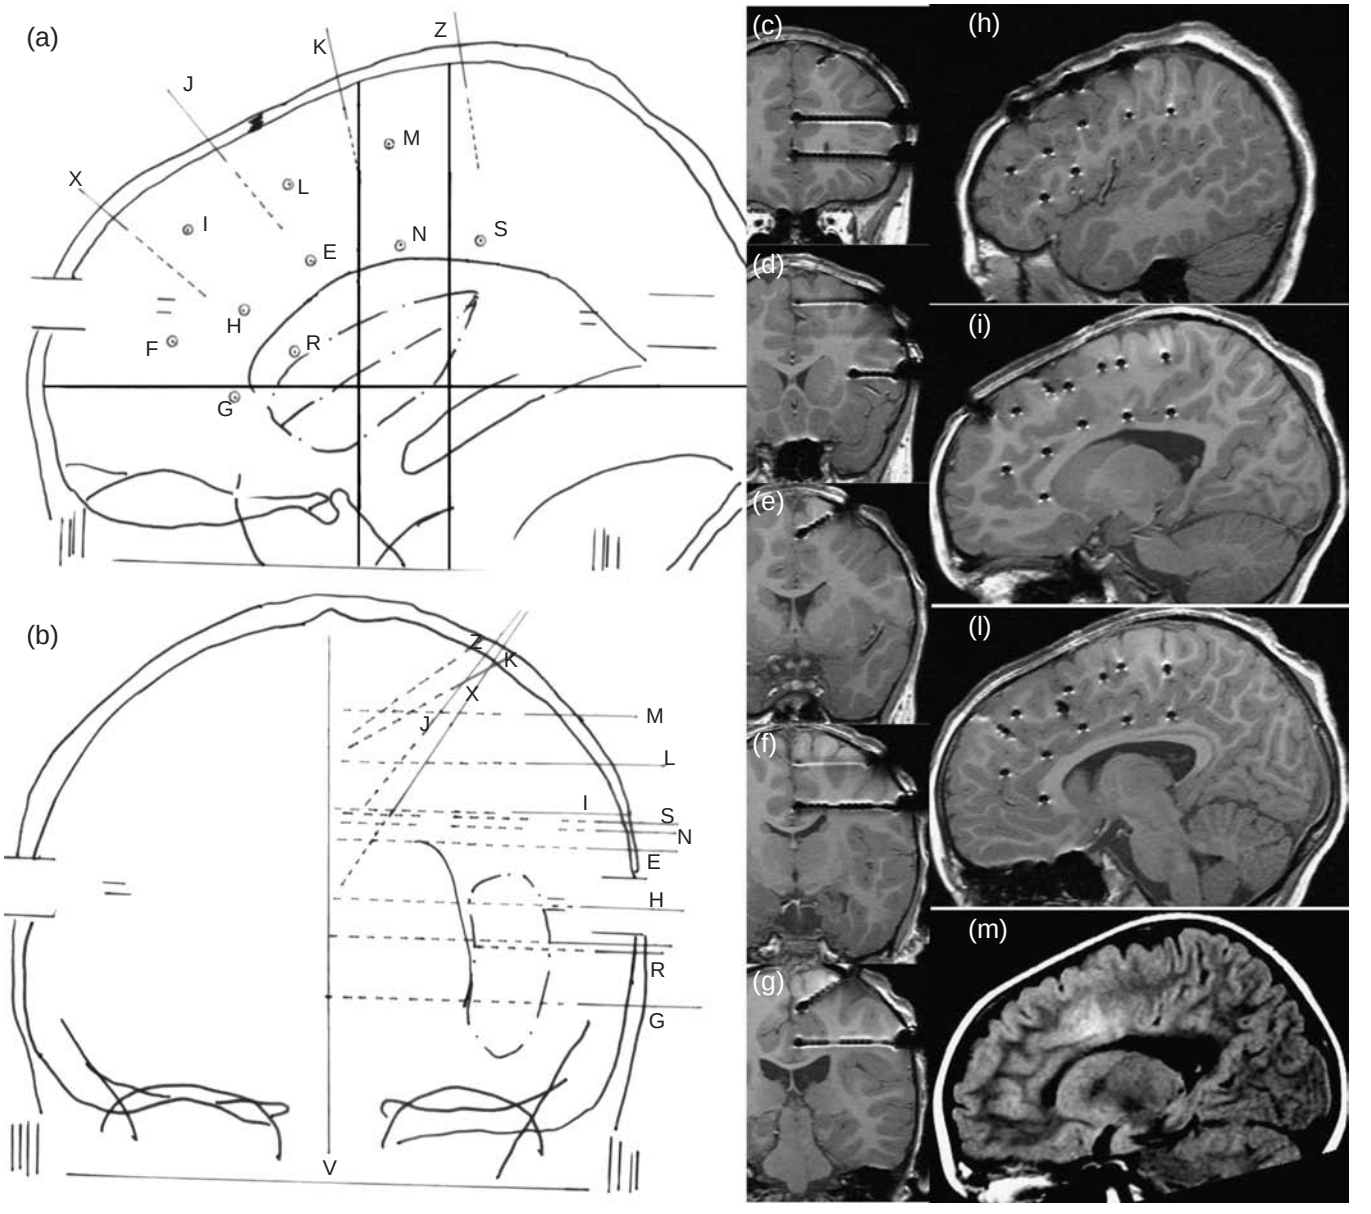

Figure 104.4 Lateral (a) and antero-posterior (b) views of the stereotactic sketch, according to the bicommissural reference system, of a left fronto-parietal SEEG exploration. Electrodes are indicated with either circled dots or dashed lines labelled by upper case letters. c–g: T1-weighted 3D post-implantation MRI, coronal slices, showing the arrangement of some of the intracerebral electrodes. h–l: same MRI, sagittal slices. m: preimplant T2-weighted FLAIR sagittal sequence, showing a precentral mesial focal cortical dysplasia, which was sampled by internal contacts of electrodes 'E', 'J' and 'L'.

The X-ray sources are placed at 5 m distance from the patient's head in order to obtain nearly distortion-free images in the lateral and anterior-posterior views. Two series of angiograms are obtained by both an orthogonal and a slightly oblique incidence (±6 degrees) of the X-rays. The coupled vision of corresponding phases of the two series enables a stereoscopic 3-dimensional effect, which is particularly helpful to distinguish vascular structures in different anatomical planes. Furthermore, 3D MR images (spoiled gradient echo T1-weighted gadolinium-enhanced sequence, slice thickness 1 mm, no gap, matrix 512×512) are imported in a computer-assisted neuronavigational module (STP 4.0, Leibinger/Fischer, Freiburg, Germany, or Voxim, IVS, Chemnitz, Germany) and co-registered with angiographic images. In this way, a stereotactic diagram may be plotted, which includes arterial and venous vessels, anatomical structures and possible lesions within the same geometrical referential space (Figure 104.6). This direct stereotactic localization procedure is employed in order to plan avascular trajectories for electrodes intended to reach well defined intracerebral structures.

Placement of electrodes

Placement of intracerebral electrodes is performed usually in a separate procedure (in order to dedicate all the time required to the accurate planning of trajectories), under general anesthesia and following refixing the frame exactly in the same position as for the previous stereotactic arteriographic study.

Several thousands of commercially available, platinum-iridium, semiflexible multilead intracerebral electrodes

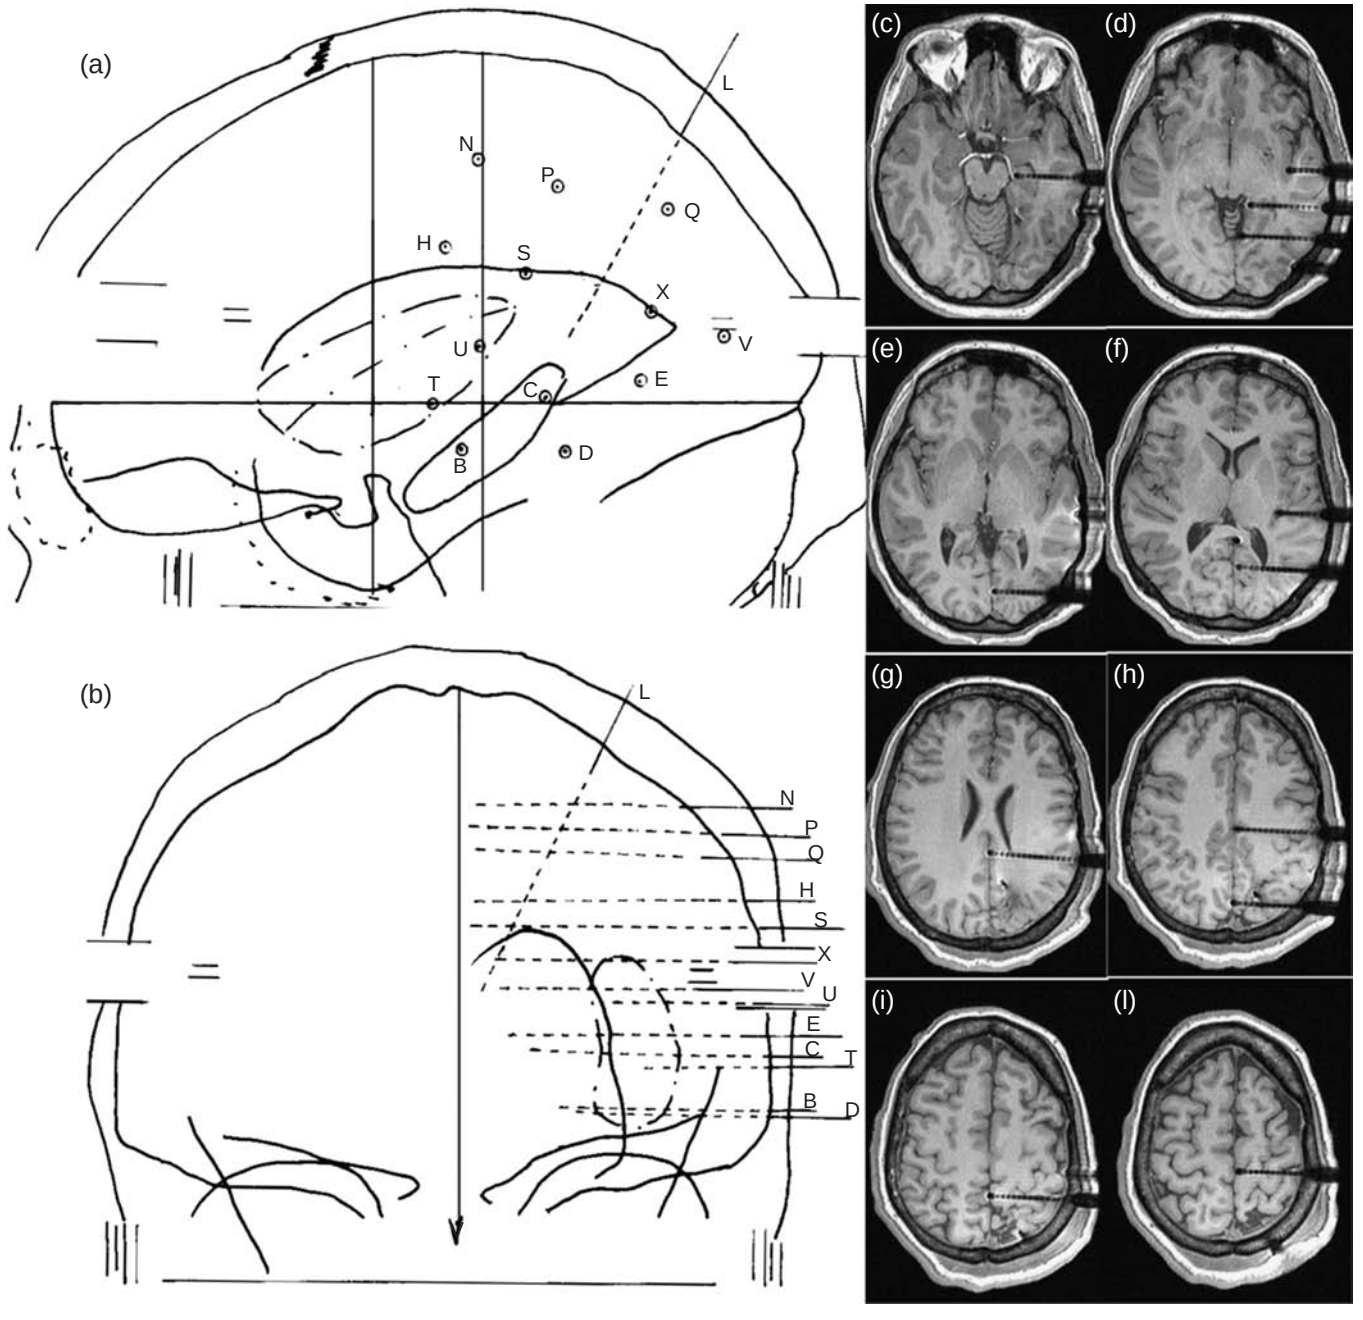

Figure 104.5 Lateral (a) and antero-posterior (b) views of the stereotactic sketch, according to the bicommissural reference system, of a left temporo-occipito-parietal SEEG exploration. Electrodes are indicated with either circled dots or dashed lines labelled by upper case letters. c–l: T1-weighted 3D post-implantation MRI. The electrode arrangement is shown in eight axial slices.

(diameter 0.8 mm; 5–18 contacts of 1.5 mm length, 2 mm apart) have been implanted so far in our Centers, the number of electrodes per patient ranging from 3 to 20 (mean 12 ± 3 electrodes/patient). The exploration is unilateral in most cases; bilateral (but not symmetrical) explorations account for less than 20% of the procedures.

Antibiotics (cephamezine, 1–2 gr i.v. depending on patient's weight in a single bolus) are routinely administered at anesthesia induction.

Electrodes may be successfully placed by either orthogonal (i.e., perpendicular to the frame 'midline' plane or, less frequently, to the 'coronal' plane of the frame itself) or oblique trajectories in all the cerebral lobes. Targeting of deep-seated or mesial structures such as the amygdala, hippocampus, cingulated gyrus, calcarine cortex is feasible, as well as excellent sampling of the insular cortex by electrodes inserted through the supra- or infra-sylvian opercula or by a retro-insular trajectory with a fronto-polar entry point (Figures 104.7–104.10).

For the implantation of each electrode, a skull percutaneous trephination is performed with a 2.3 mm twist drill, guided through metallic double grids. Alternatively, a computer-assisted robotized tool holder fully dedicated to stereotactic procedures (NeuroMate, Integrated Surgical Systems, Davis, CA, USA) which enables practically infinite degrees of freedom, is employed to insert electrodes with complex obliquities.

Figure 104.6 The lateral view of this stereotactic scheme shows several anatomical structures incorporated into the stereotactic space. The different structures are imported from the stereotactic skull X-ray film (bone profiles, black lines), from the stereotactic angiograms (profile of the insular vessels and of the sylvian fissure, dotted and dashed red line; some mesial and dorso-lateral arteries, red lines; a mesial vein, blue line) and from a co-registered 3D MRI (profiles of the ventricular cavities, violet; profile of the hippocampus, pink). The bicommissural referential system (thick black lines) has been drawn on the sagittal midline MRI slice and imported in the stereotactic space as previously described. (See Color plates.)

The dura is perforated by low-current monopolar coagulation. Minor leakage of cerebro-spinal fluid is often observed at this stage, but it does not require particular attention. Titanium hollow pegs (external diameter 2.5 mm), for the insertion and the fixation of the electrodes, are then screwed to the skull. A rigid stylet (diameter 0.8 mm) is then advanced through the peg as far as the established target under fluoroscopic control, in order to trace the intracerebral track of the electrode. After removal of the stylet, the electrode is inserted and advanced to the target. A plastic cap fixes the electrode to the peg and prevents possible CSF leakage. EEG signal provided by all implanted electrodes is checked in the operating room, enabling replacement of malfunctioning electrodes, which is however an uncommon occurrence. The cables are sutured to the skin and a sterile medication is applied. The patient is then awakened from anesthesia and moved to the recovery room.

Intensive video-EEG monitoring usually starts the day following implantation, with the purpose of recording patient's habitual ictal manifestations. After an adequate number of seizures is obtained, the patients undergo the sessions of intracerebral electrical stimulations (see below). Mean duration of video-SEEG monitoring approximates 10 days.

An MRI with implanted electrodes is obtained in all cases, in order to define the actual position of each electrode contact. Nevertheless, local artifacts generated by the electrodes may prevent the accurate anatomical location of each individual electrical contact. This technical problem can be overcome by image fusion of post-implantation MRI or CT scan and preoperative 3D MRI investigation.

Removal of electrodes

Once monitoring is completed, electrodes are withdrawn. In most patients local anesthesia is employed, though sedation may be required in less cooperative patients and children. The plastic caps are removed, then each electrode is gently withdrawn and accurately inspected in order to check its integrity. Once all the hollow pegs have been unscrewed, a skin suture is applied to each electrode entry site and a sterile medication applied. The patient is usually discharged the day after.

Functional mapping

High- and low-frequency intracerebral electrical stimulations, delivered to pairs of contiguous contacts, have the two-fold goal to induce habitual ictal manifestations and to provide a functional map of the implanted regions.[32–34] For these issue see also the chapter by Minotti.

Intracerebral electrical stimulations performed for functional purposes enable the identification of regions related to different critical functions: primary somatomotor and somatosensory, visual, acoustic, and speech. Positive responses consist of either objective clinical events (e.g., clonic jerks of circumscribed body districts, errors in naming or reading, tachyphemia) or subjective manifestations (dysesthesic sensations, positive or negative visual and acoustic phenomena) concurrent with electrical stimulations. For primary sensory-motor functions low-frequency stimulations (frequency 1 Hz, duration of single stimulus 2–3 msec, current intensity 0.4–3 mA) are preferred.[32] In most cases, positive responses may be obtained from stimulations both in grey and white matter, thus allowing to map critical pathways extensively. Speech and visual areas are mapped using a combination of low and high-frequency (frequency 50 Hz, duration of single stimulus 1 msec, current intensity 1–3 mA) stimulations. Low-frequency stimulations are usually adequate in inducing subjective acoustic changes, the effect of high frequencies resulting often unpleasant for the patient.

Chronic intracerebral seizure monitoring coupled with functional mapping is crucial in distinguishing between patients with early ictal involvement of highly eloquent regions, who should be excluded from surgery, and those with later spread of the discharge to these structures, who can be operated on with limited surgical risks and with predictable benefit on seizures. Functional mapping allows to anticipate potentially acceptable postoperative deficits, such as visual field defects in posterior temporal, occipital and parietal resections, as well as to evaluate the risk-to-benefit ratio of excisions close to more critical regions, such as sensory-motor and language areas. Though similar functional information can be obtained also from acute intraoperative electrical cortical stimulation, the following points must be stressed. First, chronic SEEG intracerebral electrical stimulations makes mapping of both cortex and fibres feasible, allowing to plan safer resections also in potentially critical subcortical areas. Second, availability of functional information before and not during surgery allows the patient to participate in the discussion of the risk-to-benefit balance in a relaxing and comfortable setting. Third, intraoperative electrocorticography only exceptionally results in spontaneous seizures recording, which is essential in evaluating the actual ictal involvement of eloquent areas.

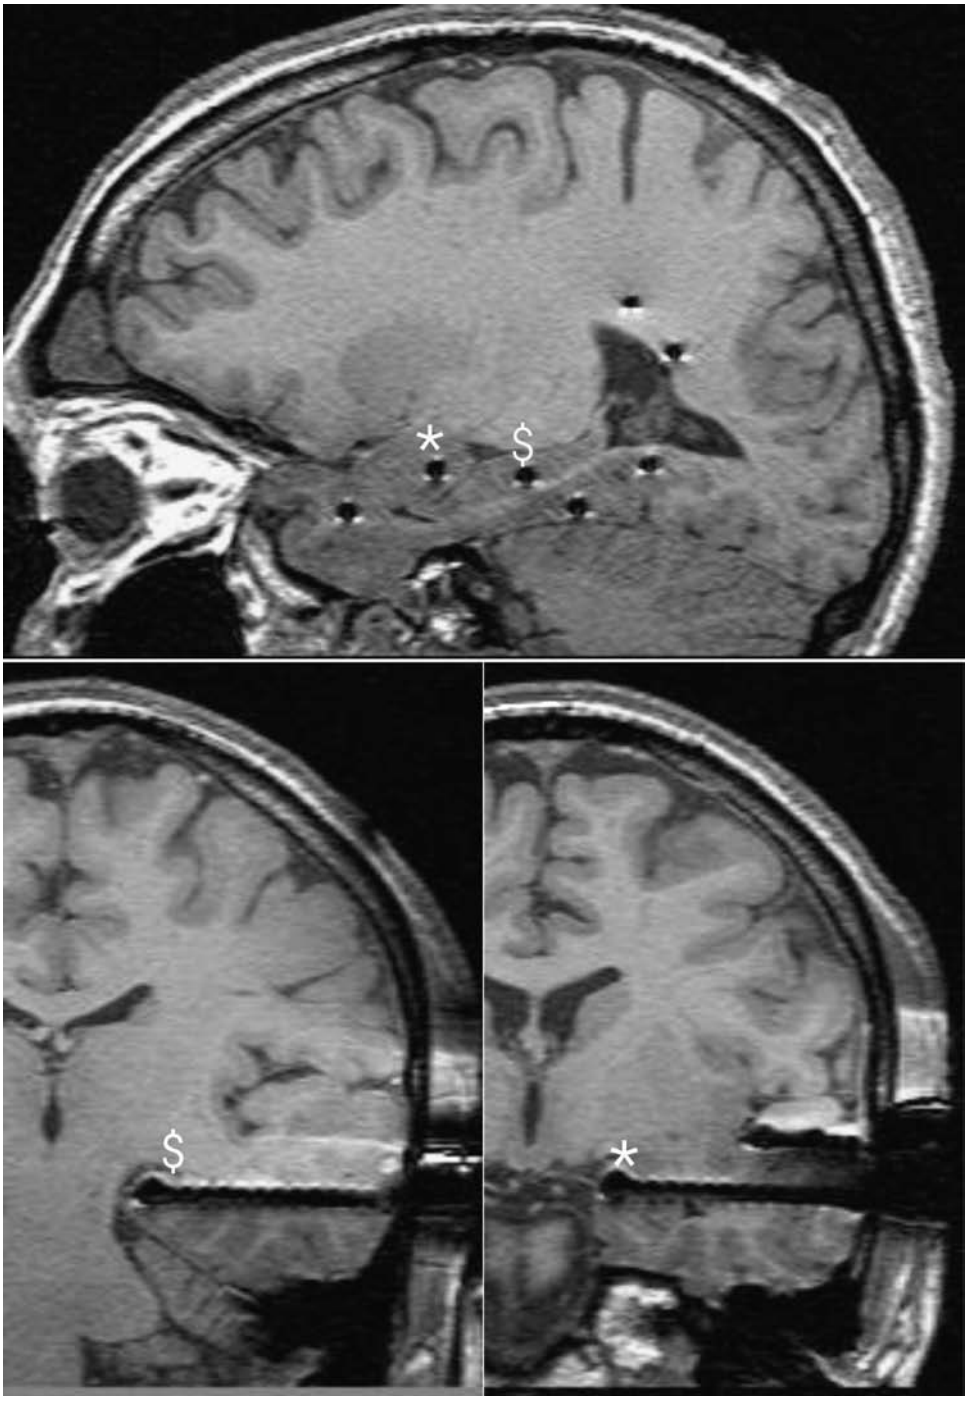

Figure 104.7 T1-weighted 3D post-implantation MRI. In the sagittal slice at the level of the left mesial temporal structures electrodes sampling the amigdala (*) and hyppocampus ($) are highlighted. The coronal slices are parallel to the trajectories of the two electrodes.

SEEG-guided thermo coagulation

Though SEEG is merely a diagnostic tool, the employment of this technique for possible therapeutic purposes has been suggested.[35] Following a complete SEEG monitoring, intracerebral electrodes may be used to generate focal lesions of the SEEG-defined EZ. A thermocoagulation with a diameter of 5–7 mm is produced by a radiofrequency generator connected to adjacent electrode contacts. By these means, a variable number of lesions may be produced in the cortical areas selected according to the SEEG data, with no relevant morbidity. Preliminary results are encouraging, with 15% of patients seizure free and 40% with significant improvement after the procedure.[35] This technique, though deserving further evaluation in order to assess its feasibility, safety and efficacy, has been proposed as a possible option in cases with a limited and well-confined EZ, or when resective surgery is contraindicated.

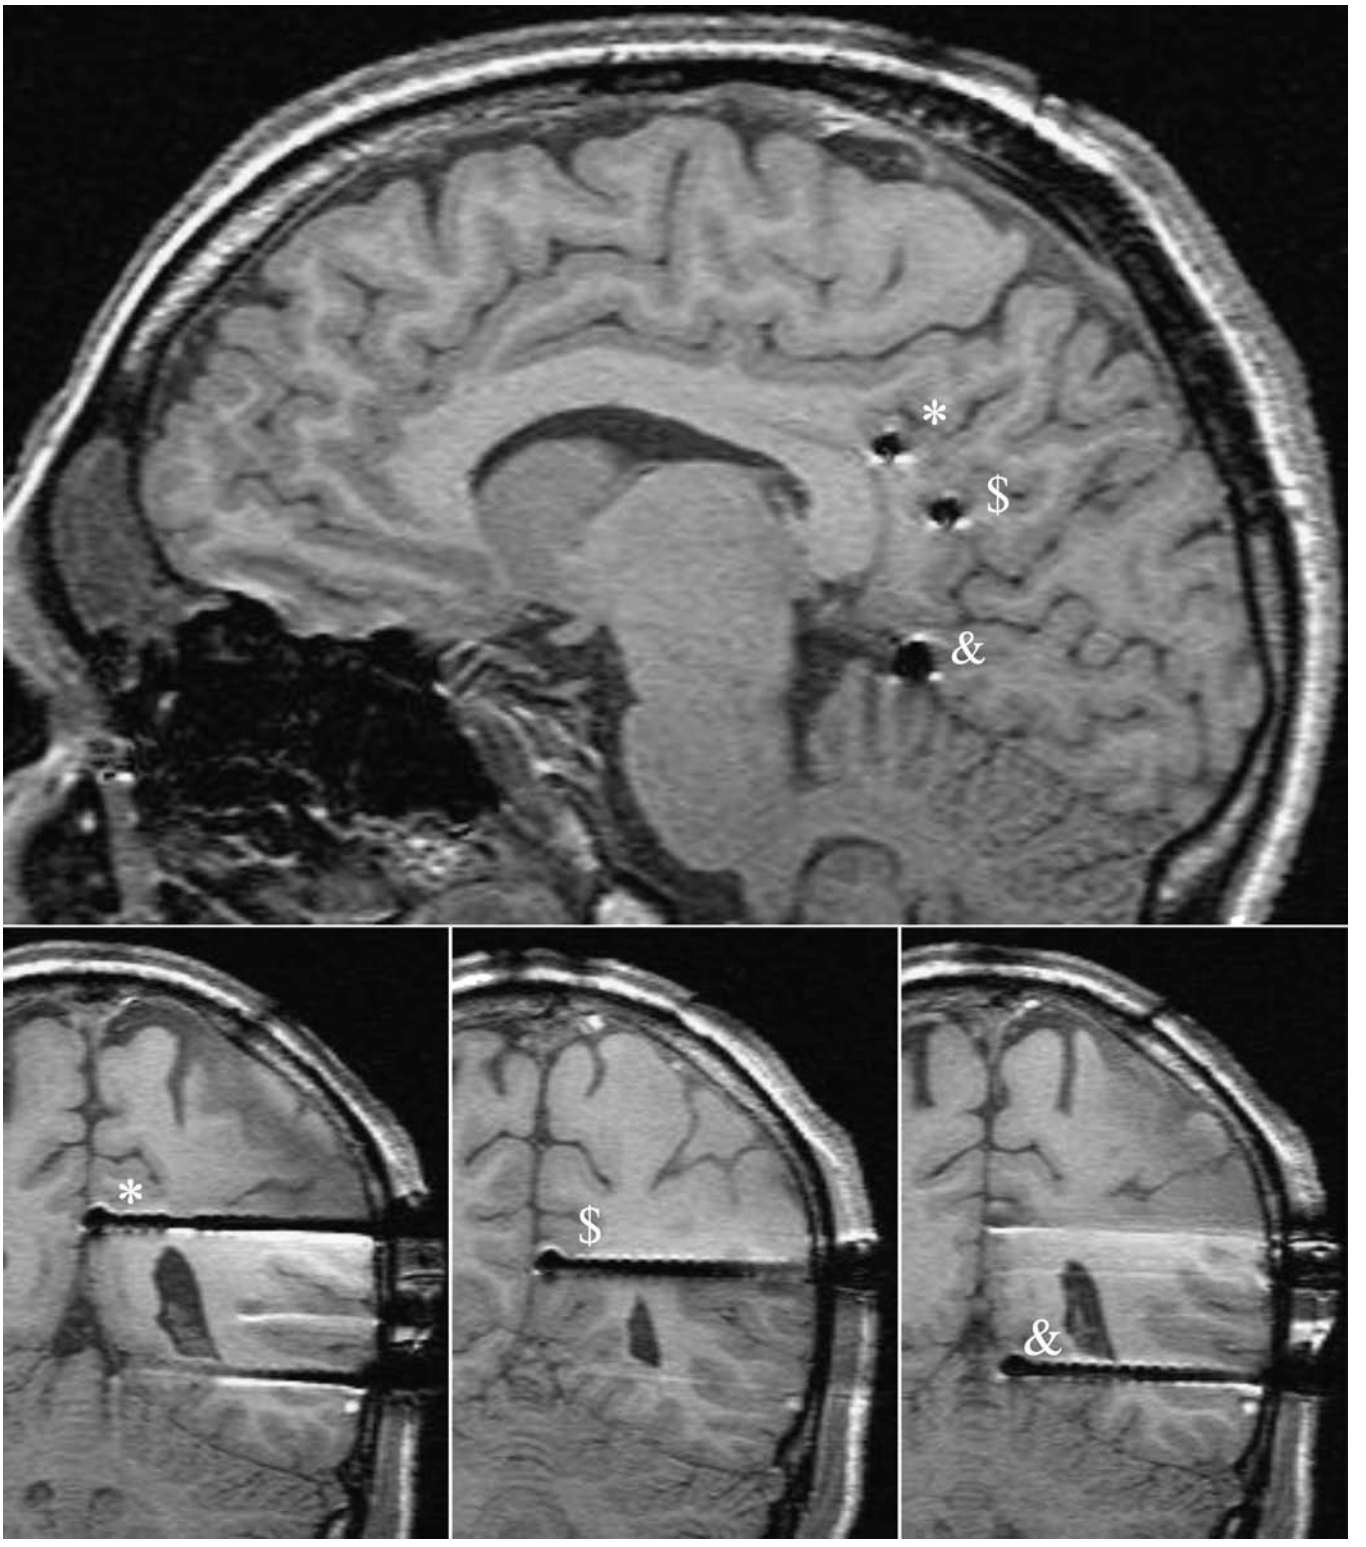

Figure 104.8 The sagittal slice of the T1-weighted 3D post-implantation MRI details electrodes sampling the parietal portion of the cingulated gyrus (*,$) and the anterior portion of the lingual gyrus (&). In the lower row the same electrodes are shown in coronal slices.

Morbidity

Severe intracerebral hemorrhage is the most feared complication of intracerebral electrode placement.[36] Talairach and Bancaud,[16] in a series of 560 cases, report three cases (0.5%) operated on for removal of intracerebral hematomas which developed after SEEG implantation. It is not clear whether these authors observed other cases with intracranial bleeding which did not require surgical treatment, but it is unlikely that such cases were diagnosed by the neuroradiological techniques available in the pre-CT scan or MRI era, even if mild neurological impairment was evident following implantation

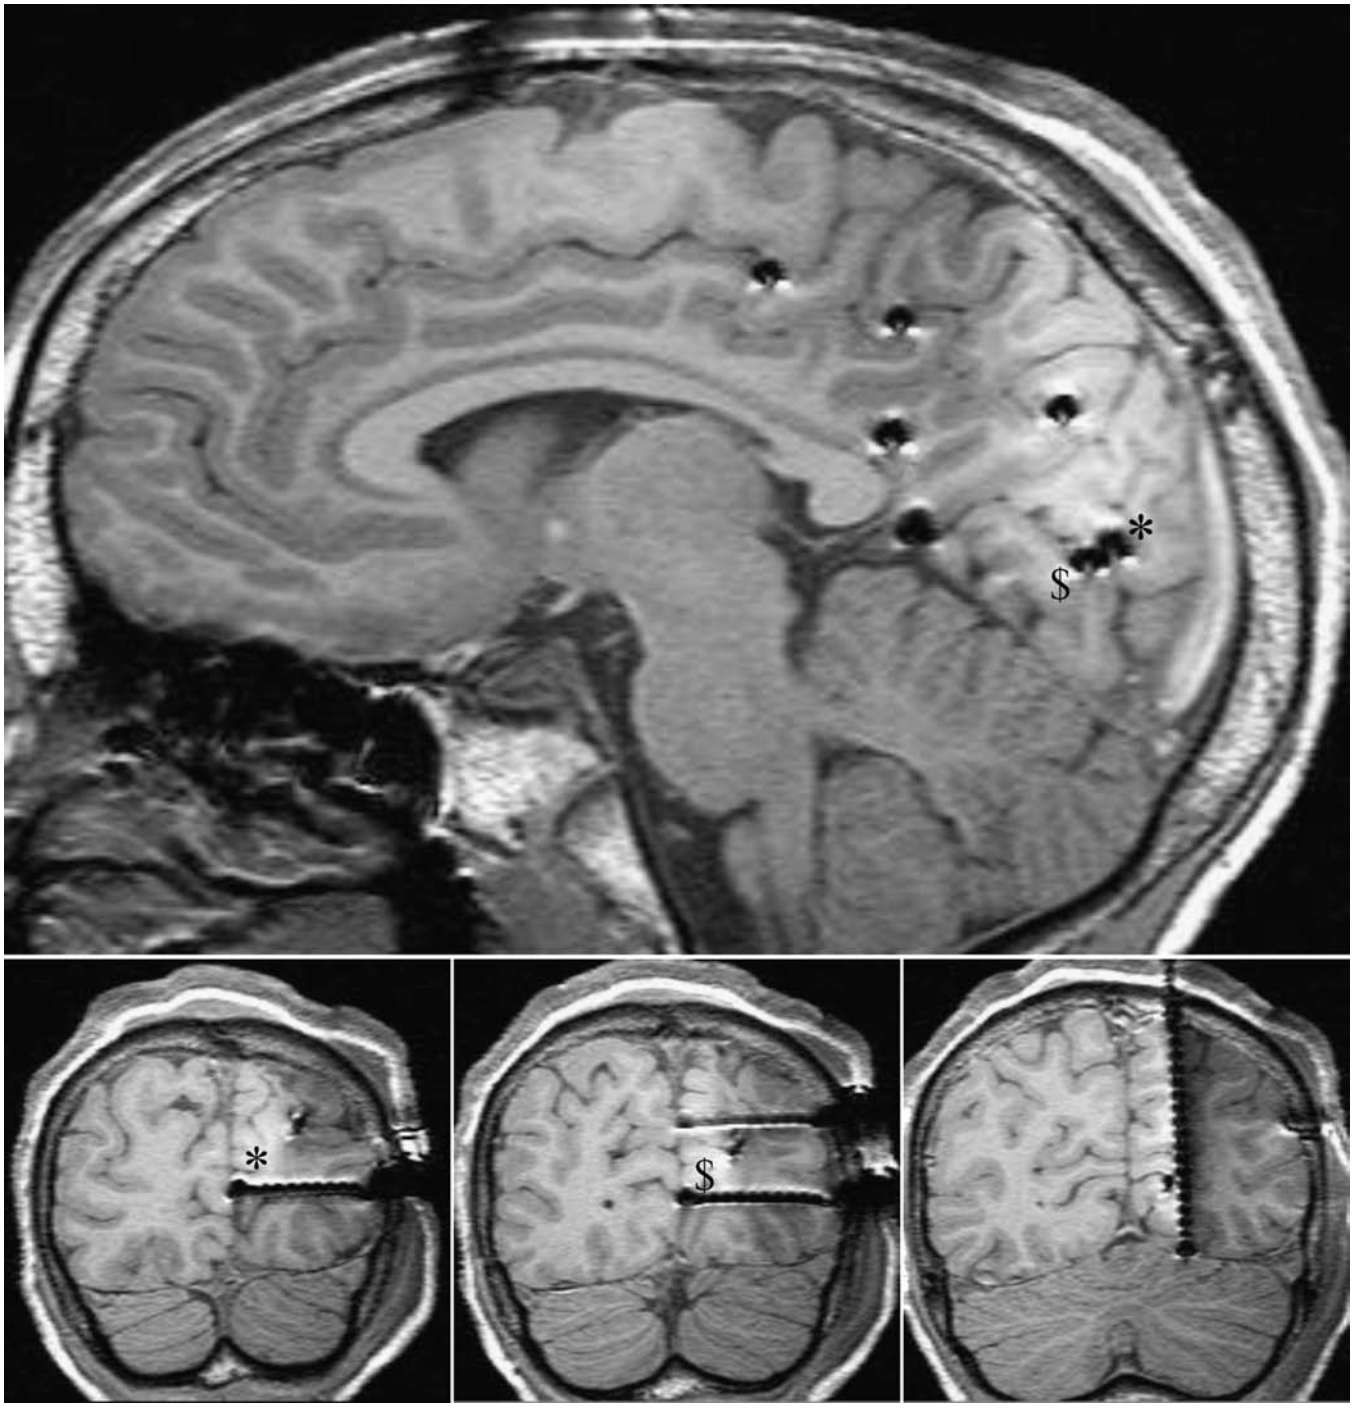

Figure 104.9 The sagittal slice of the T1-weighted 3D post-implantation MRI details electrodes sampling the superior (*) and inferior ($) lips of the left calcarine fissure. In the lower row, the same electrodes are shown in the coronal slices (left and centre). A different trajectory has been employed for an additional electrode which encroaches the calcarine fissure with an entry point in the parietal parasagittal cortex (right).

of intracerebral electrodes. The MNI group experienced one subdural bleed out of 170 cases (0.6%) investigated with intracerebral electrodes.[37] Mortality has also been associated to such complication. Engel *et al.*,[38] in a series of 140 patients, reported two deaths (1.4%) from intracerebral hemorrhage. In a series of 100 SEEG cases one death secondary to an intracerebral clot (1%) has been reported in a patient under anticoagulant treatment for deep vein thrombosis.[39]

The morbidity associated to the SEEG technique described in the present chapter has been recently reported.[27] Out of 215 procedures in 211 patients, complications of different nature occurred in 12 SEEG procedures, for an overall incidence of morbidity as high as 5.6%. There were three acute symptomatic intracerebral hemorrhages which required emergency surgical evacuation, five asymptomatic intracranial bleedings detected at postimplantation MRI, one obstructive

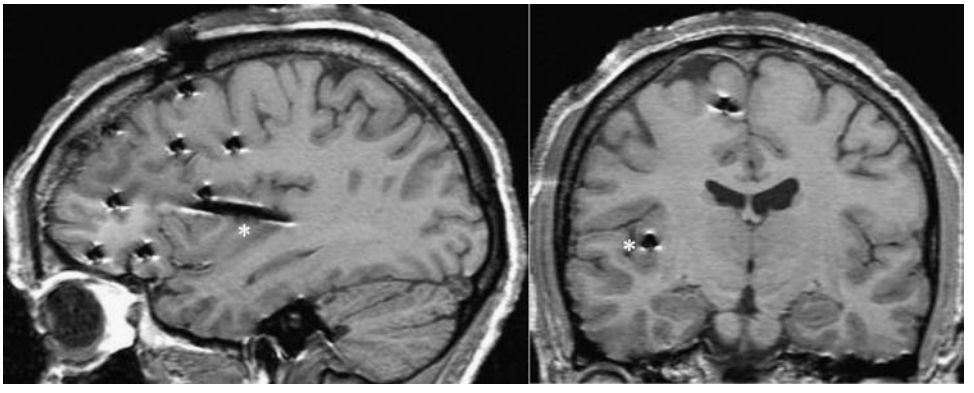

Figure 104.10 Sagittal (left) and coronal slices of a T1-weighted 3D post-implantation MRI, showing an electrode (*) placed in the insular cortex with a fronto-polar entry point.

hydrocephalus due to a clot in the aqueduct in a patient with a platelet disorder, one symptomatic brain abscess, one focal cortical edema and one retained broken electrode. In two cases (0.9%) a permanent motor deficit resulted from massive intracerebral bleeding. No death occurred in that series.

SEEG-guided resection

The contribution of SEEG in addressing the decision whether to operate or not, the choice of an adequate surgical strategy, and the results of SEEG-guided resections may vary among different epilepsy surgery teams.

The results of resective surgery performed relying on the SEEG methodology described in this chapter have been previously reported.[27] Temporal lobe resections have been performed in approximately 25% of the studied patients. In several of these cases the indication to SEEG recording was formulated in the previous decade and, as experience of the teams has increased with time, the rate of temporal lobe resections performed after SEEG has currently dropped to 16%, with invasive tests having been reserved to temporal lobe cases with atypical ictal clinical features[40] (or with poorly localizing ictal EEG. In most patients (75%) SEEG indicated an extratemporal or multilobar ictal onset, a proportion which is comparable to other studies,[41,42] though several reports on invasive EEG tests show a preponderance of temporal lobe epilepsies over other localizations.[43–46]

Overall surgical results on seizures show that 56% of our patients operated on after SEEG investigation are in Engel's[47] class I, with 44% of them being completely seizurefree (Engel's classes Ia and Ic). These proportions conflict with the much more favourable results obtained in patients operated on after noninvasive evaluations (in our experience, 83% in class I and 69% completely seizure-free). It has been reported that employment of invasive EEG predicts a non-favourable outcome on seizures, compared with surgery performed after a noninvasive workup,[48] a finding which probably reflects the particular complexity of patients who need intracranial monitoring.

In a number of patients, ranging close to 13% in our centers, SEEG findings may provide contraindications to resective surgery for different reasons. First, bilateral or multifocal ictal onsets of the epileptic discharge may be detected, a situation which per se does not match a fundamental prerequisite of the surgical treatment of focal epilepsies by resective procedures. Second, coupling electro-clinical monitoring to functional mapping may disclose that not-resectable highly functional cortex is involved by the ictal onset or by the early spread of the discharge. Third, SEEG may fail to define the EZ, indicating that the previously elaborated hypothesis of localization was incorrect. The literature reports a 10–20% rate of poor localization after invasive recordings.[49,50] In this regard, no consensus exists on whether such patients should be considered for repeated invasive tests or not. In our experience, the few patients who received a double exploration before surgery had, at their first evaluation, ictal SEEG evidence of an EZ partially covered by the exploration at the margins of the electrode arrangement, which was therefore corrected in the second step.

Clinical example

This 22-year-old man with a negative familial history of epilepsy was born after a complicated pregnancy with repeat threats of miscarriage. Seizures started at 6 years of age, and prevailed during wakefulness. Administration of carbamazepine resulted in control of seizures for 2 years. Ten months following withdrawal of therapy seizures relapsed, and they persisted despite attempts with different antiepileptic drugs. Progressively, seizures became more frequent during sleep, occurring during wakefulness only occasionally. The patient was awakened by a subjective manifestation of discomfort at his left upper limb associated to a feeling of constraint at his throat which prevented him from speaking. Stiffening of the left upper limb, apnea, bilateral eyelid blinking and a complex hyperkinetic behavior occurred after the subjective phase. Postictally, no focal deficits were observed. A high seizure frequency was reported, with many episodes every night. Neurological examination was normal. Scalp video-EEG monitoring disclosed a possible right anterior onset of seizures.

Brain MRI demonstrated a possible focal cortical dysplasia in the right frontal lobe (Figure 104.11). According to anatomo-electro-clinical considerations, which suggested an early ictal involvement of areas exceeding the anatomical limits of the lesion, a tailored SEEG exploration was indicated. In particular, the presence of early subjective symptoms

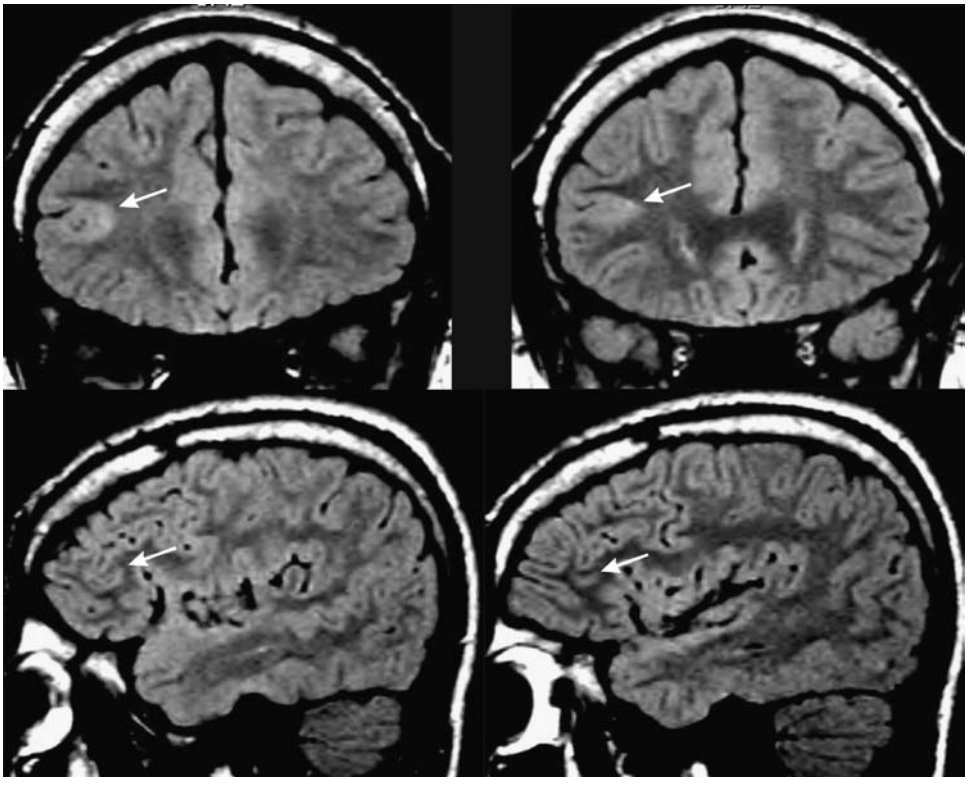

Figure 104.11 T2-weighted FLAIR MRI sequence shows a hyperintense cortical lesion in the anterior portion of the right inferior frontal sulcus (arrow) in both coronal (top) and sagittal (bottom) slices.

pertaining to the visceral domain suggested the possible involvement of the opercular-insular region. In this tailored SEEG exploration intracerebral electrodes covered dorsolateral, mesial (including different portions of the cingulated gyrus), polar, opercular and orbital aspects of the right frontal lobe, the anterior and posterior portions of the right insular cortex and the lesion disclosed at MRI (Figure 104.12). Epileptiform interictal activity, often consisting of rhythmic paroxysmal discharges with no clinical correlates, was recorded from the insular and fronto-opercular cortices (electrodes I and R, deep leads of electrode Z). Ictal discharges, recorded during 18 spontaneous seizures, originated in the same regions, with subsequent spread to the anterior cingulated gyrus (internal leads of J) and posterior-mesial superior frontal gyrus (supplementary motor area, internal leads of M) (Figure 104.13). The lesion showed only a delayed and marginal involvement in the discharge. Intracerebral electrical stimulations of the internal leads of electrode R (opercular cortex) and of insular leads of electrodes I and Z evoked symptoms identical to those experienced during habitual fits, with concomitant electrical discharges in the same sites of the spontaneous seizures.

Therefore, surgical resection of the fronto-central operculum, extended as far as the posterior aspect of the lesion, and of the suprasilvian portion of the insular cortex was performed (Figure 104.14). Histology of the 'lesional' specimen was positive for a cytoarchitectural focal cortical dysplasia, with no relevant alterations having been found in the opercular and insular specimens. It should be stressed, however, that removal of the insular cortex resulted in fragmentation of the specimens, which probably did not allow an adequate histological evaluation. One year after surgery, the patient is seizure free.

Summary

- Stereotactic placement of intracerebral multilead electrode for chronic EEG recording of seizures (SEEG) was introduced in the second half of the last century by the group of Saint-Anne Hospital in Paris, France, for the presurgical evaluation of patients with drug-resistant focal epilepsy.
- SEEG explorations are indicated whenever the noninvasive tests fail to adequately localize the Epileptogenic Zone (EZ). Currently, approximately 35% of our operated-on patients require a SEEG evaluation.
- Arrangement of electrodes in SEEG explorations is tailored according to the peculiar needs of each patient, and it is therefore customized to verify a predetermined hypothesis of localization of the EZ based on pre-SEEG anatomo-electro-clinical findings.
- Multilead intracerebral electrodes are designed to sample cortical structures on the lateral, intermediate and mesial aspect of the hemisphere, as well as deep-seated lesions.
- Planning of avascular electrode trajectories is performed employing stereoscopic teleangiograms of the pertinent vessels obtained in stereotactic conditions, co-registered to 3D T1-weighted gadolinium-enhanced MRI to improve

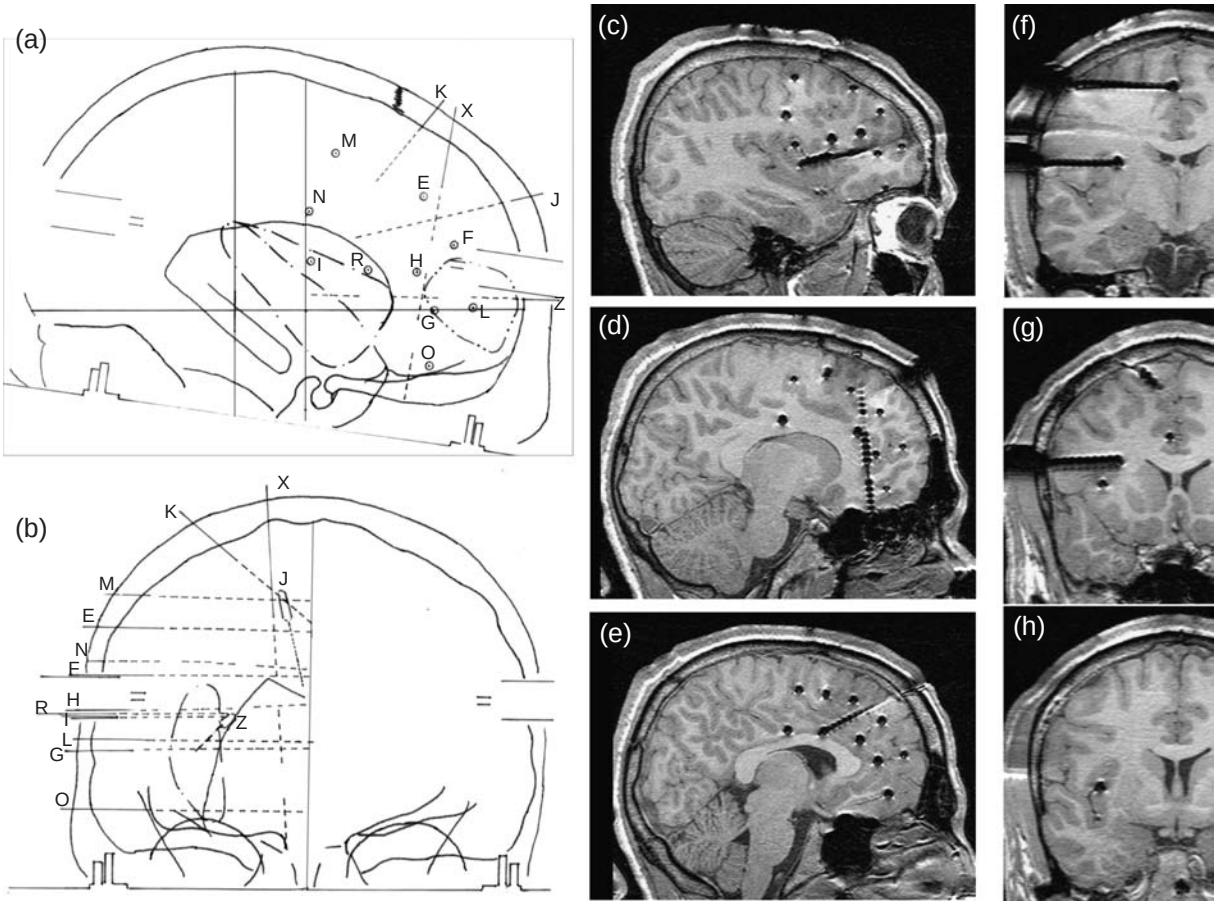

Figure 104.12 a–b: stereotactic scheme showing the electrode arrangement in this SEEG exploration. Electrodes are indicated with either circled dots or dashed lines labeled by upper case letters. The contours of the lesion, incorporated in the stereotactic space by co-registering the stereotactic angiogram and the 3D MRI, are detailed in the lateral view (double-dotted line). Electrodes 'L', 'G', and the external contacts of 'Z' sample the lesion. The insular cortex is sampled by the internal contacts of electrodes 'Z', 'I', and 'R'. In the post-implant 3D T1-weighted MRI, sagittal (c–e) and coronal slices (f–h) provide further details on the structures explored by intracerebral electrodes.

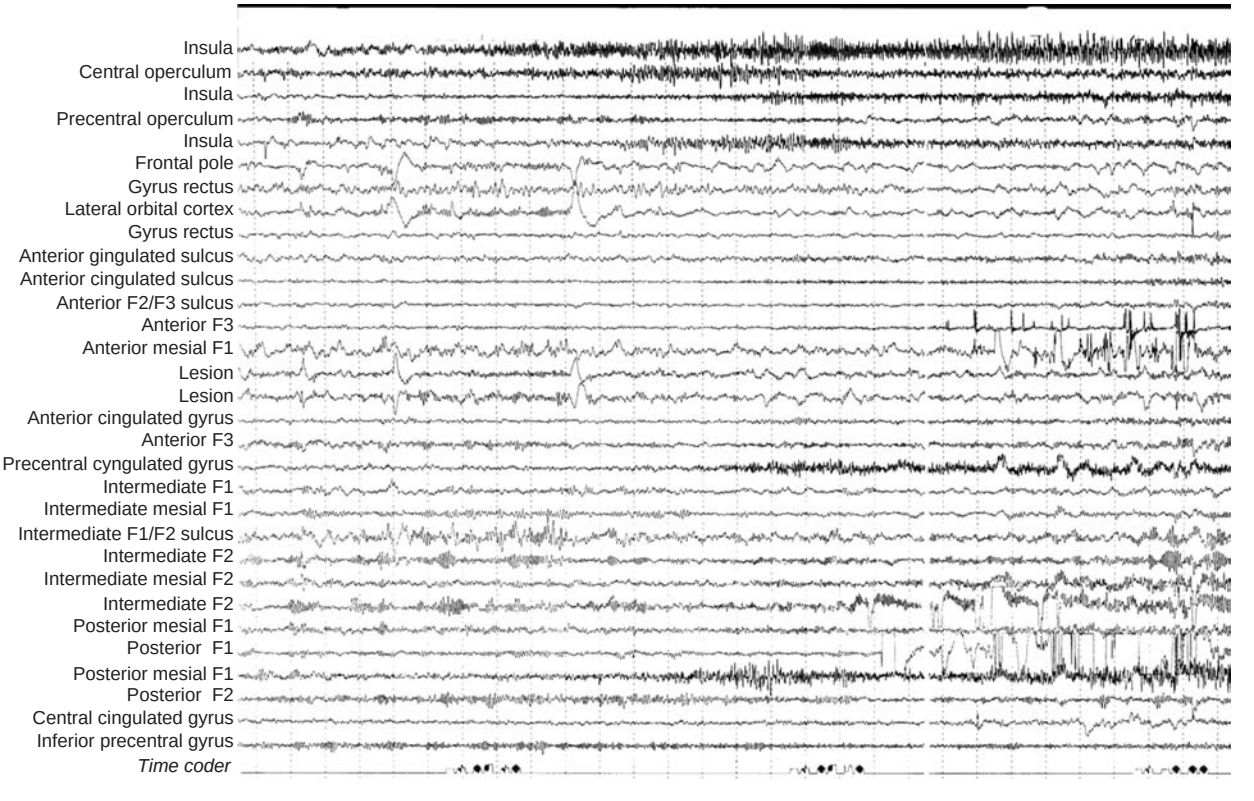

Figure 104.13 Early electrical activity during a spontaneous seizure in a synthetic montage of intracerebral EEG traces. The ictal discharge originates in the insular and opercular cortices, with subsequent involvement of the postero-mesial portion of the superior frontal gyrus (F1) and of precentral cingulated gyrus. The lesion does not show prominent ictal involvement. F2 = middle frontal gyrus; F3 = inferior frontal gyrus.

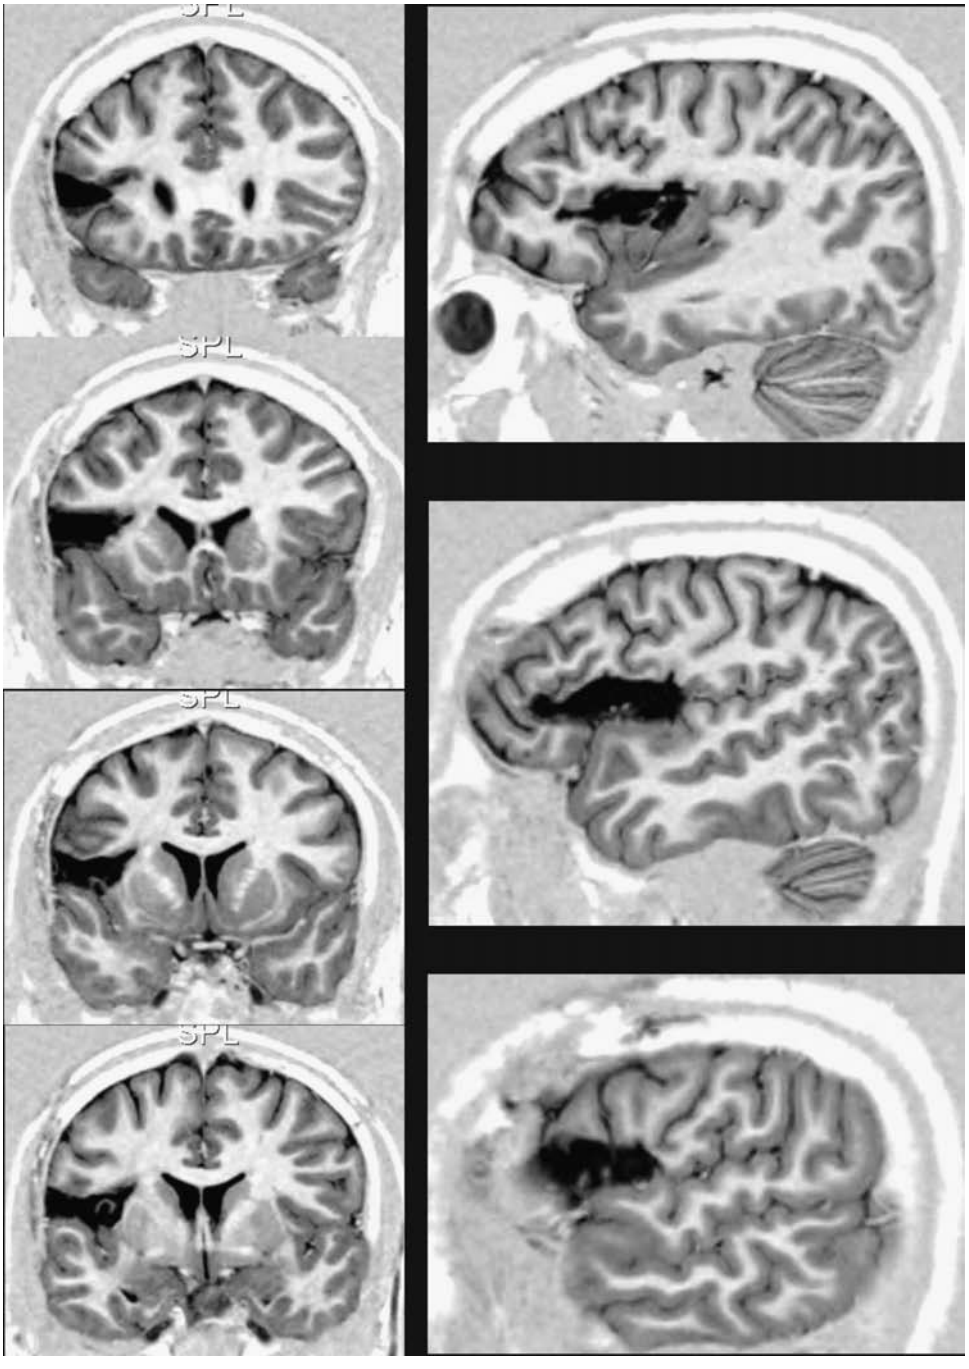

Figure 104.14 Postoperative T1-weighted Inversion Recovery MR images, coronal (left row) and sagittal (right row) slices, obtained six months after surgery, demonstrating resection of the right fronto-central operculum and of the suprasylvian portion of the insular cortex.

the targeting of the desired structures. Pre-SEEG stereotactic neuroradiology and electrode implantation are usually performed in separate procedures. Electrodes are removed once video-SEEG monitoring is completed.

- Intracerebral electrical stimulations are used to better define the EZ and to obtain a detailed functional mapping of critical cortical and subcortical regions, which enables to perform safer surgical resections in eloquent areas.
- Surgical morbidity of SEEG is reasonably low, and it mainly consists of intracerebral bleeding. Permanent post-SEEG neurological impairment is observed in less than 1% of the procedures.
- In approximately 75% of cases, SEEG evaluation enables to guide extratemporal or multilobar resections. SEEG-guided resective surgery may yield excellent results on seizures, with 56% of operated on patients in Engel's Class I.

SECTION 14

Cortical mapping and electrocorticography

105 General principles of cortical mapping by electrical stimulation

SU Schüle, C McIntyre, and HO Lüders

Introduction

History of electrical stimulation of the human brain

The modern objective of resective epilepsy surgery is the complete removal (or disconnection) of the area of cortex indispensable for the generation of clinical seizures without causing a permanent neurological deficit.[1] Electrical cortical stimulation (ECS) has been one of the essential tools not only to instigate the beginning of epilepsy surgery but also to develop the concepts of modern epilepsy surgery.

The localization of brain function with ECS heralded the first brain surgeries and at the same time the idea that seizures may arise from an identifiable 'discharging lesion'.[2] Until the first half of the nineteenth century, the brain was believed to function as a single unit.[3] Opposing views, introduced by Frank Joseph Gall, who observed that a patient with a fencing coil wound in the frontal lobe of the brain suffered from speech disturbance, were dismissed.[4] In 1861, Pierre Paul Broca, a prominent French surgeon, reported that a localized lesion in the third convolution of the left frontal lobe of man was responsible for expressive aphasia.[5,6] John Hughlings Jackson (1864), influenced by the work of Bravais (1827) and Todd (1856) on postictal hemiparesis, supported Broca's observation and introduced the concept of focal epilepsy as a 'discharging lesion' of the brain.[2,7–9] Jackson conceived that during a focal motor seizure there is a discharge in the gray matter of the brain which begins at a local point and spreads from that point, producing a march of outward phenomena.[10] Experimental evidence to Jackson's ideas was provided by Fritsch and Hitzig (1870) who performed the first direct electrical stimulation of mammalian cortex. When they applied galvanic current through bipolar electrodes to the anterior half of the canine cerebral hemisphere, they obtained movement of muscle groups in the opposite half of the body.[11] Fritsch and Hitzig used voltaic current, i.e., direct current, polarizing the nerve cells and producing undifferentiated twitches. A few years later, Ferrier employed Faradic stimulation, i.e., alternating current, thereafter used by all investigators, and provided incontrovertible evidence for functional localization.[12]

In the following decades, animal studies using electrical cortical stimulation revolutionized the understanding of brain function and allowed the description of the supplementary motor area,[13,14] the primary auditory and olfactory cortex,[12,15] and the visual area, corroborated by the results of experimental lesions.[16] Grünbaum and Sherrington were able to separate the pre-Rolandic area for motor function from the post-Rolandic area for sensory function in anthropoids and discovered the frontal eye field.[17] Direct stimulation of the human brain to produce sensory or motor responses was first performed in 1874. A 'feeble minded' American woman in Cincinnati, Ohio, granted her neurosurgeon, Roberts Bartholow, permission to insert wires through the granulation tissue overlying the crater of an abscess in the left cerebral convexity.[18]

The ability to map human brain function with electrical stimulation revolutionized brain surgery and led to the first resective epilepsy surgeries by Macewen, Bennett, and Horsley.[19–22] However, epilepsy surgery remained focused on the symptomatogenic motor cortex and was associated with significant postoperative deficits, and consequently fell more and more out of favor when Bromide (1857) and Phenobarbital (1912) became widely available as an effective medical treatment for epilepsy.[23–27] At the beginning of the 20th century, Feodor Krause in Berlin was the only surgeon who continued to perform craniotomies on Jacksonian epilepsy in a larger number of patients.[28,29] Krause introduced faradic stimulation to map the human cortex during surgery, which until then had been used only in animal studies. His work continued to focus on the central motor area and he published the first detailed map of the primary motor area (Figure 105.1). His goal was not only to define and resect the symptomatogenic area with the help of ECS but to delineate the cortex from which the habitual (motor) seizures could be induced with weak current. He thought the area of increased irritability to stimulation represented 'das primaer kramfende Zentrum' (the primary convulsing center) which should be included in the resection.

Advancements in anesthesia permitted Cushing to perform an awake craniotomy eliciting a sensory response from the postcentral region in humans.[30] In Breslau, Ottfried Foerster continued the detailed mapping of the human cortex using local anesthesia so that the patient could report subjective responses during the operation (Figure 105.2).[31–34] He was the first to describe 'erregbare' (excitable) or 'epileptogenic' regions outside the central area, and reported on stimulation induced somatosensory, auditory, olfactory, gustatory, visual, and prefrontal symptoms. (Figure 105.2). Foerster operated in various areas of the brain and correlated the results of ECS with the immediate and 'nachhaltigen' (long-term) deficits after resection.[32,34] Foerster's seminal work coincided with the discovery of the EEG[35] and he reported the first series of intraoperative cortical EEG records together with Altenburger in 1935.[36]

Wilder Penfield, after spending time with Sherrington, Cushing, and Foerster, extended the work of Foerster through

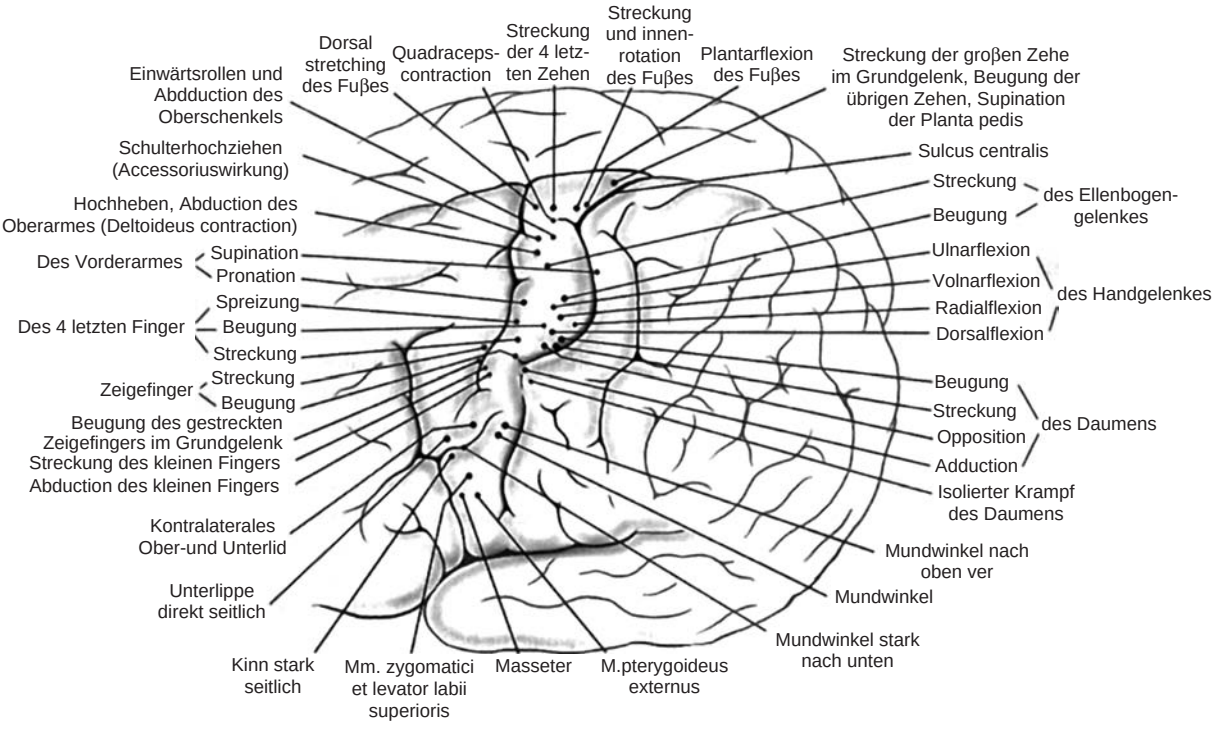

Figure 105.1 The first published map of the human motor cortex by Feodor Krause, 1911.

a more detailed mapping of cortical areas subserving speech, hearing, vision, and further refined cortical representation of sensory and motor function. The work of Penfield lead to the mapping of a posterior and superior language area, the vestibular cortex, the secondary sensory area, autonomic areas, simple, and complex psychic responses, and negative motor areas.[37,38] 'Dreamy states' associated with stimulation of the uncus were first described by Jackson. Penfield realized the high prevalence of intractable epilepsy arising from the temporal lobe and pioneered temporal lobe surgery for these patients.[39] His initial limited antero-lateral approach was influenced by the perioperative interictal EEG findings using intraoperative electrocorticography with grids over the lateral temporal region.[40] Clues from experimental animal studies and stimulation responses during surgery, however, began to point to the mesial and inferior parts of the temporal lobe as

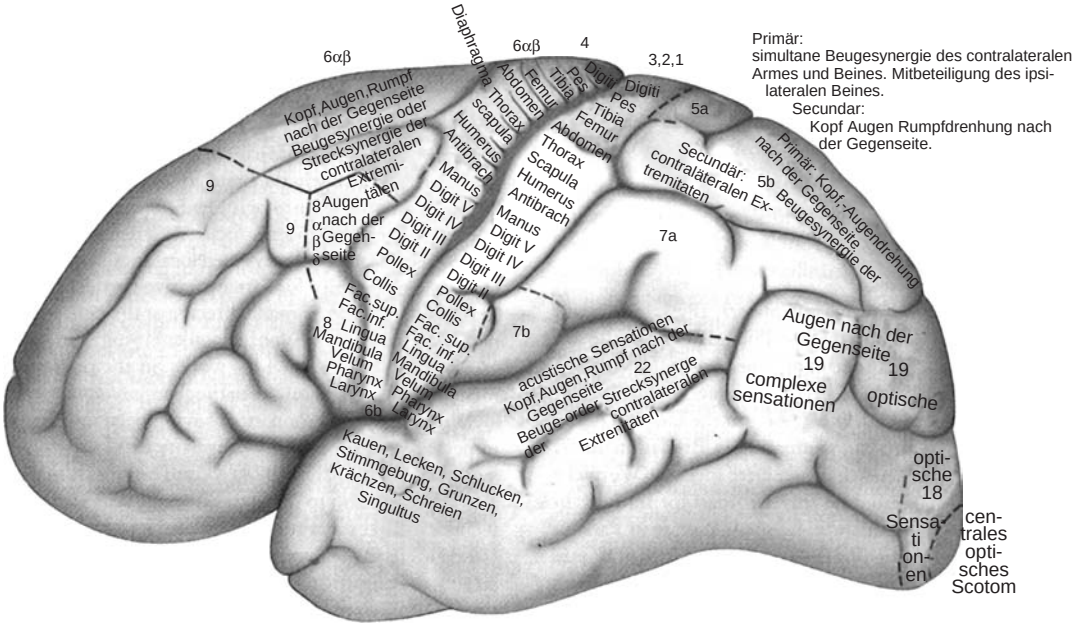

Figure 105.2 Foerster and Penfield's map of the human cortex, 1930.

the origin of the epileptic attack. Subsequent surgical series included the mesial structures in the resection improving the outcome significantly.[41–43]

In the minds of Talairach and Bancaud in France, Penfield's localization approach could only be truly applied through EEG recording directly from the involved brain structures allowing not only interictal but also ictal recordings. This goal was accomplished in 1959 when Talairach introduced a stereotactical method to accurately place numerous intracerebral electrodes which could be left in place for several days, followed by recording of electrical activity from involved cerebral structures during the course of a seizure.[44,45] Similar to Krause, Foerster, and Penfield, the French school emphasized the usefulness of electrically induced seizures to delineate the epileptogenic network to be included in the resection. In North America, extraoperative ictal recording became feasible by the work of Ajmone-Marsan and Van Buren who introduced subdural strip electrodes in temporal lobe epilepsy.[46] Epidural grid electrodes were introduced by Goldring, but proved to be less useful for simultaneous cortical mapping.[47,48] Subsequently, large array subdural plates which permitted not only invasive ictal recording but also detailed extraoperative mapping were developed.[49,50] The extraoperative mapping with ECS allowed the verification of Penfield's intraoperative results, and, with less interference by anesthesia and time constraints, lead to a revised map of eloquent language areas, and a more detailed description of the supplementary sensorimotor area, the negative motor area, and the secondary sensory cortex.[51–54]

Definition of eloquent cortex by electrical stimulation

Epilepsy surgery is based on the assumption that human functions are localized in discrete anatomical modules and that there are areas of the brain which can be resected without causing noticeable deficits.[55] Historically, electrical cortical stimulation was the first experimental technique which established the concept of functional brain localization. Based on the results of ECS the human brain was divided in 'eloquent' and 'silent' areas and it became soon apparent that the effect of stimulation was able to predict functional outcome after surgical resection.

Response to electrical stimulation includes not only positive (motor) signs which can be readily observed, but also subjective symptoms reported by the patient and negative signs which become only apparent to the patient and the examiner while testing specific functions.

Classical areas of eloquent cortex defined by electrical cortical stimulation include:

- Primary motor area (Figure 105.3)
- Primary sensory area
- Supplementary sensory motor area
- Secondary sensory area
- Language areas (Figure 105.4)
- Visual cortex
- Auditory cortex
- Negative motor area

Additional areas of functional localization based on ECS have been described but are not predictably obtained: the cortical representation of olfactory, gustatory, vestibular, autonomic, and nociceptive function.[56] Elementary emotional

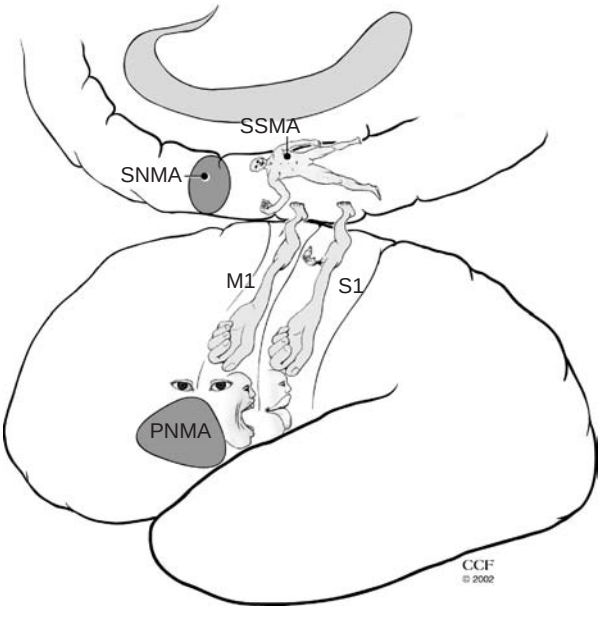

Figure 105.3 Diagram showing the location of the primary motor area (M1), the primary sensory area (S1), the primary (PNMA) and supplementary negative motor area (SNMA), and the supplementary sensorimotor area (SSMA).

responses, e.g., fearful sensations, are well localizable to the amygdala and bilateral resections are associated with noticeable impairment in the perception of fear.[57] More complex psychic responses seem to occur predominantly in patients with epilepsy including the déjà vu and deja vecu experience seen during stimulation of the temporoparietal association cortex.[37]

Negative signs associated with the localization of discrete cognitive functions have been mapped with electrical cortical stimulation, e.g., Gerstman syndrome over the dominant angular cortex.[58] However, except in unusual situations, it is impossible (because of time constraints) to check at any given electrode for interference of more than two or three specific functions. In other words, in the absence of a positive response, the possibility that stimulation of an electrode interferes with a function that was not tested for cannot be excluded. Absence of a response does not exclude functional localization for other reasons: the stimulus intensity may be insufficient to interrupt function or the area stimulated is too limited to interrupt function in larger functional networks. Notably, memory in the temporal lobes and executive function in the frontal lobes cannot be predicted by ECS and intracarotid amobarbital injection, neuropsychological evaluation, and functional MRI seem better tools for predicting preoperatively cognitive outcome in resective surgeries involving these areas. However, despite its shortcomings, electrical stimulation remains the gold standard for presurgical functional mapping, particularly in patients requiring invasive evaluations, providing the surgeon with the most accurate correlation of ictal onset and eloquent cortex.

Dispensable versus indispensable cortex

Eloquent cortex as defined by ECS may have the highest correlation with postoperative functional outcome but has to be validated with the results of surgical resections. The resection of eloquent areas may lead to no recognizable or only a temporary deficit, or may provoke a permanent, noticeable impairment for the patient or the physician during testing.

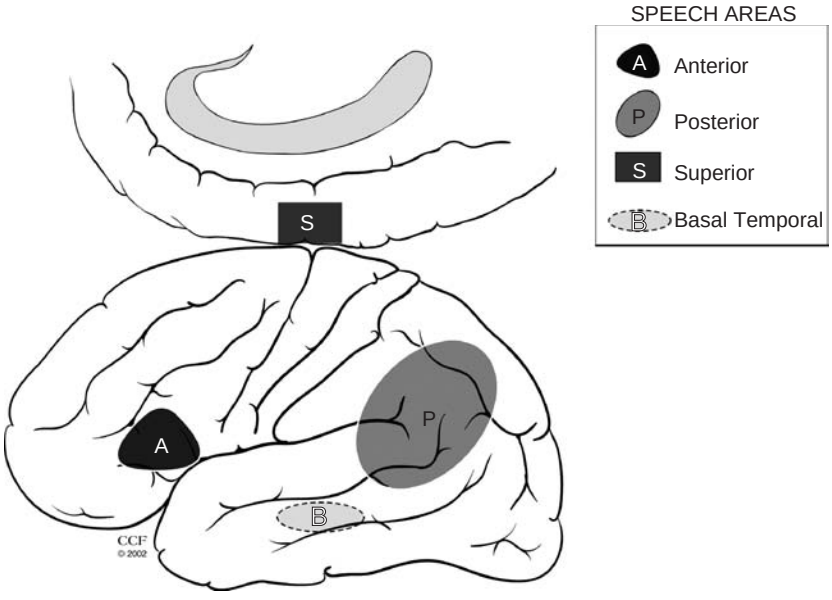

Figure 105.4 Diagram showing the location of the anterior, posterior, basal temporal language areas and Penfield's superior language area.

The benefit of neurosurgical resections often outweighs the risk of a minor or temporary deficit, but permanent deficits are usually not acceptable for most adult patients. Influenced by Foerster, Penfield introduced the terms 'dispensable' and 'indispensable' eloquent cortex to differentiate between these areas of the brain.[37,59]

Indispensable eloquent cortex:

- Primary motor area (corresponding to the distal portion of upper and lower extremity)
- Primary sensory strip
- Primary visual area
- Anterior and posterior language areas

Resections involving the primary motor, sensory and visual cortex are mostly associated with a permanent and functionally significant deficit.[59] These areas can be reliably mapped with ECS and show a well-defined contralateral somatotopic response. The language areas seem to safely allow resection up the gyrus adjacent to the functional sites based on ECS. However, there are reports that for the posterior language cortex resections closer than 1 cm to sites with stimulation-induced naming errors may increase the risk for a postoperative deficit.[60] We have not been able to confirm these observations.

Other motor areas with a positive response during ECS, the premotor cortex (possibly also including the frontal eye field) and the supplementary motor area, can often be resected without significant permanent impairment and in the context of intractable epilepsy or tumor surgery may be considered dispensable.[61,62] However, resection of these areas may produce significant acute deficits and more detailed postsurgical testing may reveal permanent but subtle changes in motor coordination or eye movement control.[63–65] Besides, most reported cases only refer to partial resections and it is unclear if more extensive resections could result in more significant permanent deficits.

Besides, resection of the face motor area which has a bilateral cortical representation has mostly a good recovery of function on long-term follow-up.[66,67] The basal temporal language area in the dominant hemisphere can lead to a temporary naming deficit which usually resolves long-term.

Dispensable eloquent cortex:

- SSMA
- Primary auditory cortex (Heschl's gyrus)
- Brodman's area 6 (probably including the frontal eye field)
- Face area of Brodman's area 4
- Secondary sensory cortex
- Basal temporal language area

Subjective factors may play a role of what constitutes a dispensable eloquent area: unilateral resection of the primary auditory cortex will not lead to any noticeable deficit for many of us, but certainly impair an orchestra conductor depending on the ability of dichotic listening. The permanent deficit after resection of the supplementary motor cortex may be subtle, however, the immediate consequences with contralateral weakness and mutism are dreaded by patient and surgeon. Age-dependant cortical plasticity has a strong impact on recovery and may allow extensive hemispheric resections with at least partial recovery in children and may become a consideration in catastrophic hemispheric epilepsy.

Predicting postoperative functional deficits in areas silent to cortical stimulation is even more complex. Most of the frontal lobe cortex, except for motor and premotor cortex, the anterior language area in the dominant and the negative motor area in the dominant and non-dominant hemisphere show no response to electrical stimulation.[66] The same is true for the parietal lobe caudal to the postcentral sulcus in the nondominant hemisphere. Experience has shown that limited surgical resections of these silent cortical areas are usually not associated with any neurological deficits.[68,69] Resection of the 'nociferous' epileptic brain, a term used by Penfield, may actually lead to improvement in cognitive function.[37,70] However, it is less defined to what extent larger surgical resections

of silent cortical areas are permissible without behavioral consequences.[71] Whereas limited unilateral frontal resections are well tolerated, bilateral lesions of the frontal lobes will produce a typical frontal lobe syndrome.[72–74] In other words, so-called silent areas most probably are involved in functions for which the brain has extensive capacity for compensation either by using adjacent cortex (when only small areas of cortex are resected) or due to bilateral representation of these functions. The fact that no deficits are detected even when the brain is inactivated acutely by electrical stimulation implies that these silent areas of the brain have extremely flexible compensation mechanisms that are immediately effective. In addition, whatever defect the excision might have produced in a completely normal individual can not to be determined. Therefore, the risk of cognitive decline can only partially be predicted by the size, location, dominance, and preoperative functional deficit.

Neurophysiological effect of electrical stimulation of the cortex

Electric field generated by cortical stimulation

The electric field generated by clinical cortical stimulation electrodes is a three-dimensionally complex phenomenon that depends on the stimulation parameters and the electrical conductivity of the surrounding medium. Experimental measurements of the field are difficult to perform, but detailed theoretical models can be constructed to study both the potential distribution in the brain and the neural response to the stimulation.[75,76] These studies show that the strength of the field directly transmitted to the brain is strongly regulated by the relative position of the electrode contact to the cortical surface, and the presence of CSF between the contact and the cortex. The high conductivity of CSF can shunt current flow around the brain, instead of through the brain, thereby increasing the stimulus amplitude necessary to generate a behavioral response.

The voltage distribution generated in the brain is the starting point for understanding the neural response to extracellular stimulation. The first derivative of the voltage distribution is related to the current density. The second derivative of the voltage distribution is related to membrane depolarization and hyperpolarization.[77,78] The stimulation induced membrane polarization interacts with voltage-gated ion channels, and given the appropriate conditions, can result in the generation of propagating action potentials that underlie the clinically observable behavioral response. The electric field is applied to the complex three-dimensional geometry of the surrounding neural processes (i.e., axons and dendrites). Each neuron (or neural process) surrounding the electrode will be subject to both depolarizing and hyperpolarizing effects from the stimulation.[77–81] As a result, a neuron can be either activated or suppressed in response to extracellular stimulation in different ways and in different neural processes depending on its positioning with respect to the electrode and the stimulation parameters.

Neural response to cortical stimulation

When electrically stimulating the brain, three general types of neurons can be affected by the applied field: local cells, afferent inputs, and fibers of passage. Local cells represent neurons that have their cell body in close proximity to the electrode (i.e., cortical pyramidal neurons). Afferent inputs represent neurons that project to the region near the electrode and whose axon terminals make synaptic connections with local cells. Fibers of passage represent neurons where both the cell body and axon terminals are far from the electrode, but the axonal process of the neuron traces a path that comes in close proximity to the electrode. Each of these classes of neurons can be activated by stimulation with extracellular sources. And, experimental measurements indicate that local cells, axon terminals, and fibers of passage have similar thresholds for activation when stimulating with extracellular sources.[82] However, activation of each different class can result in substantially different physiologic and/or behavioral output. Therefore, it is important to understand the factors that regulate the neural response to applied electric fields so accurate inferences about anatomical structures or physiological mechanisms involved in stimulation can be made.

Most work addressing the neural response to extracellular electric fields concentrates on the direct effects of the stimulation on individual neurons. When neurons are directly activated by extracellular electric fields, action potential initiation takes place in the axon because it is the most electrically excitable part of the neuron.[80,81] However, the threshold for indirect, or trans-synaptically evoked excitation (or inhibition) of local cells, is similar to the threshold for direct excitation of local cells. Indirect excitation (or inhibition) of local cells is the result of stimulation induced release of neurotransmitters from the direct activation of afferent inputs by the stimulus pulse. This stimulation induced trans-synaptic activity can be predominantly excitatory, predominantly inhibitory, or any relative mix of excitation and inhibition depending on the types and numbers of afferent inputs activated. Therefore, the interpretation of the effects the stimulation on the neural output of local cells is made up of two components: 1) The direct effect of the extracellular electric field on the local cell, and 2) The indirect effect of the stimulation induced trans-synaptic excitation and/or inhibition.

In general, the indirect effects of extracellular stimulation of local cells result in a biphasic response of a short period of depolarization followed by a longer period of hyperpolarization. This biphasic response is the result of the interplay between the time courses of the traditionally fast excitatory synaptic action and the traditionally slow inhibitory synaptic action. The role of indirect effects on the output of local cells can be enhanced with high frequency stimulation. If the interstimulus interval is shorter than the time course of the synaptic conductance, the indirect effects will summate. Because inhibitory synaptic action traditionally has a longer time course than excitatory synaptic action the effect of this summation is hyperpolarization of the cell body and dendritic arbor of the local cell. This hyperpolarization can limit the neuronal output when stimulating at high frequencies. However, because action potential initiation takes place in the axon of local cells in response to the direct effects of the stimulation, local cells can still fire action potentials in response to each stimulus pulse given that the stimulus amplitude is strong enough.[76,83,84]

Effects of stimulation parameters on cortical stimulation

The complexities of the neural response to applied electric fields are further complicated by the vast array of stimulation hardware and stimulation parameter options available. Stimulation pulse generators are either current-controlled or voltage-controlled. Voltage-controlled pulse generators are more simplistic in design, but the current delivered to the tissue is regulated by the electrode impedance, which may be variable.[85] And, the shape of the stimulus waveform transmitted to the tissue under voltage-controlled stimulation is distorted by the electrode capacitance.[86] Therefore, current-controlled stimulators are suggested for scientific investigation or clinical situations where long-term consistency of stimulation delivery is required.

Once a stimulus pulse has been generated, the physical dimensions of the electrode contact can substantially impact the shape of the resulting electric field and subsequent neural response to stimulation. Microelectrodes enable focal stimulation of targeted populations of neurons, but their small surface areas limit the amount of charge that can be safely delivered to the tissue.[87,88] Macroelectrodes enable stimulation of large volumes of tissue and are commonly used in clinical contexts, but their neural and spatial specificity of stimulation is limited. However, the focus of stimulation can be manipulated by simultaneously activating multiple contacts. Detailed computer models of the electric field generated by clinical epidural, subdural, and deep brain electrode designs have been generated.[75,76,84,89] These results show that bipolar stimulation or current steering with any number of anodes and cathodes can substantially change the shape of the electric field in the tissue.

The stimulus waveform plays an important role in the neural response to extracellular stimulation. Square waves are typically used in clinical settings; however, sinusoids or any other arbitrary waveform can also be implemented. One of the fundamental requirements of a clinical stimulation device is to use biphasic stimulus waveforms to limit stimulation induced tissue damage.[87,88] In addition, the axon represents the most excitable part of a neuron, so extracellular stimulation of fibers of passage, afferent inputs, and local cells are all regulated by the response of the axon to the stimulation.[80,81] In turn, the strength-duration properties of extracellular stimulation have a relatively short time constant of ~100 μs. Therefore, to maximize the stimulating influence of the injected charge, a pulse duration of 100–200 μs is suggested. Typically, anodal stimulation preferentially excites neural elements perpendicular to the electrode surface, and cathodal stimulation excites those with a direction component parallel to its surface. When stimulating bipolarly, the excitation of neural elements parallel to the bipole axis is additionally facilitated.[84] Manipulating the shape of the stimulus waveform can also be used to improve the neural selectivity of the stimulation. In general, local cells will be preferentially activated with anodic pulses, and fibers of passage will be preferentially activated with cathodic pulses.[90]

Comparison of stimulation with subdural and depth electrodes

Both subdural and depth electrodes, are usually made of nonferromagnetic platinum electrodes which allow postoperative verification of placement not only with two-dimensional X-ray or CT scanning but also postoperative MRI imaging. Postoperative CT and MRI can be co-registered to a (preoperative) volume-rendering 3D-MRI. Subdural electrodes have an interelectrode distance of 0.5–1 cm and are available in variable sizes, from 1×6 strips to 8×8 grids. Depth electrodes with four up to 15 contact leads are available from various vendors, with interelectrode distances of 3.5–10 mm.

Table 105.1 Stimulation parameters: Subdural and depth electrodes

	Subdural	*Depth*
Polarity	Biphasic	Biphasic
Stimulated electrode	Monopolar or bipolar	Bipolar
Stimulus intensity	1–15 mA (Grass S88) 1–17.5 mA (Grass S12) 1–20 mA (Ojeman)	1–3 mA
Duration of stimulus	0.3 ms	1–3 ms
Frequency	50 Hz	50 Hz
Duration of train	5 s	< 5 s

For subdural grids, we use stimulus pulses of 0.3-ms duration of alternating polarity at a rate of 50 Hz using a monopolar stimulating electrode to a remote reference over non-eloquent cortex. The testing is routinely begun at low intensity of 1.0 mA and increased gradually by 0.5–1.0 mA until afterdischarges, a clinical response or maximum stimulus strength of the instrument is reached (15 mA with Grass S88 stimulator, 17.5 mA with Grass S12 stimulator, and 20 mA with an Ojeman stimulator). The duration of the stimulus train is usually 5 s for the initial screening. When afterdischarges occur, one can usually repeat testing at the same or lower stimulus intensity without the recurrence of afterdischarges. Subsequently, a gradual increase in the stimulus intensity much beyond the initial threshold for afterdischarges can usually be attained, without continued afterdischarges. It is important to bear in mind that the afterdischarge threshold can vary even within adjacent electrodes and from one day to the other, and hence one must establish the afterdischarge threshold for each area tested for every testing.[91] We are usually screening for negative responses by testing reading and alternating hand and tongue movements. Subdural cortical stimulation is no longer used to induce restricted afterdischarges or habitual seizures. However, stimulation induced auras without the occurrence of afterdischarges seem to overlap with the ictal onset zone in a significant portion of patients and may be useful in surgical planning.[92,93]

Stereotactic electrodes used in centers in France and Italy are 0.8 mm in diameter and include 5,10, or 15 leads, 2 mm in length and 1,5 mm apart (Dixi, Besancon, France) depending on the target region. Stimulation is delivered in bipolar mode through adjacent contacts only 3.5 mm away from each other (center to center) and not located on the pia-arachnoid (as for subdural electrodes), thus avoiding shunting of the current through cerebrospinal fluid.[75] Electrical stimulation is performed using bipolar contiguous contacts at 1 Hz (pulse width: 3 ms) and 50 Hz (pulse width: 1 ms) by delivering biphasic rectangular stimuli.[94,95] Stimulation intensity ranges from 0.2–3.6 mA. The duration of the stimulation, usually fixed (40 s for 1 Hz stimulation and 5 s for 50 Hz stimulation) can be shortened, depending on the type of manifestation induced[96,97] Stimulation is stopped at the onset of a clinical response or the

appearance of afterdischarges. Spatial sampling around the stimulated electrodes is mostly reduced to the neighbouring leads, and limits the ability to assess for afterdischarges and systematic delineation of functional cortex. Electrical stimulation with stereotactic depth electrodes has been used primarily to explore the epileptogenic network following the concept of Talairach.[98] Single shock, 1 Hz stimulation has been found to be more specific in eliciting the habitual aura or seizure semiology, whereas 50 Hz stimulation seems more effective to detect eloquent regions.[97] However, evidence to support the usefulness of electrically induced seizures in defining the epileptogenic zone remains limited. Wieser reported on 133 patients with bilateral temporal depths and compared the concordance of electrical and chemical induced seizures with spontaneously recorded events, demonstrating a concordance of 77% for electrical and 60% for chemical induced events.[99] On the other hand, depth electrodes may allow mapping in the depth of the rolandic fissure and the associated subcortical motor and sensory pathways to guide surgical resections close to the central white matter tracts.

Mesial structures in the temporal lobe and deeper structures in the insula and opercular regions may be only accessible with depth electrodes. Electrical cortical stimulation and ictal recording with stereotactic depth electrodes in these areas have widened our understanding not only of the ictal onset zone but also of the functional anatomy of man.[37,94,100–109]

General correlation of eloquent cortex defined by electrical stimulation and eloquent cortex defined by non-invasive methods

Mapping of human brain function can be divided into two conceptually different methods.[55] One method uses interference of brain function to deduct localizing information. These include the study of brain lesions, electrical cortical stimulation (for higher cortical functions), transcranial magnetic stimulation (TMS), and intra-arterial amobarbital injection (WADA test), with varying degrees of spatial accuracy. The other method measures the activation of the human brain at rest or during a specific task or event and includes fMRI, nuclear imaging with positron-emission tomography (PET) and single-photon-emission computed tomography (SPECT), magnetoencephalography (MEG), and event-related potentials (ERP).

Brain interference methods are based on the assumption of a 'modularity' or localized segregation of function. The concept of functional modularity is crucial for any form of brain surgery and implies that although any brain region has functional importance in that it can theoretically be activated by the appropriate task, some regions are less dispensable than others. In that sense, interference methods allow in many cases a better prediction of postoperative outcome than activation methods.

Table 105.2 Methods for functional brain mapping

Interference methods	Activation methods
Brain lesion (including surgical resection)	fMRI (high spatial resolution)
Electrical cortical stimulation	PET/SPECT
Transcranial magnetic stimulation	MEG (high temporal resolution)
WADA	ERP

Traditionally, functional mapping aside from ECS has been largely limited to Wada and Neuropsychological testing to determine preoperative language lateralization and functional reserve and adequacy of memory.[110–115] Hypometabolism in the temporal lobe on Fluro-deoxyglucose (FDG-) PET seems to correlate with the memory results of Wada testing.[116–118] In the last two decades, additional non-invasive mapping methods have been developed which offer a similar spatial accuracy as ECS to localize sensory and motor function as well as language, but with less specificity and without the ability to correlate function directly with the ictal onset zone obtained during the invasive recording.

Magnetic source imaging (MSI) is a technique in which the equivalent current dipole sources of the magnetoencephalography (MEG) are coregistered to an MRI image of the brain. MSI can have a resolution on the order of millimeters.[119] Moreover, when spatially separate predominant sources are sequentially activated, MEG allows temporal resolution (milliseconds) that is not possible with other modalities. The time course of neuronal language processing can be imaged noninvasively with millisecond resolution.[120] There is relatively good correlation between intraoperative ECoG and MEG,[121] although direct measures of differences in localization cannot be performed because of the intrinsic tendency of sulcal localization with MEG versus surface maps with electrical stimulation. Detailed homuncular maps have been reported in normal subjects generally following the Penfield homunculus.[119]

fMRI has the advantage that it can produce functional and anatomic maps and is equally sensitive to superficial and deep regions. However, a criterion to determine what statistical thresholding should be used to obtain a map of 'true' activation is not feasible. Simply varying the magnitude of the correlation coefficient will result in apparently striking different activation maps. Activation of the primary sensory and motor areas yields robust BOLD signals (5% signal change in a 1.5 T scanner), and it is relatively easy to determine precise boundaries of functional tissue of these regions with fMRI. Motor cortex representing tongue, hand, finger, arm, and foot areas is readily identified with tongue movement, finger tapping, and toe wiggling,[122–126] including demonstration of the somatotopic organization of these regions.[123,127,128] Analogous sensory areas are identified with brushing or an air puff. With more complex motor paradigms, the supplementary motor area and cerebellar areas are also activated. Motor cortex localization with fMRI is generally highly concordant with intraoperative electrocortical stimulation mapping.[129–136]

Numerous studies have demonstrated that fMRI is able to identify hemispheric language dominance reliably. However, the areas of language processing vary markedly in different studies, likely related to use of different linguistic activation or control tasks, imaging, and postprocessing techniques, among other factors. The most common types of tasks successfully used for lateralization purpose are word-generation tasks (also called verbal-fluency tasks) and semantic decision-making, the former tending to show relatively consistent activation of anterior language areas and the latter demonstrating a more widely

distributed network including anterior and posterior hemispheric regions.[137,138] In addition to information on lateralization, fMRI has the potential to provide detailed maps of the intrahemispheric localization of critical language areas. There are a number of studies suggesting a close spatial relationship between fMRI activation and intraoperative electrocortical stimulation.[139–146] A recent study by Rutten *et al.* compared the results of fMRI quantitatively with intraoperative electrocortical stimulation mapping in 13 patients with temporal lobe epilepsy.[147] In eight patients, critical language areas were detected by ECS, and in Seven of eight patients, the sensitivity of fMRI was 100% (i.e., fMRI correctly detecting all critical language with high spatial accuracy). This indicates that areas not activated by fMRI could be safely resected without the need for intraoperative electrocortical monitoring. However, a combination of three different fMRI language tasks (verb generation, picture naming, and sentence processing) was needed to ensure this high sensitivity, as no single task was sufficient for this purpose and only 51% of fMRI activations were confirmed by ECS stimulation, resulting in a low specificity of fMRI.

Noninvasive preoperative assessment of brain function can support or obviate the need for invasive mapping and several indications for noninvasive functional activation studies have emerged:

1. In patients with a single epileptogenic lesion with predictable borders, e.g., cavernous angioma or low-grade tumors non-invasive preoperative mapping may obviate the need for invasive mapping.
2. Malformations of cortical development may or may not harbour eloquent cortex and preoperative noninvasive mapping can assist in the decision-making if invasive studies and surgery should be pursued.
3. Interference method can be of limited usefulness to predict outcome of cognitive functions organized in larger networks, e.g., memory. fMRI may be used to detect clinically relevant asymmetries in memory activation in patients with temporal lobe epilepsy.[148–150]

Safety issues

Two principle safety concerns have to be considered when subjecting a patient to electrical cortical stimulation.

The first concern should be the risks associated with placing invasive subdural grid or intraparenchymal (stereoencephographic) depth electrodes. The morbidity in patients undergoing subdural electrode implantation is probably not greater than that for neurosurgical patients in general when proper care is taken. The complication rate has decreased over the last two decades probably related to grid technology, surgical technique, and postoperative care. Complications include infection, (mostly transient) neurological deficits, epi- and subdural hematoma, increased intracranial pressure, status epilepticus, and death.[151] Depth electrodes can lead to breakages of electrodes and intraparenchymal hemorrhage.[152–154] The rate of complications seems associated with a greater number of grids, longer duration of monitoring, older age of the patient, left-sided insertions, and burr holes in addition to the craniotomy.[151] The risk of infection can be minimized by observing strict intraoperative and postoperative antiseptic techniques and by tunneling the wires for a distance under the scalp before their final exit. Antibiotics are routinely given, either continuous or as a single postoperative dose.[50] The infection risk is higher in patients with previous craniotomy or reimplantation.[155] A decreased level of awareness postoperatively without signs of infection can be related to raised intracranial pressure either due to brain swelling and a disproportionate high number of electrodes, or an intracerebral hematoma, but also caused by nonconvulsive status epilepticus. Intravenous corticosteroids are routinely given postoperatively to reduce brain edema and close monitoring with video-EEG and CT imaging is paramount. The overall complication rate with stereoencephalographically placed depth electrodes which do not require a craniotomy may be even lower according to a recent larger series (5.6%) with only a 1% risk of intraparenchymal hemorrhage related to the placement of the depth electrodes.[153,156]

The second concern involves the safety of electrical stimulation itself. Intermittent cortical stimulation for mapping with the current protocols does not result in cortical damage and is felt to be safe in adults and children.[157–159] A case report of a patient who had received occipital cortical stimulation over a period of 10 years for the purposes of artificial vision reproduction failed to show pathological changes when the electrodes were removed.[160] The concern of kindling with repetitive electrical stimulation has been raised, which the potential to render the brain more epileptogenic. Although the afterdischarge thresholds may vary over a tested region of the brain with recurrent electrical stimulation on different days, there is no evidence to support any progressive decrease in the afterdischarge threshold which would be expected with a kindling phenomenon.[91,161]

Symptomatology induced by electrical stimulation of the cortex

1. General principles

As previously outlined, eloquent cortex defined by electrical cortical stimulation includes an area of the cortex, the stimulation of which leads to a reproducibly demonstrable change in neurological function. This change of function can be either a positive or a negative phenomenon. Positive phenomena can be either verified by direct observation or can consist of subjective phenomena reported by the patient. Negative phenomena are unnoticed by physician and patient unless appropriate and often task specific testing is performed.

2. Positive effects

The following areas have been extensively studied in stimulation studies and have demonstrated a relatively stable and reproducible positive response:

- Primary motor area
- Supplementary sensorimotor area
- Primary sensory area
- Secondary sensory area
- Auditory cortex
- Visual cortex

Primary motor area

Brodmann (1909) cytoarchitectural map distinguishes between a primary motor area (area 4) encompassing the anterior bank

of the precentral sulcus and a premotor area (area 6) in the precentral gyrus and the posterior portion of the superior frontal gyrus. (Figure 105.5)[162,163] In 1937, Penfield and colleagues noted that it was impossible to confine functional representation within Brodman's areas 4 and 6.[164] Their results revealed a disproportionate somatotopic map of the body as depicted by Penfield's famous figurine or homunculus [37] Motor responses are not limited to the precentral gryus and may be found as much as 4 cm anterior to the central sulcus and up to 2 cm posterior.[165–167] Stimulus duration, frequency and intensity alter the type of motor response with distal muscle groups being activated first. Mapping of the motor cortex is performed to maximize resection in patients with nonlesional frontal lobe epilepsy and in patients with lesions encroaching the precentral area or distorting anatomical landmarks. A number of case reports suggest that small excisions, even of cortex directly adjacent to the Rolandic fissure may be followed by surprisingly limited functional deficits. It is not known, however, what the size limits of a 'safe' perirolandic excision might be.[168]

Supplementary sensorimotor area

The mesial aspect of the superior frontal gyrus, just anterior to the primary motor area for the lower limbs, was known to elicit motor responses in monkeys more than a century ago.[13] The difficulty in accessing this area of the cortex limited systematic studies on humans until the later half of the 20th century when implantable depth electrodes and subdural grid electrodes were available.[169–171] It became apparent that this area has both sensory and motor representation, and hence the preferred use of the term supplementary sensorimotor area (SSMA).[170] There are some patterns of responses that are more likely to be obtained upon stimulation of SSMA and are referred to as SSMA-type responses. While stimulation of PMA gives rise to predominantly distal and clonic responses, the SSMA leads to predominantly proximal and tonic responses. Bilateral asymmetric tonic movements of lower or upper extremities, head and eye deviation, vocalization are some other SSMA-type responses. Sensory responses consisting of numbness, tingling or pressure can be elicited contralaterally or bilaterally. The somatotopic organization of SSMA is posterior to anterior with the representation of lower extremity followed by the upper extremity followed by head. A supplementary eye field which causes conjugate contralateral eye deviation is located within the area of the head representation.[170]

Various studies have shown that resection of the SSMA produces a temporary state of contralateral weakness with mutism and intact comprehension.[61,172–174] Forced grasping in the contralateral hand has also been described in the acute postoperative period.[37] On long-term follow-up of patients who had partial resections of the SSMA unilaterally, no gross motor deficits were noted. It is not known if complete unilateral SSMA resection could lead to significant and lasting neurological deficits. In this sense it is important to emphasize that the SSMA is not only rostral to the mesial frontal MI area, but also extends caudally immediately ventral to the MI and SI area of the foot.

Sensory areas

Somatosensory sensation can be elicited from the human brain by electrical stimulation, from three areas – the primary sensory cortex (SI) in the post central gyrus, the secondary somatosensory cortex (SII) in the frontal and parietal operculum and the supplementary sensorimotor area in the mesial surface of the frontal and parietal cortex.

The primary sensory cortex (SI) can be defined as the postcentral or anterior parietal region consisting of areas 3a, 3b, 2, and 1 (Figure 105.6). The clear somatotopy of SI corresponds to that of the motor strip with the exception of the representation of the genitals that is only found in the postcentral cortex.[37,38,164] SII is located on the superior bank of the sylvian fissure in the region of the planum infraparietale of the operculum.[37,38,164] Stimulation effects in this area consist of sensations of the whole body on the contralateral side and quite often also on the ipsilateral side. The sensations are not different from those obtained by stimulating SI with the exception that there is a whole body representation in SII. Sensory responses obtained from the supplementary sensorimotor area consist of a mixture of bilateral, ipsilateral and contralateral sensations. The sensory responses are mixed with motor responses. The mesial cortical areas of precuneus, paracentral lobule, superior frontal gyrus and cingulate gyrus have shown supplementary sensorimotor type responses upon electrical stimulation. Resection of the primary sensory cortex leads to permanent cortical sensory deficits in the corresponding contralateral body part. These deficits affect primarily the position sense and fine touch. Vibration and pain sensation is not affected by SI resections.

Visual cortex

Following Munks' work on hemianopia after unilateral parieto-occipital lesions and Henschen's original description of the primary visual cortex in the calcarine fissure,[16,175,176] Brodman divided the visual cortex into areas 17, 18 and 19.[177–179] Area 17 corresponds to the striate cortex defined by the presence of the striae of Gennari which is identified histologically by a distinctive myelin band. It receives input from the lateral geniculate body and is considered the major gateway for visual information to the cortex. Areas 18 and 19 are visual association areas and are difficult to identify histologically. Three categories of responses can be obtained in the surrounding of the primary visual cortex and correspond well with the visual auras seen during spontaneous epileptic seizures. Simple visual hallucinations consisting of unformed circles of flashing light which may be white or colored can be obtained during stimulation of the area just above and below the calcarine fissure.[179] More elaborate geometric shapes such as diamonds, triangles, or stars, which can be white or colored and flashing are seen with stimulation of the fusiform gyrus and the lateral temporal or temporo-occpitial cortex.[179] Visual illusions leading to distortion of the image in a localized visual field consist of micropsia, macropsia, and metamorphopsia and can be produced in the basal temporo-occipital region. All these responses are localized to the upper or lower quadrant of the contralateral visual field. The switch from upper to lower quadrant corresponds to the calcarine fissure. A considerable proportion of patients with occipital lobe epilepsy may already present with a visual field defect. In patients with intact visual fields, surgical resection in the occipital lobe is mostly associated with a persistent postoperative visual field defect.[180]

Auditory cortex

Ferrier first noted a peculiar head turn in monkeys after stimulation of the contralateral superior temporal gyrus and was

able to confirm the presence of the auditory cortex by inducing deafness with bilateral lesions.[12,15]

The primary auditory cortex (area 41) lies in the posteromedial aspect of the gyrus of Heschl. The secondary cortical auditory areas include the contiguous areas of the transverse gyrus of Heschl, which extend dorsally into the planum temporale and ventrally in the region of the superior temporal sulcus (areas 42, 52, and 22). Electrical stimulation is carried out, and the patient is asked to describe the subjective symptoms during and after each stimulus. The stimuli should be separated by a sufficient time interval (5–10 min) such that the local background electrical activity has returned to the prestimulation status before the next stimulus is delivered.[181–183] Penfield divided the auditory sensations in elementary crude sensations or auditory hallucinations and termed the altered interpretation of heard sounds auditory illusions. Stimulation of the primary auditory area of the Heschl's gyrus (area 41) gives rise to high-frequency hallucinations. The secondary auditory area of Heschl's gyrus provokes illusions in a majority of patients. Stimulation in the region of planum temporale gives rise to auditory illusions and hallucinations with equal frequency. Patients with unilateral Heschl's gyrus lesions do not have any obvious hearing difficulties.

Negative effects

The following areas have been extensively studied in stimulation studies and have demonstrated a relatively stable and reproducible negative response:

- Language areas: anterior, posterior and basal temporal
- Primary and secondary negative motor area
- Other negative effects

Language areas

The initial localization of speech was based on lesional studies, describing an anterior speech area in the left inferior frontal lobe and a posterior or auditory speech area in the first temporal convolution (Figure 105.5).[5,6,184] Penfield and Roberts were able to map these areas intraoperatively inducing speech arrest, alexia, agraphia, anomia, paraphasia, and occasional positive grunting noises with electrical interference.[37,185,186] They also described a superior language area anterior to the Rolandic motor foot area in the mesial frontal lobe,[186] which is now thought to be related to an overall inhibition of movement.[187] A third speech area has been described in the basal temporal region.[52,188] Reading aloud is a reliable screening task for mapping both language areas. Additional testing is warranted whenever slowing of speech or speech arrest is elicited and includes: object naming, auditory word repetition, auditory and reading comprehension, and spontaneous speech. Although electrical stimulation preferentially affects verbal fluency when stimulating Broca and evokes comprehension deficits when stimulating Wernicke, a significant overlap of symptoms is seen.[189,190] Other mechanisms interfering with speech production have to be excluded: perioral muscle contraction, arrest of motor movement other than speech, or distracting hallucinations.[191]

Broca's area resides within the inferior and middle frontal gyrus (Figure 105.3). The anterior and posterior borders are 4.0–4.5 cm and 1.5–2.0 cm anterior to the rolandic fissure respectively. The superior border is about 3.5 cm above the sylvian fissure.[190] Wernicke's area resides within the posterior aspect of the superior and middle temporal gyrus, angular gyrus and the supramarginal gyrus (Figure 105.3).[192] The anterior border is felt to be approximately 1 cm behind the junction of the rolandic and sylvian fissures. The posterior border is approximately 5.5–6.5 cm behind this junction. The areas most consistently involved with language function in the basal temporal area are the fusiform gyrus, inferior temporal gyrus and the parahippocampal gyrus (Figure 105.4) in decreasing order of frequency.[193] The anterior and posterior borders of the basal language area are about 1.1 cm and 6.1 cm posterior to the anterior temporal tip respectively. The most lateral and mesial borders are felt to be 1.4 cm and 5.9 cm from the lateral edge of the temporal lobe respectively. Similar to the anterior and posterior speech areas, electrical stimulation of the basal temporal area results in speech arrest as well-impaired comprehension.[52,187,193–195] This is particularly noticeable at higher stimulus intensities. In patients who underwent resection of the basal temporal language area, after the area had been identified by preoperative stimulation

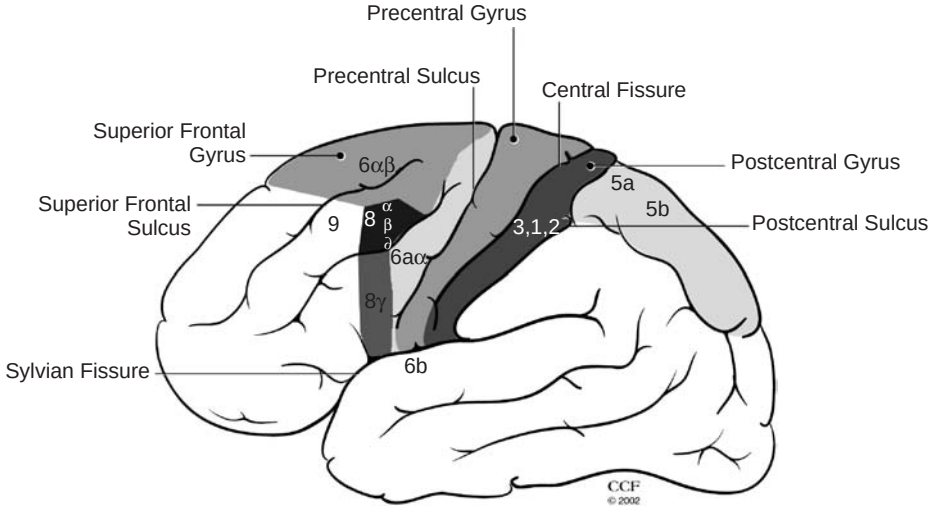

Figure 105.5 Diagram showing lateral view of sensorimotor cortex and neighboring brain areas.

studies and who demonstrated a postoperative language deficit, the language deficit tends to clear by 6 months after surgery.[195]

Negative motor area

Negative phenomena induced by electrical stimulation other than language function are less well described in the literature, partially since they may not lead to readily acknowledged postoperative deficits (Figure 105.4).

Penfield and Jasper noted a negative motor effect in selected cases that underwent cortical stimulation in the inferior frontal gyrus, just anterior to the primary facial motor representation, termed the primary negative motor area (PNMA).[37,53,196] Subsequently, a supplementary NMA (SNMA) was identified in the mesial portion of the superior frontal gyrus immediately in front of the face motor area of the supplementary sensory motor area.[54,170] Stimulation in this region may result in a negative motor response involving the contralateral and, to a lesser extent, even the ipsilateral muscle groups. More recently, a more broader distribution of NMAs for the upper extremities were found throughout the lateral premotor cortex, while NMAs for the tongue were only found in the inferior frontal gyrus of the dominant hemisphere.[197] During selective removal of the PNMA in two patients, transient hand clumsiness was observed in one patient, consistent with its presumed role in motor control.

Other negative effects

The angular gyrus (Brodmann area 39) forms a part of the temporoparietal (heteromodal) association cortex along with the supramarginal gyrus (area 40) and the banks of the superior temporal sulcus, including Wernicke's area and the caudal aspects of area 7 in the superior parietal lobule. Lesions of heteromodal association cortex produce deficits involving higher cortical functions, as opposed to lesions of unimodular association cortex, which lead to deficits specific to a single sensory modality. Lesions of the dominant temporoparietal region sparing Wernicke's area produce a combination of deficits including Gerstmann syndrome, alexia, anomia, and constructional apraxia.

Neurophysiological substrate producing positive and negative symptoms

Brodmann's (1909) cytoarchitectural map distinguishes between a primary motor area (area 4) encompassing the anterior bank of the precentral sulcus and a premotor area (area 6) in the precentral gyrus and the posterior portion of the superior frontal gyrus.[162] These findings, along with converging lines of evidence from clinical observations and cortical ablation experiments performed in monkeys, led Fulton (1935) to propose that the motor cortex could be divided into a primary motor area (area 4) and a premotor area (area 6).[163] In contrast to the hierarchical concept proposed by Fulton in which the higher level motor areas participate in the generation and control of distal movements through projections to the primary motor cortex.[163,198] it is known that only a third of the corticospinal and corticobulbar fibers arise from the primary motor area. Another third arises from the premotor cortex located on the lateral aspect of Brodmann area 6, the supplementary sensory motor area located on the medial aspect of Brodmann area 6, and the cingulate motor area located along the dorsal and ventral banks of the cingulate sulcus.[199] The remaining fibers have their origin in the parietal lobe (arising mainly from the somatosensory cortex of the postcentral gyrus).[200,201] These projections explain the positive motor effects seen with electrical cortical stimulation outside the primary motor area.[199,202] In contrast to the clonic movements elicited with stimulation of the primary motor cortex, responses from the premotor areas tend to be tonic involving more proximal muscle groups bilaterally. The characteristics of the response and the unilateral somatotopic representation seen over the primary motor and somatosensory cortex correlate well with permanent functional deficits after resection suggesting a high degree of functional specialization and limited ability for recovery.

Stimulation-induced negative symptoms interfere with the function of the cortex being stimulated, with the patient unaware of the effect until they are asked to perform a specific function. This can either lead to the inability to perform a language or motor task, but includes other cognitive tasks when tested. In the dominant hemisphere, the anterior language area is thought to be involved in the organization of fine motor movements allowing speech production, whereas the negative motor area in the non-dominant hemisphere participates in the overall organization of fine motor movements. However, a direct inhibition of the primary motor areas resulting in the observed negative motor effect cannot be ruled out. Both potential mechanism may explain why small lesions restricted to the primary negative motor area but also in the anterior language area often recover substantially after a temporary deficit and show a higher degree of cortical plasticity than the primary motor and sensory cortices (see Figure 105.5).

Special considerations in children

Cortical mapping in children poses additional unique challenges.[191] The changes inherent to the developing nervous system and lack of firm guidelines for electrical safety necessitate that the energy and charge requirements be kept to a minimum. The longer chronaxies in children can be often more effectively stimulated by not only increasing the stimulus intensity but also the pulse width from 0.3 ms used in adults up to a maximum of 1.0 ms.[203] The authors were also able to elicit responses as well as afterdischarges, in some young patients (< 5 years), by increasing the stimulus duration after failing to obtain any response at the maximal fixed duration stimulation. Clinical responses in children are often obtained at or above the afterdischarge threshold.[203] Language and motor tasks should be adapted to the patient's age and neurocognitive status. Attention span and cooperation in children are often limited and several sessions may be necessary.

Motor movements are obtained at all age groups with some ontogenic trends. In children younger than 2 years of age, tongue movements are difficult to elicit and in this age group, stimulation may induce bilateral rather than unilateral responses from lower face when the lower rolandic region is activated.[191] Individual finger movements are usually first manifest at or after 3 years of age. Clonic finger movements appear after tonic finger movements. These observations are likely to be a result of the maturing systems in cortical area 4. Children with developmental disorders or disorders with aberrant cortical formation are more likely to show atypical distribution of the motor or language cortex and the results may have to be validated with data obtained from functional imaging studies.

106 Cortical mapping by electrical stimulation of subdural electrodes: primary somatosensory and motor areas

AS Tanner and HO Lüders

Introduction

One of the most important issues faced during invasive evaluation of patients with intractable epilepsy is the localization of the epileptogenic zone and its surrounding eloquent areas with the goal of planning a resection that renders the patient seizure free with minimal or no neurologic deficits. The task of 'cortical mapping' is to assist in determining the location and extent of the eloquent regions and to establish their relationship to the epileptogenic zone. This information will then be used to define a surgical strategy.

This chapter will review the cortical mapping of the motor and somatosensory areas.

Historical background

In 1870, Gustav Fritsch and Eduard Hitzig published a paper entitled 'On the Electrical Excitability of the Cerebrum.' They found that

> A part of the convexity of the hemisphere of the brain of the dog is motor . . . another part is not motor. The motor part, in general, is more in front, the nonmotor part more behind. By electrical stimulation of the motor part, one obtains combined muscular contractions of the opposite side of the body.[1]

Their experiments, which were conducted mostly in dogs, were groundbreaking not only because up until that time it was believed that the cerebral hemispheres were not excitable by any stimuli, but also because this publication had a major impact on subsequent work in cerebral physiology.[2,3]

A few years later David Ferrier's experiments published in his monograph on *The Functions of the Brain*[4] not only confirmed Fritsch and Hitzig's work, but found in the brain of monkeys several more areas where movement could be elicited by electrical stimulation. His ablation work also contributed to the localization of sensory functions as well. He was able to produce convulsions experimentally and also elicited precise movements of individual muscles and groups of muscles by electrical stimulation of localized cortical centers in dogs, rabbits, cats, and guinea pigs.[5]

Charles Sherrington continued the work of Ferrier, but he added a new emphasis involving the use of the concepts such as integration, evolution, and reflex as guiding principles. His work in the laboratory also promoted a change from the concept of a large, overlapping sensorimotor cortex to the concept of a more narrow and discrete frontal motor cortex separate from the parietal sensory area.[6]

In subsequent years this research was continued by Sir Victor Horsley who conducted brain stimulation experiments in primates, but also went on to perform one of the first surgeries for epilepsy.[7] During these operations he actually used intrasurgical electrical stimulation in humans to localize the motor strip.

The work of Sir Victor Horsley was later expanded by Fedor Krause and Otfrid Foerster in Germany, who made major contributions to this field. Krause introduced faradic stimulation and suggested this was the best method to map the different areas of the human motor cortex which he mapped in exquisite detail. Foerster continued the detailed mapping of the human cortex and in the operating room he used local anesthesia so that the patient could report sensory responses during the operation.[8–12]

Finally, Wilder Penfield, deeply influenced by Charles Sherrington, Sir William Osler and Otfrid Foerster, used the technique of intraoperative cortex stimulation under local anesthesia to confirm the somatotopic distribution of the human motor cortex. He was the first to use the homunculus to graphically visualize the organization of the human cortex.[13,14]

The work of Penfield and his antecessors set the stage for further development of invasive recordings for localization of the epileptogenic zone and detailed mapping of eloquent cortex in the extraoperative setting.

Anatomy of the primary somatosensory, motor and premotor cortex

The primary somatosensory and motor cortices form together what has been termed the central lobe, a concept that has been

considered and in use since these areas were defined by stimulation studies. This central cortex includes the precentral and postcentral gyri. The characteristics of the surface anatomy of these regions are important when studying the area using MRI imaging specially when attempting to define the localization of subdural electrodes.

The primary motor cortex (MI) is contained within the precentral gyrus which extends from the precentral sulcus to the central sulcus. The cortex in this area is unusually thick due to the presence of giant pyramidal cells of Betz that vary in size and density in different areas of MI: they are usually largest in the paracentral lobule, and smallest inferiorly in the opercular region. The central sulcus is usually interrupted before it reaches the sylvian fissure and, therefore, the inferior segment of the precentral gyrus tends to communicates with the postcentral gyrus to form the central operculum. The central sulcus is also interrupted in the mesial surface before it reaches the cingulate sulcus, leading again to a communication of the mesial MI and the primary sensory area (SI) regions in the paracentral lobule. There are no clear boundaries of the anterior extent of MI in the paracentral lobule and inferiorly MI touches the caudal extension of SSMA (supplementary sensorymotor area). The functional representation of MI in humans was first defined by Fedor Krause and later confirmed by Otfried Foerster.[10–12] Wilder Penfield refined their observations and was the first one to represent the organization of the human MI by a homunculus.[14] Their studies showed that there is ample overlap and minor differences among individuals, but that the orderly sequence of motor representation appears relatively constant. Some studies have also suggested that there may be some redundancy for particular motor and somatosensory functions. In general though, the face is represented inferiorly, followed superiorly by the thumb, hand and shoulder; the trunk lies near or in the area of the interhemispheric fissure, and the leg and foot are located within the mesial surface. These four groups perform as functional units rather than individual isolated areas. Electrical stimulation of MI evokes contractions that usually involve functional muscle groups concerned with specific movements; however individual movements can be contracted separately.

The premotor cortex lies between the primary motor cortex and the prefrontal lobe. Histologically, it corresponds to Brodman area 6. It resembles MI and it is composed primarily of large pyramidal cells but there are no giant cells of Betz. The anterior boundary is variable, but is placed approximately on a line linking the eye fields with the anterior border of the supplementary sensorymotor area.

The cortical eye field lies rostral to the premotor area and occupies the caudal part of the middle frontal gyrus. Stimulation usually causes conjugate deviation to the opposite side.[15,16]

The primary somatosensory area is located in the postcentral gyrus in the posterior part of the paracentral lobule. Its configuration is similar to the precentral gyrus with comparable functional units.[16–18]

The secondary somatosensory area (SII) lies in the superior bank of the lateral sulcus and extends posteriorly into the parietal lobe.[19]

A concept that is important to discuss when reviewing functional anatomy is that of the degree of neurologic deficits produced after resection of certain eloquent areas. While it has been thought that the resection of such regions will always produce a major significant deficit, we now know that some of these areas can be resected with minimal consequences. With this in mind, eloquent cortical areas can be further divided into dispensable, partially dispensable and indispensable based on the deficit and recovery expected, as well as the ability of the brain to compensate for certain of these lesions. Therefore resection of indispensable cortex will lead to a chronic deficit without major recovery (i.e., resection of hand motor area), resection of partially dispensable cortex will produce a chronic deficit but some recovery and compensation are expected (resection of SSMA), and resection of dispensable cortex will produce no detectable neurologic deficits (i.e., Basal language area).[20]

Primary motor cortex: an experimental point of view

Perhaps one of the most exiting fields of experimental neuroanatomy is the study of functional anatomy in nonhuman primates. Among them, the macaque brain has been extensively studied.

Various architectonical maps of the motor cortex of the macaque monkey have been published since the early nineteenth century. Traditionally, the agranular frontal cortex of nonhuman primates has been subdivided into two regions: areas 4 and 6 according to Brodman[21] or 'precentral' and 'intermediate precentral' areas according to Campbell.[22] Area 4 (or 'precentral' area) is characterized by giant pyramidal cells, whereas, these cells are missing in area 6 (or 'intermediate precentral'). This somewhat simple map corresponded to a similarly simplistic view of functional organization that included the motor, premotor and supplementary sensorymotor areas. However, over recent years, research has shown that instead of three functional entities, the primate motor cortical system is made up of many structural and functional fields, each processing different aspects of motor behavior.[23] Similar to the motor cortex, a multiplicity of areas have been identified in the posterior parietal cortex, each of them involved in the analysis of distinct visual and somatosensory information.[23]

An interesting observation is that the maps have changes substantially over the years: Brodmann for instance defined two areas [21] while Matelli has defined seven.[24] The above is not only due to obvious advances in research techniques but also to different criteria to define extent and function. A classification that is widely used, and appears to have been validated by other techniques [25–28] is that one of Matelli.[24] He divides the motor cortex in seven areas: area F1 corresponding to the primary motor cortex proper, areas F2 and F7 located on the dorsolateral cortical convexity, areas F3 and F6 on the mesial cortical surface, and areas F4 and F5 on the ventrolateral convexity.

Area F1 is characterized by low cell density and a very prominent giant pyramidal cell in layer V. It receives inputs from several areas of the nucleus ventralis of the thalamus, as well as corticocortical connections from the supplementary motor area (SMA), the premotor cortex and areas 1, 2 and 5.

Somatotopically the face area is represented laterally close to the Sylvian fissure, the leg medially, and the arm and hand in between. Proximal parts of the extremities are represented on the exposed cortical surface whereas distal parts of the extremities and acral parts of the face are represented in the rostral bank of the central sulcus. Fingers, lips and tongue have larger areas of representation. Evidence shows that muscles, joints or movements are represented as overlapping (not as segregated neuronal populations), with individual muscles activated at multiple, spatially separated locations or multiple muscles activated from a single site. In fact, there is evidence indicating that most of a primate's motor cortex is active during movement. Intracortical micro-stimulation (ICMS) triggers movements that are fast, short-acting and restricted (i.e., one joint).[23]

Areas F3 and F6 correspond to what is described as 'SMA' in humans. In the primate, it is divided in SMA proper and pre-SMA. These two are differentiated on histochemical bases: F3 is comparable to F1 (poorly laminated) whereas F6 is clearly laminated. F3 lies mesially immediately anterior to F1, and F6 lies anterior to area F3. It appears that their connections and inputs are different as well: F3 receives more information from the putamen and pallidum, while F6 receives information from the cerebellum and the caudate. Somatotopically, area F3 has representation for the arm, leg, and orofacial areas, while F6 has only arm representation. ICMS of area F3 requires higher thresholds than for F1 and elicits more complex and proximal movements. ICMS of area F6 requires higher thresholds than for F1 and F3 with decreased excitability and more proximal movements. The function of the primate SMA (SMA proper and pre-SMA) has been the subject of extensive research. It appears that it contributes to many aspects of motor behavior including the control of both simple and complex motor tasks, externally triggered as well as self-initiated tasks, and both distal and proximal movements.[29,30] There is evidence to suggest that area F3 (SMA proper) corresponds to the supplementary sensorymotor area (SSMA) and that F6 (preSMA) is equivalent to the supplementary negative motor area in humans.[31]

Areas F2 and F7 constitute the dorsolateral premotor cortex (PMd) and are part of parieto-frontal connections. Their function is believed to be related to planning and controlling arm and leg movements using external cues. They are also involved in controlling saccades in the context of complex motor movement.

Areas F4 and F5 form the ventrolateral premotor cortex (PMV). They are also part of complex circuitries that involve the parietal lobe. It is thought that its function is related to planning movements directed towards specific objects, goal-directed movements and execution of a motor action.

The somatotopic organization of the primary motor cortex of the macaque and the human brain is therefore similar, but for both this should not be oversimplified as overlaps exist. An excellent review by Meyer and Matelli[23] suggest that an organizational principle similar to the macaque also exists in the human brain (i.e., primary motor cortex, SMA and pre-SMA, dorso- and ventrolateral premotor cortex) and that functional gradients likely exist within the human nonprimary motor cortex.

Indications and objectives for mapping of the primary somatosensory and motor cortices

Cortical mapping of the motor, premotor and somatosensory cortex is a valuable pre-surgical technique in those cases in which the pre-surgical noninvasive evaluation suggest that the epileptogenic zone is partially overlapping or in close proximity to these cortical areas.

Responses of motor stimulation

Stimulation of MI, SSMA and the premotor cortex elicits clonic and tonic responses. Stimulation of MI tends to elicit primarily distal, clonic muscle contractions whereas stimulation of the SSMA and of the premotor area produces preferentially proximal, tonic muscle contractions. However, tonic responses may also be elicited by stimulation of MI and clonic responses may occur when stimulating the SSMA. There is also evidence that the stimulus parameters determine the clonic or tonic character of the response.[32,33]

There is evidence that continuous high-frequency (20–100 Hz) stimulation can induce a clonic muscle contraction that is a subharmonic of the actual stimulation frequency (5–10 Hz). However, the response becomes tonic when the intensity of stimulation is increased.

From a more practical point of view, the stimulation of subdural electrodes should be done in an organized and orderly fashion. Ideally all electrodes in a grid should be stimulated. If this can not be done due to time constraints or other causes, a rationally planned group of electrodes should be stimulated. The technical details of stimulation are discussed elsewhere in this textbook, but it is important to note that all electrodes analyzed should be stimulated with the same parameters, starting at the same current and using the same techniques in each of them. To make sure that the results are reliable, it is advisable to reproduce all positive responses.[20,34–37]

Stimulation of the premotor cortex can produce positive or also negative motor responses.[36,38] The negative motor responses are discussed in a separate chapter.

Mapping of the eye fields should be done in the same fashion. Findings include eye version or contralateral conjugated eye movements. In many cases saccades can be observed as well. In one study [39] head version, following the eye movement, was seen in roughly half of the patients studied. In the same study it was noted that most patients had motor cortex contiguous to the eye field and that there was no silent cortex between the strip and the motor cortex.

Stimulation the motor cortex frequently also elicits sensory responses. When stimulating at relatively low stimulus intensity the patient will describe sensations such as numbness, tingling or feelings such as 'tension', pain, or 'spasm' in the same muscles that eventually contract when the stimulus intensity is increased. Sometimes these represent actual sensory responses, but not infrequently they may represent motor responses that the patient perceives but are invisible to observers.

In these cases, the stimulus intensity should be increased in small increments (0.1 to 0.2 mAmps) starting at subthreshold intensities in an attempt to differentiate motor from sensory responses.

Similarly, motor responses can also be obtained when stimulating the sensory cortex, usually at relatively high intensities. In this case, starting with lower intensities and using smaller increments may avoid eliciting motor responses.[20]

Responses of somatosensory stimulation

The responses to electrical stimulation of the primary somatosensory area include strictly contralateral sensation in a defined, relatively limited somatotopic distribution. The most common responses include: numbness, tingling, warm sensations, pulling sensations, throbbing sensations and alien sensations. Stimulation of SII consists of contralateral, ipsilateral or bilateral responses, most frequently tingling or numbness, that tend to have a widespread distribution.[19,20,40,41]

Complications of stimulation of somatosensory and motor cortex

Electrical stimulation of subdural electrodes can produce afterdischarges and seizures.[20]

Afterdischarges are characterized by the appearance of runs of epileptiform discharges triggered by electrical stimulation of a given intensity, repetition rate and duration. They frequently are seen in the exclusively in the stimulating electrodes, but may spread to neighboring electrodes and occasionally even extensive cortical areas without producing signs or symptoms. Symptoms or signs elicited by electrical stimulations that induce afterdischarges can be caused by activation of the stimulated electrodes but also by activation of other electrodes to which the afterdischarge spread. Therefore only the symptomatology obtained by stimuli that do not produce afterdischarges should be used for cortical mapping. EEG recordings of the stimulated and adjacent electrodes is essential to make sure that no afterdischarges occurred when the stimulation elicited signs or symptoms.

Seizures can also occur during electrical stimulation. In these cases, the electrical stimulation tends to elicit first afterdischarges that spread leading to focal seizures or even secondarily generalized motor seizures. Seizures occur when stimulating the epileptogenic zone as also any other nonepileptogenic cortex. The seizures elicited by cortical stimulation may be similar to the patient's habitual seizures (usually when stimulating at the epileptogenic zone or its neighborhood) or semiologically totally different seizures. The localization value of inducing habitual auras or seizures by electrical stimulation of subdural electrodes will be discussed elsewhere.

Correlation with other techniques

Accurate identification of MI, SI, and SSMA is essential to minimize deficits after resective surgery around the central sulcus. Therefore, other techniques should be used routinely to supplement the information provided by cortical stimulation. This includes somatosensory evoked potentials recorded from sunbdural electrodes and noninvasive techniques like functional magnetic resonance (fMRI), positron emission tomography (PET), MEG of somatosensory evoked potentials, and transcranial magnetic stimulation. A detailed description of each of these techniques is beyond the scope of this chapter and some of them are explained elsewhere in this textbook. A brief overview will be presented in this section.

Median nerve SSEPs recorded from subdural grids are characterized by large amplitude N1 and P2 peaks, a restricted distribution in the immediate perirolandic area and a phase reversal across the central sulcus, making them ideal for localization.[42,43] SSEPs to lip stimulation are also used. However, because of this relatively short short latency special attention should be taken to avoid that the early response can be is obscured by stimulus artifact.[43] Lip SSEP usually shows no phase reversal across the central sulcus. Posterior tibial nerve SSEPs can also be used for localization of the leg SI area. However the unusual orientation of the generator makes its interpretation more complicated. Our experience shows that because of variations on the mesial anatomy, a clear phase reversal is not always seen, but when recorded best localizes the central sulcus.[44]

Functional MRI (fMRI) has the advantage over electrical stimulation and subdural recorded SSEP that it is not invasive and entails no exposure to radiation. Several investigators have confirmed and validated fMRI data with intracranial electrical stimulation both in normal brains as well as in patients with distorted anatomy due to lesions such as tumors, vascular malformations or when functional reorganization is suspected.[45,46]

Positron emission scanning has also been used for functional studies and previous work has confirmed the spatial concordance between PET activation and cortical stimulation Furthermore, there is some evidence to suggest that the activation produced by fMRI imaging and PET scanning correlates fairly well.[47]

107 Cortical mapping by electrical stimulation of subdural electrodes: negative motor areas

P Smyth

Introduction and historical overview

Early observations of the cessation of spontaneous movements after electrical cortical stimulation in nonhuman animals were published in the late 19th century.[1] The concept of 'inhibitory centers' in animal cortex was thus available to guide the intraoperative discovery of similar effects in humans by Penfield and his collaborators during the first part of the 20th century.[2] For Penfield, stimulation-induced motor inhibition was limited to the mesial frontal lobe in a relatively undifferentiated supplementary motor area (SMA).[2,3]

In the later decades of the 20th century, systematic extraoperative study with implanted subdural grids resulted in finer anatomic subdivision, competing descriptive terminologies, and the recognition of a lateral negative motor area.[4–7] Figure 107.1 shows the lateral and mesial negative motor areas in relation to nearby homunculi. The descriptive terms 'lateral' and 'mesial' negative motor areas used in this chapter are synonymous with primary and supplementary negative motor areas (PNMA, SNMA). Inhibitory effects due to stimulation of mesial and lateral negative motor areas must be recognized in context with other forms of cortically-mediated motor inhibition (Figure 107.2), which will be described further below.

Contemporary study of negative motor areas focuses on their strategic location between frontal and motor output cortex. Though the mechanism of the stimulation-induced negative motor effect is unknown, its existence and properties is considered indicative of 'higher level' integrative and organizational function. This idea emerged in the 19th century following stimulation experiments involving animal supplementary motor area and are based on the timing and inferred meaning of associated signals in adjacent cortex, peripheral nerve, and muscle.[3] These ideas continue to shape our view of these areas.

The histologic and anatomic techniques that provided the foundation for earlier work remain useful in defining connectivity. Extraoperative cortical stimulation, a routine clinical tool in epilepsy surgery evaluation, may also provide insights into the mechanism of stimulation-induced negative motor phenomenon; a testable hypothesis is outlined in this chapter. Of particular importance are recent functional imaging approaches used to explore the dynamic connectivity of the pre-SMA[8] as well as possible 'higher level' functions in motor and cognitive processes, including the interface between volition and movement.

Definitions and testing protocol (DVD examples)

The data and concepts summarized in this chapter come mainly from cortical mapping in epilepsy patients with subdural electrode grids. Cortical mapping in this setting involves the systematic stimulation of electrodes using parameters and procedures described elsewhere in this volume. In general, the response at each electrode to high frequency stimulus (50 Hz, varied from 1–15 mA, lasting several seconds) may be one of four kinds: a positive effect, a negative effect, no response, or excessive electrical activity called afterdischarge.

A 'positive effect' from cortical stimulation is a symptom or sign, such as an unusual sensation (inherently subjective) or muscle contraction (which may be objective), elicited by stimulating primary input or output cortex.

A 'negative effect' from cortical stimulation is the cessation or inability to do something, and may (but does not inevitably) result from stimulating associative cortex. Negative effects from cortical stimulation are well known: both receptive and expressive aphasias have been elicited with stimulation of 'language areas', presumably because nonphysiologic stimulation interferes with the function of the stimulated cortex.[9,10] So-called 'negative myoclonus' has also been elicited by cortical stimulation.[11]

Conceptual and semantic confusion has arisen from the failure to consistently distinguish categories and the relationships between them. A suggested structure, used in this chapter, considers 'negative effects' (physiological or due to stimulation) to include 'negative motor effects', which again may be physiological or due to stimulation. These relationships are summarized in Figure 107.2. The focus of this chapter is 'stimulation-induced negative motor effects', in particular those arising from high frequency stimulation of mesial and lateral negative motor areas in the frontal lobe.

A 'stimulation-induced negative motor effect' is defined as the inability to make a voluntary movement or sustain a voluntary motor contraction at a cortical stimulation intensity that does not produce any positive sign or symptom and is not

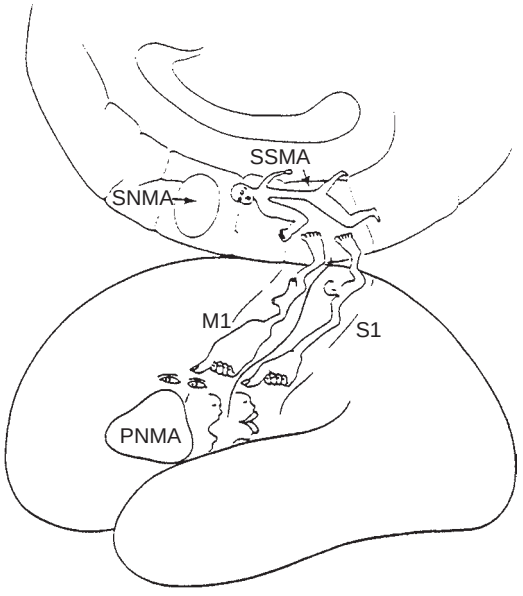

Figure 107.1 Lateral (primary) and mesial (supplementary) NMA, from ref. 6.

associated with an afterdischarge. There must also be no alteration in awareness. By definition, wherever such effects occur is a 'negative motor area'.

The Cleveland Clinic testing protocol for stimulation-induced negative motor effects includes initial screening for language followed by more detailed testing at promising sites.[6] This protocol was developed by initially exploring proximal and distal limb movements as well as trunk and face movements. From these more elaborate investigations, the protocol was devleoped to reliably identify the kinds of movements (mostly distal and mostly contralateral) known to exist and tested during routine cortical stimulation.

Screening for language function is as follows: at a given electrode, if stimulation in 1 mA increments from 1–15 mA results in no positive effect, the patient is asked to read a passage aloud while that electrode is stimulated. The intensity is set at 15 mA (by supposition, there was no obvious effect at this stimulation during earlier testing). If afterdischarges were previously seen at this electrode, an intensity just below the stimulus intensity causing afterdischarge is used.

If reading slows or halts, the read-aloud screening test is positive and further testing is done. The patient is asked to perform a repetitive movement while incremental stimulus is applied, and any inhibition of that motion during stimulation is noted and and rechecked to verify reproducibility. Movements include the tongue (stick out and move back and forth), the eyes (horizontal or vertical oscillation), sustained contraction (fist or feet), and finger and toe wiggling. Typically the patient initiates a given movement for about 5 seconds before the stimulus is applied, and the application of the stimulus is done surrepetitiously to avoid cueing the patient.

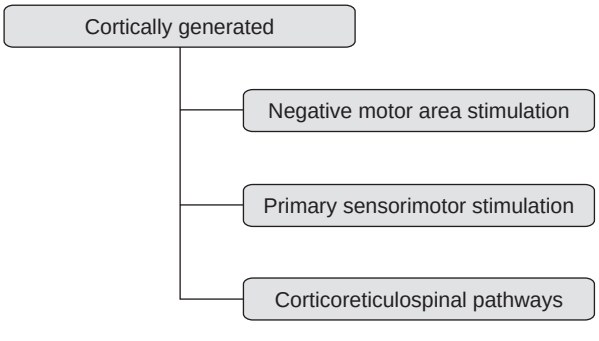

Figure 107.2 Types of cortically mediate negative motor phenomena.

The value of this protocol clinically is roughly defining boundaries of cortical function prior to surgery, as with all cortical stimulation. In terms of the phenomenon of stimulation-induced negative motor effects, the protocol reliably makes the phenomenon available for further study. It is possible that different forms of stimulation-induced negative motor (or sensory or cognitive) effects exist and have not been recognized; this protocol is unlikely to elicit them but remains useful clinically and as a starting point for further investigations.

The DVD accompanying this book includes a mesial and a lateral example of the negative motor effect. Three-dimensional image reconstructions with subdural electrode placement are shown for each case. The abrupt onset and offset of the effect seen in these example is characteristic, but responses may be delayed and partial as well (slowing versus stopping movement).

Anatomy and negative motor characteristics

Human anatomy

Two frontal lobe regions are known to produce stimulation-induced inhibition of movement. One area is lateral, the other mesial. In this chapter they are referred to in these unambiguous, anatomic terms for clarity, though 'primary' and 'supplementary' have been used in the past.

The lateral area ('primary' negative motor area) is in the inferior frontal gyrus, anterior to the motor strip representation of the face. In the dominant hemisphere, this area overlaps Broca's area.[5,7]

The mesial area corresponds roughly to the presupplementary-sensorimotor area (pre-SSMA) and is found in the mesial superior frontal gyrus anterior to the face representation of the SMA proper.[4] This area has recently been a focus of connectivity and functional imaging studies in human and non-human animals, discussed further below. Figure 107.3 illustrates a common frame of reference based on imaging[12] and receptor and histologic data showing differences in the regions defined by these imposed markers.[13–15] A line drawn between the anterior commisure and the posterior commisure is called the AC–PC line. Lines extended perpendicularly (dorsally) at the AC and PC are designated VAC and VPC, respectively. Between these lines lies the SSMA, and anterior to the VAC is the pre-SSMA,[16] a region which includes the mesial

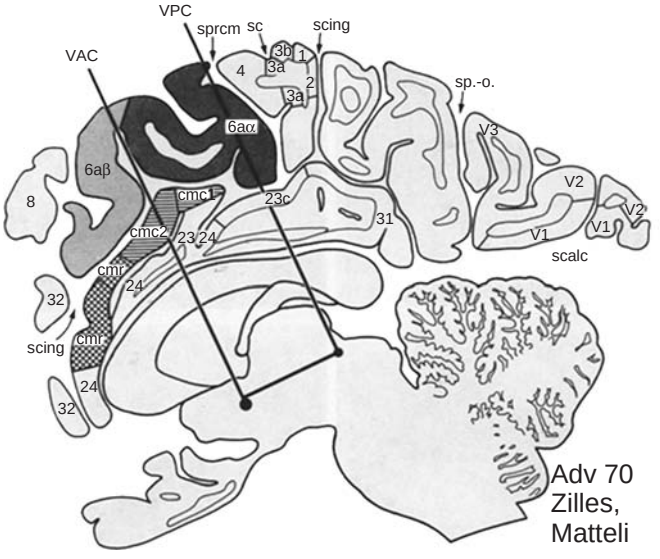

Figure 107.3 Mesial anatomy.

negative motor area. Not every stimulus in this area gives rise to a negative motor effect, though, and stimuli with different parameters may give different results, as described below. Unpublished data from two patients at the Cleveland Clinic with mesial frontal subdural electrode grids shows that the mesial area may extend up out of the fissure onto the continguous lateral surface of the superior frontal lobe. Whether this represents a region of displaced function, extended function, or a variant location for this function is unknown.

Negative motor characteristics

Conclusions based on systematic extraoperative study of negative motor areas were summarized in 1995 by Lüders *et al.*[6] In a series including 42 lateral and 15 mesial negative motor areas, proximal and distal limb movements, as well as movement of the face, tongue, and trunk were studied. 'Subjective effects' were considered in that the patient was kept unaware of which electrode was being stimulated and when it was being stimulated. By definition, stimulation at a negative motor electrode causes no known effect when the patient is at rest during routine stimulation.

Stimulation-induced motor inhibition of the mesial and lateral areas share common features.[6,7] Inhibited movements are primarily distal, involving the fingers, toes, and tongue, as well as eye movements. A given electrode may inhibit one or several of these movements, and subsequent stimulation of that electrode gives the same pattern of distribution. The response at any single site may vary from abrupt cessation of the tested movement(s) at low stimulus intensity to delayed slowing at higher stimulus intensity. Responses are mostly contralateral, but may include a less intense and momentarily delayed ipsilateral component; overall the pattern of responses suggested an abbreviated form of somatotopy in that tongue/eye responses were generally anterior to reponses including other parts of the body. Postural tone is maintained both proximally and distally (for example, if the response is 'finger tapping stops', the arm remains extended in front of the body and the fingers remain in a pincer configuration). The effect can be relatively long lasting and was seen during both brief (1–3 second) and longer (up to 20 second) stimulations. Finally, not all patients with subdural grids covering lateral or mesial areas show a negative motor effect at electrodes in the grid.

In the lateral negative motor area, 18/42 patients[6] with perirolandic subdural grids showed a negative motor effect. Once demonstrated in a given patient at a particular electrode, the effect was repeatable, so the effect is robust, but not invariable. Either the area is there and is not seen, or it is not always there. Reasons for this intriguing finding may include gaps in electrode coverage, variations in individual anatomy, local pathology, or brain states of variable duration that make the effect more or less prominent (eg, learning, compensation, or connectivity). Dominant and nondominant hemisphere responses in the lateral area were observed (12/26 and 6/16, respectively). In the dominant hemisphere, instances of simultaneous negative motor effect (inability to move the tongue) and language interference (both receptive and expressive) were noted with stimulation of the lateral negative motor area. This is consistent with prior reports of interference with both receptive and expressive language when stimulating in Wernicke's area, Broca's area, or the basal temporal lobe.[9,10] Presumably this results from interference with the function served by the underlying cortex.

Mesial negative-motor area stimulation was less well represented in the Cleveland Clinic series due to less frequent clinical indication for mesial frontal electrode coverage. Of 15 patients with such coverage, a negative motor effect was found in ten. Characteristics were similar to those found in the lateral negative motor area, but no interference with language was noted.

Context, functional significance, and mechanisms

Types of cortically mediated negative motor phenomenon

The focus of this chapter is the inhibition of movement due to direct electrical stimulation of the mesial and lateral negative motor areas in the frontal lobe. Though the exact mechanism is unknown, it is presumed to be cortically mediated. Other cortically mediated forms of motor inhibition are also known, and are here organized by their anatomic substrate and clinical correlates. This is summarized in Figure 107.2.

Corticospinal inhibitory pathways and postural tone

An inhibitory pathway connecting cortex through brainstem centers to spinal motor neurons has been characterized in animals and humans.[6] Brainstem centers in the pons and medulla are known to inhibit postural tone based on chemical agonist and electrical stimulation studies.[17,18] These include inhibitory centers in the dorsorostral pons (nucleus reticularis pontis oralis pars medialis and n.r. subceruleus), rostral medulla (n.r. magnocellularis dorsal beta), and caudal medulla (n.r. gigantocellularis).[18]

Cortical influence on these centers from prefrontal cortex, area 4, and premotor area 6 through excitatory connections has also been described,[19–21] and labelling studies have suggested bilateral distribution of corticofugal fibers in the lower pontine and medullary levels,[22] with resulting bilateral influence.

Despite an extra synaptic step in the corticoreticulospinal pathway, larger-diameter fibers may make it faster than the

direct corticospinal pathway.[23,24] This indirect but faster corticoreticulospinal system maintains axial and proximal tone, while the direct yet slower corticospinal pathway controls fine movements of more distal muscles. Profound inhibition of postural tone via the corticoreticulospinal pathway may account for bilateral clinical events including axial atonic seizures and focal seizures manifesting 'drop attacks'.[6]

Given the observed preservation of postural and proximal tone during motor inhibition with stimulation of negative motor areas, the corticoreticulospinal system should be relatively unaffected. This provides an important constraint on the relationship between negative motor area cortex and the cortical areas implicated in postural control through the corticoreticularspinal system, at least during negative motor area stimulation.

Cortico-cortical I: cortical inhibition of tonic excitatory output and negative myoclonus

Although the negative motor effect due to cortical stimulation at mesial and later 'negative motor areas' likely involves cortico-cortico interactions, a distinct inhibitory corticocortical mechanism is known from transcranial magnetic stimulation (TMS) studies. It should be noted that TMS, like electrical stimulation may also be excitatory. For example, a recent study by Matsunaga *et al.* found that 5 Hz repetitive TMS stimulation of the SMA transiently increased the excitability of connected primary motor hand areas and their corticospinal connections.[25] In addition, though motor-evoked potentials (MEP) and silent periods (SP) are discussed below with respect to TMS, they can also be elicited by electrical stimulation using single pulse electrical stimulation.[26]

TMS stimulation of motor cortex may produce a MEP followed by a SP on EMG at the affected muscle,[27,28] the SP being inherently inhibitory. The MEP and SP are not invariably associated, though and can be generated independently in close or even adjacent but nonoverlapping areas of cortex.[29,30] Furthermore, the SP is thought to consist of an early component due to intrinsic spinal cord mechanisms (reviewed in ref. 6) and a later component due to corticocortical interactions.[30]

Whether this form of cortically-mediated motor inhibition, involving interactions between primary motor and sensory cortices, is responsible for 'negative myoclonus' has been debated. When negative myoclonus is preceded by positive myoclonus, it is likely that the first clinical event (positive myoclonus) corresponds to the MEP seen in stimulation studies, while the second clinical event (negative myoclonus) corresponds to the SP.[31] A patient with negative myoclonic status epilepticus was studied and a correlation found between the duration and amplitude of an EEG spike in hand sensory cortex and the subsequent SP duration, suggesting that the discharge in the sensory region inhibited tonic excitatory output of the corresponding motor cortex through corticocortical connections.[6]

On the other hand, negative motor areas have also been proposed to account for negative myoclonus.[32,33] Ikeda *et al.* distinguished three types of responses to single pulse subdural grid responses (MEP followed by SP; SP alone; and MEP alone) when stimulating in primary and nonprimary motor areas, including the NMA in two patients.[26] Their results were generally consonant with prior TMS data suggesting inhibitory corticocortical mechanisms in primary sensorimotor cortices,[27,34] and their finding of a single MEP-SP complex in nonprimary cortex (in one of two negative motor areas tested; the other showed no response) also illustrates an additional level of complexity in that the cortex designated 'negative motor area' may display different functions and properties depending on the stimulus parameters used.

Thus while electrical correlates like those associated clinically with negative myoclonus has been seen during stimulation of the negative motor area (i.e., MEP-SP), negative myoclonus is more consistently associated with distinct, primary sensorimotor cortical inhibitory phenomenon. The relationship between this corticocortical mechanism and the negative motor effect that is the focus of this chapter is, in this light, intriguing and will be discussed further below.

On the whole, it seems reasonable to conclude that there is a cortico-cotrical inhibitory mechanism involving the inhibition of tonic excitatory output of the primary motor cortex by adjacent sensorimotor areas, and that this is the most frequent, if not exclusive, mechanism underlying clinical or epileptic negative myoclonus.

Cortico-cortical II: inability to generate voluntary movements with stimulation of mesial or lateral negative motor areas

With respect to the two additional forms of cortically mediated motor inhibition above, the picture of the inhibitory effect seen with stimulation of the PNMA and SMNA becomes at once sharper and more complex. The dissociation of fine, distal movements from preserved posture with NMA stimulation argues for separate systems, and the corticoreticular-spinal pathway is well established.

While TMS-elicited MEP-SP inhibition in primary sensorimotor cortex and the response to 50 Hz electrical stimulation in the negative motor areas do have significant differences, the relationship between them is less clear. Like the MEP-SP response, activation of the NMA may lead to combined positive and negative responses, as in a case of ictal face twitching with ispilateral paralysis.[6] This combination is not known to occur with stimulation, though. Also, the correlation between induced effect (MEP-SP) and clinical effect (positive myoclonus followed by negative myoclonus) is more compelling for the MEP-SP form of corticocortical inhibition. The existence of even the single MEP-SP complex by stimulation of a negative motor area by Ikeda *et al.*[26] highlights two further issues: the dependence of the negative motor area cortex's response on stimulus type, and the possibility that these two forms of cortical inhibition depend on each other and may use common intermediate circuits.

Additional sources of uncertainty concern the relationships between the physiologic function of these areas in a normal brain, varying pathology in the relatively small number of patients studied, and varying brain states that may affect the gating and input/output characteristics of adjacent and distant cortical areas. Precisely what a given form of stimulation achieves in terms of meaningful neural circuits (combinations of functional ablation, inhibition, or activation) is also unclear.

Overall, though, it seems reasonable to consider that the brief MEP-SP response seen on TMS stimulation of primary sensorimotor cortex depends on reciprocal corticocortal connections that inhibit tonic excitatory motor output, and that this is distinct from the motor inhibition elicited by high

frequency stimulation of negative motor areas, which persists for up to the 20-second duration reported by Lüders *et al.*[6] To gain insight into the circuits on which negative motor area effects depend, we now consider animal correlates and connectivity.

Animal correlates and connectivity

Primate studies: connections, and stimulation data

Extending early 20th century work by the Vogts[35] and Brodmann,[36] more recent studies of primates show three key results. First, primate mesial frontal cortex can be divided on the basis of cytoarchitecture,[13] connections to the thalamus[37,38] and cortical areas,[39–45] and responses to behavioral tasks and stimulation[46–52] into caudal and rostral areas that analogous to the human SMA and pre-SMA. Second, those results are consistent with a 'higher level' motor function for the area analogous to the human pre-SMA. Finally, in primate lateral frontal cortex, there is an area whose cytoarchitecture, pattern of connection, and physiologic response to goal-oriented movement is similar to the more rostral portion of the primate mesial frontal cortex.

The primate mesial frontal region corresponding to the human supplementary sensorimotor area (SSMA) has been designated F3 by Matelli *et al.*[13] It contains giant pyradimal cells in layer Vb and has output to corticospinal tracts.[41,42] The more rostral area, corresponding to human pre-SSMA, has a layer V, but not pyramidal output cells. This area is called F6, and it does not contribute directly to corticospinal output.[40,45] Where thalamic afferents to F3 from the putamen via the nucleus ventralis lateralis, pars oralis (VLo), F6 afferents originate from the caudate via the nucleus ventralis anterior, pars parvocellularis (VApc).[37,38] Corticocortical connections also differ: F3 receives afferents from F1 (corresponding to Brodmann's area 4), F2 and F4 (corresponding to Brodmann's area 6), and the cingulate. F6, in contrast, receives extensive connections from prefrontal areas and F5 (Brodmann's inferior area 6), which is anterior to the primate premotor area.[43,45,48,53] Figure 107.4 schematically shows these cortical afferents. Coupled with behavioral studies showing F6 cell response prior to reaching as a function of whether or not the target is reachable[51,52] and easily elicited somatotopic movements from F3 but more complex, natural appearing movements at higher thresholds from F6,[46,49] these studies support the notion of a 'higher level' planning or organizational function in the rostral portion of primate medial frontal cortex. The more caudal portion, F3, is tightly linked to areas with corticospinal output, and contributes corticospinal output itself, consistent with a role in the execution of movements.

The lateral primate cortex includes F2 superiorly and areas designated F4 and F5, as shown in Figure 107.4. As noted, the rostral mesial frontal area F6 receives afferents from F5, but not from F4. The firing of subpopulations of neurons in area F5 correlate with goal-related ipsilateral and contralateral distal movements involving the hand and mouth, and are also responsive to sensory and visual stimuli.[54] The overlap in humans between the lateral NMA and Broca's area, taken with these results, suggest that area F5 in primates corresponds to the human lateral NMA. It is also tempting to speculate that the evolution of language in humans, including gestures and fine motor aspects of facial and laryngeal muscles in producing speech, is rooted in the functions of this area.

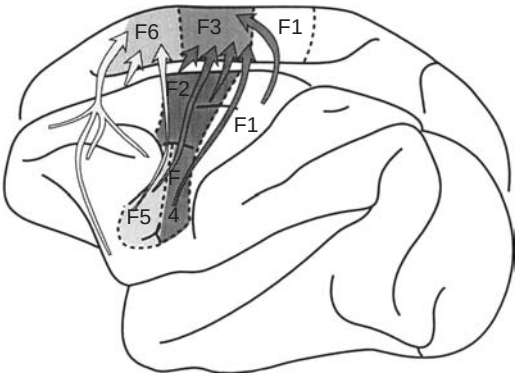

Figure 107.4 Primate cortical connectivity, from ref. 66 (Matelli *et al.*) in ref. 6.

Apraxia versus paralysis: a testable hypothesis

The considerations above suggest a testable hypothesis to distinguish a mechanism for the negative motor area effect at the level of analagous clinical descriptions: apraxia versus paralysis.

If stimulation of negative motor area cortex interferes with higher level organization of fine, distal movements, then the 'downstream' machinery, including corticospinal connections from primary motor cortex, should be intact. Simultaneous stimulation of the negative motor area (interrupts organization) and the positive motor area (intact circuitry) results in a typical brief jerk characteristic of primary motor stimulation in (for example) the finger area, which has been previously mapped with standard mapping technique. This result is consistent with metaphoric 'apraxia,' a concept that properly refers to complex volitional behavior.

If negative motor area inhibition instead operates by disabling that subset of motor outputs for the affected movements, simultaneous stimulation should result in an absence of a typical primary motor response for the affected muscles, consistent with paralysis.

Clinical correlates and effect of resection

Clinical correlates for negative motor areas include data from seizures, strokes, and electrophysiologic study. One report attributed focal akinetic seizures of the contralateral arm to lesions in the medial frontal area,[55] though the conrtibutions of the lesion and its extent, as well as the epileptic activity, are difficult to separate and may occupy altered anatomy.

Negative myoclonus in the contralateral upper limb following anterior mesial stroke has also been reported.[56] It has been postulated that negative myoclonus may result from activation of negative motor areas,[57] though this has been disputed on the basis of the time disparity between brief negative myoclonus and sustained, longer stimulation-induced negative motor effects[58]

and discussed earlier in this chapter. Differences between intrinsic activation by epileptic activity may be quite different than extrinsic activation by cortical stimulation. A recent study with stereo-EEG stimulation suggested that transient negative motor area activation following SSMA stimulation might be responsible for silent periods not preceded by enhanced EMG activity[11] despite the time disparity between stimulation-induced negative motor effects and negative myoclonus.

There appear to be no surgical outcome studies specifically addressing either the mesial or lateral NMA. An 'SMA Syndrome' following SMA resection has been described in tumor and epilepsy patients. Features include reduced spontaneous movements and movement to command with relatively unaffected limb tone and preserved overleaned motor actions; hemineglect and apraxia of contralateral limbs are also seen. Transient speech deficits are seen when the resection involves the dominant hemisphere, and there may be preoperative increased signal on functional MRI in the SMA of the healthy hemisphere.[59] If motor cortex is spared, these tend to be transient with recovery in a few weeks and virtually complete recovery by 24 months.[60] In a recent series of 27 tumor patients with variable resection of the posterior third of the superior frontal gyrus, the incidence of any deficit was 26% and all deficits had resolved at 24 months follow-up.[61] These studies comprise limited numbers of adult resections of diverse pathology that may include, but are not limited to, the pre-SMA. Inferences about pre-SMA function and postoperative deficits are therefore tenuous.[62,63] Relating functional imaging findings from cognitive and motor control studies with pre-SMA and SMA proper differentiation may be a fruitful area for further exploring the negative motor effects as well as surgical outcomes.

In the area of the lateral NMA, a small series of patients with seizures involving the face and head seemed to follow the general rule that, if primary motor cortex is spared, postoperative deficits are transient or mild.[64]

Nomenclature and the term 'negative motor area'

The term 'negative motor' is used in two ways: to specify a location (negative motor area) and to describe an effect seen with cortical stimulation (negative motor effect).

Calling a cortical location a 'negative motor area' implies that some cortically generated negative motor phenomenon (stimulation-induced, epileptic, or physiologic) is subserved by that cortical area. The term may thus be considered vague unless a more specific effect (as in the 'Mechanisms' section of this chapter) is made explicit, or unless all cortically generated negative motor effects are intentionally referred to as a group. Thus, specifying a location as a 'negative motor area' seems valid when the distinction between types of negative motor effects is clearly comprehended and communicated. At a more fundamental level is the question of whether 'negative motor' itself as an adjective is appropriate to describe a category including stimulation-induced, epileptic, or physiologic inhibition of movement.

The distinction between 'negative' and 'positive' is fundamental, and is considered coherent and useful elsewhere in medicine (e.g., the negative and positive symptoms of schizophrenia; 'negative and positive myoclonus'). In the context of inhibiting certain types of movement, a 'negative' response to cortical stimulation is perhaps less intuitive, but as robust as the clonic jerks (M1) or more complex movements (SSMA) elicited by cortical stimulation as described elsewhere in this volume. One might suppose that 'negative motor effect' means an movement that is opposite (opposing muscle group) to a corresponding positive movement. Also, since movement occurs due to muscle contractions ('positive') and there is no corresponding active 'relax' signal generated by the nervous system, the term may again seem counterintiutive or confusing. As with many terms in medicine and elsewhere, some prior knowledge is assumed in order to understand this term and how it is used. Thus, the term 'negative motor' usefully names a category of cortically mediated inhibition, and can be appropriately qualified to refer to specific kinds of inhibition within that category.

Summary

Electrical stimulation of regions in specific regions of the mesial superior and lateral inferior frontal lobe at 50 Hz interrupts distal, mostly contralateral movement of the fingers, toes, hands, tongue, and eyes in variable combinations with no alteration in awareness until the patient notices the inability to enact the movements. This may be mediated through interruption of higher-level 'organizational' aspects of motor output (apraxia) or by disabling a subset of cortical motor output (paralysis). Simultaneous stimulation of positive and negative motor areas affecting the same muscles would be informative in distinguishing these two possibilities. The category of cortically mediated negative motor phenomenon also includes corticoreticulospinal pathways with bilateral influence mediating postural and proximal muscle tone, and cortico-cortical connections that inhibit tonic excitatory output from primary motor cortex as seen with TMS-induced silent periods.

Negative motor areas have a special interest in the era of functional imaging because of their strategic location between 'lower order' motor output cortex and 'higher order' frontal cortex, promising insight into general mechanisms of interaction among cortical areas serving diverse functions at different levels.

108 Cortical mapping by electrical stimulation of subdural electrodes: supplementary sensorimotor area in humans

DS Dinner and HO Lüders

Introduction

In the second half of the nineteenth century Fritsch and Hitzig pioneered electrical stimulation studies of the brain in a animals.[1] They discovered that electrical stimulation of the cerebral cortex produced contralateral motor activity. In 1888 it was demonstrated in monkeys that electrical stimulation of the precentral gyrus and the mesial aspect of the superior frontal gyrus anterior to the primary motor representation of the lower limb could produce movements.[2] The anatomic and electrical stimulation work of the Vogts demonstrated that the different cytoarchitectonic areas correspond to functionally independent regions.[3] On the mesial surface of the cerebral cortex, they defined three motor areas that they referred to as the primary, secondary, and tertiary areas that corresponded approximately to Brodmann's cytoarchitectonic areas 4, 6aa, and 6aB (Figure 108.1). Stimulation of area 4 produced movements of individual joints. These movements could also be produced by stimulation of area 6 but at higher stimulation intensities. They showed that this was via activation of area 4. Stimulation of area 6aa on the medial surface was also able to produce complex movements. Stimulation of area 6aB required even higher stimulation intensities to produce individual movements that were dependant on area 4, but also could produce postural movements including contralateral version.

Experimental electrical stimulation of the human cerebral cortex was first performed by Bartholow in 1874.[4] Krause (1911) was the first to elicit motor responses to electrical stimulation of human cortex.[5] Foerster reported on the findings from electrical stimulation of the cortex performed in more than 300 patients. He described accurately the human homunculus in area 4 including the somatic distribution of the leg and foot in the mesial precentral region (Figure 108.2).[6] In area 6aa he described movements of isolated joint movements similar to those elicited in area 4 but triggering of isolated joint movements required higher stimulation intensities and the effects were dependant on an intact area 4. On the other hand, following lesions of area 4 stimulation of area 6aa was still able to produce complex movements. These earlier observations were complemented by the work of Penfield and Brodley, who did extensive studies using electrical stimulation intraoperatively to describe the motor and sensory representation of the human cerebral cortex.[7]

Penfield and Welch were the first to define in humans the supplementary motor area (SMA), the region of the mesial superior frontal gyrus (SFG) from where motor responses were elicited by electrical stimulation and distinguished it from the primary motor area (PMA) of the mesial and lateral convexity of the frontal lobe.[8,9] They found that stimulation of the mesial surface of the superior frontal gyrus elicited complex postural movements of all extremities. In addition vocalization, speech arrest, paresthesiae, inhibition of movement, and autonomic changes were elicited. They named this region the supplementary motor area (SMA). They chose the term supplementary not because they thought this region had a supplementary role in terms of motor function but to distinguish it from the primary motor area on the mesial and dorsolateral convexity. The SMA in humans was thus defined not anatomically but electrophysiologically. Motor and sensory representations within this functional region are intimately associated which led Lim *et al*. to refer to this area as the supplementary sensorimotor area (SSMA).[10]

Functional anatomy of the motor cortex

Traditionally the motor cortex was described as consisting of three motor areas: the primary motor cortex (PMA or M1) in the precentral gyrus, which houses a complete somatotopic representation of body movements; the supplementary motor area (SMA) or supplementary sensorimotor area (SSMA) on the mesial surface of the superior frontal gyrus rostral and ventral to the PMA, also containing a complete motor representation and the premotor cortex (PMC) on the lateral cortical convexity anterior to the PMA (Figure 108.2).[7]

However, in the latter part of the twentieth century investigations of non-human primates, particularly macaques has demonstrated a more complex division of the regions involved in the processing of movement. The use of modern anatomical and physiological techniques has enabled

researches to explore and define additional subdivisions of motor areas in both humans and primates.[11]

The PMA in macaques is in region F1 (Figure 108.1) which corresponds with area 4 in humans (Figure 108.2).[11,12] Rostral to this region area 6 can be subdivided on the mesial surface into the SSMA proper (F3) and pre-SSMA (F6) (Figure 108.1). On the dorsolateral cortical surface is the premotor cortex (PMC). Dorsolaterally is the dorsal PMC (F2 and F7) and on the dorsoventral cortical surface the ventral PMC (F4 and F5) (Figure 108.1). In addition motor responses have also been found in the cingulate cortex.

Primary motor area

It is agreed upon by most investigators that the primary motor cortex corresponds with Brodmann's area 4 and with F1 according to the nomenclature of Matelli.[11,12]

The PMA is located in the precentral gyrus on the anterior wall of the central sulcus and corresponds to Brodmann's area 4 (Figure 108.2). On the basis of cytoarchitectonic criteria, area 4 is recognized primarily by the presence of Betz cells (giant pyramidal cells) in cortical layer V and the absence of the granular layers II and IV. The central fissure marks the border between the agranular motor cortex and the granular somatosensory cortex in the postcentral gyrus.[13] The border between the two regions lies deep within the central sulcus. The rostral portion of the anterior bank and the superficially exposed part represents the anterior part of the cytoarchitectonic area 4 and is referred to as subarea 4a. The part of the precentral gyrus that is completely buried in the central sulcus and corresponds to the posterior portion of area 4 is referred to as subarea 4p. The lower layer III pyramidal cells are larger and more densely packed in area 4a and are smaller and loosely aggregated in area 4p. The cells are even larger in area 6. There are no differences in the Betz cells in area 4a and 4p. These two areas are also different in terms of their neurotransmitter binding sites, with a higher concentration of neurotransmitter binding in 4p than 4a.[14,15] The somatotopic organization of the primary motor cortex was elucidated by the pioneering work of Krause, Foster, Penfield, Jasper and others.[5,6,16] In Brodmann's area 4 simple movements can be elicited with the lowest intensity of electrical stimulation.[17] Maps of the motor cortex demonstrate an orderly arrangement with the tongue and lips close to the sylvian fissure and thumb, digits, arm, and trunk represented successively along the central sulcus ending with the leg, foot, and toes on the medial surface. The layout of the motor homunculus is topographically similar to that of the somatosensory homunculus, which resides immediately behind the PMA in the postcentral gyrus. The output of the PMA is directed to the corticospinal and corticobulbar tracts as well as to the SSMA and homologous areas in the opposite hemisphere via corpus callosum.[18]

Supplementary sensorimotor area

The supplementary sensorimotor area (SSMA) is a distinct anatomic region located on the mesial surface of the superior

frontal gyrus (SFG) and its adjacent dorsal convexity.[9] The cerebral cortex of the SSMA corresponds to the mesial portion of area 6 of Brodmann's cyto-architectonic map of the brain (Figure 108.2). The SSMA similar to the PMA cortex is referred to as agranular cortex, because the granular layers (layer II and IV) are not prominent. In contrast to area 4, area 6 does not contain Betz cells.[19] An extension of the precentral sulcus on the medial surface defines the border between the PMA for the foot and the posterior limit of the SSMA.[10,20] No clear cytoarchitectonic or anatomical boundary exists to separate the SSMA from the adjacent premotor cortex. [21]

Histological studies found very similar architectonic features in Macaque F3 and F6 and human mesial areas 6aa and 6aB respectively.[21,22] Area F3 and mesial area 6aa both have increased cell density in lower layer III and layer V. Both are well demarcated on the dorsal convexity from area F2 and from lateral area 6aa respectively. Area F6 and mesial area 6aB are clearly laminated and both have a prominent layer V, are well separated from layer III and layer VI. Both are well demarcated on the dorsal convexity from area F7 and lateral 6aB respectively. In humans the border of mesial area 4 (PMA) and mesial area 6aa corresponds with the vertical through the posterior commissure (VPC) line. The border between mesial area 6aa (SSMA proper) and mesial area 6aB (pre-SSMA) corresponds with the vertical line through the anterior commissure (VAC) line (Figure 108.1 and 108.2). These lines are perpendicular to the AC-PC line.[21,23]

Neurochemical binding sites appear to be similar in these areas in macaques and humans.[15,21,22] The receptor densities are highest in the somatosensory areas. Of the motor areas, area 4 has the lowest mean densities of GABA-A, muscarinic M1 and M2, kainite, 5-HT1, a1 and a2 receptors. Pre-SMA has higher densities of M2, kainite, 5-HT1, a1 and 5-HT2 receptors than the lateral premotor cortex. The inverse relationship between the receptor densities in both areas is found for AMPA and 5-HT1 receptors. M2 receptor density is lower in the rostral portion of the cingulate (cmr) than in the pre-SSMA, but is higher in the medially adjoining cingulate periallocortex. The NMDA, AMPA, a1 and 5-HT2 receptors are of higher densities in the cmr than in the pre-SSMA.

Microstimulation studies demonstrated that the F3 region corresponding to SSMA proper could be activated at low intensity stimuli.[24] It was found that there was a somatotopic organization within this region. The hind limb is located caudally and the forelimb rostrally. A small orofacial representation lies anteriorly at the border with area F6. This is similar to the somatotopic organization defined in the SSMA proper of human cortex.[10] The average excitability threshold in F3 was higher than in F1.

The movements elicited from stimulation of area F3 were complex, whereas those from F1 were simple movements. The majority of the movements elicited by stimulation of F3, were proximal movements alone or were combined with movements of other segments. A pure distal movement in response to stimulation of F3 was infrequent.

In contrast, in F6 excitability was less than in F3. However, movements could be produced at about 50% of the tested sites, when stimulating with long train durations or stimulating while the monkey was making spontaneous movements. The movements usually are of the forelimb but neck and upper face movements were also observed. Whereas movements elicited from stimulation of F3 were fast, those from F6 were mostly slow and many mimicked natural movements of the animal.

In terms of single neuron activity, phasic neuronal activity time locked to movement onset was more frequent in F3 than F6.[25,26] Premovement activity was longer and more frequent in F6 than in F3.[15,16]

In F6 there were neurons related to arm movements that discharge greatly in advance of the actual movement and their activity was influenced by the distance of the object from the monkey.[27]

Further studies showed that F3 and F6 differ in regard to their cortico-cortical, cortico-spinal and thalamo-cortical connections.[28]

All these differences in the two areas support that they are two distinct regions with independent functions. F3 corresponding to the SSMA proper plays a role in motor control close to movement execution. F6 corresponding to the pre-SSMA may represent a nodal point in transmitting information from prefrontal and cingulate areas to other premotor areas and thus may play a role in motor control at a higher hierarchal level. The division of these two functional areas led Tanji and his co-workers to propose that the caudal area F3 be termed SMA proper and the rostral area F6 be termed the pre-SMA.[29] Because of the similarity of the two mesial areas in monkeys and humans Zilles and co-workers proposed that the same terms be adopted in regard to human SMA, area 6aa be termed SMA proper and area 6aB be termed pre-SMA.

Premotor cortex

The term premotor cortex (PMC) was coined by Fulton in 1935 to describe the third major component of the motor cortex. This area encompasses the more loosely defined agranular cortex of the lateral frontal convexity rostral to the PMA,[7,30] which corresponds to the lateral portion of Brodmann's area 6 (Figure 108.1). It is very difficult to define the anterior border of the agranular PMC in humans, where a broad zone of progressive transition exists between area 6 and the granular cortex of Brodmann's frontal area 8.[31] In the macaque the premotor cortex is further subdivided into a dorsal portion (PMd) corresponding to F2 and F7 on the dorsolateral convexity and a ventral portion (PMv) corresponding to F4 and F5 on the ventrolateral convexity (Figure 108.1).[12] Despite the lack of direct correlation between microstructure and function in humans, the two subdivisions of the premotor cortex are considered to have homologous counterparts in the human brain.

The motor and premotor cortices as well as the frontal eye fields and the anterior cingulate cortex (area 24) have been shown to have reciprocal connections with the SSMA. Anatomic labeling experiments in the macaque have demonstrated that the more anterior dorsal PMC projects to the spinal cord challenging the notion that the premotor cortex, unlike the PMA and SSMA lacks prominent cortico-spinal connections.[30,32,33]

According to the classic schema, the PMC is responsible for the preparation and organization of movements.[21] Several recent studies have shown that the PMC also plays a

central role in non-motor attentional and receptive domains. Therefore, our current understanding suggests a dual PMC function pertaining to motor and cognitive behavior.[34]

Cingulate cortex

The cingulate motor cortex, which was previously linked to the limbic system, is now viewed as a potential fourth motor area. The cingulate in humans can be divided into an anterior and a posterior portion with the border approximately midway between the VAC line and the VPC line. The anterior part of the cingulate cortex is agranular with layer IV absent. Layer V is prominent. In contrast the posterior portion of the cingulate cortex is granular with the layer IV being present. Strick and colleagues subdivided the cingulate cortex into two zones, separated by the VAC line into the caudal cingulate zone (CCZ) and the rostral cingulate zone (RCZ).[35] The CCZ overlaps with the posterior part of area 24. The RCZ overlaps with the anterior part of area 24 and with area 32 and is subdivided into an anterior part RCZa and a posterior part RCZp.

Prefrontal cortex

The term 'prefrontal cortex' is used to define the extensive part of the frontal lobe that lies anterior to the motor and premotor zones.[14] It includes the mesial frontal cortex anterior to the SSMA, the dorsolateral cortex and the orbitofrontal cortex.

Functional neuroimaging

Activation studies using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) allude to the complex organization of the motor system. The breadth of cortical and subcortical areas activated with even the simplest movements attest to the wide distribution and extent of interconnected neural networks underlying motor control.[36] Observed movements presuppose a series of parallel or sequential processes involving the selection, planning, preparation, and initiation of action.[36,37]

PET

PET scans have shown an increase in cerebral blood flow in the mesial frontal region in association with finger movement, proximal arm movement, and eye movements. There appears to be a somatotopic organization in that the activation with finger movements is anterior to that with proximal arm movements and that with eye movements is the most anterior.[38] This is similar to the somatotopic organization that has been documented by electrical stimulation.[10] A significantly higher activation has been documented with complex finger movements rather that with simple movements.[39] The Parma group found that with simple movements only a restricted portion of the mesial frontal cortex demonstrated an increase in the regional CBF. This region by co-registration with MRI was located in the region between the VAC and the VPC lines in the region consistent with the SSMA proper. Only when the subjects were required to plan or perform complex sequences of movements was there more extensive activation of the mesial frontal cortex, the rostral region thought to be involving the prefrontal cortex and the more caudal region attributed to involvement of the SSMA. In studying the effect of simple distal movements and proximal movements, both resulted in increase regional CBF in the region of the SSMA proper.[40]

However the PET scan measures blood flow only over relatively long periods of time, 1 – 2 minutes, compared to a baseline or resting condition. This does not provide the temporal resolution necessary to examine the premovement activity associated with movement preparation.

fMRI

The early studies with fMRI studies used blocked designs in which the individual being studied alternated between periods of continuous task performance and baseline or resting conditions. Thus only static activation maps could be produced showing areas of the brain which significantly change in their activity overall while performing the task. Figure 108.3 demonstrates the activation of the SSMA in patient performing finger movements of both hands.

More recently single event related or time resolved fMRI have been employed and are able to provide some temporal resolution and to detect the time course of hemodynamic responses in the different regions with different tasks. The BOLD fMRI responses are much slower than the neuronal activity, reaching peak amplitude about 4–5 seconds after the event and returning to baseline approximately 10–12 seconds after the event.[41] Several studies using event-related and

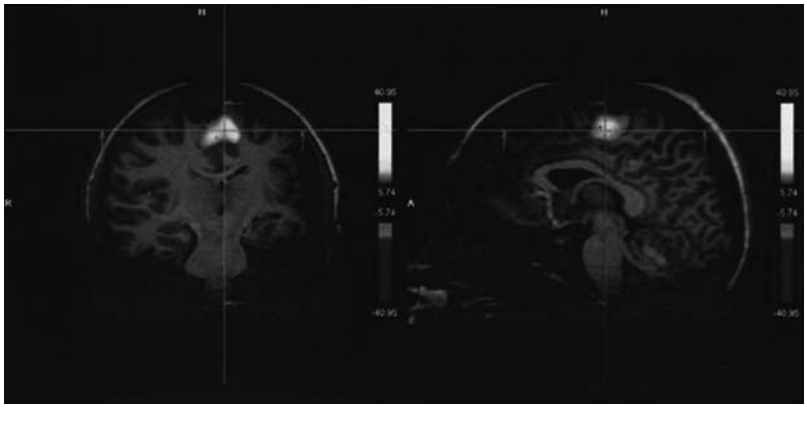

Figure 108.3 Functional MRI demonstrating activation of the SSMA in response to finger-tapping of both hands. (See Color plates.)

time-resolved fMRI have examined the time sequence of activation during self-initiated movement. These studies demonstrated that activation in the pre-SSMA preceded activation of the PMA by 2.0 secs which is similar to the premovement duration of the Bereitschaftspotential.[42–45]

High-field fMRI's obtained with 3 Tesla magnets have been used to investigate the somatotopic organization of the motor representation in the medial aspect of the cerebral hemisphere.[46] They had normal volunteers move either the right forefinger or their toes. They defined separate areas of activation in the SSMA and in the cingulate motor area (CMA). They found within the SSMA that finger movements resulted in activation more rostral than toe movements. This somatotopic organization is similar to the findings on electrical stimulation in humans.[10] The area activated by finger movements extended rostral to the VAC line into the region which usually is defined as the pre-SSMA. However, a recent cytoarchitectonic study provided evidence that the SSMA proper may be subdivided into a rostral and a caudal portion and that the rostral portion may extend as much as 20 mm rostral to the VAC line.[23]

Electrical stimulation

Methodology

The initial electrical stimulation studies of the SSMA in man were performed intraoperatively. Although during intraoperative electrical stimulation, direct visualization of the position of the electrodes in relation to the cortical surface anatomy is possible, there are distinct disadvantages to this technique. The mesial aspect of the SFG is difficult to access due to the presence of bridging veins. It is also very difficult to recognize by direct visualization specific gyral landmarks within the depths of the interhemispheric fissure. There are significant time constraints when electrical stimulation is performed intraoperatively. Extraoperative electrical stimulation via depth or subdural electrodes has definite advantages most importantly the relative absence of time constraints. Responses to electrical stimulation may be repeated to ensure reproducibility and videotaped for subsequent review. However, the disadvantages of the extraoperative technique is that it requires an additional surgical procedure and complications (infections, increased intracranial pressure) from having an intracranial foreign object implanted. Besides the electrodes are in a fixed location, cannot be moved as is the case for intraoperative electrical stimulation studies, and the relatively large size of the electrodes makes fine somatotopic studies impossible.

In regard to placement of depth electrodes, X-rays of the skull, gaseous encephalography, vertriculography, and angiography were performed to define the location of the depth electrodes in the French studies.[47] In Van Buren's study, localization of the electrodes was based on tracings of the lateral pneumoencephalogram superimposed on lateral skull X-ray films with electrodes in place.[48] In our earlier studies, the anatomic location of the electrodes[10,49] was determined by superimposing the lateral skull X-ray with the subdural electrodes in place on the pre-operative magnetic resonance imaging (MRI) scan.

The studies reported here were performed using subdural electrodes that are non-ferromagnetic thin platinum disks, with the exposed surface measuring 2.3 mm in diameter. Platinum-iridium electrodes may have a theoretical advantage in stability as compared to stainless steel electrodes when current is passed. The interelectrode distance was 1 cm. The array of electrodes varied from 8×8 to 1×11 grids or any combination there of and it was tailored to the cortical area of interest.

The position of the electrodes on the cortical surface was verified by identifying them individually on post-operative 3-D MRI. It is important to ensure that there is an adequate coverage of the cortical area whose function we attempt to evaluate by stimulation (Figure 108.4). Safe delivery of focal electrical stimulation with minimal spreading to adjacent cortical areas is necessary to determine that an observed response can be attributed to the stimulated area. Nathan *et al.*, by using finite element modeling found that the current density drops off rapidly with increasing distance from the tissue underlying the stimulating electrodes (FEM).[50] Recessing the edges of the electrodes in the plastic, which embeds them, provides reliable focal stimulation with a rapid and smooth current drop away from the stimulating site.

There is evidence that intermittent cortical stimulation carried out over several days for mapping in humans with the current protocols specified below does not result in any cortical damage and is felt to be safe.[51] The afterdischarge thresholds may vary over a tested region of the brain with recurrent

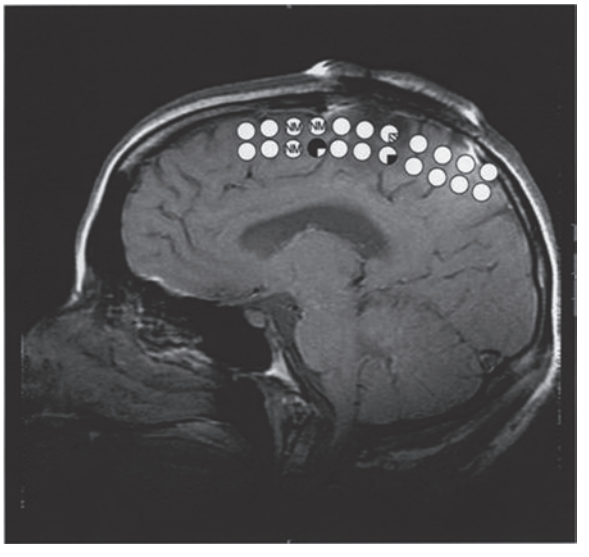

Figure 108.4 Midline sagittal MRI of the right cerebral hemisphere in a patient with electrodes for evaluation of here intractable mesial frontal lobe epilepsy. electrical stimulation on different days, but there is no evidence to support any progressive decrease in the afterdischarge threshold which would be expected with a kindling phenomenon.[52,53]

We use stimulus pulses of 0.3 ms duration of alternating polarity at the rate of 50 pulses per second. The testing is routinely begun at a low intensity of 1.0 mA and increased gradually by 0.5–1.0 mA until an afterdischarge, clinical response or maximum stimulus strength of the instrument is reached (15 mA with Grass S88 stimulator, 17.5 mA with Grass S12 stimulator, and 20 mA with an Ojeman stimulator). The duration of a stimulus train is usually 5 sec for the initial screening. When afterdischarges occur, one can usually retest at the same stimulus intensity without recurrence of afterdischarges. Subsequently, it is not unusual to observe that a gradual increase in the stimulus intensity much beyond the initial threshold for afterdischarges can be attained, without eliciting additional afterdischarges. It is important to bear in mind that the afterdischarge threshold can vary even within adjacent electrodes and from one day to the other, and hence one must establish the afterdischarge threshold for each cortical area every time it is tested.[52]

Responses

Positive motor response

In the initial study, the Montreal group found that on the dominant hemisphere, the SSMA was separated from the PMA by a strip of cortex.[8,9] The French group, however, reported no separation between the SSMA and the PMA.[47] We also found no separation between the SSMA and the PMA.[10]

In a preliminary study of contralateral upper extremity movements elicited by electrical stimulation of the PMA and the SSMA, we found that PMA responses were predominantly clonic in nature and distal in distribution, whereas the responses from the stimulation of the SSMA were predominantly tonic and proximal.[10] Based on these observations, we classified isolated movements of the contralateral lower extremity that were predominantly clonic and distal as PMA-type responses, while those that were predominantly tonic and proximal as SSMA-type responses. Besides, bilateral movements of the lower extremities, ipsilateral extremity movements, and combined upper and lower extremity movements, were defined as SSMA-type motor responses. With regard to ipsilateral and bilateral extremity movements, Fried noted that these movements were elicited almost exclusively from the right hemisphere and interpreted this as an indication of a left-right hemispheric specialization.[54] However, we found these movements from both hemispheres, more often from the left (dominant) hemisphere in five patients, than the right (non-dominant) hemisphere in two patients.[10]

SSMA-type positive motor responses can also be elicited from the dorsal convexity of the SFG; we found this in three of our 15 patients. This observation was first made by the Montreal group.[8,9] We found SSMA-type responses were elicited not only from the mesial surface of the SFG but also from the lower half of the paracentral lobule (Figure 108.2). The possibility that such responses in these regions were due to spread of current to the classical SSMA location (mesial SFG) is unlikely since in our study we ensured stimulation was always below the afterdischarge threshold and there were other types of responses or no responses between these regions and the mesial SFG. We cannot exclude the possibility of activation of the mesial SFG by interhemispheric interconnections.[55–57] In fact, there is evidence of reciprocal interconnections between the SSMA and the PMA.[58,59] However, different characteristics of movements in man when stimulating the SSMA and the PMA argue against indirect activation of the PMA.[10] The SSMA does have direct projections to many subcortical structures including the spinal cord.[60–64] It has been reported that stimulation of the anterior cingulate cortex in humans produces various complex behaviors such as touching, rubbing, and sucking.[65] In our study we confirmed that stimulation of the upper half of the middle portion of the cingulate gyrus in humans could elicit bilateral tonic lower and upper extremity movements. However, we could not verify Talairach's findings of eliciting complex automatisms by stimulation of electrodes over the anterior third of the cingulate gyrus.

Supplementary eye field (SEF)

The term supplementary eye field was introduced to refer to a region on the dorso-medial surface of the frontal lobe in monkeys where conjugate contralateral eye deviation was elicited by electrical stimulation.[66] This region was within area 6. Eye movements in response to electrical stimulation were also described with the initial description of the human SSMA.[8,9] The French group described that they elicited eye movements in association with head movement anterior to the region for the SSMA upper extremity representation.[47] Most of the responses were from the mesial surface of the SFG with some responses from the upper half of the anterior cingulate gyrus. In our study, we found also that eye movements were closely associated with head movements. These responses occurred from the mesial SFG and from the paracentral lobule.[10] The responses had similar characteristics to those elicited by stimulation of the frontal eye field over the lateral convexity.[67]

Sensory responses

The Montreal group speculated that a region with sensory representation of the extremities bilaterally should exist within the sagittal fissure posterior to the Rolandic foot area.[8,9] They referred to this region as the supplementary sensory area (SSA). However, they could not confirm its presence by extensive stimulation studies. The French group also could not confirm the presence of a SSA ('caudal to NI foot area').[47] Van Buren subsequently found sensory symptoms from electrical stimulation of the mesial SFG and the cingulate gyrus.[48] The sensory responses from the mesial SFG were contralateral and localized while those from the cingulate gyrus were diffuse with only a questionable contralateral predominance.

In our study, we found sensory symptoms consisting of numbness, tingling, or a pressure sensation which occurred in response to electrical stimulation of the mesial SFG, and cingulate gyrus. These phenomena occurred contralateral or bilaterally.[10]

Autonomic responses

Autonomic phenomena consisting of mydriasis and tachycardia were described in response to stimulation of the SSMA.[17] These findings were also described by the French group.[47] More recent studies have not confirmed these findings.

Somatotopic organization of the human SSMA

In the initial descriptions of the SMA, the Montreal group did not define the presence of a somatotopic organization.[8,9] Woolsey and colleagues were able to confirm the findings of the Montreal group but also did not define any somatotopic organization.[68] One of the great limiting factors was gaining adequate intrasurgical access to the mesial surface of the cerebral hemisphere (frontal lobe) to stimulate the SSMA. Human studies were usually preformed in regions in close proximity to structural lesions or epileptogenic cortex that could have resulted in distortions of the normal anatomy of the SSMA. A somatotopic organization was first described by the French group in their study of the SSMA with depth electrodes.[47] They described the presence of eye movements elicited in response to electrical stimulation anterior to the upper extremity responses. The presence of a somatotopic organization in the SSMA was confirmed more that 20 years later by the Yale group.[54] They demonstrated that representation of face, upper extremity, and lower extremity in the SSMA was organized in a rostral to caudal direction. We confirmed this somatotopic organization with lower extremity, upper extremity, and head representation from posterior to anterior, with the supplementary eye field located within the region for the head representation (Figure 108.5).[9] Figure 108.6 demonstrates the results of electrical stimulation in a patient with electrodes over the mesial SFG with responses from the primary motor representation of the foot and responses from the SSMA

Supplementary negative motor area

Inhibition of movement in response to electrical stimulation in the SSMA was first described by the Montreal group.[8,9] In our study, electrical stimulation of the mesial SFG resulted in inhibition of movement of all four extremities as well as the tongue.[10] This negative motor area is distinct from the primary negative motor area which is located over the lateral convexity of the frontal lobe. This supplementary negative motor area always appears to be located anterior to the SSMA ('pre-SSMA').

Speech function and SSMA

Speech arrest was first described in response to electrical stimulation in the initial description of the SSMA.[8,9] This was interpreted as aphasia, namely as indicative of speech function being represented in this region. Subsequently, Penfield and Roberts (1959) stated that speech interference could be caused

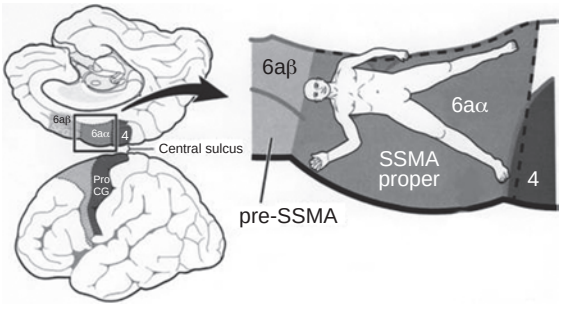

Figure 108.5 Diagram of the somatotopic organization of the representation in the SSMA proper.

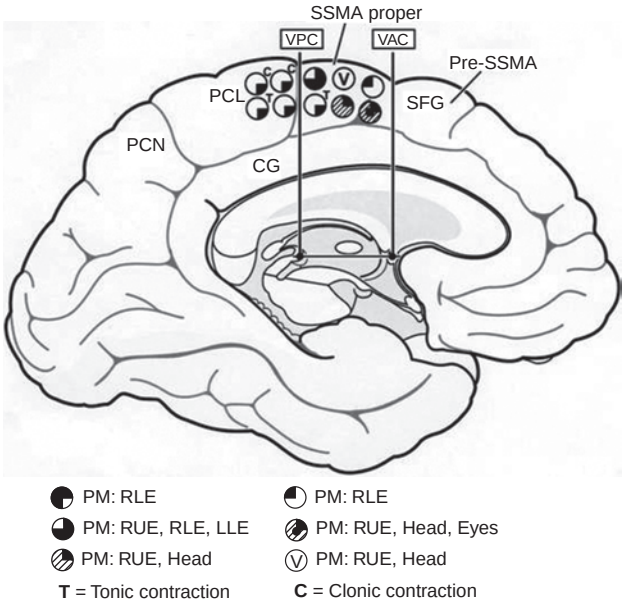

Figure 108.6 Diagram of the motor responses defined by electrical stimulation of the mesial frontal lobe in a patient with intractable left mesial frontal lobe epilepsy. Clonic and tonic contraction of the right lower extremity were observed. Somatotopic representation of motor responses in the SSMA proper is shown with tonic contraction of both lower extremities and the right upper extremity occurring more posterior and right upper extremity, head and eye movement from regions more anterior.

RLE Right Lower Extremity
RUE Right Upper Extremity
LLE Left Lower Extremity

either by inhibition of movement resulting in slowing or arrest of speech or aphasia. Van Buren and Fedio interpreted the speech interference in this region as being secondary to inhibition of movement and did not think there was an independent language area in this region.[48] In our series, two-thirds of the patients demonstrated speech arrest or a greater than 50% slowing of speech secondary to inhibition of movement of the tongue. None of these patients had any interference with language comprehension or speech arrest independent of a negative motor response involving tongue movement and frequently also the extremeties.[10] In previous studies which demonstrated speech arrest in the SSMA, there was no systematic evaluation made for the presence of a negative motor response involving the tongue that may have explained this finding. Thus it likely that the speech disturbance observed by Penfield and Roberts was also secondary to a negative motor response.

Repetitive vocalization in man from electrical stimulation of the mesial superior frontal gyrus was described by Penfield's group and subsequently by Erickson and Woolsey (1951).[69] The French group also elicited vocalization in half of the patients from both the left and the right hemisphere.[47] Vocalization was also found in the study by Fried.[54] In our study, vocalization was elicited in four patients.[10] In three patients this was elicited from the left hemisphere and in one patient from the right. The vocalization was usually associated with rhythmic movements involving the mouth and jaw bilaterally and we interpreted this response as an expression of a positive motor response.

Movement related cortical potentials

Movement related cortical potentials (MRCPs) are cortical potentials associated with voluntary movement. ('Shibasaki *et al*.[39] described 3 MRCPs'.). The initial potential is the Bereitschaftpotential (BP), which is a gradual, usually negative polarity slope with onset several hundred msec prior to the movement.[70] This is followed by an increase in the negative slope which is labeled the NS′ potential. The third potential is the motor potential (MP). Early scalp recordings already suggested that the SSMA, in addition to the PMA, was involved in the generation of these MRPs.[39,70–73] This appeared to be the case, particularly with regard to the early components of the MRCP, the BP.[74,75] Our recordings from subdural electrodes also showed that the MRCPs recorded from scalp are most probably a summation of bilateral PMA potentials[76] and bilateral SSMA potentials.[77,78] These studies also demonstrated that the BP and NS′ associated with foot movements were of similar amplitude in the SSMA proper and PMA and that these potentials also occurred simultaneously. MRCPs in the SSMA associated with single and repetitive movements were also studied showing that both types of movements were associated with potentials of similar amplitude.[78]

The study also demonstrated that MRCPs associated with any given movement were strictly localized to electrodes which by electrical stimulation elicited movements in a similar somatotopic distribution. Thus, there was a clear somatotopic organization of MRCPs in the SSMA proper corresponding with the somatotopic organization demonstrated by electrical stimulation.[77] The BPs recorded from scalp are usually of negative polarity. However, with intracranial recordings from subdural or depth electrodes in experimental animals, BPs had a bipolar distribution with a negative pole at the surface and a positive pole in the deeper gray matter.[79–83] Recordings from subdural grids in humans confirmed these observations.[77,78] The onset time of the BP from the foot area of the PMA and of the SSMA proper are similar, but the movement related desynchronization before movement onset starts earlier at the SSMA proper than at the PMA.[84] The foot area of the SSMA proper generates BP with contralateral as well as for the ipsilateral movements. In contrast the foot area of the PMA generates BPs only in association with contralateral movements. The PMA generated BPs in association with movements at both slow and rapid repetition rates.[85] Movements in response to external stimuli resulted only in transient potentials most likely related to a discrimination task (namely, selection of the appropriate movement in response to an external dichotic stimulus). These potentials were recorded at the pre-SSMA with onset and peak latencies of 200 and 600 ms after S1 in the S1-choice of Go/No Go choice and S2-reaction time paradigm.[86,87]

Role of the SSMA

It has been specualted that the function of the SSMA is only providing a supplementary role in motor function as evidenced by the fact that surgical resection of this area tends to produce just minimal permanent neurologic deficits.[10,88,89] However, a significant bilateral motor neglect, worse on the contralateral side, together with mutism may follow resection of the SSMA proper. Although most of the neurologic deficits are transient (improvement in speech occurs in days to weeks), some impairment in bimanual coordination is frequently permanent. In a recent study it was found that if resection of atumor was at a distance of less than 5 mm from the SSMA proper, then the patients were likely to have post-operative neurologic motor or speech deficits, including contralateral hemiparesis and mutism.[90] Besides, all lesional studies only consider unilateral resections of the pre-SSMA or partial unilateral resections of the SSMA proper. We certainly do not know the possible impact of a *complete* unilateral SSMA resection or of a bilateral SSMA lesion. It is very likely that such lesions would have a major effect on voluntary movements. Bloodflow studies also show an increased perfusion in the SSMA during the phase of planning and execution of complex motor movements suggesting a supramotor role.[88,91] It is likely that the pre-SSMA (supplementary negative motor area in humans) plays an important role in the preparation of movement acting as a focal point in transmitting information from prefrontal and cingulate cortex to other motor areas including the SSMA proper and thus may play a role in movement at a higher hierarchal level.

109 Cortical mapping by electrical stimulation of subdural electrodes: language areas

Nitin Tandon

History of cortical stimulation

The first record of stimulating the exposed human brain with electricity dates back to 1802, when Aldini (Luigi Galvani's nephew) produced right facial contractions by stimulating the left hemisphere of a criminal who had been judicially decapitated.[1] Shortly thereafter, there followed a publication by fellow Italian Luigi Rolando, relating to stimulation of the cerebrum and cerebellum in pigs.[2] In 1829, Rolando published the monumental *Della Struttura degli Emisferi Cerebrali*, detailing the surface morphology of the cerebrum, and describing the central area.[3] The notion of cortical localization proposed by him was contradictory to the prevailing notion of the times, which held that the motor centers of the brain resided in the corpus striatum. Advancement had to await the work of John Hughlings Jackson on patients with seizures, who proposed of this notion, a localizationist's view of cortical organization to explain the semiology of fits experienced by his patients.[4] In 1870, Gustav Theodor Fritsch and Eduard Hitzig provided irrefutable proof regarding the focal organization and excitability of mammalian motor cortex by stimulating canine cortex using Galvanic (direct) currents.[5] This, and the work of Ferrier,[6,7] confirmed the notions of Jackson, regarding the discrete spatial organization of motor functions.[8]

The understanding of cortical organization provided by this work and by postmortem studies on patients with focal neural deficits,[9,10] led to the birth of functionally guided neurosurgical procedures. In 1879, Sir William Macewen became the first to use these maps of motor function to diagnose and to operate on a patient with focal motor seizures. The first record of cortical stimulation in the awake human dates to 1874, when a Cincinnati surgeon, Roberts Bartholomew[11] elicited motor responses using insulated electrical wires passed through the dura in a patient with large bilateral calvarial and cutaneous defects. This patient had previously suffered extensive burns of the scalp, then developed bone loss related to a hair prosthesis, resulting in these large defects. She developed generalized convulsions following the stimulation and died three days later. Despite this sobering experience, the use of intraoperative cortical electrical stimulation to guide neurosurgical procedures continued, and as early as 1888, Charles Mills produced the first map of cortical localization, synthesizing data from multiple patients and using a variety of techniques.[12]

In 1886, Victor Horsley, at the National Hospital for the Paralyzed and Epileptic in Queen Square, performed a craniotomy on a patient with seizures that commenced in the face and found no visible lesion on the cortical surface. He became the first surgeon to perform intraoperative cortical stimulation, and to use localization data to plan a resection.[13,14] Two years later, William Keen became the first American surgeon to stimulate the human cortex as part of a craniotomy. He mapped motor function in a patient who experienced seizures beginning in the hand and resected the hand motor area, which improved the epilepsy.[15]

A German surgeon, Fedor Krause, used intraoperative cortical stimulation to guide the drainage of an 'encephalitic cyst' in a patient wracked by frequent focal motor seizures; the patient was rendered seizure free and led a healthy life for many years thereafter. His work on 400 patients with epilepsy led to the first detailed and accurate map of the human motor cortex.[16–18] Another German, Otfrid Foerster, a neurologist turned surgeon, through extensive work on soldiers with penetrating cerebral trauma suffered in World War I, generated maps of brain regions even outside of motor cortex. He was assisted in this by a visiting American neurosurgeon, Wilder Penfield.[19] Foerster also pioneered the use of intraoperative electrocorticography[20] to detect abnormalities in the EEG in the vicinity of cerebral lesions and was the first to describe vocalization related to cortical stimulation, of a portion of the medial frontal lobe that would later be termed the supplementary motor area.[21] He had a notable impact on many visiting neurosurgeons that included the likes of Paul Bucy, Percival Bailey, and Wilder Penfield, but his work and that of other European neurosurgeons was over shadowed by the outbreak of World War II.

Wilder Penfield's travels in Europe had been supported by a grant from the Rockefeller Foundation. Upon his return to Montreal, he obtained further assistance from them to create the Montreal Neurologic Institute. The MNI, with Penfield as its director soon became the global leader of advancements in epilepsy surgery and cortical localization. Penfield's close collaboration with Herbert Jasper led to the use of the EEG in preoperative and intraoperative evaluation of patients with epilepsy. Chief among Penfield's original contributions to epilepsy surgery were – cortical localization, including that of language,[22,23] the development of temporal lobectomy for epilepsy and the use of chronic invasive recordings.[24] In 1929,

after an initial resection of the central area of one hemisphere, and a subsequent contralateral exploratory craniotomy failed to impact the epilepsy in a patient with very frequent seizures, a partial temporal lobectomy was performed, which led to a marked improvement. During the following decade, using intraoperative EEG recordings, Penfield extended temporal lobar resections to include aspiration of the amygdala and hippocampal formation.

The concurrent development of the first generation of anticonvulsant drugs, led to a gradual decline in surgical cases for several years. It soon became apparent however, that drugs were ineffective in certain cases of medial temporal lobe epilepsy and focal neocortical epilepsy, where surgery might have much greater impact. These changes in the patient population coming to surgical intervention, coupled with advances in EEG technology and neuroimaging led to a gradual shift in the goals of cortical stimulation. While the principal therapeutic motivation in prior years had been to produce focal seizures that mimicked patients' typical events, and to use this information to guide resection of the epileptogenic zone, the principal goal now became the localization of important cortical regions to prevent injury to them during the resection. Given that many of these resections targeted the temporal lobe, awake language mapping became an intrinsic part of epilepsy surgery.

The observation that specific cortical areas were essential for language function had gained some acceptance after the work of Paul Broca and Carl Wernicke.[25] This strict localization related approach to cortical function enabled the creation of testing strategies that would localize language regions precisely and reliably. Penfield[23,26] soon established that stimulation mapping localized discrete cortical areas, much smaller than the larger regions described by Broca and Wernicke – these areas were designated 'eloquent'. Ever since, the localization of functional regions by electrical stimulation mapping has been held as the 'gold standard' for the preservation of functional cortical regions.

The first human case undergoing chronic recordings was reported in 1939. This involved the use of epidural 'peg' electrodes, which are unsuitable for stimulation mapping due to the excitation of nerve endings in the dura, and are limited by the amount of cortex they sample from. For several decades, language mapping was performed exclusively in the context of an awake craniotomy, until advances in materials sciences led to the development of sub-dural electrode arrays that allowed for chronic recordings and extraoperative cortical stimulation. In 1954 – Penfield described chronic invasive recordings using subdural strips and wires.[24] The method was not widely used initially, with epidural peg electrodes and depth electrodes being used in many centers. Further reports of the efficacy and safety of subdural recordings[27] led to wider use of subdural recordings, and ultimately, the use of craniotomies and implantation of stainless steel electrode arrays – called 'grids' or 'plates' – impregnated in Silastic and Teflon.

Further advances in miniaturizable biocompatible materials engineering aided the wider use of chronically implanted subdural electrodes. Implanted sub-dural electrodes need to possess a few salient characteristics – they need to be biologically inert for extended periods of time, produce minimal resistance to current flow, be compact enough to produce minimal mass effect on neural tissues, and preferably, be MRI compatible. Options that provide these properties are electrodes made with platinum black or an alloy of platinum-iridium. These have excellent charge deposition characteristics, are hypoallergenic by nature, and biologically inert. The non-ferromagnetic nature of these materials renders them relatively compatible with magnetic resonance imaging (MRI), allowing for the use of selected postoperative imaging sequences to corroborate the exact placement of the electrodes, and to rule out any complications.[28,29] However, these electrodes are relatively expensive and stainless steel electrodes are still widely used, especially in developing countries. The caveat here is that postoperative MRI scans cannot be obtained in these cases.

Stimulation mapping of language function

Mapping of the cortex using focal electrical currents – or cortical stimulation mapping (CSM) is carried out in one of two clinical settings. The first, (and historically older) method involves the use of a bipolar probe to stimulate a small volume of cortex. This procedure, carried out in an operating room setting, with the cortex exposed by a craniotomy, is characterized by us as 'intraoperative cortical stimulation mapping' (iCSM), and is discussed in detail in Chapter 115.

The other clinical setting involves passing controlled currents into electrodes implanted into the cranium. This type of mapping is typically carried out in an epilepsy monitoring unit, with ongoing video-EEG monitoring and is referred to as 'extraoperative cortical stimulation mapping' (eCSM).[30] While maps created using eCSM and iCSM are generally similar, there are some relative advantages and disadvantages of each method. The amount of cortical surface covered by iCSM is generally smaller than for eCSM, as regions outside the craniotomy are not stimulated. Also, there is a limited amount of time available for sophisticated cognitive or sensori-motor testing in the operating room, imposing limits on data acquisition using iCSM.

On the other hand, disadvantages of eCSM include that two surgical procedures are needed – one to implant electrodes and one to remove them. The second operation generally includes the resection of an epileptogenic zone or lesion. The placement of SDEs elevates the morbidity of the procedure, and the risks of two procedures are likely greater than a one-step awake craniotomy.[31,32] These risks appear to be greater in adults than in the pediatric population,[31,33,34] perhaps as a consequence of the atrophy produced by a combination of aging and a lifetime of seizures and the generally longer recording sessions in adults compared with children, who tend to have more frequent seizures. The benefits of delineating the ictal onset zone and obtaining a more thorough language map using SDEs should, therefore, be weighed against the relatively small but real risks.

The neural elements depolarized and rendered transiently dysfunctional track with the rate, intensity and the duration of stimulation.[35] Estimates of the charge distribution around subdural electrodes have been theoretically computed.[36] but no direct measurements have been carried out to confirm these estimates. Measurements of the effects of CSM using optical imaging of intrinsic brain signals,[37,38] a technique discussed in detail in Chapter 113B, show that the local effect of this stimulation is fairly focal. However, given that even a single

supra-threshold electrical pulse lasting less than 0.3 mSec[39,40] can result in alterations of electrical activity in remote connected cortical regions, the volume of 'eloquent' cortical regions determined by CSM appears to be affected by the currents used for the stimulation. Also, as of now, a mathematical description of the relationship between current density and the population/volume of neurons rendered transiently lesioned by subdural electrode stimulation is lacking.

Methodological considerations

The precursor to language mapping is the appropriate implantation of SDE electrodes overlying the cortical regions of interest. This of course varies depending on the brain region being studies; the archetypal implant includes a grid placed on the exposed lateral temporal cortex (usually an array four electrodes high and six to eight electrodes long, assuming 1 cm inter-electrode distance, placed along the length of the temporal lobe), a series of strips placed in the sub-temporal location and one or more grids of varying size over the lateral and orbital surfaces of the frontal lobe. While it is obvious that electrodes should be placed over brain regions that are likely targets of resection, electrodes may not be placed over classic language sites that are adjacent to proposed resection sites. It is useful to place additional electrodes over these regions so they may serve as positive controls during the eCSM process. For this reason, a large craniotomy that exposes most of the lateral temporal surface, the perirolandic region and the inferior frontal gyrus, is used. Intraoperative photographs, taken before and after placement of the electrodes (Figures 109.1 and 109.2) are very useful in relating the CSM maps to the Sylvian and Rolandic fissures and to superficial vasculature.

Patients who have undergone placements of subdural electrodes need to be observed closely in the immediate postoperative period, for the development of extra-axial fluid collections, venous infarctions, and cerebral edema.[32] The judicious administration of intravenous mannitol and dexamethasone,[31] is useful in managing elevations in intracranial pressure that may occur after the addition of the SDEs to the intracranial volume. We routinely obtain both CT and MRI scans of the brain on the first postoperative day after electrode implantation, to rule out any complications, and to assist in localizing individual electrodes. Once these scans are reviewed, the patient is transferred to the epilepsy monitoring unit (EMU) for the phase 2 evaluation. These scans can be used to generate a 3D representation of the electrodes on the cortical surface that aids in the planning of the mapping session and the subsequent resection (Figure 109.3).

Mapping is carried out in the EMU usually after localization of the ictal onset zone is complete, with the patient on therapeutic doses of anticonvulsants, although it may be done anytime during the phase 2 evaluation. It is advantageous to carry out the mapping procedure as remote from the grid implantation as feasible, so that the patient needs minimal if

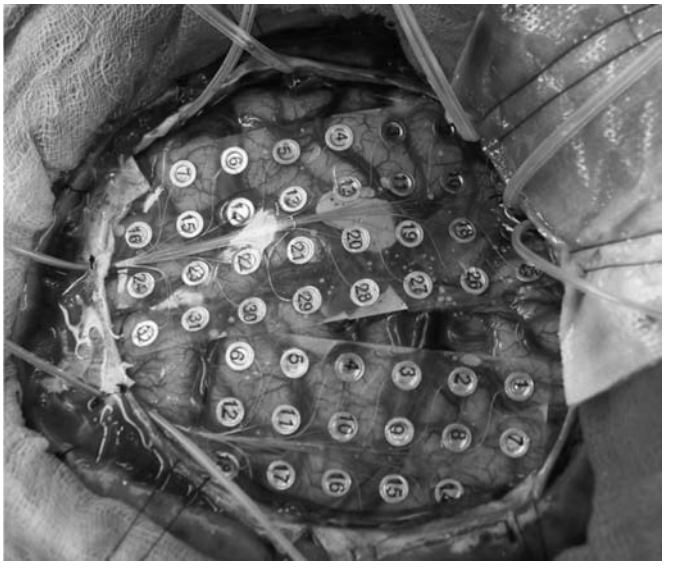

Fig 109.2 Same case as Figure 109.1 after placement of subdural electrode grids and strips. A lateral temporal grid (4 × 8 contact) and a lateral frontal grid (4 × 6 contact) are seen.

Figure 109.1 Intraoperative photograph after a left fronto-temporo-parietal craniotomy, with the dura opened. The sylvian fissure is situated in the middle of the photograph.

any narcotic pain medications, which may impair the very cognitive processes being assessed by the mapping process. Patients are familiarized with the process and introduced to the stimuli that will be presented, in advance of the actual testing, to assure comprehension of the task and reliability in task performance. To minimize confounds, stimuli that the patient has difficulty with are removed from testing during eCSM.

Stimulation parameters

Stimulation is carried out using a balanced faradic current, to avoid charge deposition in the brain. The pulse generators commonly used for this purpose are the Ojemann stimulator OCS-1 (Integra Lifesciences Corp, Plainsboro, New Jersey), a portable, constant current, battery-powered unit that generates biphasic rectangular waveforms (5–100 Hz, 0.1–2 mSec duration, 0–20 mA) and is powered by four 9-volt alkaline batteries, and the S88 Grass stimulator and variants thereof (Grass Technologies, West Warwick, Rhode Island) which can generate one or two trains of biphasic rectangular waves with greater variations of range (.01–1000 Hz, .01–10000 mSec duration, 0–1000 mA).

The usual current type used is comprised of 'balanced' positive and negative square waves, delivered at 50 Hz (or 25 Hz depending on whether the components of each wave are viewed together or separately). The total duration of each set of waves is between 200 and 500 μS. A train of theses waves is delivered for 3–5 seconds during task performance, via two contacts (bipolar stimulation) located on the cortical surface (Figure 109.4). Stimulation currents range from 1–15 mA (rarely up to 20 mA), and mapping is performed at 15 mA or at 1 mA below the potential that results in persistent after discharges (ADs), overt phenomenology or discomfort, whichever is lower. It is preferable to maximize currents at each cortical site regardless of adjacent AD threshold rather than to map the entire cortex at a single current level.[41,42] Concurrent electrocorticography is essential to monitor for after-discharges and seizures. It also provides visible evidence of completeness of the electrical circuit, by the presence of artifacts in the recording. The passage of currents meeting these parameters has been shown to be generally safe and does not appear to cause any neuronal injury.[43]

Testing procedure

The patient, having been placed back on anticonvulsants, and familiarized with the testing process, is positioned comfortably in bed (which is adequately padded), either sitting or propped up with pillows. The video camera is adjusted to view the entire body. Oxygen and a nasal cannula should be available if needed. Stimulation is started at 1 mA and increased in increments of 1–2 mA to 15 mA if no overt phenomenology (muscular contractions, eye deviation, involuntary vocalization, phosphenes, version, paresthesias, headache, ipsilateral face pain) or ADs seen. The highest integral value of current density where these phenomena are not *consistently* noted is used for CSM. The tasks used for CSM of language vary across institutions, but the ones commonly used are:[44]

- *Reading sentences* in an overt manner
- *Object naming* in an overt manner, using pictoral stimuli from the Boston naming test[45] or other similar sources[46–48]
- *Auditory comprehension* using the token test or one/two step commands[49]
- *Spontaneous speech* – counting, reciting the alphabet, nursery rhymes etc – useful in mapping anterior language sites and in mapping patients with prominent verbal deficits.

In addition, more sophisticated language paradigms can be used to provide a more holistic language map.[44,50,51]

- *Reading words* (real and non words) aloud
- *Verb generation/Action naming* from pictures of objects or actions
- *Verb generation* from written nouns
- *Repetition* of spoken words or phrases
- *Auditory naming* – naming driven by a phrase or a sentence (e.g., question – what a king wears on his head – answer – crown)

Electrodes where the screening task results in a delay/paraphrasias/anomia/dysnomia, are noted, as are those locations where stimulation produces overt phenomenology.

Functional imaging of language function shows a clear impact of overlearning in the extent and loci of neural substrates involved in language tasks.[52] Such effects have also been demonstrated to occur during CSM.[53] In other words, with repetitive stimulation of specific regions, using the same task, they may no longer seem essential to the task being performed. It is not clear whether this implies that the region is essential or not, as it is non-essential only for the overlearned task. To minimize such confounds, it is useful to have a large battery of stimuli per task that is used, to minimize repetition of individual stimuli.

Cortical stimulation mapping carries a small risk of producing seizures. While the patient population in which it is carried out are patients with poorly controlled epilepsy and generally have frequent seizures, a seizure during stimulation,

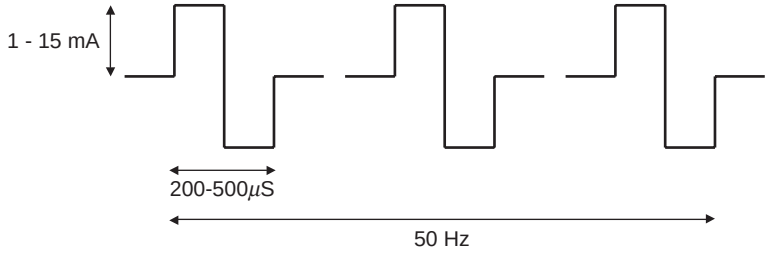

Figure 109.4 Characteristics of the electrical current typically used for stimulation with implanted electrodes.

and /or its treatment with short acting benzodiazepines, may severely curtail the mapping process or lead to a postponement of the planned return to the OR. To minimize the possibility of this occurring, patients should be on therapeutic doses of anticonvulsants prior to mapping. If it is not possible to accomplish this simply by restarting oral dosages of medication, it is useful to administer an intravenous loading dose of phenytoin or fos-phenytoin before starting the session. Intravenous levetiracetam may be considered in patients with allergies to phenytoin or in cases where ADs persist after phenytoin loading. Hyponatremia, if present, should be corrected prior to beginning CSM. Despite this, the stimulation of perilesional electrodes can result in the onset of focal seizures. In the setting of intraoperative mapping, this problem can be handled easily by the irrigation of the brain surface with ice-cold saline,[54] but in the context of eCSM, the only other option available, is to abort the seizure with a second pulse of stimulation.[55,56] A short duration (0.3–2 sec) stimulus applied at the same electrode/s that incited the ADs, within 4–5 seconds of the onset of the ADs and at the peak of the negativity of the after-discharge, may interrupt the ADs.

Given that different language processes engage spatially discrete neuronal substrates, there is likely no single task, whose disruption would provide a 'complete' map of language related areas. The picture naming task with a variable carrier phrase,[57] followed by an auditory comprehension/naming task[50] test language networks in both the visual and auditory domains and may come close to providing a holistic map of essential language areas.

Once the mapping is complete and the patient returns to the operating room for the resection, the mapping data may be overlaid onto the 3D model created earlier (Figure 113.3). In addition, it is useful to label the functional regions and seizure onset sites on the cortical surface at the time of removal of the electrodes to guide the resection (Figures 113.5 and 6).

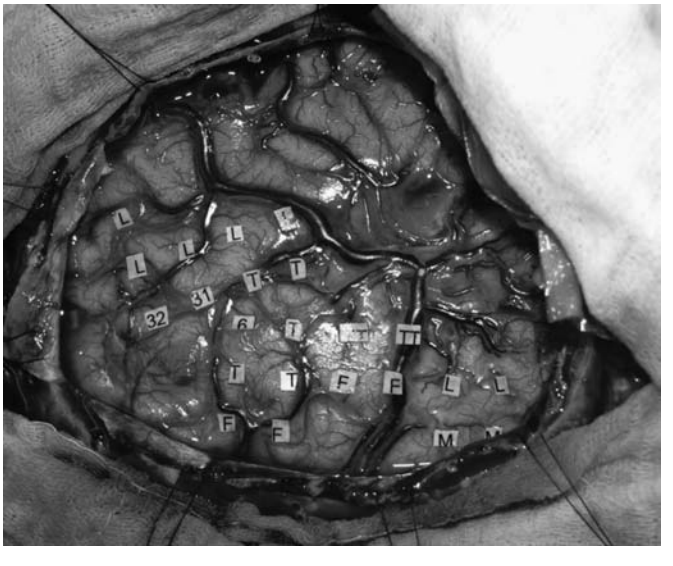

Figure 109.5 Same case as Figure 113.1. The electrodes have been removed and locations of electrodes overlying functional regions are labeled with sterile paper markers. L = language; T = tongue movement; F = face movement; TT = Throat sensation; M = Sites of verbal working memory. Ictal onset was at 31 and 32, with very rapid medial temporal seizure propagation and amplification.

Figure 109.6 Intraoperative view after resection of portion of the inferior parietal operculum, anterior temporal lobectomy and amygdalo-hippocapectomy. Patient had a mild dysnomia post-op that resolved markedly within 6 weeks post-operatively.

Special considerations during mapping in children

In addition to functional mapping in the context of a phase 2 evaluation, electrodes may be implanted purely for functional mapping in children, as some of them are unable to participate in iCSM.[58] However, it is generally difficult to disrupt cortical processing in children using electrical stimuli. Stimulation parameters that work well in adults often do not work well in children, possibly because partly myelinated or unmyelinated nerve fibers need longer pulse durations to be activated.[35] This difficulty may be overcome by lengthening the pulse durations beyond the usual 300 μs (up to 3500 μs in an incremental fashion), along with stepwise progression in the intensity, to arrive at the appropriate chronaxy[59] for each child. If these measures are not taken, it is possible to obtain one or more false-negative sites of stimulation in children.

Variations in CSM for language localization

Several aspects of stimulation mapping vary widely across institutions. Some of these variations are simply a matter of preference and have predictable impacts on the maps generated. They include variations in hardware (types of electrodes and types of current generators), the thoroughness of functional mapping and whether the mapping is performed intraoperatively or extraoperatively.

Most centers in the US use arrays with the electrodes made of platinum-iridium alloy; some still use stainless steel electrodes. The arrays used also vary in their geometry, in inter-electrode distance and in the size and shape of each electrode. Generally electrodes placed along a grid 1 cm apart from each other are used. The electrodes are either convex (disc) shaped, have recessed edges (top-hat design) or are flat discs. Nathan et al.[36,60] suggest that the 'edge effect', an increased current density at the perimeter of electrodes, may be minimized by using recessed or hemispherical rather than disk electrodes and by using arrays with an inter-electrode distance of 0.5 cm

rather than the 1.0 cm separation commonly used in clinical practice.

Another source of variability relates to the choice of the electrode pair used for stimulation. Either two adjacent electrodes (so called 'bipolar' stimulation) or an electrode coupled with a more remote reference (so called 'unipolar' stimulation) may be used. The advantage of adjacent electrodes in 'bipolar' stimulation is the relatively low charge spread, with a rapid fall-off of charge density 0.5 cm away, but it may become unclear which of the two electrodes is indeed over the eloquent region and various combinations of electrode pairs need to be used to determine this.[36] Finite element modeling suggests that 'unipolar' stimulation results in activation of a wider region, than with 'bipolar' stimulation, but this has yet to be conclusively demonstrated in vivo.

Significant variability also exists across institutions in regards to the tasks used for language mapping. In addition to the ones listed above, others that are used include the naming of pictures of famous people (proper naming), naming of places, or of tools and a word stem completion task triggered by a letter or the beginning of a word (orthographic lexical retrieval).

Language maps produced by grouped analysis of CSM data

The availability of language mapping data from more than a few individuals, allowed Penfield and Foerster to create population maps of functional localization. Such work resulted in the maps of the sensori-motor homunculus and also in several maps of the organization of human language. Additionally, Penfield's work established that stimulation of the inferior frontal gyrus led to interference with language output – including speech arrest, alexia, agraphia, paraphrasia, anomia.[23,24] These maps were expressed as two-dimensional representations of language loci overlaid on (often hand-drawn) renderings of the cortical surface[61] and not either as Brodmann Areas (Brodmann 1909), or in stereotaxic space (Talairach'88) and therefore, while quite useful in directing clinical care are untenable for accurate, unbiased comparisons between patients, or with functional imaging data (MEG, PET or fMRI). Despite these limitations, these maps have provided valuable information and advanced our understanding of human language.

The largest grouped analysis of human language organization comes from George Ojemann's seminal publication[57] based on intra-op awake mapping of 117 left hemispheric dominant patients (Figure 113.7). He determined that language sites are diffusely organized all around the left perisylvian region and that these sites are part of a multiple modular cortical system, each module being specific to a particular aspect of language function, and activated in parallel during language processing.[62] Significantly, no language sites were found in Wernicke's area in 36% of subjects and none were found in Broca's area in 21%;[57] this work was extended further to show that no posterior language area could be identified in 10% and no anterior language site could be identified in 9%.[63] These findings were taken together to imply significant language variability across patients with left hemispheric epilepsy. For many years these observations have guided the application of stimulation mapping techniques for the resection of epileptic and neoplastic lesions in and around the classic language sites.

Other work by Ojemann and colleagues has suggested that the total area of exposed cortex 'essential' for naming is rather small $\leq 6\,cm^2$ in 85% of individuals, especially in individuals with high verbal fluency; that focal sites involved in language function can be mapped using CSM in patients as young as 4 and as old as 80 years of age;[63] that there is limited variability in the location of anterior language areas and much greater variability in the locations of posterior temporal and temporo-parietal language sites;[64] and that a remarkable subspecialization of cortical regions in handling differing aspects of language such as naming, reading, phoneme identification etc. exists, with more than half of all sites localized by stimulation mapping being involved in only one aspect of language.[65]

While results from other groups have generally been in agreement with Ojemann's observations in regards to specific regions involved in categorically defined language functions, there is some disagreement regarding the extent of interpatient variability in language sites. For instance, a study of 45 patients with implanted subdural electrodes,[66] with exhaustive extraoperative language testing and a specific evaluation of 'negative' motor areas, revealed language sites in and around classical Broca's and Wernicke's locations and in the basal temporal lobe only (Figure 113.8).

This apparent disparity may be attributable either to the statistical probability method used by Ojemann, the limited time available for language testing in the intra-op environment or to the inherent limitations of making population language maps based solely on cortical surface anatomy (Schaffler and colleagues used post-op roentgenographs to co-localize electrodes). The published works by Ojemann make an incomplete distinction between areas where CSM results in consistent anomia versus those where errors or dysnomia are produced above a statistically significant threshold. Since the behavioral aspect being quantified is the 'essential' nature of the region to language, the fact that normal language (at least based on the function being tested) can be produced during stimulation of a region, at all, argues against it being 'essential'. Importantly, however, Ojemann and colleagues did show a decline in long-term language outcome if the resection margin was carried to within 1 cm of an essential language site.

The discordance of these studies have led to a wide variation in practice patterns between epilepsy groups regarding language localization prior to a dominant temporal lobectomy. A comparison of a large series of standard right versus left temporal lobectomies, in whom typical language lateralization had been shown by Wada testing revealed that in the absence of language mapping, about 7% of patients had a significant deterioration in naming ability at 6 months postoperatively. Some centers choose to map language in all cases, some choose to never map language and some focus on selective resection of medial structures trying to spare as much neocortex as possible.[67] Incredibly, there are no good data to suggest a better neuropsychological outcome with any of these strategies. It has been suggested that damage to the cholinergic outflow from the nucleus basalis of Meynert occurs in patients who undergo a trans-sylvian selective amygdalo-hippocampectomy, and is the mechanism of the verbal decline seen in them. Very recent work suggests that a sub-temporal approach that spares most

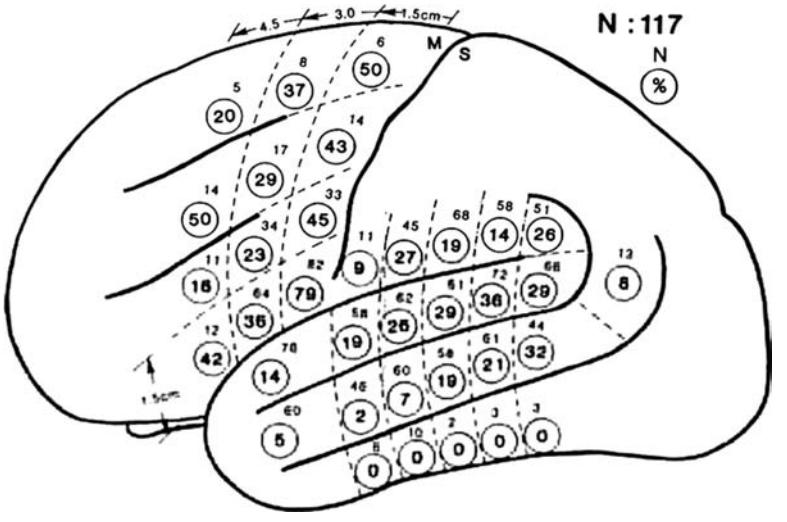

Figure 109.7 Schematic representation of language mapping results from 117 patients who performed an intraoperative naming task. Data were aligned using the central sulcus and the end of the sylvian fissure. Numbers in circles denote the percentage chance that stimulation in that grid resulted in dysnomia; numbers above the circles denote the number of times that zone was tested in the population. (From Ojemann G, Ojemann J, Lettich E, et al. Cortical language localization in left, dominant hemisphere. An electrical stimulation mapping investigation in 117 patients. J Neurosurg 1989;71:316–326).

of the temporal neocortex may minimize the decline in verbal memory;[68] but this needs to be substantiated in languages that use syllabograms rather than morphograms, and its long term impact on temporal lobe epilepsy needs to be qualified.

The results of other grouped analyses have pointed to the specific role of Broca's area in verbal[49] as opposed to non-verbal processing[44,69] and also that comprehension deficits occur with either Broca's or Wernicke's area stimulation. In some patients, stimulation of anterior language areas has been shown to result in language deficits extending well beyond language output – to include deficits in auditory verbal comprehension, such as the token test and two step commands.[49] It is unclear if some of these diverse effects stem from the long stimulation – 5–20-second trains of 25 Hz pulses, or reflect the distributed nature of language processing, or the role of Broca's region in verbal working memory,[70] as has also been suggested by the functional imaging literature.

What matters ultimately, is the specificity and sensitivity of mapping results as related to language outcome following focal resections. In this regard, Ojemann and others have pointed out that carrying the resection to within 1 cm of a site that leads to consistent anomia or speech arrest, is likely to result in a permanent long term verbal deficit.[64,71] Obviously, there are limited data in regards to actual resection of 'essential' language sites, so the exact specificity of CSM for language sites is difficult to establish. It is becoming clear though, from work on patients with brain tumors located in eloquent cortex.[72,73] that substantial plasticity in language organization is possible even in adults (more on this in a later section).

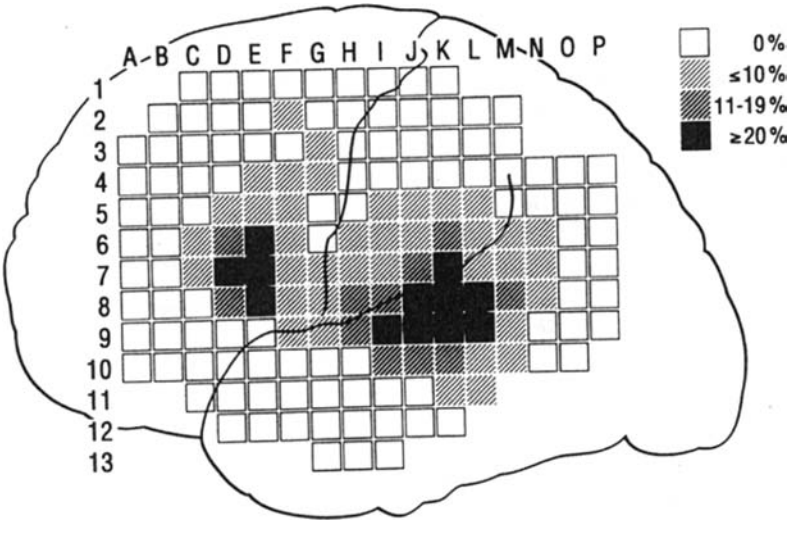

Figure 109.8 Population map showing frequency of language sites mapped using implanted subdural electrodes and extraoperative mapping in 45 patients. Coregistration was accompliahed using skull X-rays after grid implantation. (From Schaffler L, Lüders HO, Beck GJ. Quantitative comparison of language deficits produced by extraoperative electrical stimulation of Broca's, Wernicke's, and basal temporal language areas. Epilepsia 1996;37:463–475).

Insights into the neurobiology of language provided by invasive electrophysiology

Stimulation mapping has provided unique insights into the biology of human language and its organization in various disease states. This knowledge has informed other modalities of evaluating language function, such as functional imaging and has served to validate and refute various theories of language organization.[74] Ojemann's work, revealed the parallel activation of multiple, function specific modules during language processing,[62] a model that stood in distinction to traditional models of hierarchical serial processes starting with decoding in the posterior temporal lobe and eventual phonation by the inferior frontal lobe,[75] and one that is generally accepted today. Dissociation between naming and comprehension[76] demonstrated by CSM has pointed to the existence of a direct non-semantic pathway for picture naming. CSM of the dominant premotor cortex has revealed its distinct roles in articulation (ventral PMC) and naming (dorsal PMC).[77]

Language organization in multilingual patients

Lesion studies in polyglot aphasia have limited ability to tell us about the organization of multiple languages in the cortex. Plasticity after brain insults, the relatively large size of the lesions and difficulty in accurately determining the premorbid linguistic competence of an individual patient in each language, prevent exhaustive comparisons of the impact of the lesion of each language. Additionally, the spatial resolution of functional neuroimaging techniques prevents precise delineation of adjoining cortical regions that perform similar functions in different languages,[78] so electrical mapping possesses unique characteristics suited for the study of multilingualism. Varying locations of naming sites for different languages in the same individual were first described in 1978 by Ojemann and Whitaker.[79]

CSM maps reveal that naming areas in languages acquired later in life (L2) tend to cover a larger cortical area than for the primary language that is acquired earlier in life (L1). As proficiency in a language develops, the areas essential for it may become more compactly organized.[63] CSM of bilingual patients, reveals, in many, though not all patients, that sites responsible for naming and reading in two different languages are distinct from each other,[80,81] that L2 specific sites are located exclusively in the posterior temporal and parietal regions, and that these sites are more confined spatially than the L1 sites.[82] This corresponds well to data obtained by functional imaging of individuals who learnt L2 late in life.[78] Based on the spatial disparity of language sites in polyglots, mapping in each language that the individual is proficient in should be carried out, whenever practicable, to minimize the possibility of a monolingual decline in verbal fluency.[81]

Acquisition of a second language does not seem to impact upon the organization of the primary language. Interestingly, the L2 sites correspond closely to maps of language in monolingual children, suggesting that L2 acquisition is dependant on the same processes and substrates that children use to first acquire language, but outgrow, as their language skills mature.

Basal temporal language

Much like the discovery of the role of the SMA in vocalization, the role of basal temporal language areas in language is also an original contribution of CSM. Based on clinico-pathologic data, Mills and Martin postulated[83] the existence of a 'naming center' in the basal temporal lobe. The region has since been studied extensively using invasive electrophysiological techniques[84] and by functional neuroimaging techniques and has been shown to contain subdivisions, which preferentially process particular visual stimuli, such as written words (visual word form area),[85] faces (fusiform face area)[86] and places such as buildings (parahippocampal place area). Perhaps the process of learning to read, results in the development of the infero-temporal visual word form region. This region is more responsive to written words than to other stimuli when studied by functional imaging. In contrast, the representation of particular classes of objects/faces appears to not be sharply delimited to a specific region but is distributed rather widely across the ventral temporal region.[87,88]

The exact extent of the BTLA for the purposes of CSM is imprecisely defined. Strictly speaking, the term should perhaps apply just to the fusiform gyrus, including structures about 1 cm lateral to the hippocampal sulcus and 1 cm medial to the lateral edge of the inferior temporal gyrus. However, it is sometimes loosely used to describe language regions in the entire ventral surface of the temporal lobe, from the temporal tip to the temporo-occipital junction, and including the inferior temporal gyrus. Comprehensive characterization of the region by Lüders and colleagues,[89] and others,[90–92] have found language areas over a wide region, involving the parahippocampal and fusiform gyrii, extending from 11–75 mm caudal to the temporal tip. Usually, however, the BTLA is restricted to a zone that has a 4 cm or smaller extent in the rostro-caudal axis.[93] By varying the onset of electrical interference relative to a behavioral task, so called time slicing technique, it appears that processing of verbal object meaning in the occipito-temporal gyrus occurs 450–750 mSec after stimulus presentation.[94]

The most consistent deficit seen during stimulation of the BTLA is a disturbance in confrontation naming. Other deficits noted in early studies include impairments in auditory and visual comprehension (affecting reading, responsive naming, performance on a token test, and repetition).[89–91,93]

Deficits seen after dominant temporal lobectomy, comparing patients who undergo a resection of the BTLA with those where it is not, involve only confrontation naming. To explain this discrepancy, it has been suggested that stimulation of the BTLA may indirectly affect functions of remote regions such as the lateral temporal neocortex.[93] Deficits in non-visual language processing have not been found in more closely controlled recent experiments, and the mapping data may reflect the effects of larger currents that spread beyond the BTLA.[95,96] An alternative explanation is that the BTLA is 'involved' in the recognition of visually presented language materials, but is not 'crucial' to this function.[93] This implies that much like in the motor system (SMA stimulation), CSM of language may lack perfect specificity in regards to functional outcomes following resection of language sites.

Recent studies in Japanese subjects who speak using Kanji and Kana characters have shown that the BTLA may play an important role in connecting visual semantic decoders (Kanji characters, like Cantonese, uses morphograms; Kana characters,

like English, are syllabograms) with phonological processors.[96] To this end, there is a special interest in designing surgical strategies that would spare as much of the fusiform gyrus as possible by using a subtemporal-transventricular-transchoroidal approach for hippocampectomy,[97] for speakers of languages that use morphograms. Whether this actually results in improved verbal fluency without compromising seizure-free outcomes is unproven so far.

Effects of age of epilepsy onset on language organization

A comparison of distribution of language sites in pediatric patients with patients older than 16 years, reveals a relative paucity of perisylvian language sites in children[58] and also a relative deficit in the number of frontal lobe sites. These differences suggest that the language maturational process leads to the development of new cortical foci essential for language.[98] While developmental lesions and early-onset seizures do not necessarily impact on the hemispheric organization of language cortex, lesions (especially those affecting the frontal or parietal lobe language loci) acquired before the age of 5 years results in a significant local reorganization, and sometimes its displacement to the contralateral hemisphere.[58,99] Seizure onset early in life appears to displace language away from its usual location in the basal temporal locations.[93]

Markers of early left hemisphere damage, such as seizure onset in childhood, poor verbal IQ and memory dominance in the right hemisphere increase the possibility of finding essential language areas for naming and reading in the anterior temporal lobe (1.5–3.5 cm from the temporal tip) (Figure 113.9).[100] These findings are somewhat contradicted by observations suggesting that there are no significant differences in the proportion of naming errors in different parts of the brain in patients categorized into early and late onset epilepsy groups and that while male patients with low pre-op verbal IQ (VIQ) are more likely to have language sites in the superior temporal gyrus and inferior parietal lobule, patients with high VIQ tend to have essential sites for naming in the middle temporal gyrus.[57,63]

In summary, it may be safe to state that normal brain development creates a small volume of highly specialized language cortex, while pathological processes that occur early in life can induce various types of variability in the organization of language and more spatially diffuse language organization.[58,100] Yet, this specialized node is part of a more diffuse network, and individuals with higher pre-op verbal function, and the onset of the epilepsy at a later age generally have more to lose and appear to be more likely to do so,[101] following a dominant temporal resection.

Electrophysiology of language production

Recordings from an awake human brain provide an unparalleled window for the study of cortical regions involved in language. George Ojemann and Itzhak Fried pioneered this endeavor, which has led to an enhanced understanding of the

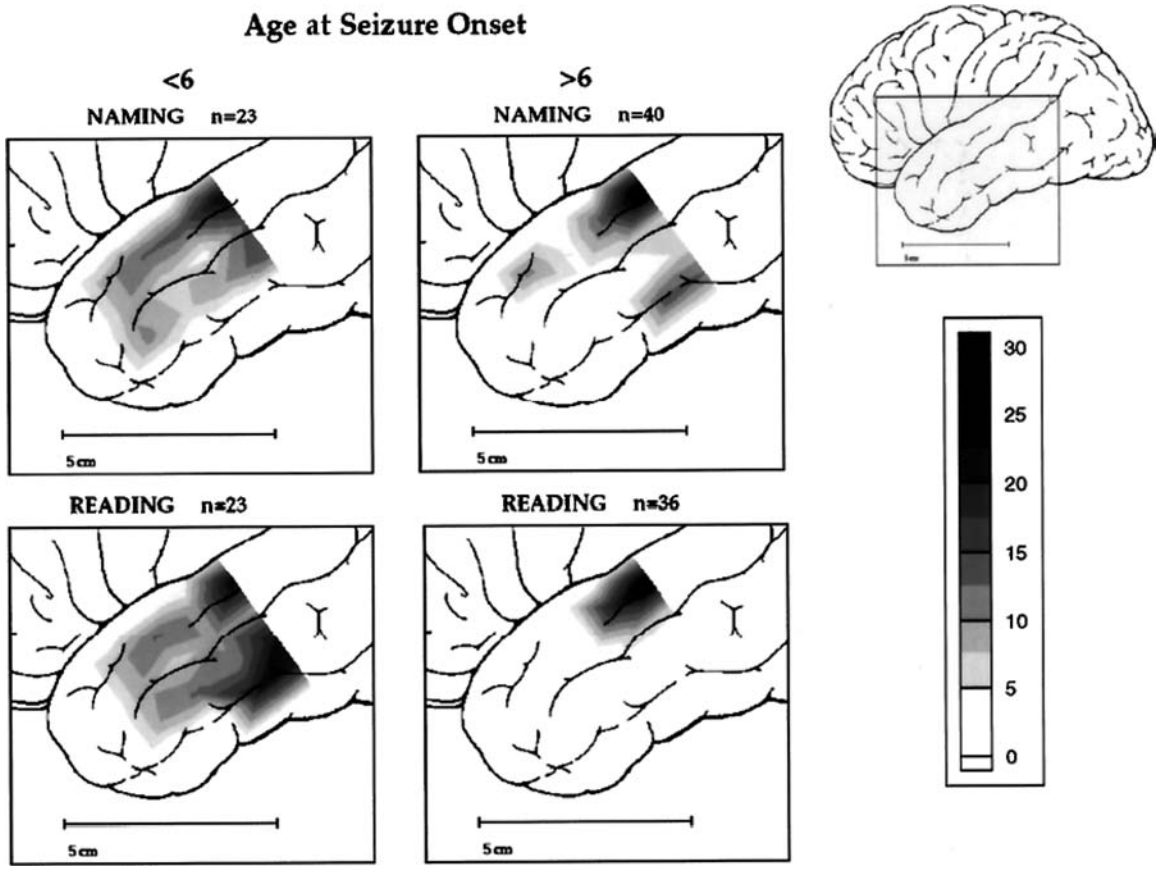

Figure 109.9 Diagrammatic representation of the distribution and frequency of naming and reading errors in the anterior temporal lobe depending age at seizure onset, in a population of 67 patients mapped extraoperatively with subdural electrodes. The gray scale represents the percentage of patients in whom stimulation interrupted a given function in a 1 cm^2 area. (From: Schwartz TH, Devinsky O, Doyle W, et al. Preoperative predictors of anterior temporal language areas. J Neurosurg 1998;89:962–970.)

behavior of neuronal ensembles (evaluated by local field potentials – LFPs) and single units (evaluated by tungsten microelectrodes) during language perception and production.

Recording cortical activity using the macro-electrodes used for seizure localization/CSM during language processes is variously characterized as local field potential (LFP) or evoked potential (EP) or electrocorticographic (ECoG) recording. A localized desynchronization in the alpha (7–12 Hz) range,[102] maximal at between 700 and 1200 mSec after presentation of a naming stimulus, with persisting low-voltage higher frequencies, occurs at most temporo-parietal, though not frontal naming sites.[103] Slow potential shifts occur at the onset of naming in frontal naming sites as well in motor cortex[103] and changes in electrical activity in the frontal and temporo-parietal language sites occur in parallel and not sequentially.[63] Evoked ECoG-potentials to words heard or spoken differ; with a wider response seen with overt speech.[104]

More recent work has focused on studying correlated activity between language regions at higher frequency ranges.[105] Activity in the high gamma range (70–150 Hz) has been shown to be spatially correlated with CSM derived language maps.[106–109] Measurements of the average dynamical changes in amplitude of the entire width of the recorded EEG spectrum – event related spectral perturbation – provide an unbiased estimate of changes in cerebral activity by an experimental event.[109] However, comparisons of the BOLD fMRI signal change with LFPs recorded from calcarine, fusiform and lateral temporo-occipital regions show inconsistent relationships,[84] with the maximal effects of duration of stimulation occurring in different frequency bands across different brain regions. This suggests the need for a clearer understanding of the relationships between these types of mapping data.

Micro-electrode recordings of neurons from regions of cortex not categorized as 'essential' to language processing show changes in activity that are specific to distinct language tasks – such as naming, listening, speaking.[63] Neurons in the (anterior) superior, but not middle or inferior temporal gyrii respond to phonetic but not semantic aspects of spoken language.[110] Responses to heard music tend not to differ as much across gyrii or across hemispheres.[111] Additionally, these techniques reveal the existence of widely distributed neural networks for modality specific identification and recall[112]

In multilingual patients, these changes are sometimes limited to naming in a single language. This suggests a lack of 'general purpose' neuronal assembliess. Also, akin to the maps produced by stimulation mapping, the electrophysiology of cortical regions, measured using micro-electrodes, identifies neurons whose functions change with the performance of only one of several language tasks.[113]

Limitations of CSM in evaluating language function

Mapping the cerebral cortex with electricity is a technology that is more than a century old at this point, but remains the existing 'gold standard' for perioperative functional localization. However, several disparate groups of evidence suggest that the technique has notable limitations.

Limitations in sensitivity

This is the ability of the technique to accurately detect an existing essential language site, i.e., minimization of false negatives. This is impacted by at least three factors. The first is that only the crowns of gyrii (i.e., only a third of all cortex) are evaluated. Although it has been suggested that 'buried' language sites are not associated with adjacent sites on the cortical surface,[57] this matter merits further evaluation. 'Acute' functional reorganization has been noted following a tumor resection.[114] A second obvious limitation is the sampling restriction imposed by where the electrodes are placed or which portion of the cortex is accessible for iCSM. Thirdly, the induction of seizures, during mapping can seriously impact mapping especially immediately around the epileptogenic zone, which is of course where the planned resection is likely to have the greatest impact. Lastly, the limited time and the obvious physical restrictions in both the iCSM and eCSM environments impose restraints on the nature and extent of the cognitive testing that can be carried out.

Whether related to these factors or not, two things are clear. First, CSM does not consistently reveal language areas. In Ojemann's 1989 series – no language sites were found in Wernicke's area in 36% of subjects and none were found in Broca's area in 21%. In another large series, known to have left-sided language function, no posterior language area could be identified in 10% and no anterior language site could be identified in 9%.[63] While it remains unclear if this is an indicator of language variability across patients with left hemispheric epilepsy, it is also possible that CSM is not sensitive enough in detecting all of the cortical substrates of language comprehension/generation. Secondly, language deficits can develop despite exhaustive language mapping and preservation of these language sites during resection. One strategy, incompletely proven at this point, to minimize this possibility may be the application of CSM to localize sites responsible for verbal memory in the temporal neocortex.[115]

Limitations in specificity

A bigger concern is the propensity of CSM to categorize regions as essential that may not indeed be so, confining the extent of resection.[106,116] Testing language by CSM creates a brief unphysiologic stimulus that is capable of influencing other brain regions. This is especially true with regions in the ventral temporal region, when despite the interruption of multiple functions during stimulation, minimal or no effect on language are seen after resection of these 'statistically significant' language sites.[44,91] Results of CSM may need to be weighed cautiously in cases where language is bilaterally organized or if the resection involves a developmental epileptogenic lesion (e.g., cortical dysplasia) in a perisylvian location.[116]

While the local effects of cortical stimulation may be well contained, there clearly are some distant effects of electrical stimulation. The recording of cortico-cortical evoked potentials from a brain region[39,40] following single pulses of current delivered to a pair of electrodes overlying eloquent cortex, suggests that the behavioral effects measured during CSM may not all relate to disruption of just the region being

stimulated, but also to its effects on the distributed components of the network to which the region belongs.

Relationship between CSM and functional imaging of language areas

Some of the concerns regarding the spatial specificity and sensitivity of CSM listed above, and the need for additional procedures (SDE placement for eCSM) or operative time (for iCSM), led to interest in supplanting CSM for localizing language function, using noninvasive mapping strategies (NIMS) to measure neural activity (MEG) or regional cerebral blood flow increases concomitant with such activity (fMRI, PET, iOIS) during language processing.

While efforts to supplant CSM for localizing regions involved in motor function with NIMS have been generally successful,[117] imaging techniques have limited applicability for localizing language sites.[118] This is especially true for temporal and temporo-parietal language regions,[119–121] but also for frontal language sites.[122] This is likely on account of a variety of reasons. The first is that these techniques provide a map of the network involved in, but not of the nodes of that network essential to, language generation. This problem worsens with increasing sensitivity of the mapping technique used – as more functional areas are detected by lowering the statistical threshold used to create the language map – the specificity of the map becomes lower. The second reason is that the cognitive 'load' of 'simple' language tasks such as object naming that are typically used for CSM is relatively low, so that the neuronal activation or its hemodynamic correlate are not easily discernible from background activity. A third limitation is secondary to multiple technical issues: spatial resolution of the imaging technique; mismatches in coregistration of functional data sets with high resolution MRI scan data used for intraoperative stereotactic guidance; and problems with patients' abilities to comprehend the task or cooperate with scanning.[123] Lastly, speech production in both MEG[124] and clinical fMRI environments is generally covert, as movement associated with articulation produces artifacts and signal dropout. Covert speech does not activate some of the frontal opercular regions that are indeed essential for articulation.[122]

A battery of language tasks is better at the functional localization of 'critical' language areas, such areas then being defined as regions consistently activated across a variety of tasks. Combining 'simple' language tasks (e.g., picture naming) with more cognitively demanding tasks, such as comprehension of visually or acoustically rendered phrases, provides a more complete map of language areas, and one where 'critical' language areas may be more easily assigned.[118,125–127]

So far, these efforts have been unsuccessful in demonstrating absolute and reliable concordance between CSM and functional imaging derived maps.[123] Hence, stimulation based mapping remains the prevailing standard for functional localization of language regions at the current time.[128] Maps derived using multimodal language activation strategies are, however, of value in guiding the CSM effort and in providing a better understanding of language localization in patients with atypical results following an intracarotid amytal procedure.

'Eloquent cortex' and degenerate neural systems

The four functions that are most frequently mapped in the neurosurgical setting are language, motor control, vision, and memory. The cortical regions without which these functions would no longer be considered to be normal are designated as 'eloquent'. This designation does not imply that other neural functions are not essential or that there are necessarily non-eloquent brain regions that can be resected with impunity.[129] Instead, it is a categorization of cortical regions based on the lasting effects of lesions and the impacts of these lesions upon the activities of daily living. The term 'eloquent' has been used in this chapter to allude to cortical regions without which language function could not be discerned as normal.[9,10] Yet, it is unclear that eloquence is absolutely determined by CSM.

It is clear from multiple lesional studies that a reorganization of language function can occur even in the adult brain.[130] Recently, it has been shown that sites localized by CSM demonstrate spatial plasticity both acutely[114] and as slow growing lesions encroach upon them.[131] While resection of language sites generally does result in an acute language impediment, significant and sometimes complete recovery of function can occur, over a period of 3 to 6 months.[72,73] Lasting deficits are more likely when the subcortical substrates of function are damaged in some way.[25] The best level of recovery is generally observed, when compensatory recruitments take place in the perilesional area, along the rim of the injured tissue, rather than in the homologous region of the non-dominant, contralateral hemisphere.[132–134]

These findings, along with the fact that large amounts of dominant temporal neocortex can be resected with relatively few deficits, support the concept of an implicit degeneracy in language systems. The term 'degenerate' is used to describe structurally discrete neural elements that perform the same function.[135] Functionally degenerate systems, capable of a particular cognitive computation, may deliver their output to a separate 'essential' or to a 'degenerate' region. Some of the lack of specificity of CSM may stem from the fact that non-physiologic stimulation of one degenerate region may interfere with the output from a second non-stimulated region that may be sufficient to carry out the cognitive function being tested.

A holistic approach that integrates the results of functional imaging, lesional analysis, CSM with the potential for plasticity (based on age, site of planned resection) would probably provide a more precise way of determining which cortical regions are truly eloquent.

Recent advances in the localization of language regions

Functional localization based on individual anatomy

High-resolution MR imaging combined with 3D reconstruction of cortical surfaces allows for representation of brain anatomy in more exquisite detail than previously possible. This may allow for the accurate delineation of the hand motor area[136] and of Broca's area[137] without functional mapping, if these regions are not involved by or adjacent to overt lesions. Scans done at high field strength MR systems (e.g., 7 Tesla systems) may allow for further development of this approach.

Functional localization based on population maps

The ability to co-register imaging data sets to each other, with adjustments made for individual anatomic differences, allows for the generation of population maps of cerebral anatomy and functional activation. The generation of high resolution 3D cyto-architectonic maps[138] or spatial probability maps from meta-analyses of functional imaging data[139] that can be co-registered onto a patient's 3D structural MRI provide novel ways for functional localization.

Focal cortical cooling

Focal cortical cooling has been promoted as an alternative to the passage of cortical stimulation for language mapping. A cooling device irrigated by cold saline[140] and a Peltier chip[141] have been used. Neurons cooled to about 30°Centigrade seem incapable of normal processes and are rendered transiently dysfunctional. At the current time this technology is experimental, and its use in the clinical environment is not proven or approved. However, there are clear theoretical advantages to a methodology that produces a transient lesion without seizure induction or spread of the stimulation effect to remote locations, especially for intraoperative mapping. It remains unclear if and how this method could be successfully applied in the extraoperative (i.e., SDE) context.

Localization of sub-cortical pathways

Essential cortical regions can function only in the context of appropriate afferent and efferent information flow. Stimulation of both the arcuate fasciculus[142,143] as well of the inferior longitudinal fasciculus[144] has been shown to interfere with language production. The ability to image these pathways non-invasively[145] with diffusion tensor imaging (DTI) provides additional information that may be useful in preventing postoperative dysphasia. The further development of DTI to generate connectivity based parcellation techniques, that imply functional segregation by variations in cortico-cortical connectivity, provides yet another method for non-invasive functional localization.[146]

110 Cortical mapping by electrical stimulation: other eloquent areas

M Hoppe

In order to avoid new neurological deficits for patients undergoing resective epilepsy surgery, the eloquent cortex in the region where resection of the epileptogenic zone is considered has to be identified and its extension has to be defined as precisely as possible.[1] This can be done on an electrophysiological basis by direct electrical stimulation of the cortex under question using subdural or intracerebral depth-electrodes. This chapter will cover the visual and auditory cortex, insular cortex, as well as those cortical structures which are functionally and anatomically connected via the Papez circuit: olfactory cortex, amygdala, and cingulum. In conclusion, the alien limb syndrom and laughter evoked by stimulation with subdural electrodes will be presented as case studies.

Visual cortex

Introduction

Already 50% or more of patients with occipital lobe epilepsies evaluated for epilepsy surgery show visual field impairments preoperatively.[2–6] Nevertheless, because resections within the occipital lobe can increase preexisting visual defects or cause new ones in unaffected patients, identification of cortex-bearing visual functions is desirable when performing resective epilepsy surgery in patients with occipital lobe epilepsies. This can be done on an electrophysiological basis by direct electrical stimulation of the cortex under question, if subdural or intracerebral electrodes are used in the diagnostic work-up.

Functional anatomy of the visual cortex

About one-third of the human brain is estimated to be involved in visual processing.[7] Brodman distinguished on the basis of cytoarchitectonic studies of areas 17–19 within the occipital cortex (cited from ref. 8). Area 17 corresponds to the striate cortex, named after the stria of Gennari. An average of 67% of it is buried in the calcarine fissure, its branches or accessory sulci.[9] It receives input from the corpus geniculatum laterale, and therefore has a retinotopic organization and is considered to be the primary visual cortex (cited from refs 7 and 8). The representation of the horizontal meridian lies roughly on the base of the calcarine fissure. The fovea is represented at the occipital pole and extending onto the lateral convexity for about 1 cm, whereas the peripheral retina is represented more anteriorly and extends to the junction of the calcarine and parieto-occipital fissures.[10] More than 50% of the striate cortex is occupied by the representation of the central 10° of vision, which causes the high magnification of central vision. The lower half of the retina (upper half of the visual field) projects below, the upper half of the retina (lower half of the visual field) above the calcarine fissure, with the meridians lying at the boundaries between striate (V1) and extrastriate (V2) cortex.[10]

Referring to microelectrode studies in primates, and supported by case studies with various lesions and anatomical and functional imaging studies, different cortical areas with different functional capabilities can be described. Besides the primary visual cortex (V1 = area 17), there are secondary visual processing areas V2 to V5 which serve for different aspects of vision, e.g., motion (V5), color (V4), and form (cited from refs 7 and 8).

Clinical ictal characteristics

Visual auras of different types – elementary or complex, unformed or formed, hallucinations or visual loss – are generated from the posterior cortex (occipital, temporo-occipital, parieto-occipital, temporo-parietal-occipital).[2,3,5,11]

Electrical cortical stimulation studies

Besides direct intraoperative stimulation these studies were done using either subdural grid electrodes, stereotactically implanted depth electrodes or a combination of both. The first to describe visual phenomena due to cortical stimulation were Krause and Foerster (cited from ref. 8). The seminal studies of Penfield and co-workers[12,13] yielded two different types of visual perceptions depending on the site of stimulation. Simple or elementary versus elaborate or complex or hallucinations. The first were the result of stimulating the mesial and lateral occipital cortex, the latter resulted from stimulation of the posterior temporo-parieto-occipital junction. Succeeding studies of other investigators[8,14–16] confirmed these findings. The elementary sensations consist of white or coloured spots with various forms, most of them stationary, but sometimes moving phosphenes occur. Studies covering

the mesial part of the occipital lobe with up to 80 subdural electrodes[8,15,16] showed that the phosphenes occur in the visual half field contralateral to the stimulated lobe, in the lower quadrant when stimulating the upper part of the striate cortex (above the calcarine fissure) and vice versa. However, Brindley *et al.*,[16] who implanted very densely distributed electrodes to serve as a visual prosthesis, noticed exceptions to this retinotopy and furthermore detected many discontinuities of the map of the visual field on the cortex. Neighbouring points on the cortex were sometimes far apart in the field, and neighbouring points in the field sometimes far apart on the cortex. This may be explained by the fact that the striate part of the mesial occipital cortex lies deep in the calcarine fissure. Thus, it is not easily made accessible to electrodes and the topograhical relationship between the stimulating electrodes and the calcarine fissure may remain uncertain. Visual responses near the fixation point were smaller than those farther away from the fixation point,[8] thus reflecting the magnification of central vision (see above).

Interestingly, in two studies[8,14] phosphenes could also be elicited outside the striate cortex on the lateral aspect of the occipital lobe. Kaido *et al.*[14] could prove that comparable to the striate cortex the phosphenes represented retinotopy, with coordinates consistent with the axis of the polar angel and the eccentricity from the center of the visual field. As a possible explanation the authors propose that there is a direct projection from the lateral geniculate nucleus not only to the striate cortex but to the extrastriate cortex as well. This is supported by transcranial magnetic stimulation studies which were able to produce phosphenes by stimulating the lateral extrastriate cortex.

Stimulation of mesial and lateral extrastriate cortex via depth electrodes implanted in posterior brain regions revealed visual phenomena different to the elementary perceptions mentioned above. Static phenomena like visual object distortion were provoked by lateral stimulation of the middle occipital gyrus, as white or colored flashes by mesial stimulation of the cuneus around the calcarine fissure, as blurred vision when mesially stimulating the posterior cingulate region and inferior precuneus.[17] Visual motion perceptions like a transparent moving circle occurred during stimulation of the medial portion of the parieto-occipital fissure and of the posterior cingulate gyrus. Stimulation at sites 1–2 cm apart did not evoke these phenomena. The authors concluded that within the extrastriate cortex the medial parieto-occipital region is the only region of specific sensitivity to motion processing effects. Due to limitations of their study they could not rule out, that additional areas might be involved, and that the medial parieto-occipital region is likely to be part of a multiarea system processing visual motion analysis.

Studying color processing with subdural electrodes, Allison *et al.*[18] found sensations like 'shimmering' or 'flashing' when stimulating the medial lingual or cuneate gyri. Changes in color perception could be seen on stimulation of the lateral and fusiform gyri. These findings support studies based on clinical, anatomical and PET imaging data, which indicate that there is a region of the human inferior occipital cortex which is involved in color perception and which may be homologous with area V4 described in monkeys.

Visual experiential responses, for example consisting of seeing a scene, a group of people or a recognizable object could be produced by Penfield *et al.*[13] by stimulating the temporal lobes. This occurred more often when the nondominant hemisphere was involved. In the right hemisphere the stimulation points were scattered throughout the temporal lobe. On the left side the responses were either on the lateral side comprising the first and second temporal gyri, or more frequently on the superior aspect of the first temporal gyrus. Summarizing, Penfield *et al.* concluded that stimulation sites associated with experiences that are largely visual tend to be located in the posterior temporal cortex near the visual sensory area of the occipital lobe on the right, nondominant side. Obviously, this area is devoted to the purposes of the interpretive cortex and apt to produce recall of visual experiences. On the contrary, stimulation of this site in the left, dominant side which corresponds to the large speech area of this lobe, never produced visual experiential responses.

VEP

VEP are generated from the primary visual cortex. Because the evoked potentials exhibit characteristics of near field potentials,[19] subdural or depth electrodes outside this cortex do not record VEP. The sequence of peaks recorded from the cortex resembles those recorded from the scalp, but the amplitudes are much higher. However, depending on the location of the electrodes, polarity may be different to scalp recordings (which can be explained by the solid angle concept theory),[20] and the latencies of the peaks also depend on the electrode location and therefore differ at least slightly from those obtained with scalp recordings.

From the perspective of planning resection of the presumed epileptogenic region within the occipital lobe and trying to define functional eloquent cortex, it can be stated that electrodes lying on the primary visual cortex will show evoked potentials on visual stimulation of the patient, whereas electrodes outside will not. VEP are applicable as pattern reversal VEP in patients with chronically implanted electrodes. Stimulation with pattern reversal using appropriate check sizes will predominantly stimulate the macular region and produce responses of the visual cortex responsible for central vision[21–23] which is the decisive part of the eloquent cortex to be preserved. Obviously, the use of VEP in presurgical diagnostics of occipital lobe epilepsies is not established very well, as reports based on larger numbers of patients do not mention their application.[2–5,11,24]

VEP might be considered in uncooperative or mentally retarded patients who can not reliably cooperate during subdural stimulation, provided they are able to fix their gaze on the screen of the monitor. In addition, in one recent study[25] a flashing strobe light was employed to study the driving response of the visual cortex intraoperatively. The occipital driving response to photic stimulation could be used as a means of monitoring the integrity of the visual cortex and offering the advantage that averaging is not necessary, and therefore, a more immediate feedback to the neurosurgeon is possible.

Conclusion

Stimulation of the posterior cortex may evoke two major groups of visual perceptions: elementary or simple ones,

consisting of white or colored different spots of variable shape (phosphenes), and more complex ones. The origin of the first is the primary visual cortex (area 17, striate cortex, V1) and can in addition encompass the extrastriate cortex on the lateral surface of the occipital lobe. Their retinotopic organization may assist in defining the borders of resection in order to prevent new or deterioration of already existing visual field defects. The more complex visual phenomena, including hallucinations, are generated in the occipital lobe outside the afore mentioned area. The site of these generators may extend into adjacent parietal and temporal cortex. It is still unclear what the clinically relevant sequelae of a resection of these cortical areas are.

Auditory cortex

Introduction

Compared to stimulation studies dealing with language functions, the number of stimulation studies confined to pure auditory functions is much smaller. This reflects both the high impact of preserving language ability and the less prominent awareness of neuropsychological deficits in the auditory domain in epilepsy surgery patients.

Anatomy of the auditory cortex

The superior temporal gyrus (STG) contains the auditory cortical areas in man.[12,13,26–28] Its superior aspect is buried in the Sylvian fissure and can be seen only after removal of parts of the frontal and parietal opercula. On its middle part lies the Heschl's gyrus (HG), demarcated posteriorly by the transverse temporal sulcus. Posterior to this sulcus begins the planum temporale (PT). The anterior border is less clearly demarcated by the acoustic sulcus, an extension of the superior temporal gyrus. There may be one or two gyri on each side. A MRI study of the normal signal intensity pattern in HG and the surrounding areas in the STG and middle temporal gyrus on T2-weighted images demonstrated lower signal intensity of the cortex in the HG and surrounding STG compared with that of the middle temporal gyrus.[29] Combining cytoarchitectonic studies and these morphologic data, Brodmann's area 41 and 42 match with HG. Areas 52 and 22 correspond to the posterior part of STG, PT and extend into the long gyrus of the insula and the parietal operculum.

Clinical ictal characteristics

Auditory auras may consist of hearing different sounds and noise or altered perception of normal sounds of the environment.[12,13,26,30] Their occurrence as an early ictal sign in temporal lobe epilepsy is indicative of an lateral, neocortical seizure origin.[31]

Electrical cortical stimulation studies

Penfield *et al.*[12] found auditory sensations when stimulating a narrow region of the STG that bordered the posterior third of the Sylvian fissure. Only infrequently Heschl's transverse gyrus on the superior temporal surface was uncovered and in these cases the same auditory sensations could be evoked. They were elementary, consisting of a wide variety of sounds. The frequency of the sounds was not found to be dependent on the localization of the stimulus sites. Most often the sounds were projected to the contralateral ear, less frequently to both ears. More complex auditory perceptions, referred to as auditory experiential responses by Penfield *et al.*,[13] could be elicited by stimulation of the lateral and superior face of STG, but not of the Heschl's gyrus. A more comprehensive access to those parts of STG hidden in the lateral fissure were achieved in further studies which applied stereotactically inserted depth electrodes.[32] Recording auditory evoked potentials with depth electrodes, Liegeois-Chauvel[28,33] were able to define the primary auditory area more precisely and limit it to the posteromedial part of Heschl's gyrus. This is supported by an elaborate stimulation study[26] with 65 patients, 71% of the depth electrodes being placed in HG (38% of leads in the right area 41, 62% in left and right area 42), 10% in PT, 17% in the middle part of STG (area 22) and 12% in the anterior part of STG (area 38). Regarding Heschl's gyrus, stimulation of area 41, the primary auditory area, provoked more high frequency sensations than that of area 42, the secondary auditory area. The nature of the sensations was mostly simple hallucinations, meaning sounds and noise which were heard binaurally or monaurally (usually contralateral), when area 41 was stimulated. Activation in area 42 provoked more illusions, i.e., perception of altered voices and sounds, rather than hallucinations. In PT and the remaining regions, illusions were more frequent than hallucinations, their type being not different from those elicited by stimulation of HG. Hallucinations were mainly binaural, illusions could be also binaural or just contralateral. Although there are some discrepancies to the aforementioned studies of Penfield and co-workers, which amongst others are probably related to the different stimulation method (monopolar versus bipolar), one consistent finding is that area 41 of HG has some unique features that distinguishes it from the rest of the auditory cortex. In two recent studies[34,35] HG was explored with depth electrodes implanted roughly parallel to its long axis. In addition, subdural grids electrodes were placed over the middle and posterior aspects of the lateral STG. Averaged auditory potentials were recorded from both sites. Thus, a posterior lateral superior temporal area (PLST) could be identified which was activated by a variety of simple and complex sounds. Bipolar electrical stimulation of HG activated a circumscribed area of the lateral STG that overlapped the acoustically defined PLST. These results provide evidence for a functional projection from primary auditory cortex on HG to an associational auditory cortex on the lateral surface of STG. This cortical area may play an important role in auditory motion processing, since Ducommun *et al.*[36] report on a patient who developed a selective deficit for the perception and discrimination of auditory motion after right temporal lobe resection. In addition to the anterior temporal lobe the resection included also the posterior STG, lateral PT, and lateral HG, because intracranial ictal recordings had shown that seizure activity had spread to these structures. Preoperatively, electrical stimulation of the posterior STG was experienced by the patient as incoming moving sounds and intracranial auditory evoked potentials revealed motion-specific responses selectively over this area. Postoperatively, analysis of auditory stimulus identity and location within the auditory scene remained intact. In two patients with focal

epilepsy caused by tumors of Heschl's gyrus intraoperative stimulation failed to produce auditory hallucinations, illusions or other acoustic phenomena.[27] In one patient, his auditory aura continua (ringing sound) ceased after resection of the tumor and stimulation after this event still failed to evoke any auditory perceptions. To our knowledge this is the only report in which electrical stimulation of the primary auditory cortex failed to provoke any auditory sensations. A possible explanation for these surprising findings could be that both tumors (astrocytoma grade III, oligodendroglioma grade II) led to alteration of the primary auditory area sufficiently enough to cause severe cortical dysfunction.

AEP

As shown in the paragraph above, the intracranial recording of auditory evoked potentials (AEP) complements direct electrical cortical stimulation. It provides valuable support in defining auditory cortex in patients presenting with auditory auras and in patients with lateral temporal or occipital-temporal epilepsies, in whom the posterior, superior or anterior borders of resection need to be determined.[33]

Conclusion

Resection/destruction of structures within the auditory cortex can impair various functions or abilities, ranging from spatial localization[37] to altered music processing.[38] This is a reflection of the complex organization of the auditory cortex which encompasses the primary auditory area and several additional, secondary auditory areas, analogue to the visual cortex.

Although modern functional imaging methods can provide a reliable measure of the activity of human cortical neurons[39] direct electrical cortical stimulation is still an indispensable tool when attempting to define auditory cortex and preserve it from unnecessary resection.

Insula

Introduction/anatomy

The insular cortex is covered by the frontal, temporal and parietal opercular cortices. Thus, it is not easily accessible to direct electrical stimulation and therefore has been explored less frequently than other areas.[40,41]

Clinical ictal characteristics

Frequent propagation of seizure activity often makes a precise differentiation between ictal symptoms of temporal lobe epilepsy and insular lobe epilepsy difficult. Isnard *et al.* were able to demonstrate a variety of symptoms which tend to occur in a particular sequence:[42,43] sensation of laryngeal discomfort, unpleasant paraesthesia affecting large cutaneous areas, dysarthric speech, elementary auditory hallucinations, often focal dystonic postures at the end of the seizures.

Electrical cortical stimulation studies

Early intraoperatively performed stimulation studies yielded varied results[44] consisting predominantly of various types of abdominal sensations: nausea, umbilical sensation or pain, borborygmi, belching, and desire to defecate (pages 107 and 424 in ref. 12).

Recent studies using intracerebral depth electrodes were able to overcome many of the limitations of earlier intraoperative stimulation studies. Applying an elaborate approach of stimulating the insular cortex by using transopercularly implanted depth electrodes[41,45,46] the responses could be subdivided into the following categories:

- Somatosensory responses were the most frequent and were elicited when stimulating the posterior insula. They comprised neutral or unpleasant and painful sensations, the majority of them being confined to the contralateral face, neck, hand and upper limb.
- Viscerosensitive responses were evoked in the anterior part of the explored area and consisted of feelings of constriction of the pharyngolaryngeal region or various types of sensations within the abdomen or thorax which resembled the initial ictal symptoms in mesial temporal lobe epilepsy.
- Less frequent – in about 10% of cases – simple acoustic hallucinations, experiential phenomena, olfactogustatory or vegetative responses were evoked.

The involvement of the insula in cardiac regulation has been demonstrated in patients with left-insular cortex lesions[47] and has been suggested to play an important part in the pathogenesis of sudden unexplained death in epilepsy via cardiac asystole.[48] Monitoring ECG and intra-arterial blood pressure, Oppenheimer *et al.* found bradycardia and depressor responses more frequently produced than tachycardia and pressor effects when stimulating the left insular cortex. The converse applied for the right insular cortex.[49]

Conclusion

Stimulation studies reveal a broad spectrum of somatosensory and viscerosensory phenomena. However, when considering a resection in an patient with medically refractory insular epilepsy, the planning of the surgical procedure is guided by the extent of the lesion and the assessment of the ictal onset zone. In suitable cases postoperative seizure freedom can be achieved without causing permanent neurological deficits.[50]

Olfactory cortex

The cortical regions subserving olfactory functions have not been definitively defined.[51,52] The primary olfactory cortex consists of the anterior olfactory nuclei, olfactory tubercle, piriform and lateral entorhinal cortex. The piriform cortex receives direct input from the ipsilateral olfactory bulb via the lateral olfactory tract and projects to the insular and orbitofrontal cortices, the latter assigned to the secondary olfactory region. These structures together with the thalamus form a loop with the thalamus receiving input from piriform cortex and olfactory tubercle and projecting to orbitofrontal and insular cortices. The lateral part of the entorhinal cortex has connections with the hippocampus.[53]

According to Greenberg[54] there is an overall paucity of olfactory hallucinations in the stimulation literature. The data

from three large epilepsy centers in Germany prove olfactory sensations to be a very rare phenomenon.[52] Halgren *et al.* studying the temporal lobes of 36 epileptic patients with depth electrodes and and performing 3495 stimulations of the medial temporal lobe found 267 mental phenomena of different modalities but no olfactory sensations.[55] Stefan *et al.*[56] as well as Weingarten *et al.*[57] failed to stimulate olfactory hallucinations when exploring the patients temporal lobes with depth electrodes. Penfield *et al.*[12] were able to elicit unpleasant smells regularly when stimulating the olfactory bulb but only occasionally when stimulating the uncus or the amygdaloid nucleus. Van Buren[58] obtained reproducible olfactory sensations when stimulating with depth electrodes 'from within or very close to the amygdala'. Andy[59] stimulated intraoperatively the right amygdala and hippocampus of a patient suffering from posttraumatic epilepsy with olfactory as well as experiential auras and complex partial seizures. Stimulation of the amygdala led to habitual olfactory sensations (in combination with afterdischarges and spread to the hippocampus), whereas stimulation of the hippocampus, although accompanied by afterdischarges but with minimal spread to the amygdala, failed to do so. Repeat stimulation of both structures after having them surgically separated yielded the same results, thus proving that the amygdala was crucial for the occurrence of the olfactory phenomena. In another case[60] electrical stimulation of the amygdala of the dominant side also produced olfactory (and gustatory) perceptions. Interestingly, their unpleasant character could be altered to a more pleasing one by interacting with the patient. There is only one study[61] in which stimulation outside the corpus amygdaloideum elicited olfactory sensations, which may be due to limited accuracy of defining the precise location of the stimulating depth electrodes. Contrary to these electrical stimulation studies, investigating the contemplable olfactory cortical regions with PET by exposing normal subjects to a set of eight different odorants, revealed a strong bilateral activation of the piriform cortex and right sided activation of the orbitofrontal cortex.[51] Both areas are difficult to access with electrodes and this represents a major disadvantage of the electrophysiological approach. Thus, we concur with the conclusion of Greenberg[54] that

> while the gross localization of epileptic olfactory hallucinations to activation of deep limbic nuclei in a proportion of patients seems secure, the exact region(s) necessary and sufficient for subserving the generation of false perceptions of smell, the precise mechanism by which this is achieved, and the factors that determine individual susceptibility all remain obscure.

Amygdala

Besides the above-mentioned olfactory hallucinations electrical stimulation of the amygdaloid corpus elicits a set of other responses which likewise consist of altered mental functions and are referred to as experiential phenomena.[62] This designation bears on their character which resembles real life experiences. Although Penfield *et al.*[12,13] ascribed them to stimulation of the lateral temporal cortex, in further studies[55,63,64] experiential responses were predominantly obtained by stimulation of the limbic structures, i.e., the medial part of the temporal lobe. This portion of the temporal lobe had been only infrequently stimulated by Penfield and co-workers. In the study of Gloor *et al.*[63] the responses elicited were most often not associated with an afterdischarge or the afterdischarge remained confined to the area of stimulation. They included perceptual hallucinations or illusions, emotions, experiential responses in the form of flashbacks as well as *déjà vu* illusions and forced thinking. The likelihood with which responses could be elicited had an anteroposterior gradient, the amygdala showing the highest incidence of responses. The likelihood further decreased from the hippocampus to the parahippocampal gyrus. This anatomical relation was also found in the studies of Halgren *et al.*[55] and Fish *et al.*[64] Among emotions, fear or anxiety are the most frequently encountered. Halgren and Chauvel [65] hypothesize as an explanation that electrical activation is a very crude means of activation and induces limbic hyperactivation and disorganization. Such limbic disorganization could also arise when the organism is confronted with an event that it can not emotionally integrate, either because it is completely novel or because it contains elements with conflicting emotional implications. Electrical stimulation would then often induce anxiety because as an external unnatural stimulus it cannot be integrated by preexisting limbic circuits. The pivotal role of the amygdaloid corpus has been demonstrated also by measuring intracranial event-related potentials when presenting frightening facial expressions to epileptic patients implanted with depth electrodes during a presurgical evaluation. Specific potentials to fear beginning 200 ms poststimulus were observed in the amygdala, occurring 100 ms earlier than potentials to disgust recorded in insula. Potentials to fear were initially confined to the amygdala and later spread to occipital-temporal, anterior temporal and orbitofrontal cortex.[66] Fear as an ictal sign, however, did not occur in four patients with fear as the main feature of their seizures until additional structures of the frontal lobe become involved.[67] These patients were studied with depth electrodes implanted in the temporal and frontal lobes including anterior cingulate and orbitofrontal regions. Ictal involvement of the amygdala alone was not accompanied with a feeling of fear. Fear behavior occurred not until orbitofrontal and anterior cingulate cortex became involved. Electrical stimulation of the amygdala evoked fear and the sensation of a shadow behind her in one patient but without the habitual ictal fear behavior. In the other reported patient with stimulation, ictal discharges did not involve the amygdala and stimulation of the amygdala did not lead to any symptoms. Another recent stimulation study with special emphasis on the adjacent perirhinal and entorhinal cortices[68] demonstrated evoking of fear or anxiety, experiential (*déjà vu*, *déjà vecu*) phenomena and viscero-sensitive perceptions when stimulating the amygdala, and also the hippocampus and both rhinal cortices. However the experiential phenomena were more frequently induced by rhinal than by hippocampal-amygdala stimulations. The involvement of medial temporal structures in generating ictal fear has also been evidenced in an study applying magnetic resonance spectroscopy to the hippocampus and demonstrating metabolic changes along its axis.[69] Summarizing, we would like to cite Gloor's hypothesis[62] that the stimulation of the amygdala and further medial temporal lobe structures:

> can induce the elaboration of patterns of excitation and inhibition in widely distributed neuronal networks, some

of which are capable of forming a specific matrix representing the substrate of a given experience. Neuronal networks engaged in parallel distributed processing have the capacity to recreate the totalness of a given experience when only a fragment of the network is activated... [Thus] ...experiential phenomena are positive expressions of temporal lobe and limbic functions.....

Cingulum

In 1949, Pool and Ransohoff[70] published data on autonomic effects provoked by bilateral stimulation of the anterior part of the cingulate gyrus in psychotic patients treated with bilateral frontal gyrectomy or fractional corticectomy of Brodmann's areas 9 and 10. Their study was designed to look only for autonomic effects. Changes of blood pressure, pulse rate and respiratory rate could be produced and consisted of either elevation or decrease of the values. Most of these effects were confined to the duration of the stimuli, but occasionally could outlast the stimuli. Control stimuli applied to medial and lateral aspects of Brodmann's areas 9 and 10 did not lead to autonomic effects. Similarly, Penfield *et al.*[12] observed that stimulation of the anterior and inferior portion of the cingulate gyrus caused patients to stop breathing, but that the patients were able to breathe voluntarily when asked to do so during stimulation. In two epileptic patients whose cingulate gyri were partially covered with subdural electrode grids[71] sensory responses occurred during electrical stimulation. Stimulation of the posterior region of the right cingulum caused in one patient a 'feeling as in a dream, like a TV scene' or 'buzzing' in the ears or a 'shock' all over the body. The second patient who was stimulated in the right midcentral region experienced bilateral 'numbness' with left preponderance in varying parts of the whole body including trunk, extremities and face. A comprehensive study[72] of epileptic patients who were investigated with depth electrodes implanted in the anterior and middle cingulate gyrus as well as orbito-frontal, lateral superior and middle frontal gyri and supplementary motor area yielded the following symptoms in the stimulated patients: 25% hallucinations, 8% signs of emotions (fear, crying, moaning), 17% visceromotor, 74% viscerosensitive, 35% sensory, 18% contralateral deviation of head, 17% grimacing and pouting, 8% clonic, 17% oroalimentary automatisms, 33% arrest of speech. Compared to the other areas, visceromotor and viscerosensory symptoms were most frequently and oroalimentary automatisms exclusively observed when stimulating the cingulate gyrus. Talairach *et al.*[73] and Bancaud *et al.*[74] reported in several studies with depth electrodes on a unique type of motor automatisms elicited by electrical stimulation of the anterior part of the cingulum. These automatisms involved primarily fingers, hands, lips and tongue, only rarely the eyes. They were based on a few simple movements, such as touching, stretching or sucking which often developed into more complex movements that seemed to be directed by the situation. They lasted for the stimulation and were involuntarily, experienced by the patients as forced onto them. Automatisms of hand and fingers occurred contralaterally to the stimulated side. Sometimes in addition, changes in mood, level of consciousness or autonomic phenomena could be observed. The pattern of stimulation points showed no somatotopic organization. This type of motor automatisms, which is different from those provoked by stimulation of the motor areas, was considered to result from the integration of motor, sensory and mnestic functions and to represent elementary basic motor functions, i.e., 'to consist of the smallest parts of movement formed by the integration of gnostic and mnestic praxial motor functions'.[73] As shown above, these motor automatisms – in contrast to the additional phenomena – have not been encountered in stimulation studies of other investigators. They were differentiated from paroxysmal, i.e., ictal behavior, on a clinical base and electrographically not accompanied by paroxysmal, that means ictal patterns. However, the authors described a 3–8 Hz regular rhythm appearing at neighboring electrodes and sometimes recordable from the scalp with maximum at the midline (vertex). This activity spread to homologous areas of the contralateral cingulate gyrus as well as to the frontal medial cortex and posterior cingulate gyrus, but not to the hippocampus. Even though these changes might lack some features to be unequivocally considered an ictal pattern they might indicate a spread of electrical activity beyond the cingulate gyrus and an involvement of additional medial frontal cortical areas. Summarizing, electrical stimulation of the cingulate gyrus produces a wide variety of motor, sensory, visceral/autonomic and psychic phenomena, the autonomic, viscerosensitive and visceromotor being the most frequent and distinguishing ones. However, its physiological function is by far more complex[75] and has been described as an 'interface between emotion and cognition'.[76]

Case presentation: alien limb syndrome evoked by stimulation with subdural electrodes

Alien limb phenomena (ALP) consist of a variety of abnormal motor and sensory symptoms of the extremities leading to seemingly purposeful but often erratic limb movements. They are perceived as foreign and forced onto, as if they were alien induced.[77] Furthermore, the ownership of the affected limb (verbal asomatognosia) is denied in some but not all patients.[78,79]

We present a 14-year-old patient who had parietal lobe epilepsy due to a malformation of cortical development in the left postcentral cortex. Neurological examination and neuropsychological testing were normal apart from a postictally occurring paresis of his right leg. The electrical stimulation of two electrodes above the border between the precentral and the postcentral gyrus and one electrode above the frontal operculum (see Figure 110.1) induced episodes of involuntary grabbing maneuvers of the right arm accompanied by the perception of alienness ('someone else is playing with that arm'). These involuntary movements persisted under visual fixation of the right arm and terrified the patient.

Focal epileptic seizures as a possible etiology of transient ALPs have already been discussed in previous reports.[80,81]

The motor activity may be interpreted as limb automatisms – otherwise neglected in complex partial seizures – but now realized under preserved consciousness. It may be speculated that the simultaneous appearance of motor automatisms

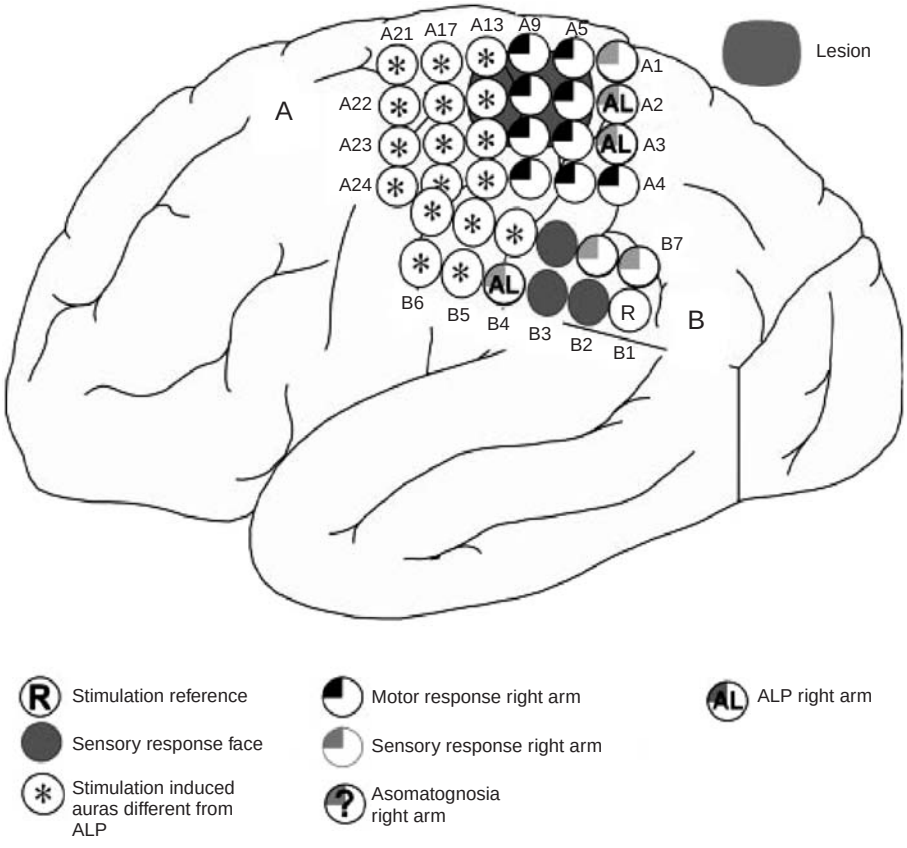

Figure 110.1 Alien limb phenomena (ALPs) were induced by electrical stimulation of the electrodes A2 against A3, A3 against A4, and A2 against reference electrode B1. The latter electrode pair induced symptoms lasting for a further 10 seconds after the end of stimulation, which was accompanied by an EEG seizure pattern over the electrodes adjacent to A2. The electrodes A2 and A3 were shown to be located above the border between the precentral and the postcentral gyrus by stimulating the adjacent electrodes. Furthermore, the stimulation of electrode B4 against B5 and against the reference B1 also induced ALP. In a widespread cortical area located anterior to the lesion (*), the stimulation induced either somatosensory (tingling) or unclassified auras (indescribable wholebody perception), indicating the irritative zone. (From Boesebeck F, Ebner A. Paroxysmal alien limb phenomena due to epileptic seizures and electrical cortical stimulation. *Neurology* 2004;63:1725–27, with permission from Lippincott, Williams & Wilkins.)

and ictal asomatognosia[82] in the same limb reflects a time-locked activation/inhibition of two or more distinct cortical areas. This could explain the relative rarity of ictal ALP because semiologies in partial epileptic seizures normally follow a topic and temporal propagation and, in the case of complex motor automatisms, are regularly accompanied by an impaired awareness of the ictal symptoms. The eliciting of ALP by previous ipsilateral movements may be attributed to the rare condition of simple partial reflex seizures induced by voluntary movements of the affected limb[83] but has also been noticed in nonepileptic posterior ALP.[84,85]

The stimulation of two distant cortical areas in the left hemisphere elicited ALPs in our patient. One cortical area is located in the crossing between the primary sensory cortex (S1) and the primary motor cortex (M1)–both representing the affected limb. The second area is located in the supplementary sensory area (S2) of the planum infraparietale.

It may be speculated that stimulation of electrodes above the rolandic fissure may have led to a bidirectional propagation of electrical current in our patients, which may have led to a simultaneous inhibition of primary sensory areas (asomatognosia) and activation of primary motor areas (involuntary movements) that were subjectively experienced as alien movements. Another possible mechanism may be a functional disconnection of association fibers between the primary (S1) and supplementary sensory areas (S2).

This case report is based largely on the report of F. Boesebeck and A. Ebner.[86]

Case presentation: laughter evoked by stimulation with subdural electrodes

Laughter is the principle symptom of gelastic seizures. Recently it has been reported also as a postictally occurring symptom.[87] This seizure type is predominantly encountered in patients with hypothalamic hamartomas (HH)[88–90] but has been observed also in symptomatic epilepsies of the frontal lobe,[91–93] temporal lobe,[92,94] parietal lobe,[95] or in cryptogenic epilepsies.[89] The character of laughter is involuntary, forced, but can seldomly be accompanied by feelings of mirth. In patients undergoing invasive presurgical evaluation, laughter as an ictal symptom of their habitual gelastic seizures could be induced by electrically stimulating with SEEG electrodes,[88,93] but only in very few patients could laughter be electrically evoked without inducing seizures.[92,96] Moreover, in these patients laughter

was not part of their habitual seizures. We present a 35-year-old woman suffering from focal epilepsy since early childhood due to a cortical dysplasia located in the middle and posterior part of the right superior frontal gyrus. Her seizures consisted of somatosensory auras of left arm and hand evolving into asymmetric tonic seizures. No gelastic seizures. She was evaluated with subdural electrodes covering laterally the primary sensorimotor area and as a 10-electrode strip mesially the supplementary sensorimotor area (SSMA). It could be shown by electrical stimulation and fMRI that the lesion lay sufficiently anteriorly to eloquent cortex to be resected completely. This rendered the patient seizure free. When stimulating the two superior electrodes of the anterior row of the mesial strip which lay on the cranial anterior part of the SSMA, the patient immediately started to laugh and stopped reading the text which she had been asked to read. This could be demonstrated repeatedly and without afterdischarges. The nature of the laughter was involuntary, forced and without a concomitant feeling of mirth. Stimulation of adjacent electrodes yielded either the habitual tonic seizures or negative motor responses (electrode beneath). To our knowledge, there is only one other case of laughter elicited by stimulation of mesial frontal cortex in or adjacent to SSMA. Unlike the other case published by Fried,[96] our patient did not experience mirth or merriment. Other sites where laughter could be evoked were anterior cingulate gyrus and orbitofrontal cortex (Sem-Jacobsen cited in ref. 92) and fusiform and parahippocampal gyrus.[92] Based on their two stimulated patients that had an accompanying feeling of mirth and one patient with proven ictal onset of gelastic seizures without mirth in the cingulate gyrus, Arroyo *et al.*[92] hypothesized that the cingulate gyrus plays a primary role in the motor execution of laughter, and that the basal temporal cortex processes the emotional aspects of laughter. Biraben *et al.*[67] who were able to demonstrate SPECT ictal hyper- and interictal hypoperfusion in the orbitolateral region continuing into the temporal region in one patient with cryptogenic epilepsy with gelastic seizures, stress the involvement of the cingulate gyrus and orbitofrontal cortex in the generation of ictal laughter. However, our and Fried's data demonstrate that stimulation of the frontal cortex in the anterior part of the SSMA also elicits the motor execution of laughter, both with or without concomitant feelings. Obviously, due to the small number of studies and the complexity of the subject, there is not yet enough knowledge to identify the essential structures (or their interplay) required to enable the motor execution of laughter, let alone the emotional perception of mirth. The data of our patient has meanwhile been published by Schmitt and Ebner.[97]

111 The role of electroencephalogram and magnetoencephalography synchrony in defining eloquent cortex

G Kalamangalam and M Iwasaki

Introduction

Attempts to correlate the human electroencephalogram (EEG) with cognitive and behavioral states go back to Hans Berger's observations on the alpha rhythm. Such relationships are implicit in routine clinical interpretations of EEG (e.g., the reactivity of the mu rhythm to motor activity), but for today's epileptologist, the EEG remains overwhelmingly a diagnostic tool for evaluation of seizures and encephalopathy. However, the vast nonclinical literature in the EEG-magnetoencephalography (MEG)/cognition/behavior area, from fields as diverse as basic neuroscience, linguistics, psychology and the emerging discipline of complex systems, provides neurologists interested in higher cognitive function with valuable signposts to investigating their own clinical datasets. Some of this literature is alluded to in this chapter; for overviews on selected aspects, see.[1–3]

Normal, 'free-running' EEG has a number of well-defined characteristics and waveforms. It is also clear that external stimuli will sometimes passively 'drive' it (e.g., the photic following response from flicker). Studies of EEG in relation to cognition are interested, by contrast, in waveforms (or other attributes) that can be clearly distinguished from normal background, not directly driven by the stimulus, but somehow 'caused' by the task. The term 'induced rhythm'[4] (distinguished from the term 'evoked response' used in its usual sense) is sometimes used for this purpose. These may be novel rhythms (waveform epochs or single potentials) or modification of pre-existing rhythms (e.g., event-related desynchronizations). Induced rhythms are conventionally interpreted, at some risk of oversimplification, into two schools. One may wish to identify discrete cerebral foci corresponding to ever more complex tasks (School I: an approach that recalls the popularly-dubbed 'grandmother cell'[5] hypothesis). Else (School II), one follows the hypothesis that the brain works by recruiting large number of simple units (neurons) into complex networks ('functional neural assemblies',)[6] and looks for interareal cooperation between distributed cortical regions (the doctrine of 'Neurons that Fire Together, Wire Together': a thesis originally attributed to Hebb.)[7,8] This chapter emphasizes the latter approach, though it should be borne in mind that everyday clinical neurology, based on lesion-deficit analysis, is School I thinking. This is also true for cortical stimulation mapping, a commonly used technique in surgical epileptology for identifying eloquent areas. Clearly, a fuller understanding of the neural basis of cognition will reasonably incorporate ideas from both schools.

Neurophysiology of cognition

The macroscopic scalp EEG represents the summated extracellular potentials (the local field potential, or LFP) of neurons in the vicinity of the recording electrode.[9] An oft-quoted figure is that simultaneous activity of about six square centimeters of cortex is necessary for a waveform to be discernible on the scalp.[10] Scalp-EEG is thus the aggregate of many millions of excitatory and inhibitory postsynaptic potentials; it does not directly represent action potentials, except under circumstances of pathological synchrony (e.g., a seizure, when the recorded LFP reflects the spatiotemporal summation of repetitive action potentials). Nevertheless, a correlative relationship between the LFPs and neuronal information processing is often assumed:[11] one interpretation of EEG is thus as a surrogate of neuronal activity. Distinct from this, the nature of EEG enables unique use as a brain mapping tool (i.e., different from metabolic methods such as fMRI or PET). First, the fine temporal resolution of EEG (limited only by the bandwidth of the recording technology) allows tracking of rapid changes inaccessible by fMRI or PET. Second, because the amplitude of EEG depends largely on neuronal synchrony, it can be independent of individual neuronal firing rates.[12] Thus EEG 'activation' can occur irrespective of overall neuronal metabolic change, a feature again invisible to metabolic imaging.

The MEG signal represents the same neurophysiological phenomena as EEG.[13] On a practical level, the biophysical aspects of signal generation and detection however give rise to information that is somewhat different, and possibly complementary to EEG.[13,14] Clearly, it is ideal for every neurophysiological study of cognition to be performed with both EEG and MEG. In the absence of such information, it is reasonable to assume that results from either method contribute towards a common neurobiological interpretation.

Which waveform?

Induced rhythms may be of various sorts, and the experimenter will usually decide beforehand what the neurophysiological 'end-point' of the study is. This may be based on an

a priori biological hypothesis or be guided by technical feasibility. In turn, determination of the waveform of interest guides, to an extent, what questions the experiment may reasonably ask.

Event related desynchronization (ERD) has a long history, arising naturally from early observations on the reactivity of the alpha rhythm. This approach identifies changes in spectral power in specific frequency bands over extended brain regions.[15] Influential theories on the neural basis of integrated cognitive function emphasize large-scale synchrony between multiple cortical areas,[16,17] a viewpoint that ERD has provided some evidence for in recent years.[18] Cognition-related event-related potentials (ERPs) are another candidate neurophysiological waveform: the literature on this is large and continues to grow. ERPs are essentially a long-latency evoked response, but thought to be independent of the physical characteristics of the stimulus, and related to the higher processing of elementary sensory information.[15] Though the advantages of ERPs in terms of their high temporal resolution and reproducibility have been stressed, their identification involves signal averaging of many trials. This limits the types of neuropsychological paradigms that may be investigated. In addition, the location of the generators of ERPs is usually controversial, and interpretation of results at a neural or structural level difficult. DC shifts are probably the electrical counterpart of functional imaging: 'slow' potentials (of the order of 1 s) due to continuous afferent input or multiple depolarizations of cortical neurons are induced by long-lasting tasks.[15] Lastly, an entire spatiotemporal 'block' of EEG (or MEG) may be of interest. Waveforms, believed to be induced by the task, are characterized by their duration, frequency content and spatial distribution. Analysis of crosschannel congruence or dissonance is the intuitive basis of EEG coherence[19] (and similar methods such as phase synchrony).

Though it appears that comparison of all the above neurophysiological measures within any particular experimental paradigm is straighforward, such published data is rare. This makes the choice of induced rhythm rather arbitrary for any particular experiment, which may, in part, explain the diversity of results reported in the literature.

Methodological issues

Experimental paradigms are naturally designed to fit the modality under study. For assessing the neurophysiological response to elementary sensation, for example, this is hardly controversial. Cognitive experiments present pitfalls such as controlling for intrinsic patient ability and attention. Nevertheless, neuropsychological paradigms described in the literature appears to be fairly homogeneous. 'Oddball' paradigms are particularly suited to the ERP literature, given the need for averaging over multiple trials to detect the waveform of interest and the requirement to precisely time stimulus presentation. Studies of language use a variety of paradigms: synonym search[20] and silent reading and naming[21,22] represent the more intensive and long-duration stimuli, recalling the paradigms of functional neuroimaging; distinguishing words from nonwords,[23,24] or vowels from nonvowel sounds[25,26] represent more passive experimental paradigms. It should be noted that there is a large literature that explores the neurophysiological correlates of different linguistic tasks. These represent an effort to understand the more complex aspects of language processing; by contrast, the former studies (more relevant to the epileptologist), merely aim to distinguish language from nonlanguage. Memory studies usually use variants on the standard Sternberg task, presented visually or aurally.[27,28]

Data gathering is more of an issue with EEG than MEG. MEG is customarily recorded with whole-head magnetometers with dense sensor arrays. The MEG signal does not need a reference, sensors do not contact the scalp, and the signal is not distorted by the effects of intervening tissues; all these are caveats with EEG.[14] However, most scalp-EEG studies work with less than 20 electrodes, and data display is rarely more sophisticated than bipolar or referential formats. Increasing the number of electrodes to beyond 100, and the use of spatial deblurring algorithms may enhance the data value of raw EEG.[29,30] The latter also usefully contributes to the debate on reference contamination, a particular issue in the computation of coherence.[31–39]

Post processing methods employed for cognitive neurophysiological data range from the simple averaging methods well-known in evoked potential work, through the spectral methods of classical signal processing, to newer methods derived from the analysis of nonlinear time series.[15,40] For a review of the promise of the latter methods in EEG, see ref 41. Measuring EEG synchrony between brain regions is based on the Hebbian idea that regions of the brain that work together must temporally bind. For an equivalent EEG signature one simplistically imagines two EEG time series being synchronous if there is a high degree of 'overlap' when they are superimposed. Formally, the cross-correlation R of two signals s_1 and s_2 (EEG or MEG time series) with Fourier transforms S_1 and S_2 is

$$R(\tau) = \int_{-\infty}^{+\infty} s_1(t)\, s_2(t+\tau)\, dt;$$

its Fourier transform $\Im(R) \equiv S_{12}(f) = S_1(f) S_2^*(f)$ is the cross-spectrum (the asterisk denotes the complex conjugate). If S_{11} and S_{22} represent the autospectra (i.e., individual power spectral densities), coherence is defined by

$$C(f) = \frac{|S_{12}(f)|^2}{S_{11}(f) S_{22}(f)}.$$

In practice, ideal spectra do not exist, and the above values are best estimates from the data.[40] The coherence at any frequency is thus a number between zero and unity, independent of the mean amplitude of the original signal. A nonzero value of coherence at a particular frequency of two EEG epochs implies that both epochs possess that frequency, with larger values implying greater sharing of power at that frequency. The phase of the cross-spectrum is a measure of the temporal relationship between the signals at that frequency; this may be used, for instance, in the detection of small time differences between EEG events that appear synchronous between channels.[42] However, cross-spectral phase is a meaningful quantity only if the coherence is itself significant;[42] this limits the use of the former as a 'pure' measure of synchrony. Other drawbacks in using coherence to assess synchrony are that large-amplitude signal overlaps may swamp low-amplitude,

possibly physiologically more meaningful frequencies, and that the analysis is unable to follow modest frequency trends in the data[43] (i.e., the method, like most classical signal-processing paradigms, assumes stationary data). The method of phase synchrony overcomes these limitations by explicitly 'decoupling' amplitude fluctuations from the signal epochs of interest, so that comparison is made purely of phase overlaps.[43] That is, the question is *whether* the signals are synchronous, not *how much*. Formally, the method defines the analytic function Z associated with a narrow-band signal *s* as

$$Z(t) \equiv s(t) - iH\{s(t)\},$$

where the operator H is the Hilbert transform

$$H : s(t) \rightarrow \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{s(\tau)}{t-\tau}\, d\tau$$

The analytic function uses the antisymmetry properties of the Hilbert transform in the Fourier domain, so that the original real-valued function $s(t)$ is recast as $Z(t)$ on the complex plane, which allows disambiguation of amplitude and phase.[44] Instantaneous phase ϕ is then uniquely 'tracked' (independent of amplitude) by

$$\phi(t) = \arctan \frac{H\{s(t)\}}{s(t)}.$$

Thus defined, analytic phase is restricted to the interval $[-\pi, +\pi]$ and its time series are repeats of a cycle increasing from $-\pi$ to $+\pi$, with 2π-phase-slips occurring at $-\pi$ and $+\pi$. The function can be made continuous ('unwrapped') by adding 2π at these points. Phase difference between two signals is calculated by simple subtraction

$$\psi(t) = \phi_1(t) - \phi_2(t),$$

with synchrony being defined as ψ = constant (or zero) over an agreed time period. Intuitively, this corresponds to two waveforms bearing a fixed relation to each other (either a constant distance apart, or exactly in step). Over a total length of time T, the degree of phase synchrony may be summarized by the phase-locking factor (PLF), the time average of phase differences between candidate signals. For discrete data with N data points $T = N\Delta t$, where $1/\Delta t$ is the sampling rate of the continuous data and

$$\mathrm{PLF} = \left| \frac{1}{N} \sum_{j=0}^{N-1} e^{i\psi(j\Delta t)} \right|.$$

Perfect synchrony between two EEGs implies a PLF of unity; complete asynchrony, a PLF of zero.

See refs. 3, 43 and 45 for a fuller discussion of the method; Figures 111.1(a–e) illustrate the central concepts.

Language and memory

How have neurophysiological studies contributed to brain mapping? The literature points to great variability of results; nevertheless, we suggest a synthesis along three main lines. First, there is little doubt that activity-related EEG and MEG changes are a robust and readily identified phenomenon. Second, widespread and bilateral activation is seen with many paradigms. Neurophysiological correlates of perception, attention and awareness have been explored by both EEG[46,47] and MEG[48–50] in normal subjects; typically, these studies describe event-related band power, coherence, or phase synchrony changes over widespread areas during the target task. Diffuse induced rhythms are also described in more focused cognitive activation paradigms. The review of Weiss and Mueller[2] (this paper provides a large bibliography of similar work) describe a study of EEG activation with respect to word categories. Activations were classified into six frequency bands between 1–31 Hz, related to concrete nouns, abstract nouns and verbs; coherence calculations suggested low-frequency increases related to nonspecific and attentional mechanisms, with higher frequency increases more associated with word type. A verbal memory study carried out by the same group[51] demonstrated that the likelihood of a presented word being recalled was related to widespread coherence networks involving both hemispheres, anteriorly and posteriorly. Klimesch and colleagues[27] carried out an ERP study of memory, measuring also event related band power in the theta range. Remembered stimuli in their Sternberg-type task could be distinguished from nonremembered ones by a different ERP profile as well as theta-frequency spectral power measured over the centroparietal region. Gruber and co-workers[52] measured phase synchrony in a paired association learning task. When the second stimulus of a previously memorized stimulus pair was presented, widespread synchrony in the gamma range was observed between multiple electrode sites across both hemispheres. Sarnthein and colleagues[53] described high theta coherence between prefrontal and posterior electrode sites during a working memory task. The third strand of synthesis is that, in several EEG studies certain subparadigms produce reliable *regional* activation. Dobel and colleagues[54] studied responses to semantic, versus syntactic, tasks to line drawings of concrete objects. In their healthy, right-handed cohort, a significant left-lateralized anterior activation was seen in the slow wave component of the ERP between 300–600 s, for the syntactic, but not semantic task. In a similar study,[55] two visually-presented stimuli (either letter strings or nonverbal graphics) were compared by healthy, right-handed subjects according to various verbal and graphic criteria. A remarkable observation was that just the presentation words and word-like strings elicited an N470 in the left, but not right, temporal region. Among processing tasks, there was an asymmetry (left enhanced) of the P620 for phonological matching as opposed to semantic matching. In another study described by Weiss and Mueller,[2] healthy, right-handed subjects were presented a succession of spoken sentences containing either a subject-subject (SS), or a subject-object (SO) relative clause. The latter are acknowledged to be more demanding of verbal processing ability; this was reflected in a significant asymmetry of coherence between frontal sites, left greater than right. The MEG literature, on the other hand, is conclusive in obtaining language-related activations over the dominant hemisphere in both normals[56] and neurological[24,25] patients. Activations in these studies are ERPs modelled as equivalent current dipoles with standard algorithms. Similar results have been obtained with alternative MEG signal-processing techniques.[21,23]

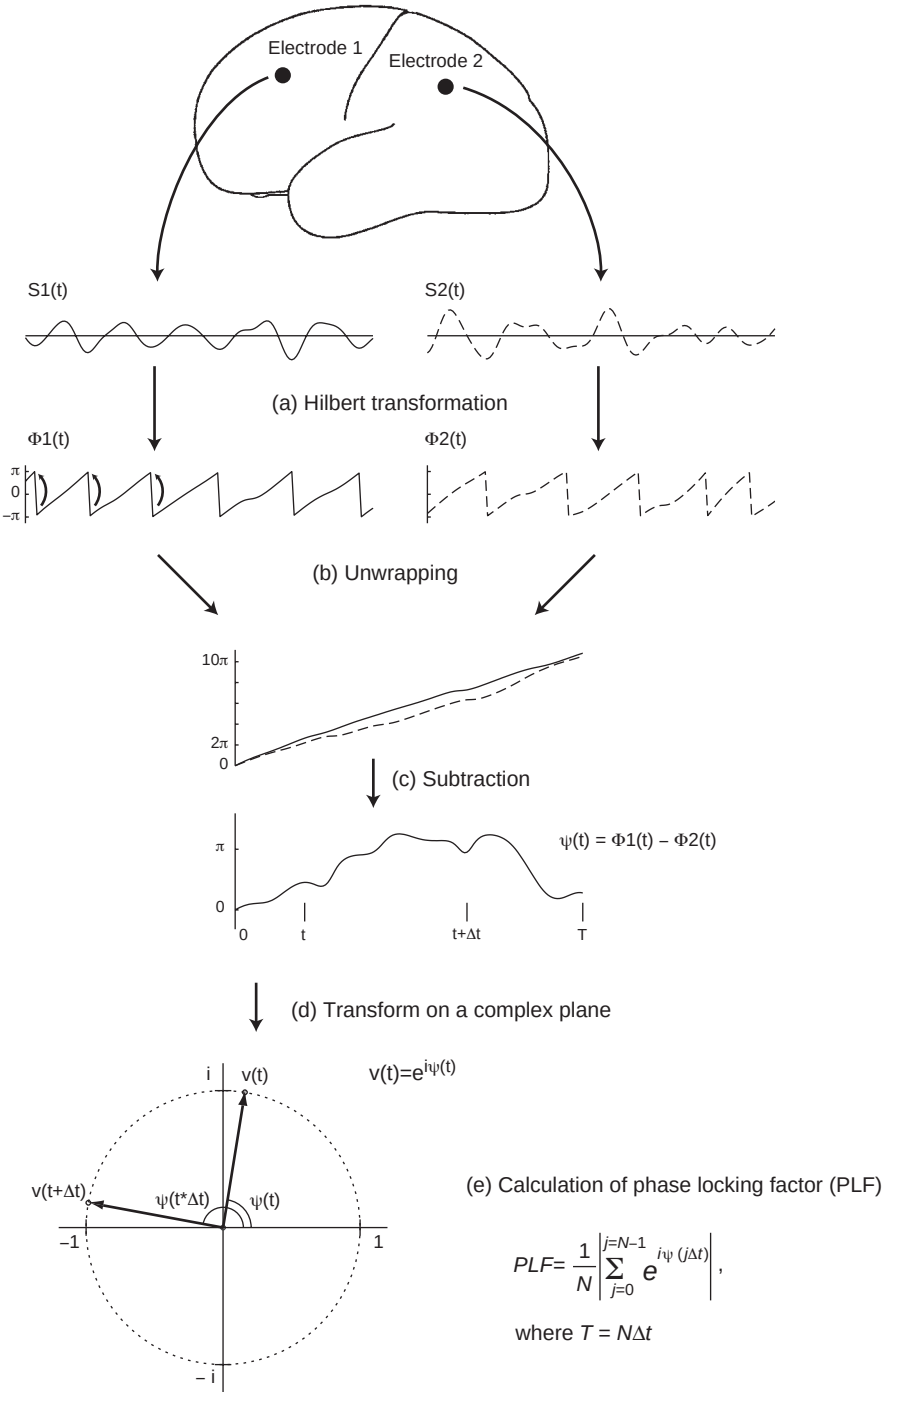

Figure 111.1 Schematic illustration of phase synchrony analysis. See text for details. (a) Two segments S_1 and S_2 of length T of bandpass-filtered EEG are picked up by different electrodes and subjected to the Hilbert transform to extract analytic phase ϕ_1 and ϕ_2. (b) Analytic phases are 'unwrapped' and overlaid for comparison. (c) Pointwise subtraction of the two waveforms yields ψ, the instantaneous phase difference. (d) Successive values of $v = \exp i\psi$ are plotted on the complex plane. (e) Their averaged vector sum provides the phase locking factor (PLF), the length of which grows to unity if the phase difference is constant over T, or shrinks to zero if the phase difference is random.

Intracranial studies

A comprehensive review of the neurophysiology of cognition with invasive recording has recently been provided by Lachaux and colleagues.[57] As these authors point out, the majority of studies record LFPs or spike trains (the latter with intracellular electrodes). A smaller number of studies record oscillatory activity (usually in the high-frequency gamma range) in a few contiguous electrodes. The activity recorded by a single intracranial electrode is essentially that of a small volume (approximately 1 cm^3) of neighboring brain tissue,[57] so that cognitive paradigms explored through such means are restricted to testing School I hypotheses. Aspects of attention,[58] emotion[59] and mental imagery[60,61] have been explored through such studies, in addition to studies of language[62,63] and memory.[64] Though there is evidence for high specificity of single sites for complex stimuli (see refs 65 and 66, for instance) it is also clear that responses to highly-defined stimuli may arise from widepread, disjoint parts of the brain.[67]

The latter naturally lead to the question of spatially distributed networks for cognition (School II). The intracranial EEG literature on this is rather more limited. There is no published study on cortico-cortical interactions during language processing; the study of Sinai and colleagues[63] identified local changes of gamma-frequency activity over sites that were subsequently identified as language-eloquent by electrical stimulation. Short-term visual memory was explored in a study of two patients,[68] who were asked to identify whether a presented shape had been shown previously or not. Synchronies in the beta range were found between the inferior temporal and occipital regions in both patients during the retentive portion of the task. Verbal memory was explored in patients with depth electrodes in the limbic structures and adjacent temporal lobe.[69] Gamma band synchrony was higher between the entorhinal cortex and hippocampus for words that were successfully recalled.

Summarizing, scalp EEG studies suggest that certain aspects of language and memory have a large cortical distribution; other aspects, relating to some paradigms and choice of particular induced rhythm, point to a more focal distribution over the classical areas of the dominant hemisphere. By contrast, MEG studies with source localization methods reliably achieve asymmetric activations. For memory, the current EEG literature perhaps indicates nonspecific aspects of processing, pending further studies that arrive at the appropriate paradigms and signal-processing methods to identify more focal activation. Neurophysiological results obtained with invasive data are thus anticipated: there is evidence of *both* extreme focality as well as distributedness to the representation of cognitive function.

Language-associated phase synchrony in intracranial EEG

We studied auditory language perception in five pre-surgical epilepsy patients undergoing invasive EEG (iEEG) evaluation with subdural grids.[70] The clinical indication for iEEG in these patients was to precisely identify the ictal onset zone (which was unclear on standard noninvasive investigations), as well as demarcate this area from (traditionally-defined) eloquent cortex. The research study sought to further identify 'language-eloquent' areas by the method of phase synchrony in contrast to those identified by conventional means.

Methods

Study participants were recruited from consecutive patients who were older than 15 years, right-handed, native English speaking, having normal or near-normal baseline cognitive function, and electrode coverage over the left (language dominant) hemisphere including at least the posterior part of the lateral temporal lobe. Three of the five patients had normal high-resolution MRI brain scans. Clinical characteristics of the patients are summarized in Table 111.1. Recordings were performed extraoperatively, at least 48 hours after the operative procedure for grid implantation, and before any EEG or clinical seizures were observed. For technical reasons, not all implanted electrodes could be recorded from in every patient.

Full details will be provided elsewhere; essential methodology and central results are described here. Stimuli were presented on a computer screen (Superlab; Cedrus Corp, San Pedro, CA, USA) and marked simultaneously on running digital EEG. Data processing was done offline (Matlab; The Mathworks, Inc., Natick, MA, USA) and adapted from recently published sources on phase synchrony analysis.[3,43,45] Two types of auditory stimuli were presented: either a short segment (~20 s) of normally-spoken English, or an equivalent length of 'pseudospeech' (defined below). The subject was asked to pay attention to the stimulus and try to understand it, while looking at a visual target (a black dot) on a computer screen placed a convenient distance away. Subjects were informed prior to the experiment that they would hear a random assortment of speech segments in English or an unknown language. The 'unknown language' (unintelligible to all patients) was in reality pseudospeech – reversed play of the same English segment presented either immediately before, or after. Six different sets of speech and pseudospeech segments were presented; the experimental data thus comprised 6 sets of 20-second EEG, each set corresponding to one speech and one pseudospeech segment. Raw EEG was filtered into two passbands (10–30 Hz; 30–50 Hz), after which each epoch was further divided into four 5-second blocks. PLFs (as above) were calculated for each data block for every possible combination of electrodes. Thus, 24 PLFs (4 blocks of 6 sets) were calculated for each electrode pair, corresponding to each speech and pseudospeech perception task.

Results

Significant differences of mean PLF (mPLF) between the target and distractor tasks were assessed with a Student's

Table 111.1 Clinical characteristics of subjects

Case	Age, sex	Epilepsy	MRI	No of electrodes implanted
I	18, M	Left TLE	Normal	116
II	40, M	Left TLE	Normal	140
III	18, F	Left FLE	Cortical dysplasia left orbitofrontal region	122
IV	21, M	Left PLE	Previous resection left parietal PNET	147
V	17, F	Left TLE	Normal	90

TLE: temporal lobe epilepsy; FLE: frontal lobe epilepsy; PLE: parietal lobe epilepsy. PNET: primitive neuroectodermal tumor.

t-test ($p = 0.01$). Both increases and decreases of mPLF were observed, corresponding to the physical conditions of 'synchrony' or 'desynchrony'. We sought to obtain a 'map' of significant, language-related dynamic connections, between different pairs of electrodes. This is diagrammatically illustrated in Figure 111.2, which shows real data from an experimental subject (Case I). We identified 93 significant dynamic connections in this patient during auditory language processing, roughly half corresponding to a significant increase of synchrony, the remainder corresponding to a significant decrease of synchrony (i.e., increase of desynchrony). We interpreted these as foci of language-participating cortex.

At a later stage in their pre-surgical evaluation, all patients also underwent mapping of language-eloquent areas with electrical stimulation. We used the usual method of delivering 50 Hz electrical pulses of various amplitudes to the cortical surface through the electrodes for several seconds, while the patient was tested with tasks such as reading, naming objects, or following spoken commands. The patient's inability to follow the task during the stimulation was attributed to the presence of elementary language function in the cortex directly beneath the stimulating electrode.

Summarizing the results, statistically significant changes of phase synchrony were observed in a small (1–2%) proportion of electrode pairs, in Cases I, II and III. For brevity, only Case I's results are amplified below; Cases II and III were qualitatively similar. Significant changes were either an increase (synchrony) or decrease (desynchrony) of mPLF during the target speech perception task, in comparison to the control task, and were independent of frequency band (10–30 Hz or 30–50 Hz). Significant nodes (electrodes) were scattered over the hemisphere, bearing no clear spatial relation to the classical language areas identified by cortical stimulation. Figures 111.3a–c show the location of significant nodes in this patient, along with their transcortical projections. The position of the classical language areas identified by cortical stimulation is also shown. Figure 111.3(a) gives an impression of the overall subdural grid positioning; a total of seven significant nodes (electrodes) of synchrony or desynchrony are marked (with a number, as well as small letter 's' or 'd'). This denotes the number of significant connections made by that electrode, and whether they were of synchrony or desynchrony. Figure 111.3(a) thus shows there were 2 nodes of desynchrony (10–30 Hz) in the posterolateral temporal region, one node of desynchrony (30–50 Hz) and one of synchrony (30–50 Hz) in the orbitofrontal region, two nodes of synchrony (10–30 Hz; 30–50 Hz) in the anterolateral temporal region, and one node of synchrony in the lateral frontal region (10–30 Hz). It can be seen that none of these overlapped the receptive or expressive language areas identified (in their usual locations) by cortical stimulation. Transcortical connections of the seven significant electrodes were mainly projections to the anterolateral temporal lobe (Figure 111.3(b, c)).

Comments

Our language paradigm was designed to be easily reproducible and non-demanding of patient effort. Nevertheless, the literature[23–26] suggests that it may have been sufficiently discriminatory to separate language from nonlanguage and attentional confounds. For data processing, we chose to use phase synchrony for reasons outlined above. Our finding, in three of five patients during language processing, was of distant projections of a small number of significant nodes to other areas in the hemisphere, mostly to the convexity of the adjacent temporal neocortex. Significant nodes had no particular relation to eloquent areas identified by stimulation mapping. Long-distance interaction occurred between electrodes without involvement of intermediate sites, excluding volume conduction or reference contamination as an explanation for inter-electrode synchrony.

EEG/MEG-defined eloquent cortex

This chapter has discussed EEG and MEG synchrony in the more general context of the neurophysiological correlates of cognition. We have presented the view that the majority of EEG

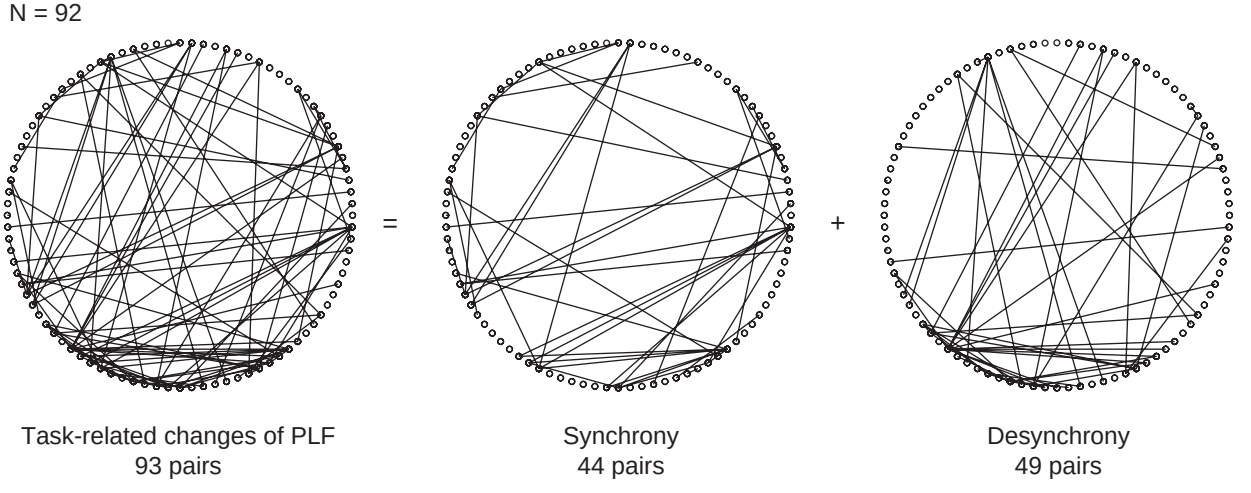

Figure 111.2 Connectivity map (10–30 Hz passband) of Case 1. Each circle represents an electrode. Each line represents statistically significant changes of PLF during the language task between the two corresponding electrodes. There were a total of 92 electrodes in this patient; 93 electrode pairs (out of a possible 4186) showed significant language-related phase changes (left figure). These were either increases (synchrony; middle figure) or decreases (desynchrony; right figure) during the task.

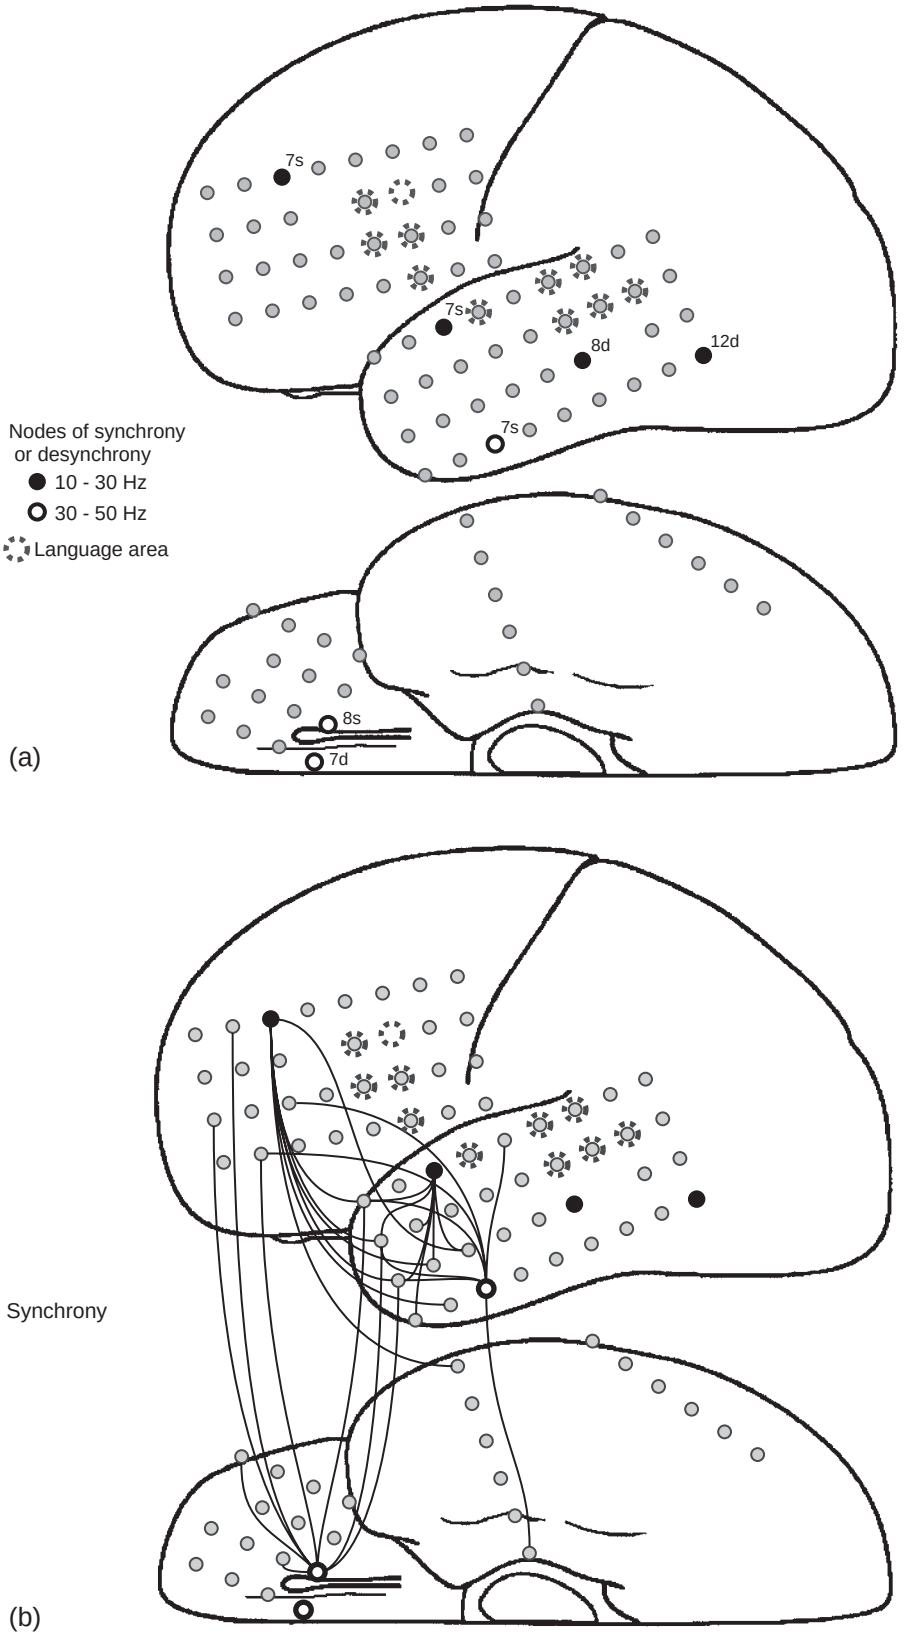

Figure 111.3 (a) The overall positioning of subdural electrodes in Case I, covering the left frontotemporal convexity, orbitofrontal region and basal temporal and temporo-occipital regions. Each circle (of any type) denotes an electrode contact. Electrodes with a sunburst halo denote language-eloquent sites as determined by stimulation mapping. Solid (10–30 Hz passband) and empty (30–50 Hz passband) circles indicate nodes of significant synchrony or desynchrony, along with the number of such connections. For example, the solid circle marked '12d' over the lateral posterior temporal cortex indicates a node of significant desynchrony connecting to 12 other nodes in the 10–30 Hz passband. (b) Transcortical connections of the synchronous nodes (lines emanating from solid and empty circles).

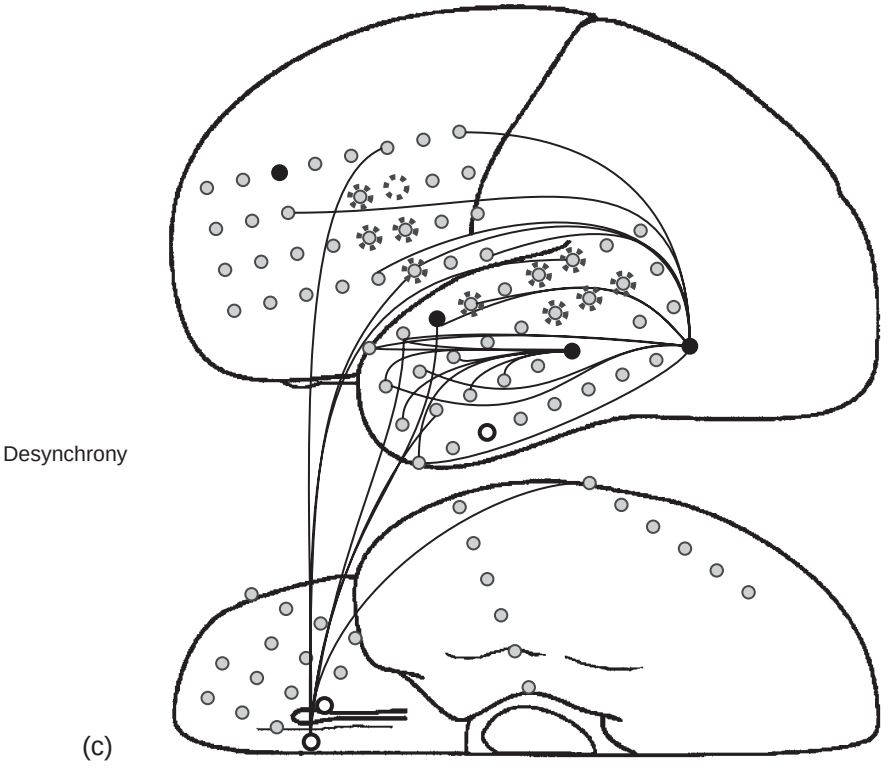

Figure 111.3, cont'd (c) Transcortical connections of desynchronous nodes (lines emanating from the solid and empty circles).

(both nonivasive and invasive) and MEG work may be grouped into an interpretation that argues for both the 'grandmother cell' and 'functional neural assembly' models of cognition. Indeed, experimental design and data gathering/processing methods are influenced by whether the experimenter's biases are 'localizationist' or 'globalist'.[71] We have described phase synchrony analysis as a tool for investigating hypotheses driven by the latter view.

The clinical coalface demands that resective surgery in patients spare eloquent cortex, however that may be identified. It is clear that resection of primary speech, motor, sensory and visual areas (as unequivocally identified by stimulation mapping) results in significant long-term neurological deficit. Beyond this bare fact, the interpretation of research studies is just one of several practical difficulties in defining 'eloquent' cortex. First is the familiar situation of the patient who wakes up postoperatively with a neurological deficit, even after 'safe' resections.These deficits usually resolve in a few weeks, and are put down to local tissue changes from trauma. Yet, the argument that such deficits result from resection of truly eloquent cortex whose function is rapidly subsumed by neighboring areas, cannot be dismissed. Second, all epileptologists recognize that certain areas of the cortex (e.g., the basal temporal language area; the supplementary motor area) are 'eloquent' to electrical stimulation, yet perfectly dispensible. Third, some patients experience minor longer-term deficits from even carefully-tailored resections. Finally, eloquence as defined by electrical stimulation is not identical to that obtained by focal cooling or transcranial magnetic stimulation, and is substantially different from techniques that map activity-related blood flow (functional imaging).

These caveats notwithstanding, what role may be envisaged for phase-synchrony identified eloquent cortex? The current state of the art only admits speculative interpretation, pending further work that reveals common patterns to synchronous nodes across patients. The outstanding observation of our language study was that significant nodes did not overlap Wernicke/Broca. While this indicates the corresponding regions of cortex were not indispensable to language, the question of their functional significance remains. Ojemann and colleagues document the wide perisylvian representation of language, essentially over a region distributed between, and surrounding, the classical speech areas.[22] Our results, particularly those of the projections of significant synchronous nodes, appear visually similar. A more formal comparison must await further work. Clearly, this is just one of a number of open issues: what is the reproducibility of synchronous node patterns? is there a dependence on type of language task? what paradigms *do* in fact activate Wernicke/Broca?

The most persuasive evidence for phase synchrony analysis relating to 'orthodox' eloquent cortex, to our knowledge, is the MEG study of Simoes and co-workers.[72] The right median nerve was stimulated in normal volunteers. The normal MEG response over the contralateral primary sensory area (S1) phase-locked with activity from the ipsilateral second sensory area (SII) at frequencies ≈20 Hz and at a latency of 80–90 ms after stimuli. The authors excluded the possibilities of synchrony arising from a common response to the stimulus, and volume conduction from a common source. Again, though these results identify areas of cortex known to be eloquent, the interpretation of phase synchrony itself is less clear. Ipsilateral sensory deficits with lesions of SII are not described to our knowledge, though sensory symptoms during seizures or stimulation involving SII commonly include the ipsilateral side of the body.[73]

Neurobiological issues

The scientific underpinnings and implications of electroencephalography and magnetoencephalography have traditionally stayed ahead, and aside, of clinical application. Some argue that recent advances in data gathering, signal processing and multimodality imaging may change this relationship in the future.[74] However, there is little doubt that the neurophysiology of phase synchrony and coherence requires further systematic study in patient groups before it can be put to practical clinical use. The gathering of such data, though, may be valuable to wider scientific enterprise.

The profound 'perceptual binding problem' is one such: how does the sense of a unified percept arise, despite the distributed processing architecture of the brain? The observation of Gray and colleagues[75] of intercolumnar synchrony in the cat visual cortex relating to global stimulus attributes provided the first experimental evidence for the Hebbian idea of perceptual binding occurring via neural 'temporal correlation'.[76] This idea now pervades integrative neuroscience (for reviews, see refs 16 and 17) and has been the foundation for recent theories of brain function.[77] While detection of interareal synchrony inform the binding problem, identification of participating areas constitute brain mapping. Apart from identifying eloquent cortex, this is relevant to understanding neural information processing (e.g., language) and the functional anatomy of integrated action (e.g., motor tasks).[78] Clinical relevant applications include identification of epileptogenic neural networks and tracing of seizure propagation pathways.[79,80] Finally, results of neurophysiological investigation may retrospectively inform experimental hypotheses and help develop brain theories.[3,81]

112 Cortical mapping using evoked potentials and Bereitschaftspotentials

A Ikeda and H Shibasaki

Introduction

Surgical treatment for medically intractable partial epilepsy is currently regarded clinically useful, and the ways of presurgical evaluation especially in mesial temporal lobe epilepsy have been well formulated among institutes.[1] On the other hand, the success of epilepsy surgery in patients with neocortical epilepsy, i.e., the maximum seizure control and the minimum functional deficits, strongly depends on presurgical evaluations.[2]

It is essential to delineate an epileptogenic zone and to define the functional area at or close to the epileptogenic zone for demarcating the boundary between resectable and unresectable areas, that varies significantly among patients. Detecting structural abnormalities is very important in epilepsy surgery, because it often plays a key role in generating seizures or in amplifying the seizure activity arising from or very close to the lesion. A great advance in imaging studies, especially fine anatominal analysis by MRI, enabled us to delineate even subtle, but very important, anatomical abnormalities such as cortical dysplasia or minute bleeding with cavernous angioma, that have not been detected by MRI in the old era. However, (1) we still have many patients who have cortical malfomation as intractable epileptogenic zone which is not detected by even current MRI investigation, and thus it is still very difficult to delineate the boundary between the epileptogenic and functional zones. (2) There are no established methods other than electrophysiological approach (i.e., cortical stimulation or evoked potentials, etc.) to define the functional area in a specific way. Functional MRI or magnetoencephalography could localize the eloquent area but its specificity and the reliability are not sufficient for presurgical decision. Based on these two reasons, presurgical examination by means of chronically implanted subdural electrodes is still a very specific, gold standard to complete the above two purposes (delineate an epileptogenic zone and functionally important zone), as compared with other invasive methods (depth electrode, foramen oval electrodes, epidural electrodes).[3] Furthermore, not only the primary sensori-motor areas but also ones employing higher cortical functions such as language, higher motor control or memory are very important, and so far only electric cortical stimulation can assess all of them. Evoked potential studies could delineate most of the primary cortices and several, nonprimary higher cortical areas as well.

In this chapter, we will describe the functional mapping of the primary and non-primary cortices by means pf evoked potentials, including Bereitschaftspotentials (BP)[4,5] for motor mapping from the viewpoint of epilepsy surgery.

Recording of sensory evoked potentials

Currently both cortical electric stimulation (employing high-frequency electric pulses) and sensory evoked potentials are clinically established methods for functional cortical mapping. Cortical electric stimulation will be extensively discussed in another chapter, and it would be worthwhile mentioning that this method activates or depolarizes the cortical neurons by intensive electric current (exogenous excitation), and elicits the behavioral response of the patients. The obtained cortical mapping would not be necessarily identical to one by evoked potentials because the latter reflects the intrinsic, cortical neuronal activation by means of positive afferent input or by endogenous neuronal activation before voluntary movements. Therefore, the final interpretation for cortical mapping should be made by taking all the considerato n into account.

Subdural recording of somatosensory-, auditory- and visually-evoked potentials can localize the primary sensory cortices.[6] For somatosensory evoked potentials (SEPs), the primary somatosensory cortex (SI),[7–10] the second sensory area (SII)[11–13] and supplementary motor area (SMA) proper[14–16] can generate them (Table 112.1).

Recording equipment and methods

Clinical applications of those short-latency, evoked potentials in epilepsy surgery has started in the 1980s,[6] and the recording principle is essentially the same as that in noninvasive recording. The only difference is decreased sensitivity setting by 1/7 – 1/10 because of direct epicortical recording. Since the purpose of the recording is to delineate cortical function by detecting near field potentials, it is important to select the proper reference electrode at Grid 2 which would not pick up either far-field or near-field potentials. One of the implanted subdural electrodes is chosen which records neither spikes or slow waves, and thus is presumably located on the

Table 112.1 Sensory evoked potentials for cortical mapping in epilepsy surgery

	Main generators depending on the latencies		
Sensory evoked potentials	***Short***	***Middle***	***Long***
Somatosensory			
electric	SI (area 3b,1)	SII, SMA	TPJ
pain			SII,SMA SI (area 1) TPJ
passive movements	SI (area 3a,2)	SMA	TPJ
Visual			
pattern reversal		V1	
motion		V5	
flash		V1 and others	
Auditory			
tone burst	PAC	PAC and others	

Essential criteria of short, middle, and long latencies (<30 msec, 30–75 msec and >75 msec, respectively) were adopted from Chiappa.[61]
SI = primary somatosensory cortex, SII = second sensory area, SMA = supplementary motor area, TPL = temporo-papietal junction, PAC = primary auditory cortex.

nonfunctional area. With regard to the occurrence of far-field potentials, it is usually negligible because the sensitivity is too low to pick up the far-field potentials arising from the reference electrode. Currently available equipment for evoked-potential recording could record and average signals in multiple channels of more than 20 or 40 simultaneously, or digital EEG machines could record ECoG signals of more than 100 electrodes with a high sampling rate applicable for even short-latency evoked potentials, and thus the data are transferred to the other software to make averages and analysis.[17]

Somatosensory evoked potentials (SEPs)

Short-latency SEPs

Short-latency SEPs to peripheral nerve stimulation by electric current are clinically useful to define the central sulcus. In electric stimulation, median, tibial and lip (or trigeminal) nerve stimulation are clinically applied in subdural recording. Low-frequency filters (LFF) and high-frequency filters (HFF) are set to 15–30 Hz and 1500–3000 Hz, respectively, and the HFF depends on the limitation of the sampling rate, which is set to 3–5 per sec, as is done in the scalp recording.

For median nerve stimulation, N20–P20 complex, P25, P30–N30 complex, and N35 are identified in the contralateral hemisphere[7–10] as shown in Figure 112.1 and Table 112.2. Tangential and radial dipoles are located in the posterior bank of the central sulcus and in the crown of the postcentral gyrus, respectively. It would be noteworthy that: (1) since the central sulcus is not always oriented perpendicular to the lateral convexity surface even in normal brain, the tangential dipole is not well detected as a pair of positive and negative fields across the central sulcus in a rostra-caudal direction, and thus, if so, only one polarity would be picked up; (2) a tangential dipole not infrequently shows 0.5–2.0 msec time difference of the peak latency between a pair of negative and positive field potentials since the whole layers of cerebral cortex are not activated simultaneously by an afferent volley but sequentially from layers III–IV to more superficial layers;[14] and (3) in patients with partial epilepsy having seizure focus close to the central sulcus, normal functional distribution could be distorted very much. Thus, the final interpretation of the data should take all the other aspects including anatomical information and location of the epileptogenicity into account.

For tibial nerve stimulation, the initial peak latency potential is identified as P35 and is located in both pre- and post-central gyri in the paracentral lobule in the interhemispheric fissure.[18] There is no apparent phase reversal activities in subdural recording, as opposed to median nerve stimulation. It is because, in the paracentral lobule, the central sulcus becomes shallow and is ill-defined in the upper half of the paracentral

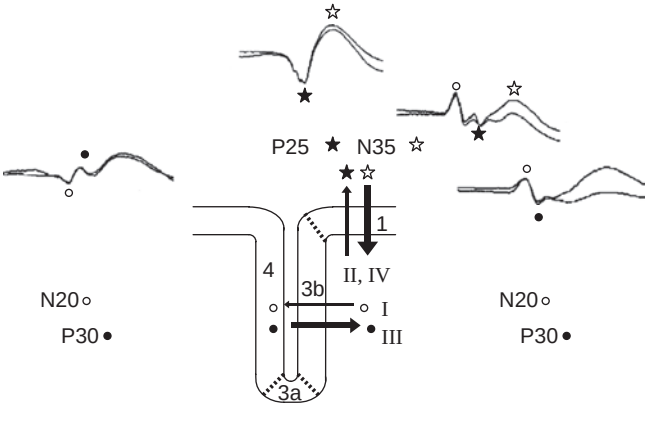

Figure 112.1 Schematic representation of origin of short-latency SEPs in humans. Nomenclature of potentials and dipole locations are adopted from the publications of Allison's group.[7–10] N20-P20 arises from the posterior bank of the central sulcus (area 3b), represented by a tangential dipole (I) generating parietal N20 and frontal P20 (as shown by open circles). It is followed by P25 arising from the crown part of the postcentral gyrus (area 1), represented by a radial dipole (II) which generates central P25 (as shown by a filled asterisk). Later, similar sequential activations occur in N30-P30 by a tangential dipole (III) in area 3b (as shown by filled circles), and then N35 by a radial dipole (IV) in area 1 (as shown by an open asterisk).

Table 112.2 Cortical generators of short latency SEPs to median nerve stimulation

Dipole	*Direction*	*Polarity*	*Origin*
N20–P20	Tangential	Frontal positive, parietal negative	Area 3b
P25	Radial	Central positive	Area 1
P30–N30	Tangential	Frontal negative, parietal positive	Area 3b
N35	Radial	Central positive	Area 1

lobule, and disappears in the lower half, that results in all the short-latency SEPs defined as the radial dipoles on the paracentral lobule. There is no apparent time difference of peak latencies between pre- and postcentral gyri.[18,19]

For lip stimulation, a pair of skin electrodes are placed in the edge of the unilateral lip and stimulated at 3–5 Hz, as done previously.[6] From the technical points of view, as opposed to the median or tibial nerve stimulation, lip stimulation on the skin easily causes large stimulus artifacts through Grid 1 or Grid 2, as the reference if placed in the contralateral mastoid process, and waveforms sometimes become obscured. Therefore, stimulation with alternate polarity between the stimulus skin electrodes or an ensemble with each half-set of stimulation by opposite polarity in one session is useful to eliminate the stimulus artifacts.[6] The initial evoked potential is labeled as P15 just located in the central sulcus.[6,20] The largest response to lip stimulation was located 1.5 cm ventrolateral to a response to median nerve stimulation.[21] Since the central sulcus in the face area is much deeper, a tangential dipole can be clearly present, but as mentioned above, when the central sulcus happened to be buried from the lateral convexity with an oblique angle, it would produce essentially one polarity activity across the central sulcus (Figure 112.2).[20]

Short-latency SEPs are also recorded from the SMA proper and pre-SMA. Initially all the responses from the SMA proper and pre-SMA were reported with latencies later than 40 msec irrespective of the stimulus sites in the body.[14,15,22] Recently, both pre-SMA and SMA proper showed the early potentials by means of depth electrodes, but the generators were judged to be remote, deep-seated structures,[16,23] and thus the potentials with peak latencies longer than 40 msec is clinically useful for functional mapping. From the practical point of view for functional mapping, primary foot motor area and foot area in the SMA proper are located very closely and the latter is, at times, defined in the lower half of the paracentral lobule extending the precentral sulcus posteriorly.[24] Electric cortical stimulation is not sufficient to differentiate between the two, and short-latency SEPs to tibial nerve stimulation is sometimes useful to define the boundary.[19]

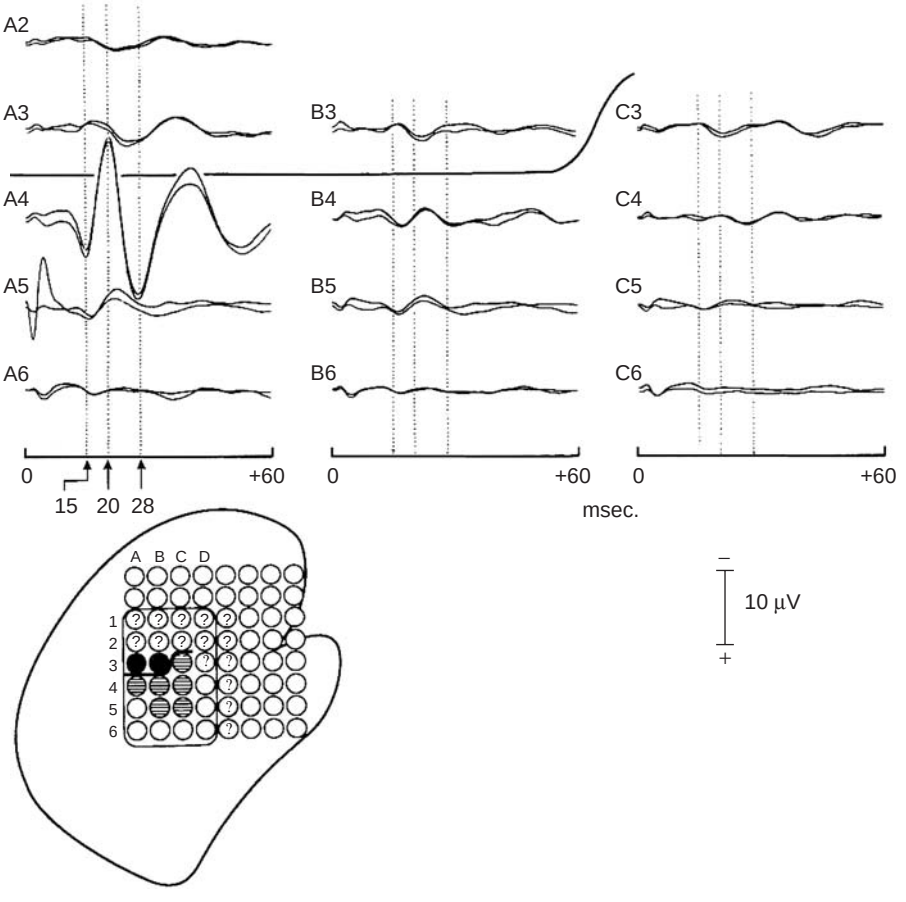

Figure 112.2 Subdural recording of SEPs to lip stimulation in a patient with electrode grid on the right pericentral cortex. A positive response (15 msec), a negative response (at 20 msec) and a positive response (28 msec) are shown by vertical dotted lines, respectively, which are maximum at the tongue sensory area delineated by cortical electric stimulation (cited from ref. 19 with permission).

In addition to electric stimulation for short-latency SEPs, passive movement SEPs are applied in scalp recording, and application to the subdural recording provides physiological information by showing the cortical generators of P22–25 most likely in the area 3a, 2 or 4.[25]

Middle to long latency SEPs

One of the most robust responses are from SII located along the sylvian fissure.[11–13] SII is located in on the superior bank of the sylvian fissure in the region of the planum infraparietale of the operuculum.[26] As opposed to the short-latency SEPs, it usually needs long interstimulus interval of more than 3 sec, and opened LFF is more preferable. Most of the response to median nerve stimulation showed the peak latencies of 140 msec, although delayed P25 by 2.4 msec was also recorded to the median nerve stimulation (Figure 112.3).[11]

In addition to electric stimulation, pain SEPs (Figure 112.4), and passive movement SEPs (Figure 112.5) employing proprioception are applied in scalp recording, and application of those modalities to the subdural recording provides physiological information. Pain SEPs in subdural electrodes or depth electrodes showed the sources in the SII and parietal operculum, and recently in SI with the peak latency of 220 msec.[27–29] Passive movement SEPs with short-latency showed broad positive potentials of 23.8–27.4 msec of latency along the central sulcus, suggesting the activation at areas 2, 3a, and 4 (Figure 112.5). Passive-movement SEPs with long latency will be described below in the section on temporo-parietal junction. As compared with short-latency SEPs, midde-latency SEPs may provide rather limited information for functional mapping in epilepsy surgery, mostly because those sources often showed no positive symptoms by cortical electric stimulation, or resection resulted in little functional deficits. However, in order to clarify the functional significance, it will be very important to accumulate the combined information on evoked potentials, cortical stimulation, functional MRI, and surgical outcome of function.

Auditory evoked potentials (AEPs)

The primary auditory cortex (PAC) (Area 41) is located on the transverse gyrus (Heschl's gyrus; HG) which lies on the dorsomedial surface of the superior temporal convolution, and is buried in the floor of the sylvian fissure. Therefore, a subdural electrode grid placed on the lateral convexity can record the potentials distant from PAC or from the surrounding cortices.[30] Only depth electrodes can approach PAC and the related structures which generate AEPs.

Currently, at least six auditory cortices are described within the superior temporal gyrus (STG), i.e., PAC located in the medial and intermediate part of the HG, secondary auditory cortex (SAC) located in the lateral part of HG, planum temporale (PT), caudal portion of the STG, anterior part of the STG and the long insular gyrus. In response to the tone burst stimuli of 1 kHz about every 1 sec with intensity of 70 dB, a series of near-field potentials are recorded. Only PAC can generate N13/P17/N30 complex as the earliest potentials, and other areas generate middle latencies of around 70 msec and then 140 msec in latency.[31–33]

Those auditory cortices other than PAC can contain the several specialized functions. The PT was for language processing, different types of spectrotemoral pattern processing such as spatial analysis pitch sequences, environmental sounds and music; the caudal portion of the STG for hierarchical auditory processing such as complex sound perception; and the insular cortex for auditory motion perception and vestibular functions. In general, resection of these auditory cortices may lead to a difficulty in sound localization, musical, or complex sound perception. From the practical point of view, differentiation of these several auditory cortices provides little clinical significance until each function will be established, and further accumulated studies is essential.[34]

Visual evoked potentials (VEPs)

In scalp recorded VEPs, N75, P100, and N145 are well observed in the occipital area with paradoxical lateralization, and thus the main generators are most likely the primary visual cortex burid in the calcarine fissure.[35,36] Setting of LFF and HFF is the same as one for scalp recording (1–100 Hz).

More than 50% of the striate cortex is occupied by the representation of the central 10° of vision. Therefore, with full-field stimulation, the net vector almost entirely reflects activity in the macular and paramacular areas of the visual area, the former being more representative than the latter. Nevertheless, central and peripheral vision may be checked by employing different stimulus conditions. Small checks (12–16 minutes) and small fields (2–4°) are for central vision, and the large checks (40–50 minutes) and large fields (16–32°) for peripheral vision.[37] Namely, in scalp-recorded VEP studies, peripheral hemifield stimulation can enhance contralateral negativity (N105) while the ipsilateral P100 markedly diminish (Figure 112.6).[38]

Nonprimary visual cortices such as V4 (inferior occipitotemporal region) and V5 (the lateral aspect of the posterior temporal lobe) are responsible for color and motion, respectively. Motion VEPs are not widely used in clinical medicine, but it would be useful to deliniate the V4 in patients with partial epilepsy as one of cortical mapping, but currently it is of limited use from the practical point of view (Figure 112.7).[39]

Flash-evoked VEPs are also applied but in the limited situation of scalp-evoked potential studies, because they are much more widespread, complex and variable than that of pattern reversal VEPs, their clinical significance would be very limited.

It was reported that frontal eye fields also generated VEPs with a latency of about 100 msec,[40] but it is not well supported by other institutes. In a CNV paradigm employing paired visual stimuli for both S1 and S2, the lateral dorsal premotor area can generate signal-related potentials (with a peak latency of 176–194 msec always after visual LED signals).[41]

Multisensory convergence of middle latency, evoked potentials

Temporo-parietal junction (TPJ) lesion is related to visual, auditory, and tactile extinction, and the posterior part of the STG lesion causes hemispatial neglect. In the subdural evoked-potential studies, SEPs, VEPs and AEPs were employed to obtain

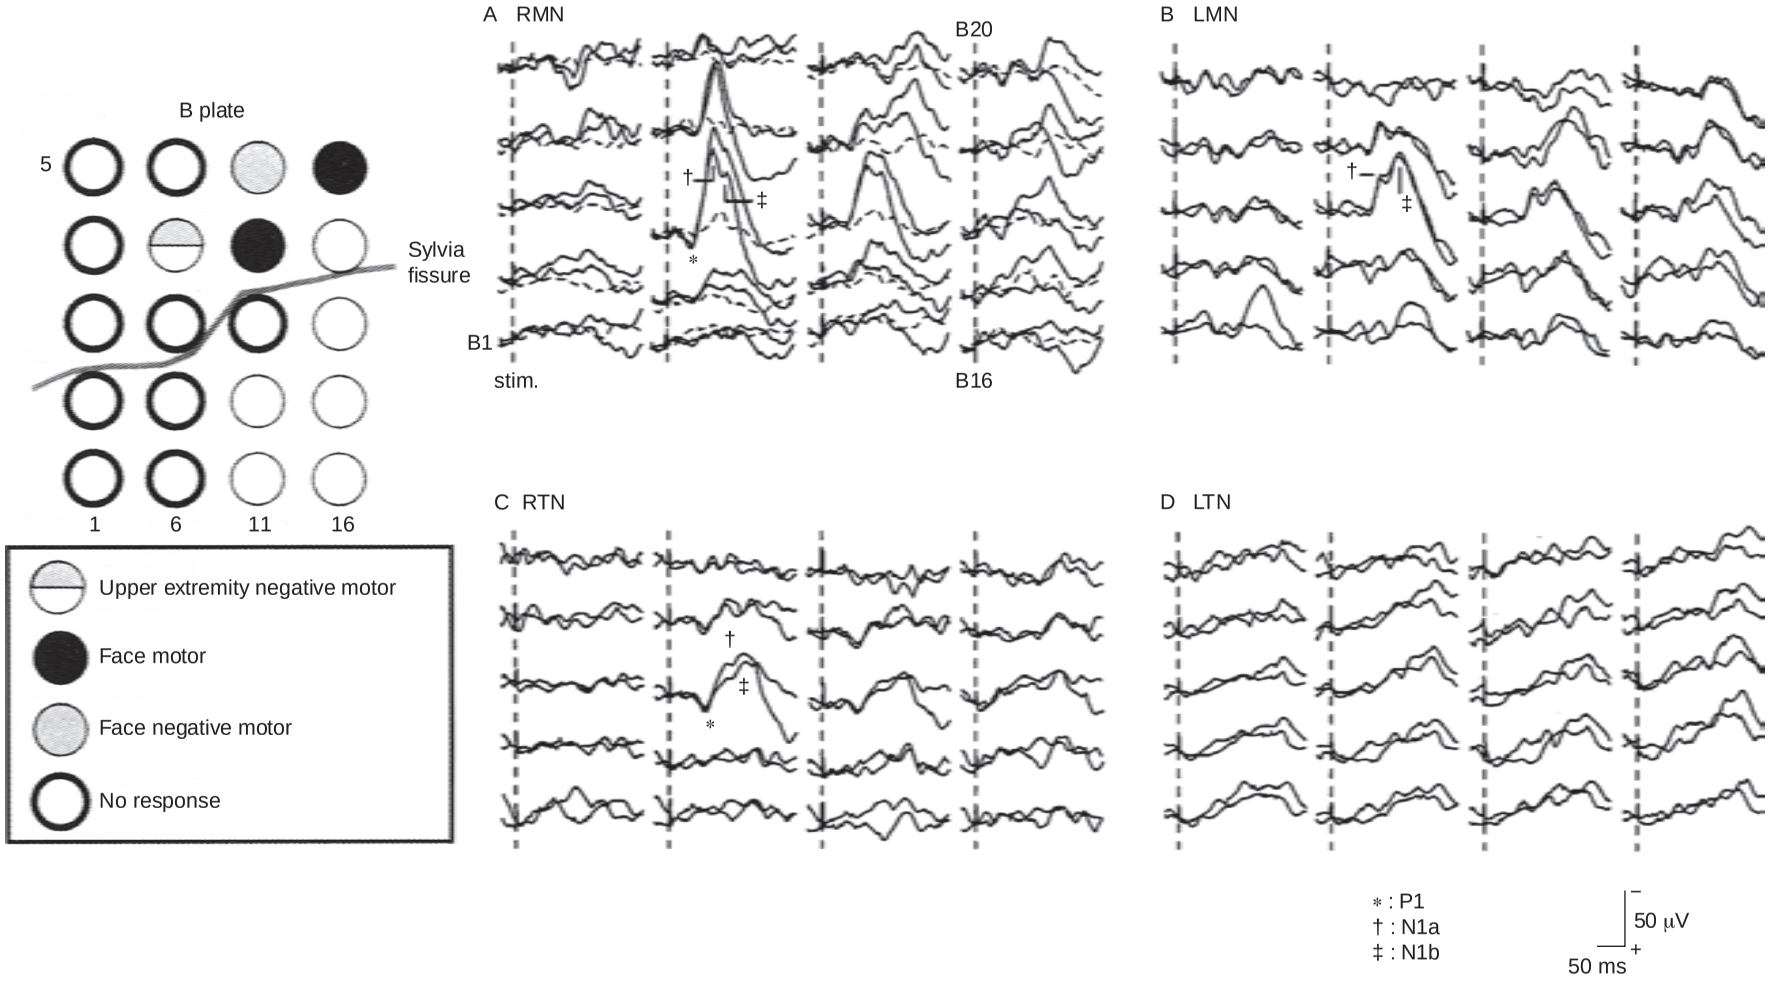

Figure 112.3 SEPs recorded subdurally from the electrode grid on the left frontal cortex (left half), in response to electric stimulation of the right (A) and the left (B) median nerve at the wrist, and the right (C) and the left (D) tibial nerve at the ankle (right half). Two sets of SEPs with ISI of 2.9 s are superimposed. SEPs with the shorter ISI (0.9 s) are also shown by interrupted lines in (A). Vertical interrupted lines show the stimulus onset. Each recognisable peak is indicated in the figure by the same symbols (cited from ref. 12 with permission). RMN = right median nerve, LMN = left median nerve, RTN = right tibial nerve, LTN = left tibial nerve.

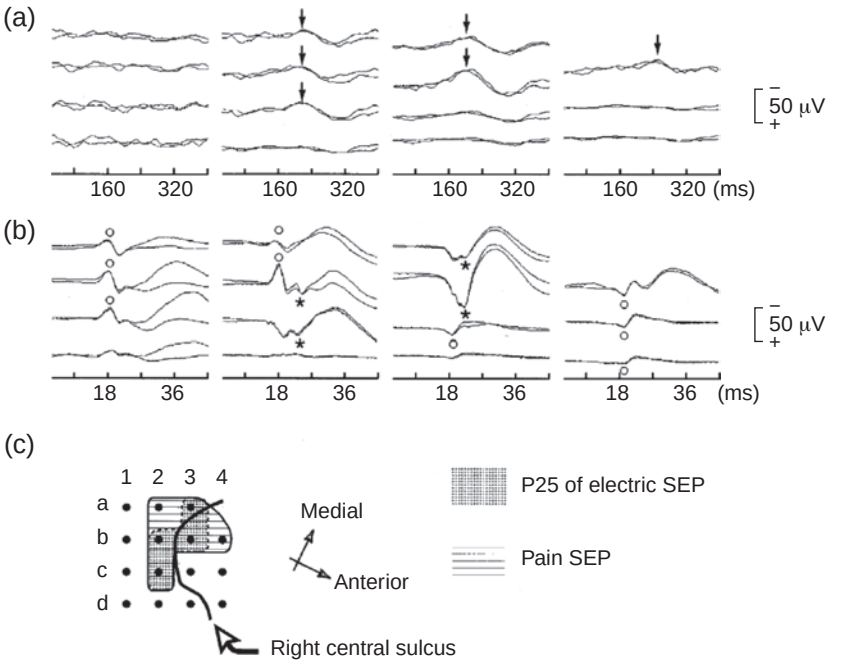

Figure 112.4 SEPs recorded subdurally from the right perirolandic cortex to painful CO_2 laser stimulation of the dorsum of the left hand (a) and to electric stimulation of the left median nerve at wrist (b) in an epileptic patient. Each electrode position is shown in c. a: Arrows indicate the first negative deflection to painful CO_2 laser stimulation with a peak latency of 220 ms. b: Open circles indicate N20 and P20 of electric SEPs along the postcentral gyrus, and asterisks show P25 located slightly medial-anterior to N20. Note that the cortical area involved by the negative potential of pain SEP is larger than that for P25 of electric SEPs (cited from ref. 29 with permission).

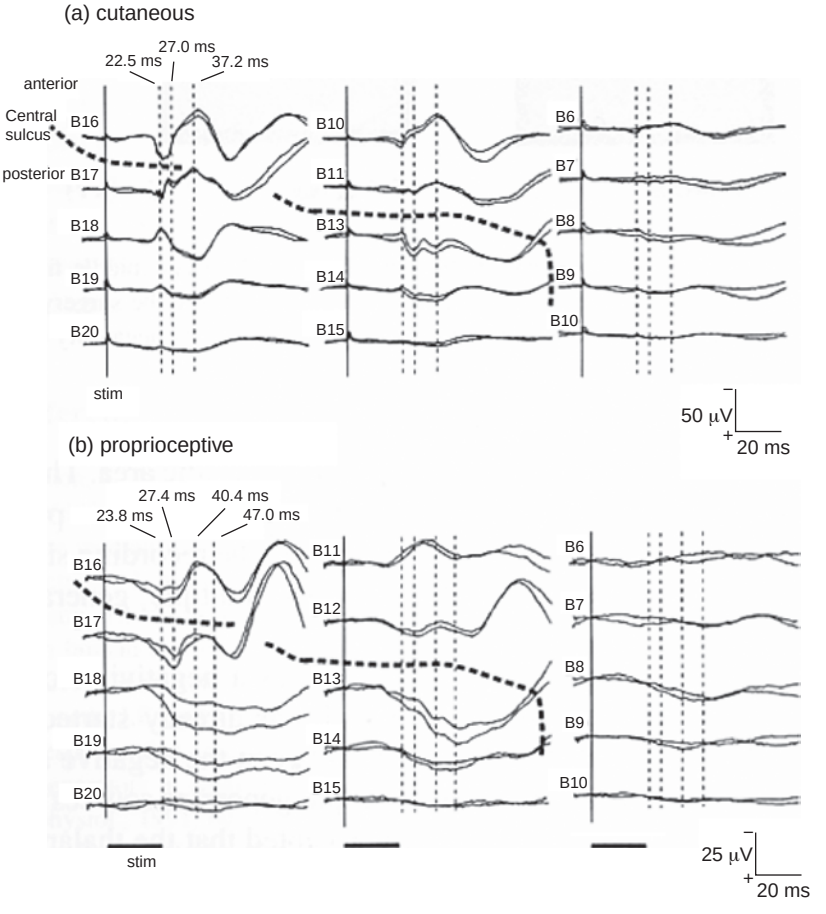

Figure 112.5 SEPs recorded subdurally from the right perirolandic cortex to electric stimulation of the right middle finger (a), and to the proprioceptive stimulation of the same finger by passive finger motion. Thick, dotted lines indicate the location of the central sulcus. For proprioceptive stimulation, the duration of the passive movement is demonstrated as a horizontal black bar at the bottom (4° in 25 ms) (cited from ref. 25 with permission).

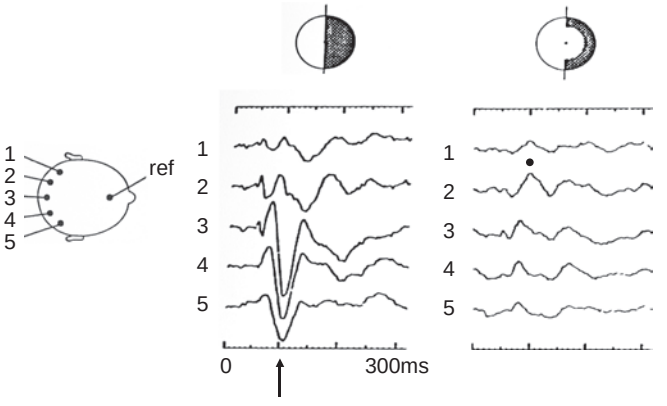

Figure 112.6 The effects of increasing of radii experimental scotomata on the right half-field stimuli in a normal subject. Results of intact half-field (left) and 10° of scotoma (left) are shown. P100s (as shown by an arrow) are elicited more on the right occipital area in response to the right half-field stimuli (left), while contralateral N105 (as shown by a dot) is enhanced and P100s are attenuated for right half-field stimuli with 10° of scotoma (right). (modified from ref. 38 with permission).

the common response area.[42] As compared with ordinary short-latency, evoked potential studies, LFF was set to shorter, and the interstimulus interval was set to longer; every 3–4 sec in SEPs, every 3.33 sec in AEPs, every 294 msec in pattern-reversal VEPs. In motion VEPs, the gating pattern moved to a horizontal direction at an angular velocity of 22° per sec for 500 msec.

In the results, the most prominent responses were either positive or negative in polarity among subjects, and the polarity was consistent regardless of the stimulus modality within each individual subject. The peak latencies of SEPs were 50–115 msec to median nerve stimulation, 75–160 msec to tibial nerve stimulation, 60–120 msec to passive finger movement and 310–340 msec to hand pain stimulation. The peak latencies of AEPs ranged from 50–220 msec, pattern-reversal VEPs of 105–130 msec, and motion VEPs of 125–300 msec. Among five patients investigated in a previous studies, essentially one electrode within the large electrode grid showed a common respose in the posterior end of the superior temporal sulcus (Figures 112.8 and 9). It may correspond to the superior temporal polysensory area (STPA) in monkeys.

The response from the SII is described in above. TPJ is clearly different from SII as follows: (1) SII is located more anterior along the sylvian fissure close to the rolandic fissure; (2) SII generates potentials to the somatosensory stimulation of either hand or foot but not to the other modalities; and (3) a somatotopy in response to upper and lower nerve stimulation is present within SII whereas TPJ show a small, common response area.

Bereitschaftspotential (BP) for mapping of motor cortices

For mapping the SI, recording of SEPs and high frequency-cortical stimulations are equally useful. Central sulcus could be delineated by SEPs, but it does not directly represent the location of the primary motor cortex (MI) but merely either radial or tangential dipoles arising from the postcentral gyrus, as shown in Figure 112.1. Therefore, only cortical stimulation was reliable for direct mapping of MI, and no evoked potentials arising from MI were clinically available. As with SEPs for the postcentral gyrus, we have proposed the clinical usefulness of BP for localization of the motor cortices in epilepsy surgery.[43–47]

BP is defined as the slow cortical potentials arising from the motor cortices occurring about 1.5 sec before the onset of self-paced voluntary movements, and it is only recorded with the long time constant of the amplifier. BP reflects excitatory postsynaptic potentials (EPSPs) in the superficial layer of the motor cortex occurring in the apical dendrites of the pyramidal neurons.[48]

It is well accepted that premovement potentials consist of three components regardless of movement sites of the body; BP in a narrow meaning or readiness potential,[4] negative slope (NS')[5] and motor potential (MP) (Table 112.3).[4] It is followed by postmovement potentials called reafferente Potentiale (RAP).[4] All the four components are called together as movement-related cortical potentials (MRCPs).[5]

Motor mapping by BP accompanies the following four positive characteristics: (1) it reflects the endogenous activity of the motor cortices which are actually involved in preparation for and execution of voluntary movements, (2) BP is examined for voluntary movements of any parts of the body,[49,50] (3) cortical activity at the bank in the sulcus (like the anterior bank in the central sulcus) can be recorded as a tangential dipole, and (4) it is not associated with the risk of seizure induction in contrast to high frequency cortical electric stimulation. On the other hand, BP has the following two negative characteristics as compared with cortical electric stimulation: (1) voluntary movements of one kind should be repeated at least 50 times to obtain averaged wave forms, and (2) thus it needs the patient's cooperation to conduct the task of voluntary movements and to obtain the satisfactory results.

We routinely perform direct recording of BPs by using chronically implanted subdural electrodes in the presurgical evaluation of the motor cortices.

Recording condition and methods

As conventional chronic subdural EEG monitoring, HFF is set to the same condition as that of scalp-EEG recording, but

Table 112.3 Movement-related potentials (MRCPs) for cortical mapping in epilepsy surgery

	*Onset time**	*Origin*	*Laterality*
BP	–2–1.5 sec	Pre-SMA, SMA proper, MI-SI, premotor	Bilateral
NS'	–0.3 sec	Pre-SMA, SMA proper, MI-SI	Bilateral Contralateral dominance
MP	–50 msec	SMA proper, MI-SI	Contralateral
RAP	after movement	SI	Contralateral

* Onset time is measured from EMG onset of movements.
BP = Bereitschaftspotential (readiness potential), NS' = negative slope, MP = motor potential, RAP = reafferent potential, MI-SI = primary sensorimotor cortices.

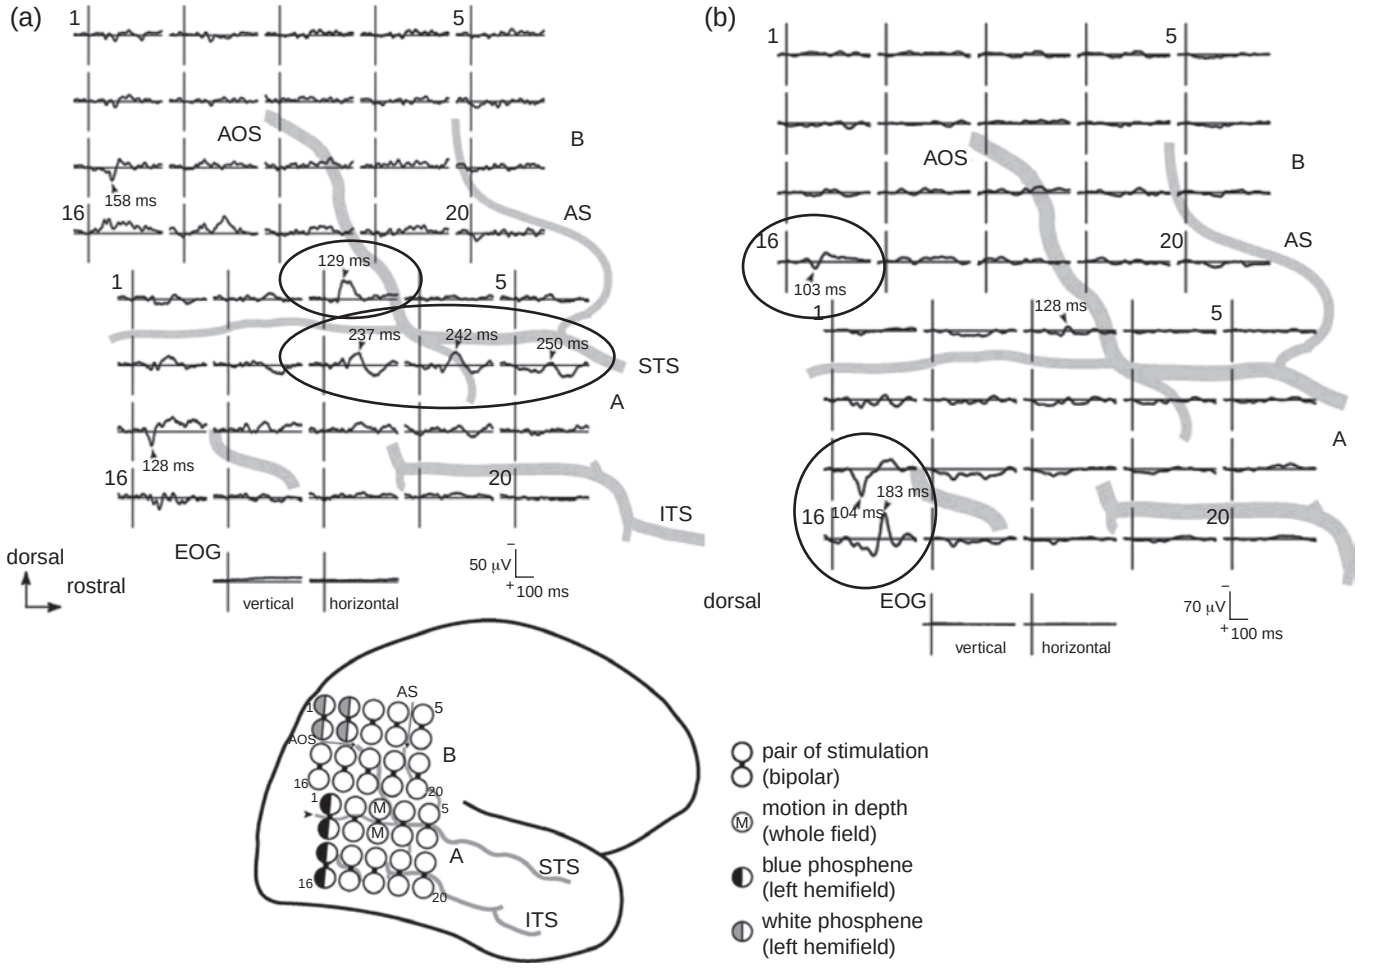

Figure 112.7 Subdural recording of motion-related visual-evoked potentials (motion VEPs) (left) and visual-evoked potentials to pattern reversal stimuli(pattern VEPs) (right). Group average waveforms are shown in relation to sulci. In motion VEPs, prominent responses were recorded in the dorso-rostral quadrant of Plate A (A3, A8–10), whereas in pattern VEPs large primary potentials at the caudal end of plates (A11, A16, B16) in the lateral occipital area. Results of cortical electric stimulation are shown in the lower figure. Motion-in-depth perception involving the whole visual field was elicited by stimulating a pair of A3 and A8, while stationary phosphenes in the left visual hemifield were elicited by stimulating the caudal part of grids (pairs of A1-6, 11-16, B1-6, 2-7). STS: superior temporal sulcus, ITS: inferior temporal sulcus, AS: angular sulcus, AOS: anterior occipital sulcus. STS had double ending to AS and AOS. An arrowhead shows a sulcus extending to the occipital area from the end of STS (cited from ref. 39 with permission).

opening of LFF down to 0.03 or even 0.01 Hz is important to record slow subdural EEG satisfactorily. As opposed to scalp-recorded BP, subdural EEG of slow shift is well recorded without significant slow artifacts, even though the patients do not necessarily remain motionless on the bed. EEG signals are continuously recorded with the sampling rate of at least 200 Hz, preferentially 500 Hz. When fast activity is aimed for analysis, a larger sampling rate such as 1000 Hz is recommended. Sensitivity is usually set to 70 μV/mm, one seventh of that of scalp EEG.

Recording can be started soon after patients recover from the first craniotomy to place the subdural electrode grids. Surface EMG and EOG are recorded simultaneously as done in the scalp-EEG studies. In scalp EEG studies, EOG is monitored in order to exclude the EOG artifacts on the scalp-EEG. Subdural EEG is almost free from artifacts of extracranial origin such as EMG or EOG. Therefore, EOG is not necessarily monitored in this respect.[51]

For obtaining BP, voluntary movements of any parts of the body can be examined as long as fiducial points can be accurately timed with the movement onset, and this depends on the purpose of the recording. The movement should be identical and self-paced at intervals of 5–10 sec. Subdural EEGs are finally averaged backward and forward time-locked to the trigger pulse, for which the onset of surface EMG discharge is usually used. Subdural EEG has a better S/N ratio than scalp EEG, but at least 50 trials should be averaged for one session. Rapid-rate of movement task (1–2 Hz) is also applicable to delineate the cortical generator of MI.[52]

Multiple cortical generators of BPs

Based on the distribution of each component over the scalp, the BP was thought to represent the activity of the bilateral supplementary motor areas (SMAs), while the NS' and MP mainly reflect the activities of the contralateral primary motor and sensory cortices (MI-SI). So far, subdural EEG studies revealed that MI-SI, SMA proper and pre-SMA are main cortical generators of those premovement potentials (BP, NS′, and MP) (Figure 112.10) (Table 112.4),[53] and a part of the premotor area also generates BP of positive polarity.[54]

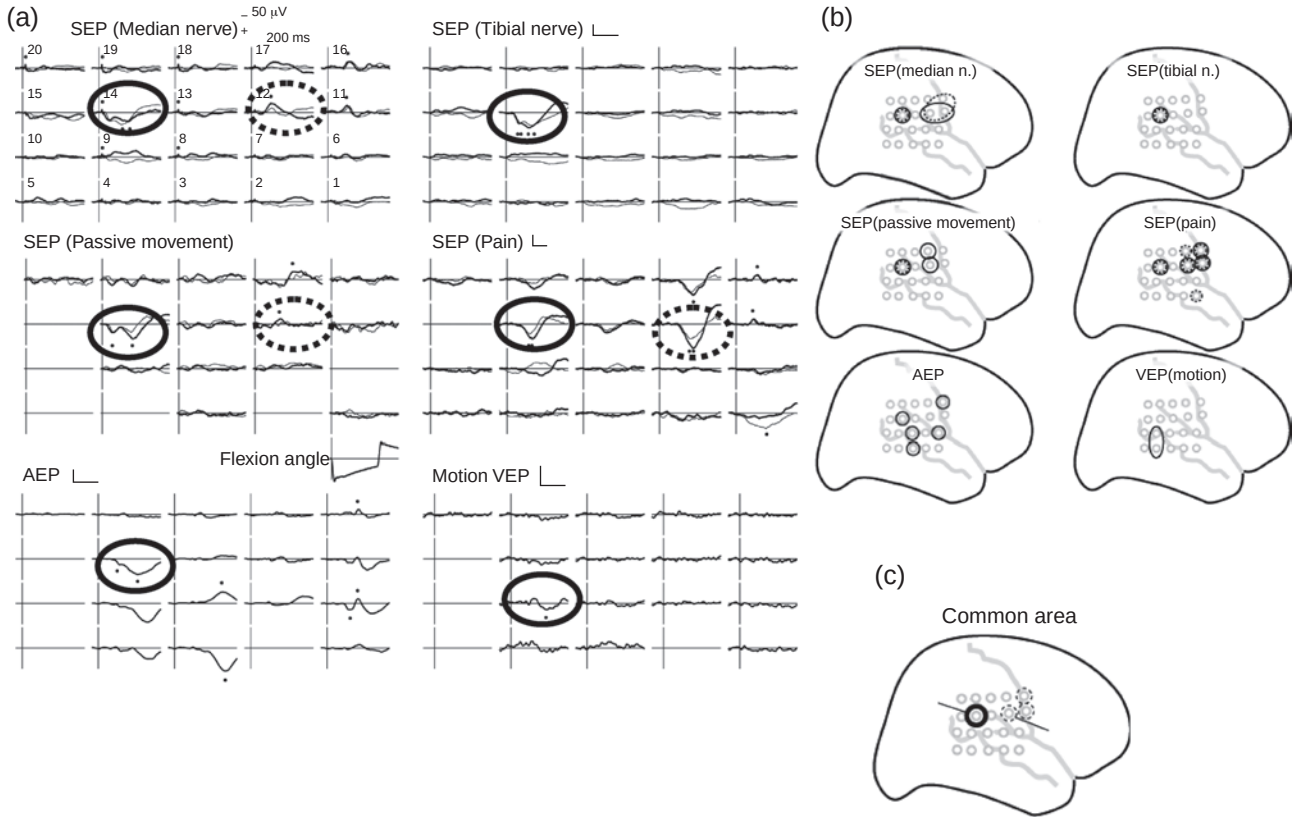

Figure 112.8 Subduraly recorded waveforms, distribution and common response area in the right temporo-parietal junction from a patient. (a) Waveforms of evoked potentials to each form of sensory stimulation. Thick lines: responses to the contralateral (left) stimulation, thin lines: those to the ipsilateral (right) stimulation. Dots indicate response peaks. Calibration shown on top of each plate: 200 msec, 50 μV, negative polarity shown upward. (b) Distribution of evoked response peaks to each sensory stimulation. Electrodes showing peak amplitude of 75% or larger of the local maximum are circumscribed for each stimulus modality. Electrodes showing independent peaks are highlighted by separate circles. For SEPs, electrodes showing response peaks to the contralateral stimuli are marked with solid lines while those to the ipsilateral stimuli with broken lines. (c) Distribution of the response area common to stimuli of multiple modalities. Electrodes which showed responses to two or more modalities are marked. Circle by thick line (14): common response areas to five forms of stimulation. Circle by broken line (12): common response areas to two different forms of stimulation. (cited from ref. 42 with permission).

Precentral gyrus (positive motor area) and postcentral gyrus

In early studies, Neshige *et al.*[55] recorded BP associated with self-paced finger movements from subdural electrodes placed over the lateral frontal convexity in epilepsy patients. All of three components; BP, NS′, and MP, were highly localized at a part of MI and SI each somatotopically corresponding to the moving finger, particularly at the part of MI where high frequency (50 Hz) cortical electric stimulation elicited positive motor response such as finger twitching. With unilateral finger movements, the BP was recorded from bilateral MI-SI hand areas, and the NS′ was predominantly from the contralateral MI-SI hand area, while the MP was recorded only from the contralateral MI-SI hand area. Those potentials were surface negative in polarity at all recorded sites, and no phase reversal was observed across the central sulcus (Figure 112.11).

In the self-paced tongue protrusion task, clear premovement slow potentials were recorded from the ventral perirolandic area where high-frequency cortical electric stimulation produced positive motor responses in the tongue.[20]

It was expected that the MP might represent the activity of pyramidal neurons that directly project to the corticospinal tracts as the final motor output to the spinal cord whereas BP and NS' could represent preparatory activity of the neurons in MI and the adjacent areas. In the epicortical recording of premovement potentials, BP, NS′, and MP are not necessarily generated from common electrodes, but rather from different electrodes within MI. Our recent observation showed that the

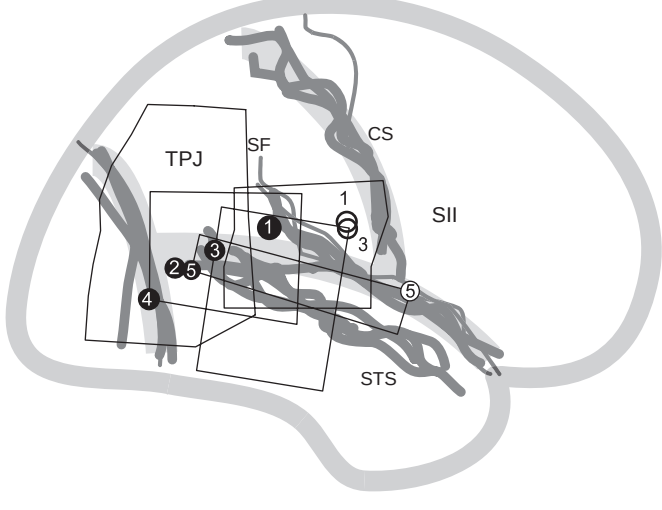

Figure 112.9 Multisensory response area vs. second sensory area (SII). White numbers in filled black circles indicate multisensory response area in each patient. Open circles indicate SII. CS = central sulcus, SF = sylvian fissure, SFS = superior temporal sulcus. (cited from ref. 42 with permission).

Table 112.4 Characteristics of Beietschaftspotentials (BP) recorded from subdivisions of motor cortices

	Pre-SMA	*SMA proper*	*Lateral rostral frontal area*	*MI-SI*
Surface polarity	Negative	Negative	Positive	Negative
Somatotopy	(–)	(+)	(–)	(+)
Effect of movement rate		(++)	(+)	(–)

SMA = supplementary motor area, MI-SI = primary sensorimotor cortices, (–) = absent, (+) = present, (++) = strongly present.

electrode on the crown part of the precentral gyrus selectively generating MP for hand movements elicited MEPs in the hand muscle when electrically stimulated. When recording premovement potentials (BP/NS′/MP) in association with self-paced movements of various parts of the body, the distribution of the potentials along the central sulcus was consistent with the somatotopic representation in the precentral gyrus. Therefore, BP or rather MP analysis by subdural electrodes is clinically useful for functional mapping of the so-called 'primary motor area' (MI) (which is defined by positive motor responses to high-frequency electric cortical stimulation) in epilepsy surgery.

In summary, a somatotopic representation of MI disclosed by BP/NS′/MP recording is consistent with that of the positive motor area in the precentral gyrus as revealed by electric cortical stimulation (Figure 112.10),[19,55] but BPs for each task often appear to be distributed wider than the motor map made by cortical stimulation. It may be partly because BP is generated not only by the anterior bank of the central sulcus but also by the crown part of the precentral gyrus,[20] from both of which the corticospinal pathways essentially originate.

Lateral rostral frontal area

Recently we observed that, whichever part of the body was voluntarily moved, the lateral frontal area at or adjacent to the lateral negative motor area (LNMA),[56] located just rostral to the MI face area, generated surface-positive premovement slow potentials (Omni-BP).[54] It still remains to be solved whether this potential is generated from areas 44 and 45 anterior to the precentral sulcus, or from the ventral premotor area (area 6aα) posterior to that sulcus.

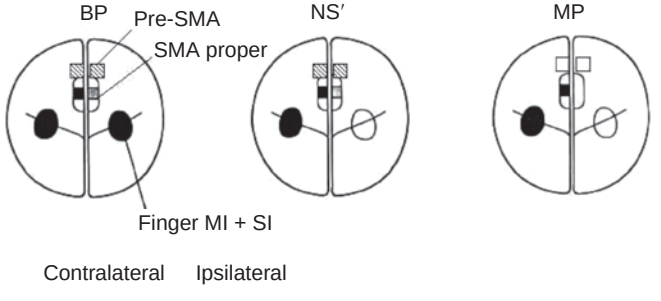

Figure 112.10 Schematic representation of the cortical generators of BP, NS′, and MP for hand movements viewed from the top. The degree of darkness of the shading in the pre-SMA, SMA proper and MI-SI is approximately proportional to the amplitude of the corresponding potentials. MI = primary motor area, SI = primary sensory area (cited from ref. 55 with permission).

Supplementary motor area (SMA)

SMA is currently subdivided into caudal- (SMA proper) and rostral (pre-SMA) parts by VAC line in humans as well as in monkeys, and both SMA proper and pre-SMA generate premovement potentials. SMA proper, like the precentral gyrus, has a somatotopic organization based on electric cortical stimulation as well as BP/NS′/MP (Figure 112.12).[19,57,58] Pre-SMA generates BP invariably regardless of the sites of body movements (Figure 112.13).[59]

Furthermore, the following findings aid us in differentiating the motor cortices located in the mesial frontal area.

1. Onset time of BP in the foot MI area and the foot area at the SMA proper has no significant difference, but movement-related desynchronization before the movement onset starts earlier at the SMA proper than at MI.[58] Foot area at the SMA proper generates BP not only for the contralateral but also for the ipsilateral movements whereas the foot MI generates BP exclusively for the contralateral foot movements. The latter generates clear

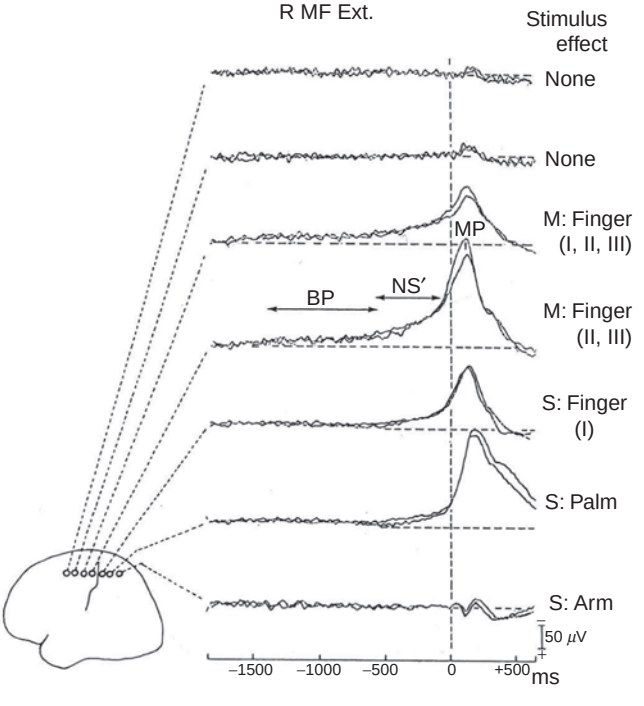

Figure 112.11 Movement-related cortical potentials in association with self-paced extension of the right middle finger recorded from the subdural electrodes placed across the left central sulcus in an epilepsy patient. BP, NS′, and MP are well localized to the finger motor area, and to a lesser degree, to the sensory area. M = motor, S = sensory (cited from ref. 51 with permission).

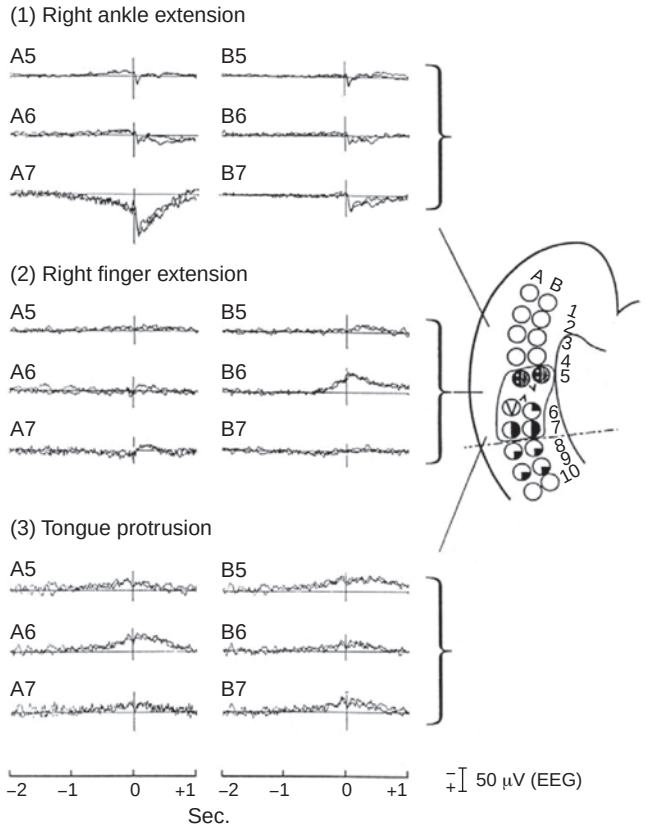

Figure 112.12 Movement-related cortical potentials in association with self-paced movements of the right foot (1), right finger (2), and tongue (3) recorded from the left SMA in an epilepsy patient. The figure illustrates the somatotopic distribution of the BP within the SMA proper, consistent with the results of cortical stimulation. The broken line shows the boundary between the foot MI posteriorly (lower part in the right figure) and the SMA proper anteriorly (middle part in the right figure). Symbols in the figure show the results of electric cortical stimulation (A5 and B5 = positive motor response in the face and negative motor response of the bilateral hands; A6 = rhythmic vocalization; B6 = tonic motor response of the right hand; A7 and B7 = positive motor response of the right hand and foot; A8, B8, A9, and B9 = clonic motor response of the right foot). (cited from ref. 19 with permission).

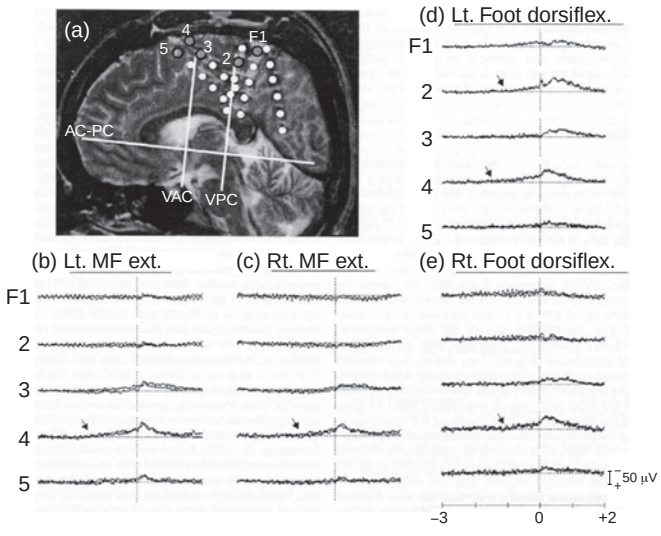

Figure 112.13 Movement-related cortical potentials in association with self-paced extension of the left middle finger (B) and the right middle finger (C), and dorsiflexion of the left foot (D) and the right foot (E), recorded from the right mesial frontal cortex in an epileptic patient. In all tasks, negative BP is observed at F4, located anterior to the VAC line, being most likely pre-SMA. F2 just on the paracentral lobule (most likely foot MI area) generates BP only in association with the left foot movements. VAC = a line on the anterior commissure perpendicular to AC-PC line, VPC = a line on the posterior commissure perpendicular to AC-PC line. (cited from ref. 59 with permission).

RAP immediately after the movement onset whereas the former does not.[19] Since SMA proper is often defined in the lower half of the paracentral lobule,[24] the boundary between the foot MI and the foot SMA proper could not be delineated only by anatomical finding.

2. Pre-SMA and SMA proper generate clear BP in the slow-rate repetition of voluntary movements but little BP in the rapid-rate repetition of movements, whereas MI generates clear BP equally for slow- and rapid-rate repetition of movements.[52] In the rapid-rate repetition of movements, voluntary movements may be conducted as a kind of so-called 'automatic' movements, while in the slow-rate repetition of movements each movement is regarded as discrete, individual execution, each of which may involve different motor control mechanisms. Characteristics of BP recorded from subdivisions of motor cortices are summarized in Table 112.4.

Currently, in epilepsy surgery, the functional delineation between the primary foot area and the foot area at the SMA proper, or between the SMA proper and the pre-SMA is made exclusively by high frequency cortical stimulation or just by anatomical approach. BP can be clinically useful at least for complementing the result of cortical stimulation.

Conclusion

Multiple cortical generators of sensory evoked potentials and BPs are revealed for cortical mapping before epilepsy surgery from the clinical point of view. The results of short- and middle-latency evoked potentials are relatively clear, whereas the generators of long-latency evoked potentials and event-related potentials are usually multiple and the degree of significance of each generator remains to be solved. At this moment, three points are stressed as below.

1. Similar to short-latency, sensory-evoked potentials, BPs are useful to delineate the motor cortices responsible for voluntary movements since their cortical generators are already well investigated in subdural recording.
2. Cortical mapping of primary (sensory or motor) cortices are relatively clear because it is judged by the direct response of motor or sensory phenomena, by means of cortical electric stimulation or evoked-potential techniques.
3. When nonprimary cortices are targeted for mapping, intercortical connection plays a significant role in manifesting higher cortical function or the compensation mechanism of function, and thus just one modality for cortical mapping may mislead the final decision. Since cortical mapping in epilepsy surgery especially

needs reliable, specific findings to decide the resectable and unresectable areas, it should be very important to take into account the results of several modalities such as electric cortical stimulation, evoked potential, magnetoencephalography, and functional neuroimaging. Analysis of event-related potentials and long-latency sensory-evoked potentials would be useful for functional mapping of nonprimary or association cortices in epilepsy surgery or functional surgery in the near future as well.

113a Cortico-cortical evoked potentials to define eloquent cortex

R Matsumoto and DR Nair

Introduction

Cortical electrical stimulation was first performed by Bartholow in 1874 and was extensively developed by the Montreal group in the early to middle 1900s. It has become a gold standard methodolgy to explore various cortical functions and greatly enhanced the field of functional neurosurgery by defining regions of eloquent cortices. Standard cortical stimulation is performed using a train of biphasic square-wave pulses with a stimulus duration of 0.1–0.5 ms at a rate of 10–50 Hz. Each train of electrical stimuli is delivered to the cortex for a duration lasting from 2–5 seconds. Together with direct cortical electrical stimulation, various advancements in the last decade in functional neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), has brought additional insight into the functional organization of the cortex. In order to better understand the workings of the brain systems, a detailed knowledge of neuronal connectivity between these functional cortical regions is essential. There is in fact very little that is known regarding human interareal or cortico-cortical neuronal connectivity. This is mostly due to the fact that there is a limited repertoire of suitable anatomic techniques that can be used in the living human brain.[1] At present, knowledge of human white matter connectivity such as cortico-cortical and cortico-subcortical connections has mainly come from extrapolation from invasive tract-tracing studies performed in nonhuman primates. Retrograde and anterograde tracer techniques were introduced in the early 1970s with horseradish peroxidase (HRP) as the tracer and have revolutionized the understanding of connections in the nonhuman primate brain.[2,3] Besides anatomical tracer studies, neuronal connectivity has been investigated physiologically using electrical stimulation in nonhuman primates. Intracortical microstimulation technique in combination with single- or multi-unit recording has successfully evaluated orthodromic or antidromic responses in the remote cortical regions via cortico-cortical connections.[4,5] It is also noteworthy to state in this epilepsy textbook that a technique based on tracing the spread of experimentally-induced seizures, namely strychnine neuronography, was used to study these pathways before the advent of these modern tract-tracing techniques.[6–8]

As it relates to higher brain functions proper to humans, such as language and cognitive functions, studies performed in nonhuman primates are largely not relevant. In this sense, it is essential to explore interareal or cortico-cortical connectivity directly in humans. Moreover, functional brain systems, such as the motor and language systems, need to be evaluated in the *in vivo* setting for each individual patient in functional neurosurgery. Nevertheless, the corresponding information has almost exclusively come from 'admittedly impoverished' data obtained from postmortem studies such as gross anatomic dissections[9] or clinical pathological correlation of postmortem brains using a modified reduced silver method.[10] Obviously the latter has limitations due to the inability to control lesion size and location.

In vivo connectivity studies in humans have only recently begun using noninvasive methods, such as diffusion tensor imaging (DTI) and combined use of transcranial magnetic stimulation and positron emission tomography/functional magnetic resonance imaging (TMS-PET/fMRI).[11,12] DTI promises to shed new light on the understanding of white matter pathways by its ability to image fiber trajectories.[13,14] This technique enabled to visualize '*in vivo* dissections' of association and commissural fibers, and confirmed the presence of major white matter fasciculi in the living human brain.[15,16] DTI, however, cannot provide details of functional aspects of the brain, i.e., cortical functions and functional connectivity among cortical regions. It would be optimal if both functional cortical regions and their white matter connections could be mapped within the same patient, to be able to tract exact neuronal connections. We have recently developed an *in vivo* tracking method using direct cortical stimulation, which we termed 'cortico-cortical evoked potential (CCEP)'.[17,18] By means of subdural electrodes chronically implanted for the presurgical evaluation of intractable partial epilepsy, a single electrical pulse is applied over the cortex to look at the cortical evoked potentials that emanate from a distant region of the cortex via cortico-cortical connections. This technique provides a unique opportunity to track functional connectivity among the various cortical regions that are physiologically and anatomically defined within the same subject by means of standard cortical electrical stimulation and MRI-electrode co-registration, respectively. We will review the methodology, recent studies[18–20] and the future perspective of CCEP in this chapter.

CCEP methodology

We hypothesized that the external or surface electrical stimulation of the cortex could similarly generate orthodromic discharges in cortico-cortical projection neurons, thus activating the cortico-cortical short- or long-association fibers to convey the impulses to the cortical area where they project. The efficacy of surface cortical stimulation upon activating projection neurons is supported by the fact that surface electrical stimulation of the motor cortex successfully produces motor-evoked potentials through activation of pyramidal tract neurons in humans[21] and that the surface electrical stimulation produces stereotypical postsynaptic responses, called 'the direct cortical response (DCR)' in the very adjacent cortex in humans and other species.[22,23] It is further supported by the TMS-PET/fMRI studies in which TMS of the cortex gave rise to increased cortical activity, as measured with an indirect hemodynamic response, in the remote cortex.[11,12]

The recording procedure is as follows. After the standard presurgical functional cortical mapping with 50 Hz electrical stimulation,[24] single-pulse electrical stimulation is applied in a bipolar fashion to a pair of adjacently placed subdural electrodes (1 cm apart) by a Grass S88 stimulator (Astro-Med, Inc., RI) or an equivalent constant-current electric stimulator. The electrical stimulus used for this purpose consists of a constant-current square-wave pulse of 0.3 ms duration, which is given at a fixed frequency of 1 Hz. Polarity of stimulus current is alternated to; (1) reduce the stimulus artifacts, (2) avoid electrical charges building up at the cortex (a safety consideration), and (3) avoid polarization of platinum electrodes which can decrease the current density over time. The current is given at 80–100% of the intensity that produces either clinical signs or afterdischarges (ADs) during the standard 50 Hz stimulation. The intensity is set at 10–12 mA if no clinical sign or ADs are present at 15 mA. In cases in which excessive artifact obscures the recordings, the intensity is lowered stepwise by 1 mA until artifacts become small enough to visualize the evoked responses. The artifact usually consisted of a baseline drift that typically persisted for several milliseconds from the stimulus, and appeared to originate from either relatively poor electrode impedance or possibly the existence of the cerebrospinal fluid beneath the stimulating electrode. Electrocorticograms (ECoGs) are recorded with a bandpass filter of 1–1000 Hz (or 0.5–1500 Hz) and a sampling rate of 2500–5000 Hz (Axon Epoch 2000 Neurological Workstation, Axon Systems Inc., NY or Biotop; NEC–Sanei, Tokyo, Japan). All the subdural electrodes are referenced to a scalp electrode placed on the skin over the mastoid process contralateral to the side of electrode implantation. CCEPs are obtained by averaging ECoGs with a time window of 200–500 ms, time-locked to the stimulus. In each session, at least two trials of 20–100 responses are averaged separately to confirm the reproducibility of the responses. During the recording of CCEPs, the subjects are not requested to perform any specific task, just lying or sitting on a bed. Anatomical location of each electrode is evaluated with a three-dimensional MRI co-registration technique reported elsewhere.[18]

Figure 113a.1 shows examples of CCEPs. CCEPs are elicited in the adjacent cortex and/or in the remote cortical regions. CCEPs usually consist of a small positive deflection followed by a large negative potential (N1). Some CCEPs are followed by the second negative potential (N2). In Figure 113a.1(a), stimulation of the basal temporal area (symptomatogenic zone of the habitual aura revealed by 50 Hz stimulation) elicited CCEPs from the adjacent electrodes with its maximum at electrode D5 peaking at 12 ms. Figure 113a.1(b) shows CCEPs recorded from the right fronto-parietal area by stimulating the prefrontal area at the inferior frontal gyrus. In addition to large short-latency CCEPs (peak latency 12–15 ms) observed in the electrodes adjacent to the electrode pair of stimulation, CCEPs were recorded remotely in the posterior part of the inferior parietal area with N1 and N2 potentials peaking at 25–37 ms and 106–138 ms, respectively. The responses were site-specific: stimulation of Pair 3 (most caudal pair), and, to a lesser degree, Pair 2 (middle pair) elicited CCEPs while Pair 1 (most rostral pair) did not.

The generator mechanism of CCEP, however, is not precisely known. Because of the alternating polarity of the stimulus current employed to counterbalance the stimulus artifact and electric charges, the stimulated neurons are indeed the mixture of different neuronal populations depolarized by anodal and cathodal stimulation.[25,26] Thus the excitation of projection neurons occurs likely through synaptic action by activation of afferent input as well as direct depolarization of the initial segment. The relatively long peak latency (≤10 ms) observed in the locally evoked DCR[27,28] supports that direct cortical stimulation produces oligo- or multi-synaptic responses in the local cortical circuits. This local jitter of synaptic activity at the site of stimulation and at the target cortex could account for the relatively long-latency, blunt negative peak of the N1 potential (e.g., up to15 ms at the very adjacent electrodes). The first positive deflection (usually several milliseconds in the absence of stimulus artifact) at the target cortex might reflect the very first monosynaptic impulse projecting into the middle or deep cortical layer via large cortico-cortical projection fibers, giving rise to a surface positive potential. It is also possible that antidromic activation of the presynaptic axonal terminals of the association fibers could play a role in generation of CCEP. Compared with highly structured pyramidal neurons or interneurons, poorly organized arrangements of these small axon terminals are less favorable for effective direct activation.[29] Nevertheless, extensive arborization of the presynaptic terminals might increase the chance to be excited by cortical surface stimulation. In this case, the antidromic activation of the pyramidal neurons in the deep cortical layer at the target cortex would be recognized as a small surface positive potential reflecting the very first volley of impulse. The following large blunted negative potential could then be produced at the target cortex upon the first impulse arrival or generated as a result of mixture of both orthodromic and antidromic excitation of the neurons in the target cortex. In addition to the direct cortico-cortical pathway, the cortico-subcortico-cortical pathway may be an alternative mechanism. Nonreciprocal cortico-thalamo-cortical circuits[30] or cortico-basal ganglia-thalamo-cortical circuits[31] could be a candidate. The N2 potential usually has a larger distribution than the N1 potential. After the excitation of the cortex via mechanims mentioned above giving rise to the N1, the N2 potential could then be generated in and immediately surrounding the cortex via either a local cortico-cortical or a cortico-subcortico-cortical reverberating cirtuit.

Although the CCEP technique is applicable only during the invasive presurgical evaluation of intractable epilepsy patients,

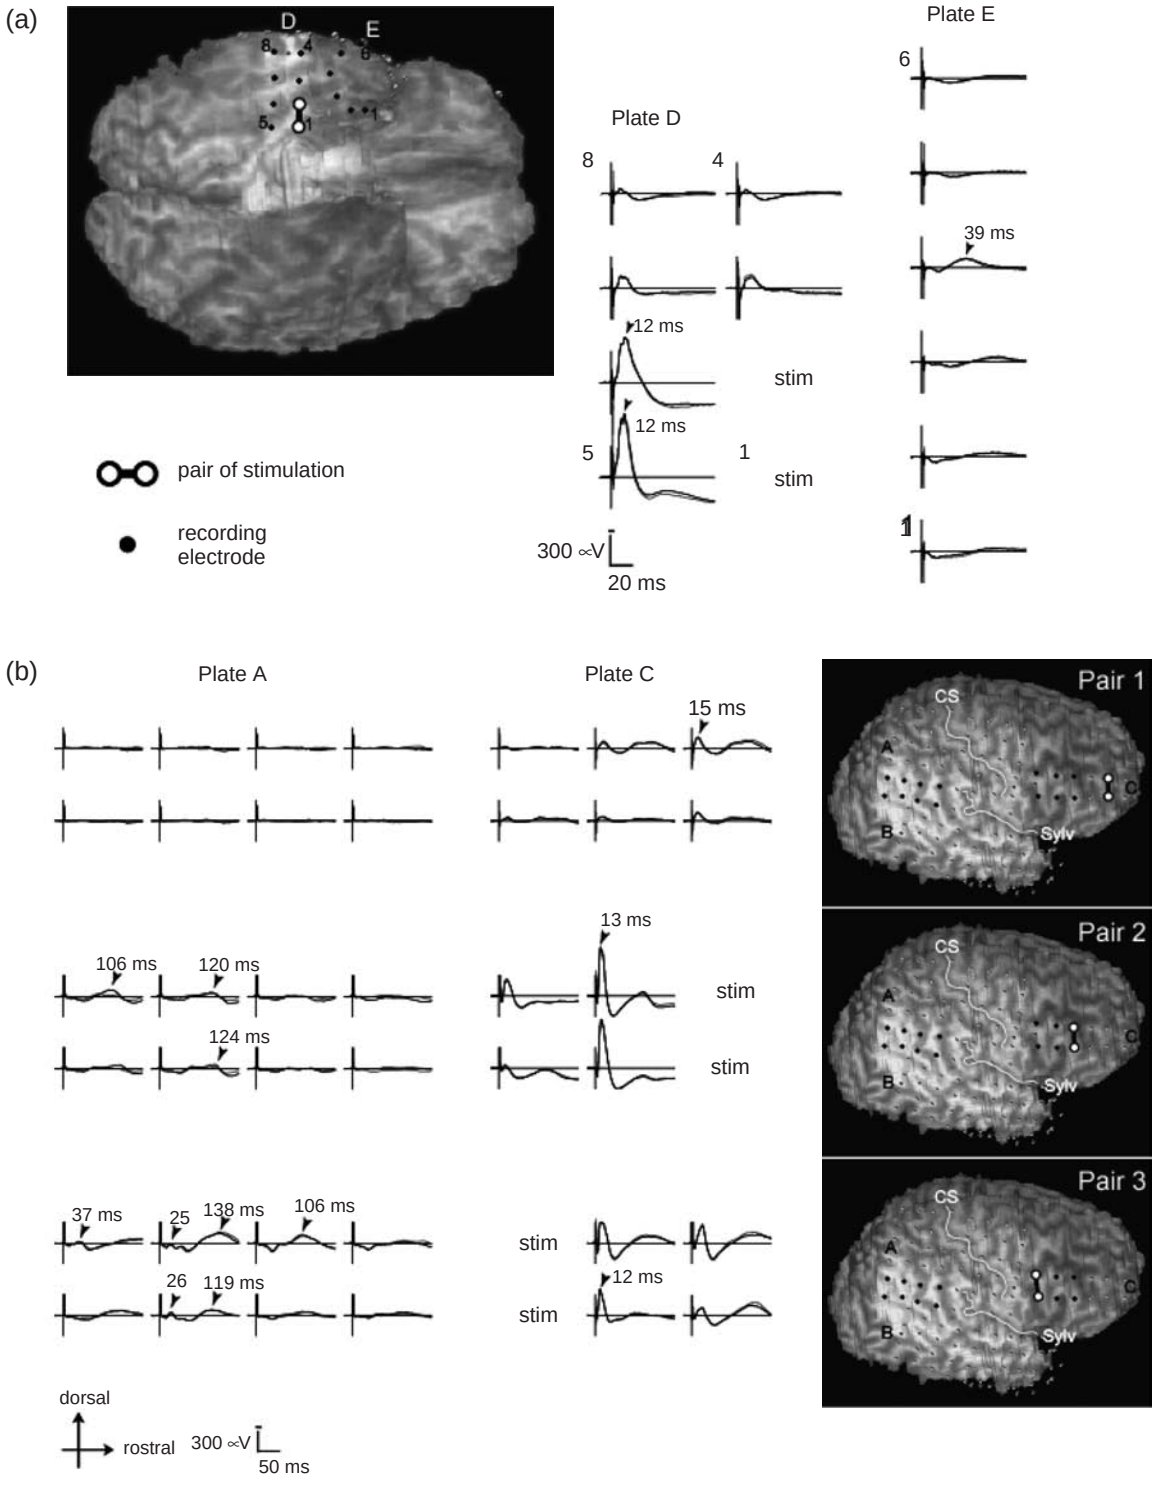

Figure 113a.1 Short and long latency CCEPs recorded from a patient with mesial temporal lobe epilepsy. (a) CCEPs recorded from the basal temporal area (Plates D and E) by stimulating electrodes D1 and D2 (symptomatogenic zone of the habitual aura revealed by standard 50 Hz stimulation). Stimulation elicited short-latency CCEPs from the adjacent electrodes in Plate D (maximum at D5) as well as from Plate E (maximum at E4). The vertical bar corresponds to the time of stimulation. Two trials (black and gray lines) were superimposed. Black circles denote the recording subdural electrodes co-registered with 3D MRI. (b) CCEPs recorded from the right frontoparietal area by stimulating the prefrontal area at the right inferior frontal gyrus. In addition to large short-latency CCEPs (peak latency 12–15 ms) observed in the electrodes adjacent to the electrode pair of stimulation, CCEPs were recorded remotely in the posterior part of the inferior parietal area with the early and late negative potentials peaking at 25–37 ms and 106–138 ms, respectively. The responses were site-specific: stimulation of Pair 3 and, to a lesser degree, Pair 2 elicited CCEPs while Pair 1 did not. CS, central sulcus; Sylv, sylvian fissure. Other conventions are the same for Figure 113a.1(b). From ref. 17 with permission.

it provides a unique opportunity to track *in vivo* cortico-cortical networks and has advantages over other methods. Compared with TMS-PET/fMRI studies, the CCEP study provides: (1) direct neuronal responses to the stimulation; and (2) more localized cortical stimulation with better temporal and spatial resolution. Moreover, in contrast to the DTI study, this technique is capable of providing the direction of connectivity, at least electrophysiologically, by stimulating both ends of connection. The CCEP study, however, cannot identify the actual anatomical pathway of the circuit, and in this regard it may well be regarded as 'functional tractography' as compared with 'anatomical fiber tractography' by DTI. Combination of the functional and anatomical fiber tractography will complement each other and become one of the powerful tools to explore human *in vivo* connectivity.

In terms of clinical practicality, the CCEP method is highly practical because it can be done: (1) easily with online averaging technique in a short time (less than a minute or two for each stimulus site); (2) without any cooperation of patients; and (3) with least chance of provoking seizures (no seizures reported in references).[17,18,20]

Studies using CCEP methodology

Exploring the functional systems of the brain

Combined with functional cortical mapping of the eloquent cortex, the CCEP technique allows us to understand specific functional brain systems. Our initial focus in studying particular functional systems was on language.[18]

Eight patients who underwent chronic subdural electrode placement for the presurgical evaluation of medically intractable partial epilepsy were studied (age 13–42, two FLE and six TLE patients). Six patients had subdural electrodes placed in the hemisphere dominant for language and two had bilateral language representation as judged from the intracarotid amobarbital test. Stimulation of the anterior language area elicited CCEPs in the lateral temporo-parietal area (7/8 patients) in the middle and posterior part of the superior temporal gyrus, the adjacent part of the middle temporal gyrus and the supramarginal gyrus (Figure 113a.2). CCEPs generally consisted of early N1 and late N2 potentials. The peak latency of N1 ranged from 22–36 ms (mean 27.9 ms) and that of N2 from 113–164 ms (mean 144.6 ms). The distribution of N2 (3–21 electrodes) was larger than that of N1 (1–20 electrodes) ($P < 0.01$, two-tailed paired T-test). In relation to the electrodes which produced language impairment at 50 Hz stimulation, CCEPs occurred at or around these electrodes. The connection between the anterior and posterior perisylvian language areas was electrophysiologically bi-directional. Stimulation of the posterior language area elicited CCEPs (3/4 patients), though less well defined, in Broca's area and the surrounding silent prefrontal or face motor area. In addition to these interlobar connections, two adjacent interareal circuits with shorter-latency CCEPs were observed within the perisylvian area (Figure 113a.3). First, stimulation of the anterior language area elicited CCEPs in the frontal operculum (N1 peak; 11–19 ms, 2/2 patients), which is the presumed region for the articulatory planning.[32,33] Second, stimulation of the face motor area produced CCEPs (N1 peak; 13–24 ms) in the ventral postcentral gyrus (the face somatosensory area) and the adjacent portion of the anterior inferior parietal area (2/2 patients).

Upon stimulation of the anterior language area, similar CCEPs were obtained in the anterior to middle portions of the inferior temporal and fusiform gyri (the basal temporal language area)[34] in all three patients studied (N1 peak at 19–47 ms, N2 peak at 120–187 ms) (Figure 113a.4).

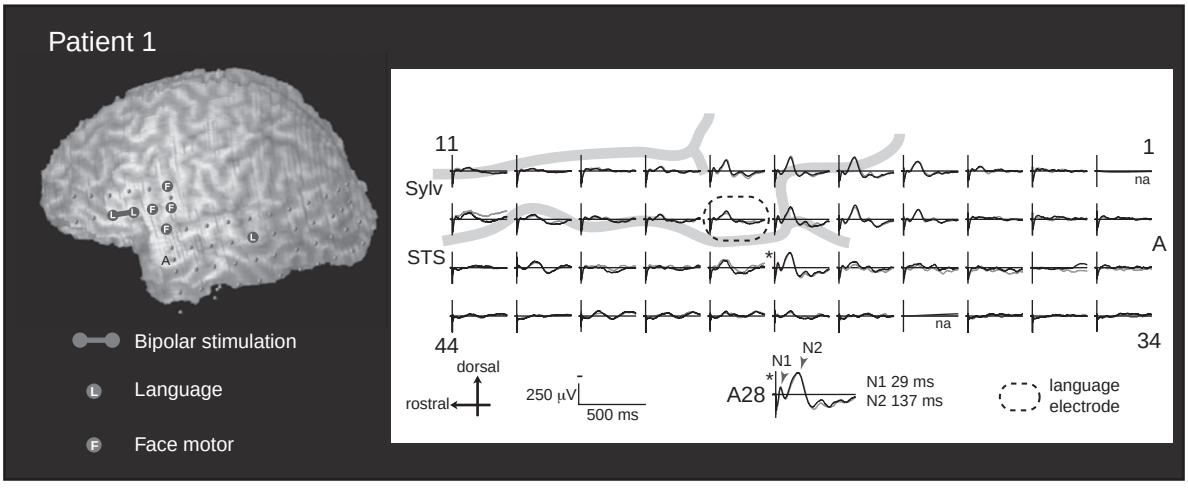

Figure 113a.2 CCEPs recorded from the posterior language area (plate A) time locked to single-pulse stimulation delivered at the anterior language area. Two trials are plotted in superimposition for each electrode. The vertical bar corresponds to the time of stimulation. Evoked responses were mainly recorded from the posterior part of the superior temporal gyrus and the adjacent portion of the middle temporal gyrus in and surrounding the language electrode defined by standard cortical stimulation (A18: highlighted with a dotted circle). Maximal activity was seen at electrode A28 with a clear early N1 and a late N2 potential, peaking at 29 and 137 ms, respectively. STS – superior temporal sulcus, Sylv – sylvian fissure, na – CCEP not available due to high impedance in the recording electrode. Other conventions are the same as for Figure 113a.1 From ref. 18 with permission.

In contrast, stimulation of the adjacent face motor area did not elicit CCEPs in the basal temporal area. Stimulation of the posterior language area did not evoke clear CCEP responses, while stimulation of more caudally situated electrode pairs at the temporo-occipital junction elicited small N1 and N2 potentials in the inferior temporal gyrus.

The present study revealed cortico-cortical connections within the perisylvian language area as well as between the perisylvian and extrasylvian language areas, via long and short association fibers and/or through the cortico-subcortico-cortical pathway. Different from the classical Wernicke-Geschwind model, our study revealed, at least electrophysiologically, a bi-directional connection between Broca's and Wernicke's areas likely through the arcuate fasciculus. Larger distribution of CCEPs than that of the posterior language area identified by electrical stimulation suggests the existence of a rather broad neural network surrounding the previously recognized core region of this area. This broad distribution is consistent with the recent DTI study that demonstrated the connection of the anterior language area (Broca's territory) to the lateral temporal (Wernike's territory) as well as the inferior parietal (Geshwind's territory) area.[35] Since the evidence in the nonhuman primate brain points to a much more extensive parietal than temporal projections to the ventral premotor area – a presumed homologue of Broca's area,[36,37] one may speculate that increased connectivity demonstrated between Broca's and Wernicke's territories in humans is the results of the evolution and acquisition of language function.

Functional connectivity demonstrated here supports the contemporary concepts of language organization, namely that neuronal groups participate as components of a network by means of feed-forward and feed-back projections.[38] In contrast with classical aphasiology descriptions, the conventional electrical stimulation of either Broca's, Wernicke's or the basal temporal language area can interfere with both language production and comprehension.[39,40] It is likely that the language network itself is functionally disturbed by high frequency stimulation, because even a single-pulse stimulus in one language area reaches the other language areas via different cortico-cortical connections.

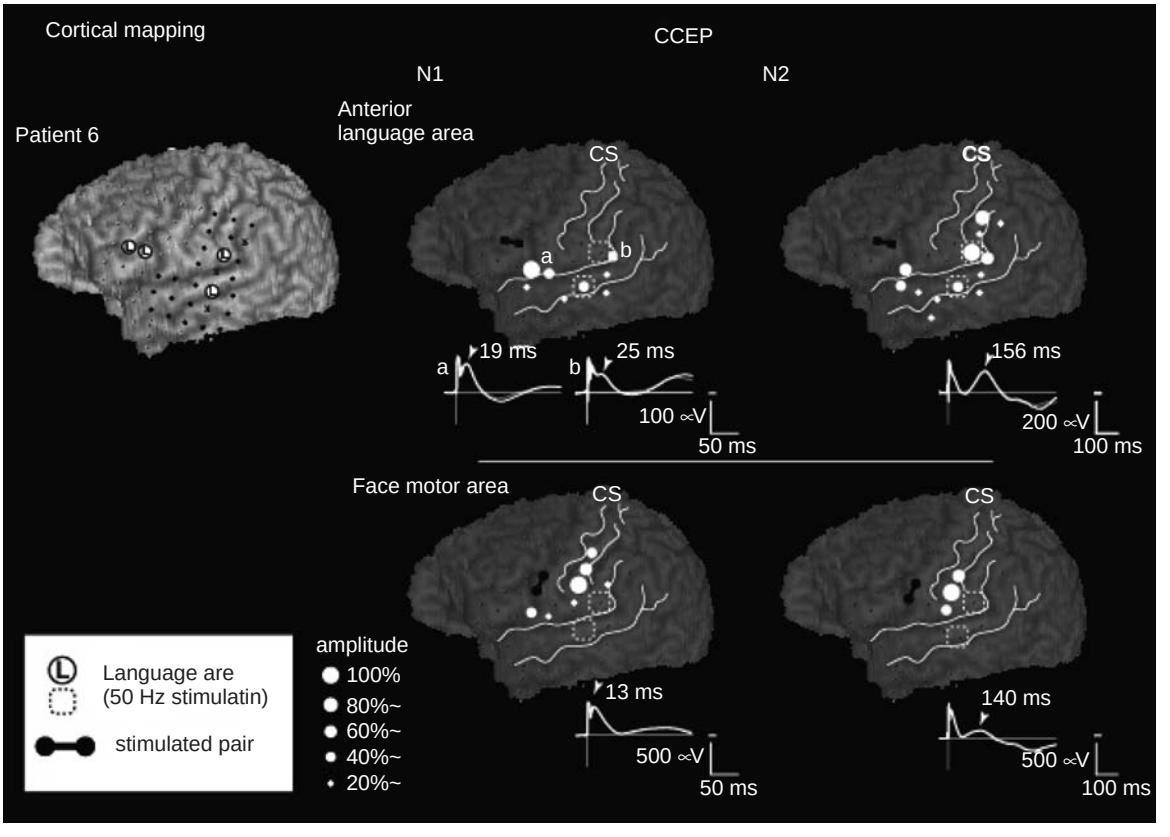

Figure 113a.3 Long and short cortico-cortical connections within the perisylvian language area. The distribution of CCEPs is presented in a circle map which shows amplitude percentage distribution in relation to the maximal response displayed below each map. Middle and right columns show the distribution of N1 and N2 activities, respectively. The result of cortical mapping and the distribution of recording electrodes (colored black) are shown in the left column. Electrodes highlighted with a dotted square in the middle and right columns correspond to those which stimulation produced language impairment on standard 50 Hz stimulation. Stimulation of the anterior language area (upper column) elicited CCEPs in the lateral parieto-temporal area (maximum at Circle b). In addition to this inter-lobar connection between the anterior and posterior language areas, another CCEP field with shorter peak latency (19 ms vs. 25 ms) was recorded in the frontal operculum region (Circle a). On the other hand, stimulation of the face motor area (lower column) showed entirely different CCEP distribution in the ventral postcentral and adjacent anterior parietal areas with shorter N1 peak latency (13 vs. 25 ms). Modified from ref. 18 with permission.

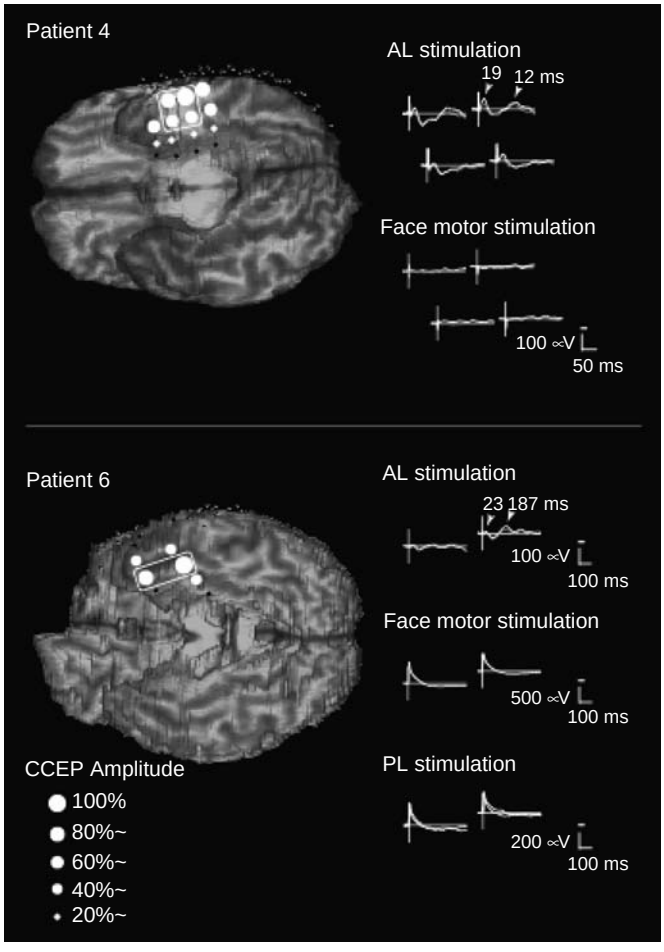

Figure 113a.4 CCEPs recorded from the basal temporal area. Stimulation of the anterior language area (AL) elicited clear N1 and N2 potentials in the inferior temporal and fusiform gyri in all three subjects studied for this connection. In contrast, no CCEPs were observed when stimulating the adjacent face motor area (2/2 patients). Waveforms of evoked responses are shown for electrodes encompassed by a rectangle. Circle maps are shown for the N1 potential of the AL stimulation. PL: the posterior language area. Other conventions are the same as for Figure 113a.3. Modified from ref. 18 with permission.

The connections revealed within the perisylvian area most likely reflect normal brain function since the epileptogenic focus or EEG seizure onset zone was outside the perisylvian area. It is interesting, however, to note that CCEPs could also be recorded from pathological brain tissue (microcalcification and cortical dysplasia in the lateral temporal area) in two patients as well as from the epileptogenic focus (the basal temporal area) in two (Figure 113a.5). The CCEP study may help identifying normal cortico-cortical connections in the brain region where normal brain function co-exists with pathology.

Our next attempts to study brain systems using CCEPs involved investigations in the motor system. In order to understand the rapid spread of epileptic discharges through the cortico-cortical networks involved in ictal motor manifestation, cortico-cortical connections between the lateral and medial motor cortex were studied by means of CCEP. The study demonstrated a human cortico-cortical network connecting: (1) anatomical homologous areas of the lateral and medial motor cortex along the rostro-caudal cognitive-motor gradient (e.g., supplementary motor area (SMA) to the caudal lateral premotor/primary motor (MI) area, pre-SMA to the rostral lateral premotor area); and (2) the somatotopically homologous regions in the lateral and medial motor cortex (e.g., the hand SMA to the precentral hand motor area, see Figure 113a.6) in a reciprocal manner.[20] These circuits could account for the propagation of epileptic discharge from/into SMA[41,42] and the atypical motor responses infrequently seen in standard cortical stimulation: tonic and clonic responses in MI and SMA stimulation, respectively.[43]

Detailed knowledge of the parieto-frontal network is important for understanding the spike propagation from the parietal to the frontal lobe in parieto-occipital lobe epilepsy. From the neuroscientific point of view, this network is essential in sensori-motor integration for various complex behaviors, and is associated with pathophysiology of apraxia. CCEP investigation of this network revealed that the human rostral and caudal parietal areas connect to the caudal and rostral frontal areas, respectively, (e.g., the primary somatosensory to the primary motor area, the superior/inferior parietal lobule to the dorsal/ventral premotor area) in a one-to-one or in a divergent fashion (unpublished data, reported preliminarily as an abstract form).[44]

Exploring pathophysiology of epilepsy

In addition to explore organization of the brain systems, the CCEP methodology could be applicable to *in vivo* exploration of the pathophysiology of epilepsy – to investigate the epileptogenicity and to locate the circuit involved in the spread of epileptic discharges.

Little is known about *in vivo* epileptogenicity, especially transition from the interictal to ictal state in humans. Although extensive researches have been performed in this field by means of animal models and surgical specimens, alternation of intracortical excitatory and inhibitory system has not been well elucidated *in vivo* in humans. This is because of the paucity of the techniques that allow the investigation of excitatory and inhibitory mechanisms of the cortex *in vivo* in humans. Paired-pulse stimulation paradigm, either noninvasively by TMS or invasively by direct electrical cortical stimulation, offers a unique opportunity to assess intracortical excitatory and inhibitory mechanisms.[45,46] This paradigm, however, has been confined to MI where the final common pathway can be assessed by the motor evoked potential (MEP) in the target muscle. Reported here is based upon the notion that, by analogy to the motor system, the intracortical inhibitory and excitatory mechanisms could be evaluated at the site of cortical stimulation by applying subthreshold conditioning and suprathreshold test electrical pulses to analyze the size change of CCEPs. In this way, instead of the corticopyramidal neurons giving rise to MEP, the cortico-cortical projection neurons whose excitation elicits CCEP were evaluated. Indeed, though with much longer interstimulus intervals (ISIs), similar paired-pulse stimulation has been infrequently employed to study the *in vivo* epileptogenicity in patients with mesial temporal lobe epilepsy by means of depth electrodes placed in the hippocampus.[47] By applying paired-pulse stimulation directly to the focus, we documented *in vivo* alternation of intracortical inhibitory and excitatory mechanisms in epileptogenesis or ictogenesis of focal cortical dysplasia (FCD).[19]

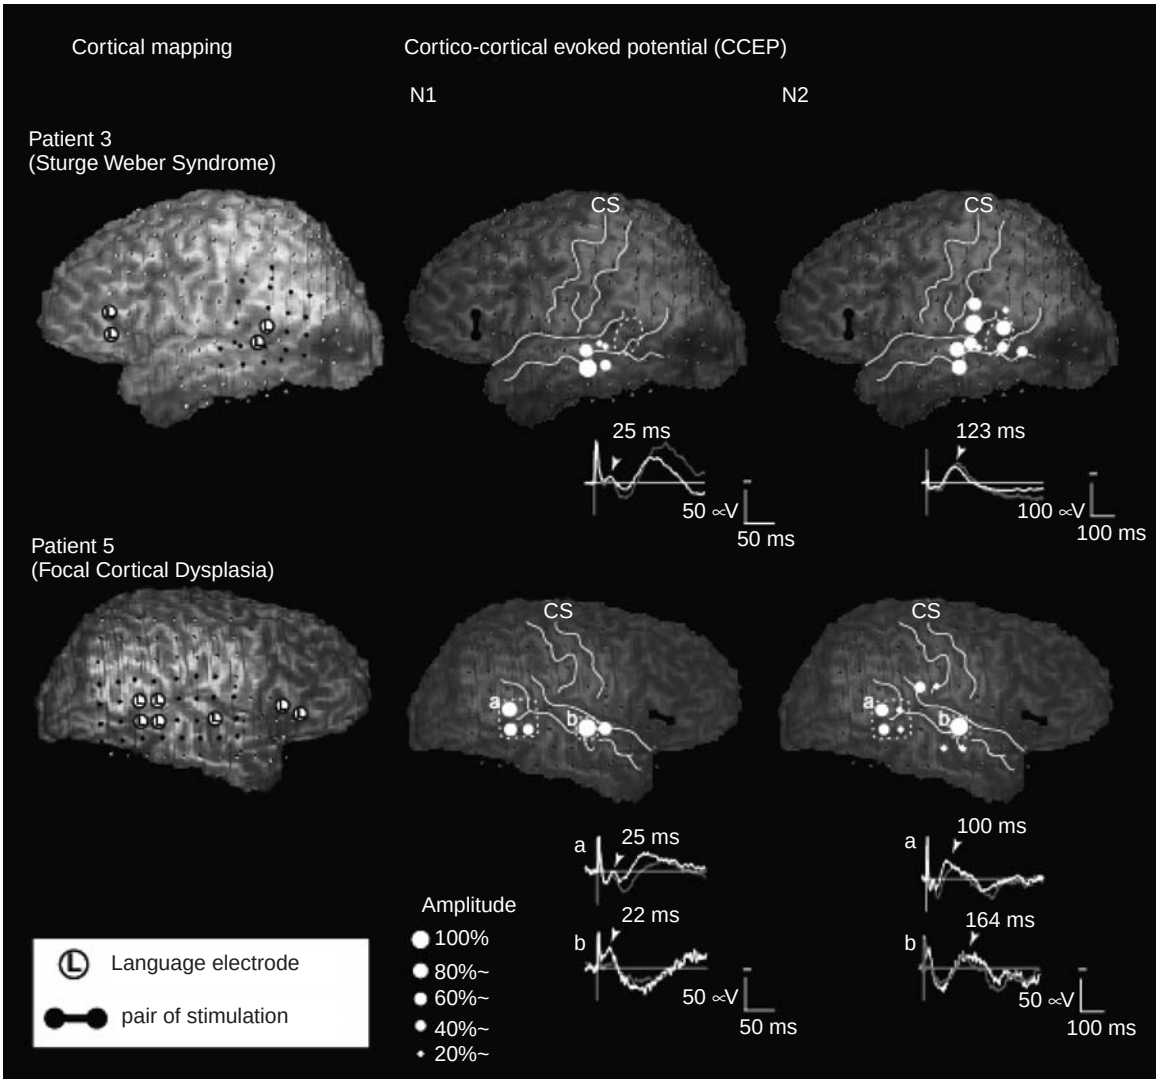

Figure 113a.5 Cortico-cortical connections within the pathology. Upon stimulation of the anterior language area, CCEPs were obtained at and around the posterior language area defined by standard cortical stimulation within the MRI abnormality consistent with Sturge-Weber syndrome (Patient 3) and cortical dysplasia (Patient 5). In Patient 5, CCEPs were *seen split* in the two distinct language areas possibly separated by abnormal nonfunctioning dysplasic cortex. Conventions are the same as for Figure 117a.3. Modified from ref. 18 with permission.

A 31-year-old man with intractable partial epilepsy who underwent invasive monitoring with subdural electrodes was investigated. The seizures started with somatosensory auras of the left foot, which evolved into either left foot clonic seizures or bilateral asymmetric tonic seizures. Invasive evaluation revealed a seizure onset zone in the primary sensorimotor area of the left foot. The patient underwent resection of the focus and the pathology was FCD (Type IIB of Palmini *et al.*).[48] First, single-pulse stimulation was performed in order to determine the threshold intensity to elicit CCEPs (TH_{CCEP}). Stimulation of the focus was performed at the primary foot somatosensory area (foot SI), while that of the control cortex at the hand SI, a functionally homologous area away from the focus. Current intensity was gradually increased by 0.5 mA, and TH_{CCEP} was determined when two trials of 20 averaged responses first showed reproducible CCEPs. Then, the paired-pulse stimulation was performed by conditioning (TH × 50%) and testing (TH+1 mA) stimuli with interstimulus interval (ISI) of 1–100 ms. Intracortical inhibition (ICI) at the stimulated site was investigated by analyzing amplitude change of CCEP at the electrode showing the maximum CCEP in comparison with the CCEP amplitude of single-pulse stimulation.

Single-pulse stimulation at the foot and hand SI elicited CCEPs from the surrounding areas with the maximum CCEP at the foot and hand MI, respectively, most likely via projection from SI to MI. Paired-pulse stimulation of the focus revealed abnormally enhanced intracortical inhibition at ISI of 1–10 ms (max 22%) compared with control stimulation of the hand SI (ISI of 1–2 ms; max 18%) in the interictal state ($P < 0.01$) (Figures 113a.7 and 113a.8). Owing to the incidental seizure, we had an opportunity to demonstrate dynamic alternation of the cortical excitability during transition from interictal to ictal state. In another series of paired-pulse stimulation, subjective paraesthesia of the left foot occurred spontaneously between stimulus sessions. Confirming the absence of ictal discharges on ECoG, the study was continued in the

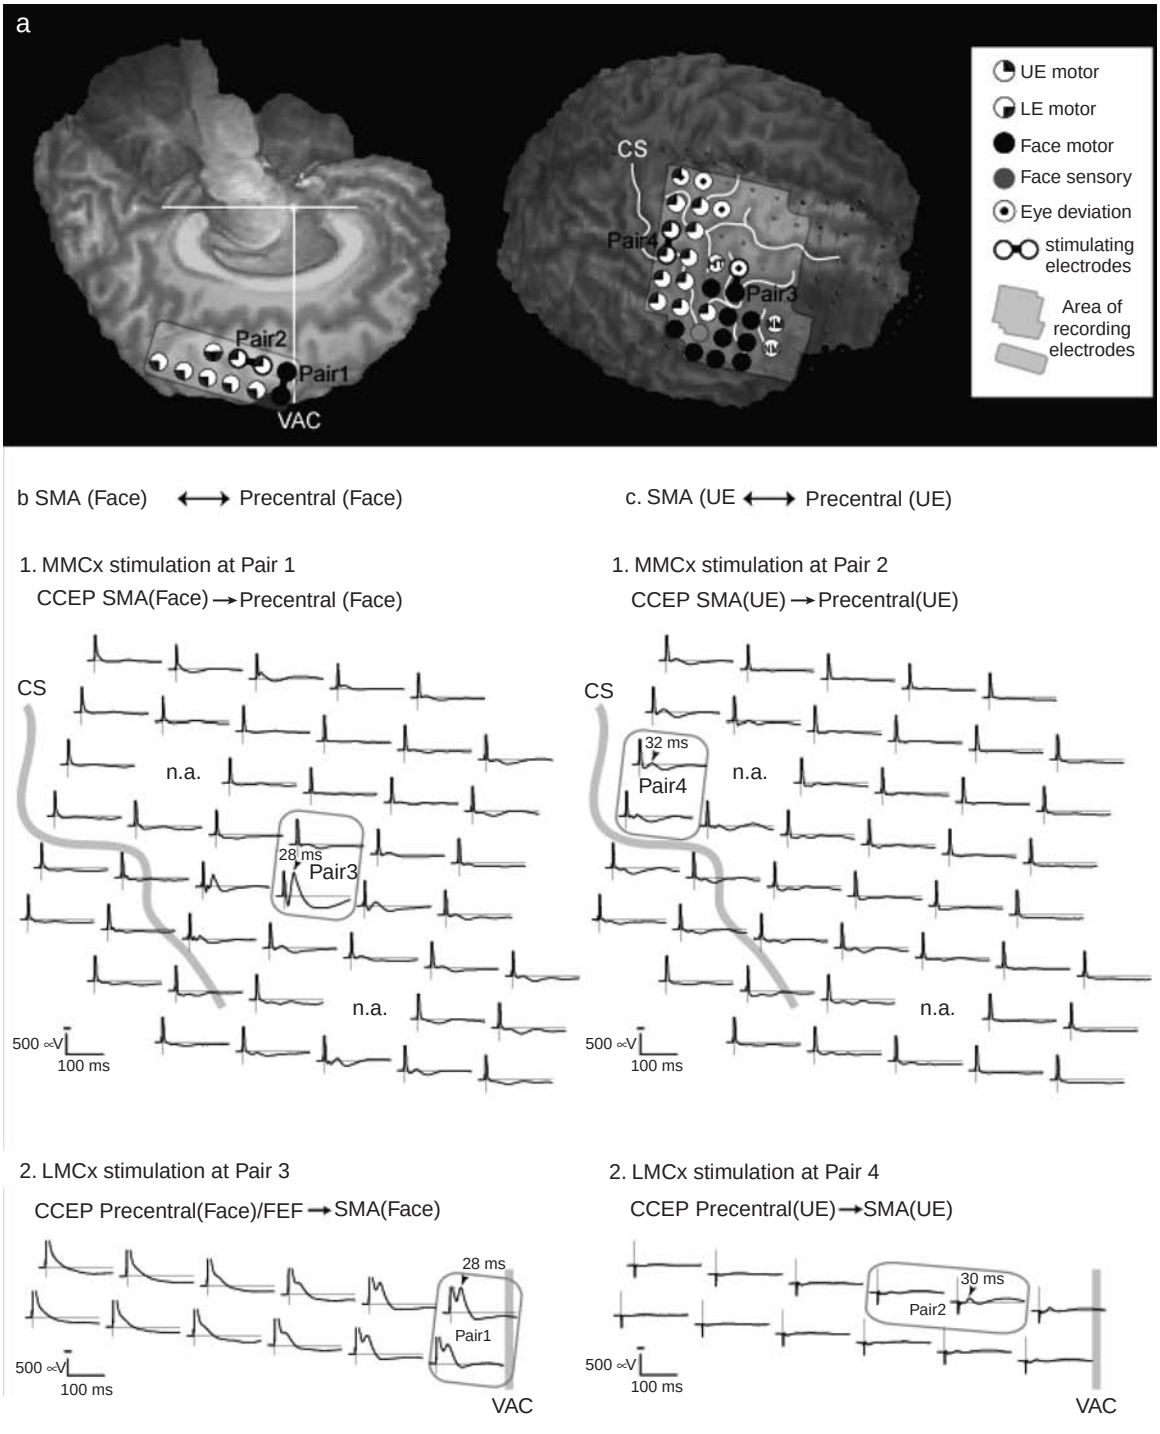

Figure 113a.6 Reciprocal connections between the somatotopically homologous regions in the medial (MMCx) and lateral (LMCx) motor cortex. (a) Results of functional cortical mapping and placement of recording electrodes shown on 3D MRI. Stimulating pairs (Pair 1-4) are plotted as well. UE: upper extremity, LE: lower extremity, HT: head turning, NM: negative motor area. (b) Reciprocal connections between face SMA and the precentral face motor area. Stimulation of face SMA (Pair 1) elicited CCEPs in LMCx with the maximum CCEP at the precentral face motor area (a lower electrode of Pair 3) (b-1). Stimulation of Pair 3 (precentral face motor area/frontal eye field (FEF)), in return, gave rise to CCEPs in the rostral part of SMA, being maximum at the initial stimulation pair (Pair 1: face SMA) in MMCx (b-2). CS: central sulcus, VAC: vertical anterior-commissural line. Other conventions are the same as for Figure 113a.2. (c) Reciprocal connections were also observed between the upper extremity portion of SMA (Pair 2) and that of the precentral motor area (Pair 4) (c-1,2). The procedures and conventions are the same as for Figure 113a.7b. Modified from ref. 20 with permission.

presence of this sensation under the notion that this protocol did not at least provoke the somatosensory aura. The patient, however, presented with the left foot/leg clonic seizure in eight minutes after the sensation started, and it was concluded at that time that the somatosensory sensation frequently observed during the standard 50 Hz cortical mapping was actually the somatosensory aura. This series of stimulation was cancelled with limited investigation. While the patient was having the somatosensory aura, cortical excitability was increased as judged from the enlarged CCEP (140%) in response to single-pulse stimulation (Figure 113a.7). This was accompanied by a decrease of the interictally enhanced

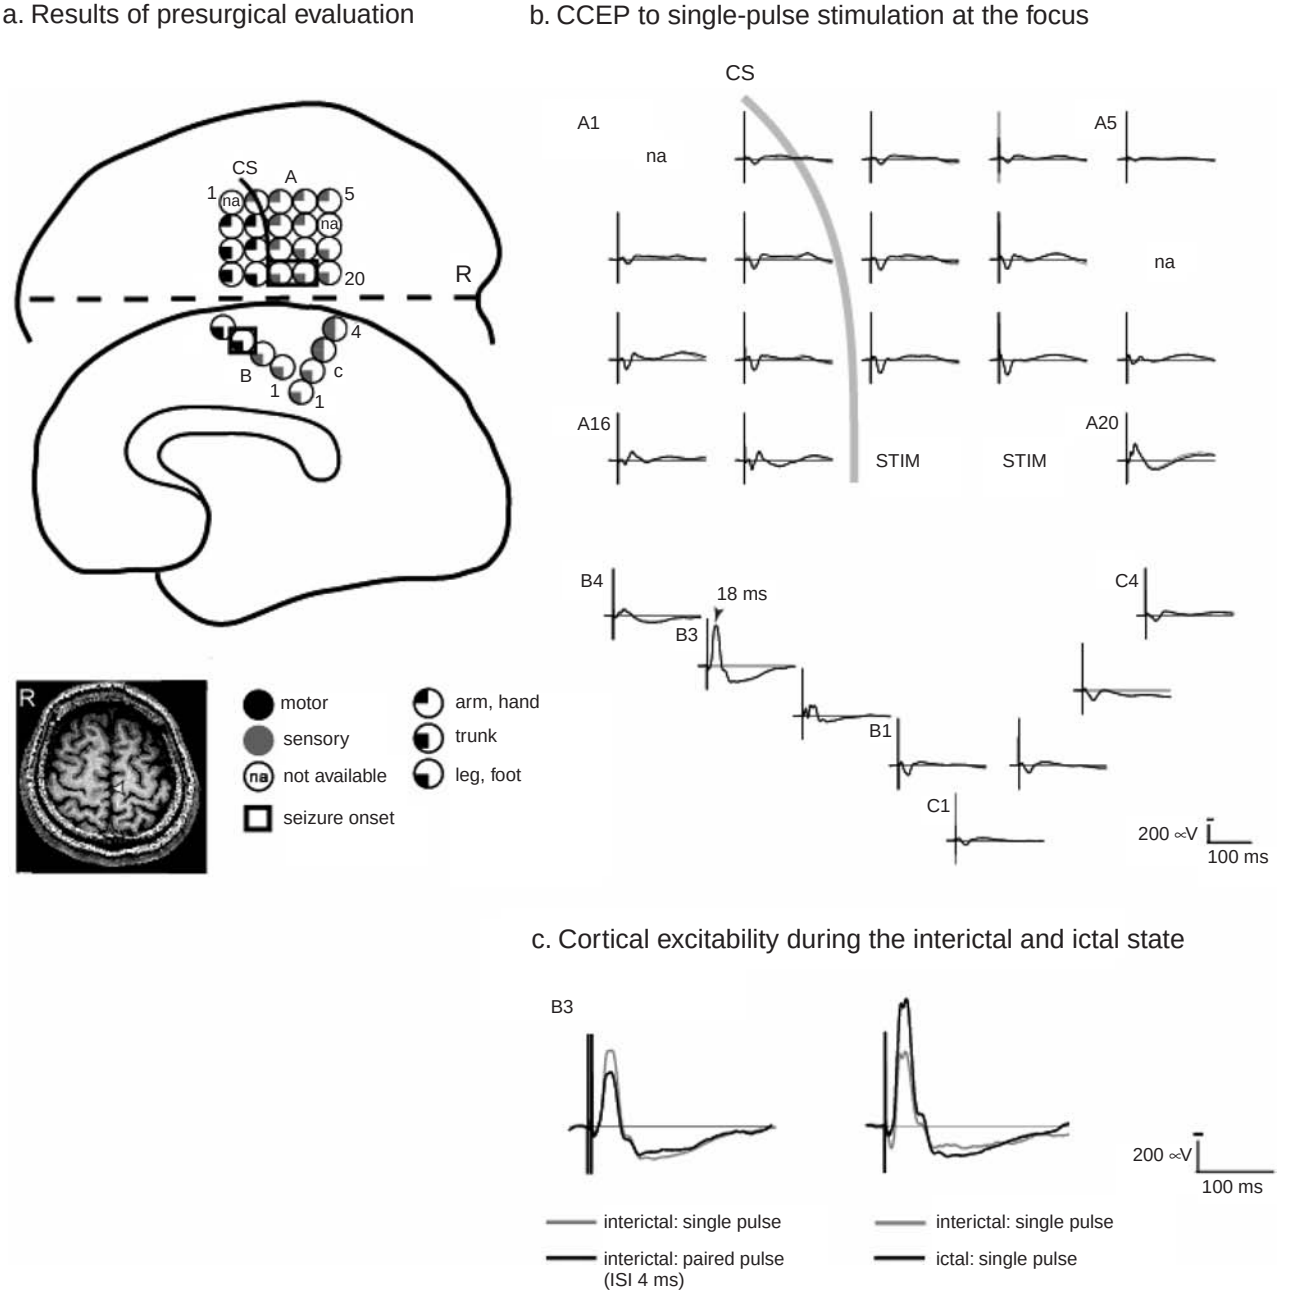

Figure 113a.7 Interictal and ictal CCEPs elicited by stimulation of the epileptic focus in a patient with focal cortical dysplasia at the left foot primary sensorimotor area. (a) Arrangement of subdural electrodes and results of the invasive presurgical evaluation. Ictal onset zone was situated in the foot primary sensorimotor area at and around the right central sulcus (arrowhead) where T1-weighted MRI (3 tesla) showed blurring of the gray/white matter junction. CS: central sulcus, na: no data of cortical function available due to high impedance of the electrode. (b) CCEPs elicited by single-pulse stimulation of the focus in the interictal state. Subaverage waveforms are plotted in black and gray lines. CCEPs were recorded in the adjacent cortices with the maximum response at the foot MI (electrode B3), most likely via projection from the foot SI to MI. STIM: site of stimulation. Other conventions are the same as for Figure 113a.1. (c) Cortical excitability during the interictal and ictal state. Magnified waveforms are shown at electrode B3 where maximum CCEPs were recorded. During the interictal state (left column), paired-pulse stimulation of the focus showed decrease of CCEP size (intracortical inhibition, maximum 22%). During the left foot somatosensory aura (right column), single-pulse stimulation showed the enlarged CCEPs (140% at electrode B3) compared with those in the interictal state, suggesting increased cortical excitability during seizure generation. ISI: interstimulus interval. Modified from ref. 19 with permission.

intracortical inhibition albeit studied at limited ISIs (4, 8 ms) (Figure 113a.8). In summary, during the aura, interictally enhanced intracortical inhibition at the focus was replaced by increased cortical excitability and decreased intracortical inhibition, suggesting increased net intrinsic epileptogenicity during seizure generation (ictogenesis) in this particular patient with FCD.

This 'paired-pulse CCEP method' could be of help in delineating alternation of the intracortical inhibitory and excitatory mechanisms *in vivo* at and around the epileptic focus. In particular, detailed comparison between the *in vivo* excitability at the focus electrodes and immunocytochemical findings in the corresponding surgical specimen will be useful.

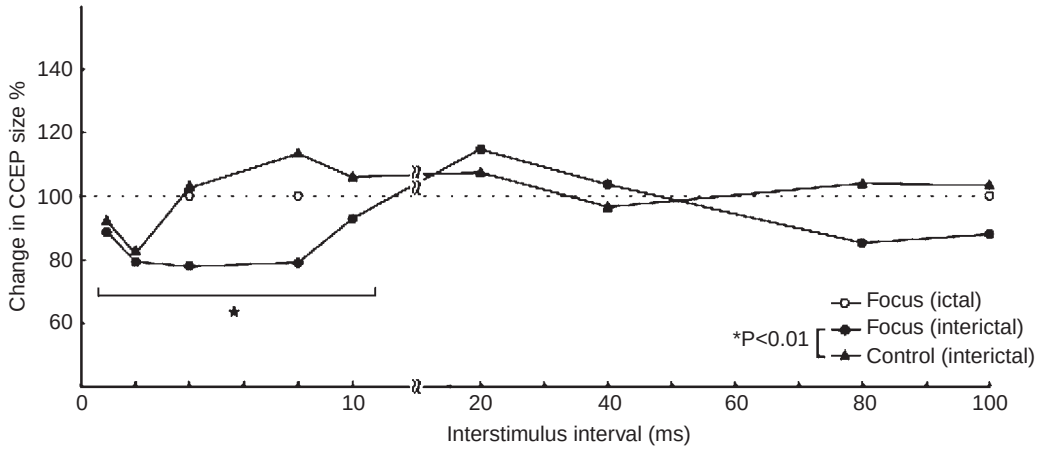

Figure 113a.8 Cortical excitability studied by paired-pulse stimulation of the epileptic focus (foot SI) and control (hand SI) cortex. At each interstimulus interval (ISI), the mean size of the conditioned responses is shown as a percentage of that of the unconditioned CCEP. Interictally, focus stimulation showed intracortical inhibition throughout the 1–10 ms range of ISIs (maximum of 22 % at ISI 4 ms) whereas intracortical inhibition was seen only at ISI of 1–2 ms in the control stimulation (maximum of 18 % at ISI 2 ms) ($P<0.01$ at ISIs of 1–10 ms; Mann-Whitney U-test). When the patient was having the left foot somatosensory aura, intracortical inhibition was not observed, though tested for limited ISIs (4, 8, 100 ms). Solid circle, open circle and solid triangle denote results of interictal focus stimulation, ictal focus stimulation and interictal control stimulation, respectively. From ref. 19 with permission.

Another potential clinical use of CCEP for understanding epilepsy is to track the pathways involved in the spread of epileptic discharges. Knowledge of the underlying physiological cortico-cortical connections is essential for a better understanding of pathological connections involved in the spread or propagation of epileptic discharges. When combined with detailed analysis of interictal and ictal discharges, the CCEP technique seems useful in this regard because it could track the pathway for each individual patient based on stimulation in the epileptogenic or irritative zone. This approach would be of importance in the presurgical evaluation of extra-temporal lobe epilepsy in which the complex functional and anatomical organization with multiple reciprocal connections facilitates rapid spread of epileptic discharges and thus produces a variety of seizure semiology.[49,50] Whether the excitability of these connections is enhanced abnormally (normal vs. pathological connection) at the epileptic focus will be an important issue to be solved.

Conclusion

CCEP provides us a new way to explore interareal connectivity *in vivo* in humans. In addition to its impact on the basic systems neuroscience, this method, in combination with conventional cortical mapping, could contribute clinically to map the functional brain systems by tracking the cortico-cortical connections among the functional cortical regions in each individual patient. This approach may help identifying the normal cortico-cortical network within the pathology or the plasticity of brain systems in conjunction with pathology. In relation to epileptogenicity, CCEP helps us to study the cortical excitability as well as to locate the circuit involved in the spread of epileptic discharges. Further verification is warranted to establish the clinical utility by recruiting more patients, combing the findings of other modalities such as DTI and the feedback from surgical results.

113b Cortical mapping by intra-operative optical imaging

MM Haglund and DW Hochman

Introduction

Increases in neuronal activity trigger a number of physiological and metabolic changes, including increases in blood perfusion and the redistribution of ions in brain tissue. When neurons fire action potentials, the microscopic pial arterioles near the firing neurons dilate,[1] leading to localized changes in blood volume and oxygenation.[2] Glial cells swell and shrink as they shuttle ions between the extracellular and intracellular spaces to maintain homeostasis following neuronal activity.[3] Each of these activity-evoked physiological changes lead to localized alterations in the way brain tissue absorbs and scatters light, and hence the optical properties of brain tissue can serve as a surrogate for neuronal activity.[4] Intraoperative optical imaging (IOI) is the method of mapping the small optical changes in exposed cortical tissue that result from neurons firing action potentials. The IOI method involves illuminating the exposed cortical surface with visible or near-infrared light, and using sensitive cameras and computer imaging techniques to measure the ongoing dynamic changes in the light scattering properties of tissue.

A typical IOI setup consists of a digital CCD camera mounted on an operating microscope (Figure 113b.1). As illustrated in Figure 113b.1, the cortex is illuminated with light from a stabilized intense source, filtered at specific wavelengths of interest. Digital images are then acquired during a rest, or 'control' state, and throughout some stimulation paradigm that might involve sensory activation or electrical stimulation of the cortex. The stream of digital images provides a movie of the dynamic optical changes that occur as a result of the stimulus, and can be analyzed in a number of ways. Figure 113b.1 shows data acquired from an awake patient who was instructed to move their tongue against their soft palette for 10 seconds. Images acquire during the peak of the activation were subtracted from control-images to yield a 'difference-image' that was pseudocolored to emphasize small optical changes. All optical imaging systems are designed around this basic theme, though with variations on the detectors, illumination wavelengths and systems, and the analysis of data. An important feature of optical imaging is that the spatial resolution is determined by the optics of the microscope and the pixel-size on the CCD chip. In this way, IOI is a very flexible imaging modality in that it can monitor macroscopic changes occurring over centimeters of cortex, and quickly zoom in to map changes occurring at the cellular level with micron-scale resolution.

IOI is still an experimental technique, but has the potential to be a valuable neurosurgical tool for at least three reasons. First, since it relies on changes in the intrinsic optical properties of tissue, it does not require the administration of contrast-enhancing agents or the placement of electrodes on the cortical surface. Second, experimental data suggests that it can localize normal and epileptic activity more quickly and with significantly greater spatial resolution than is currently possible with EEG, PET, or fMRI. Finally, it is relatively inexpensive by comparison to other imaging techniques, costing on the order of tens of thousands of dollars in contrast to PET and fMRI devices which cost millions of dollars. A major limitation of IOI is that it is not capable of mapping activity in deeper structures below the cortical surface, and hence the primary application of this technology is in localizing functional and epileptic activity in the cortex.

Importance of IOI for epilepsy surgery

Approximately 1% of the population suffers from epilepsy, and 30% of epilepsy patients are not able to adequately control their seizures with existing therapeutics.[5,6] Epilepsy patients with focal onset who are intractable to antiepileptic medications may become candidates for the surgical treatment, where the primary goal is to remove the epileptogenic tissue while sparing brain regions dedicated to critical functions.[7] Ideally, a technique is desired which would allow one to accurately map areas of cortex committed to critical functions such as speech and sensory processing, as well as the boundaries of epileptogenic tissue. Surgical treatment of epilepsy is a lengthy and expensive procedure; it has been estimated that the total accumulated costs per patient in the United States from diagnosis to completion of surgical treatment is over $100 000.00.[8] A significant portion of this time and cost is consumed by the procedures presently used to localize the seizure focus and to determine the functional significance of the epileptogenic tissue and surrounding cortical regions.[9] In the United States, there are approximately three million patients who are refractory to medical therapy, with 5 000 – 10 000 added annually; yet only 2 000 surgical procedures are performed each year.[5,10] It has been suggested that this underutilization of the surgical treatment of epilepsy is slowly being reversed as a direct result of technological improvements in neuroimaging and EEG methods for the localization of functional areas and seizure foci.[11] IOI is a relatively inexpensive technology that is capable of providing

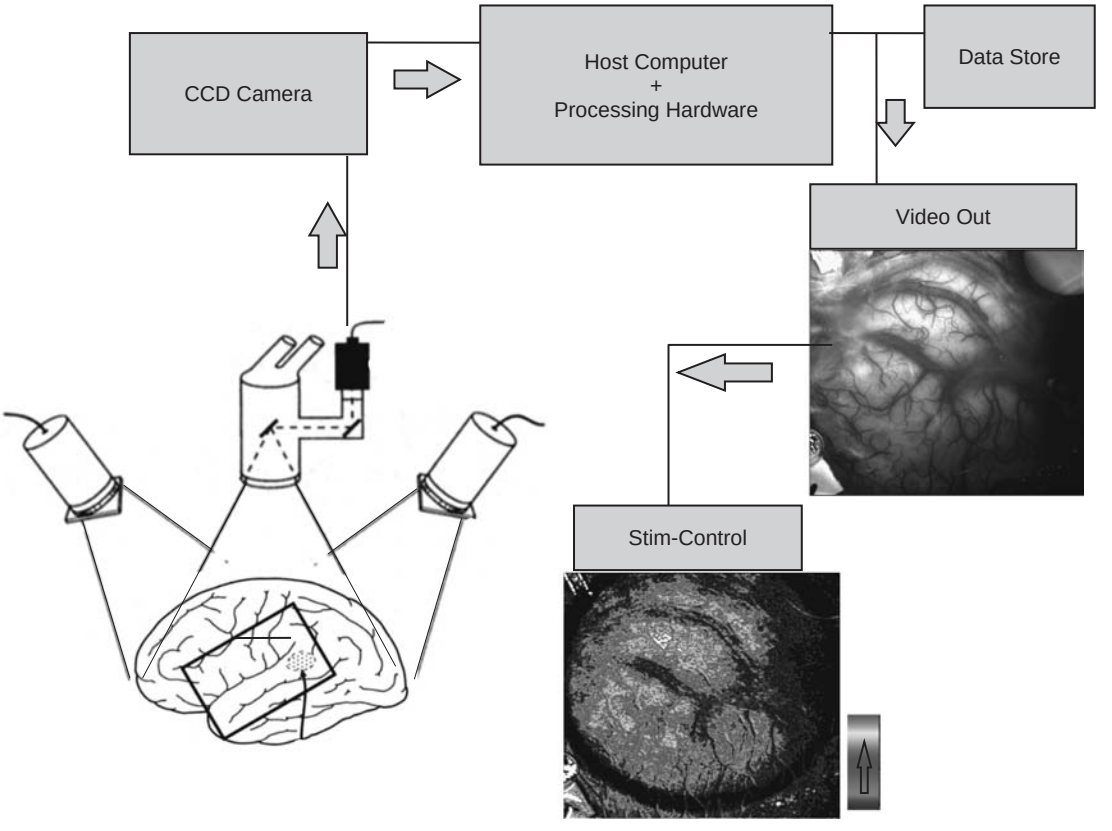

Figure 113b.1 Schematic of an intraoperative optical imaging (IOI) device: the amount of light absorbed and reflected from cortical tissue varies as a function of neuronal activity. These small changes in the optical properties of tissue can be used as a means to map dynamic patterns of neuronal activity. Shown in this figure is a schematic of a typical IOI setup, which includes a sensitive optical detector, such as high-quality cooled digital CCD camera, mounted to the operating microscope. The surface of the cortex is illuminated with a highly stable light source, such as a regulated xenon lamp. The light is usually filtered to allow illumination with specific wavelengths of light. A small glass plate can be place on the cortical surface to reduce small movements caused by respiration and heartbeat. A series of digitized images of ongoing activity are stored in computer memory, and can be replayed as a movie showing patterns of neuronal activation. The gray image shown here is a view of tongue motor and sensory cortex when illuminated with 535 nm (i.e., green) light. In this experiment, the patient was instructed to move their tongue against their palate for 10 seconds, which elicited a significant increase in neuronal activity and associated optical changes. A spatial map of the activity-evoked optical changes was generated by subtracted an image acquired during tongue-stimulation from a 'control' image acquired when the patient was at rest. This difference-image was then pseudo-colored to render small differences in the optical properties between the two images readily apparent. The maximal changes were colored red and white, representing in increase of approximately 5% in light absorption by the tissue during tongue movement. Black and blue pixels represent baseline noise. (See Color plates.)

'online' intraoperative mapping of functional cortex and seizure activity with significantly greater resolution than other imaging modalities.[4] Consequently, IOI has the potential to make a dramatic impact on the surgical treatment of epilepsy by reducing costs, improving patient outcomes, and allowing surgical treatment to be accessible to a larger number of patients. The greatest impact of IOI in the near future may be as a tool for the localization of epileptic foci on those patients with neocortical epilepsy showing no evidence of a lesion with MRI or metabolic imaging, especially since these patients consume the greatest proportion of the resources.[12]

A brief history

Detection of activity-evoked optical changes in neuronal tissue has a long history, although it has only been recently applied to mapping the human cortex. More than 50 years ago, Hill and Keynes first reported that optical changes occurred in nerves from an invertebrate when electrically stimulated.[13] They noted that upon electrical stimulation, the opacity of a nerve increases and light-transmission through the tissue is reduced; this optical change could be quantitatively measured with the simple photocells that were available in that era. These observations demonstrated that the light scattering properties and the electrical activity of axons were correlated, and served to motivate a series of further studies on invertebrate preparations over the subsequent decades, ending in the early 1970s with Larry Cohen's extensive set of studies on the birefringence changes that single neurons undergo when firing action potentials.[14] The rebirth of interest in optical brain mapping techniques occurred following a pair of publications in *Nature* in 1986 where researchers applied the newly available video and computer imaging technologies to studying primate visual cortex.[15,16] Those studies demonstrated the power of optical imaging by providing high resolution maps of the functional organization of visual cortex. Researchers showed that it was possible to generate striking images of ocular dominance and orientation selectivity columns from data acquired during a single experiment (Figure 113b.2).

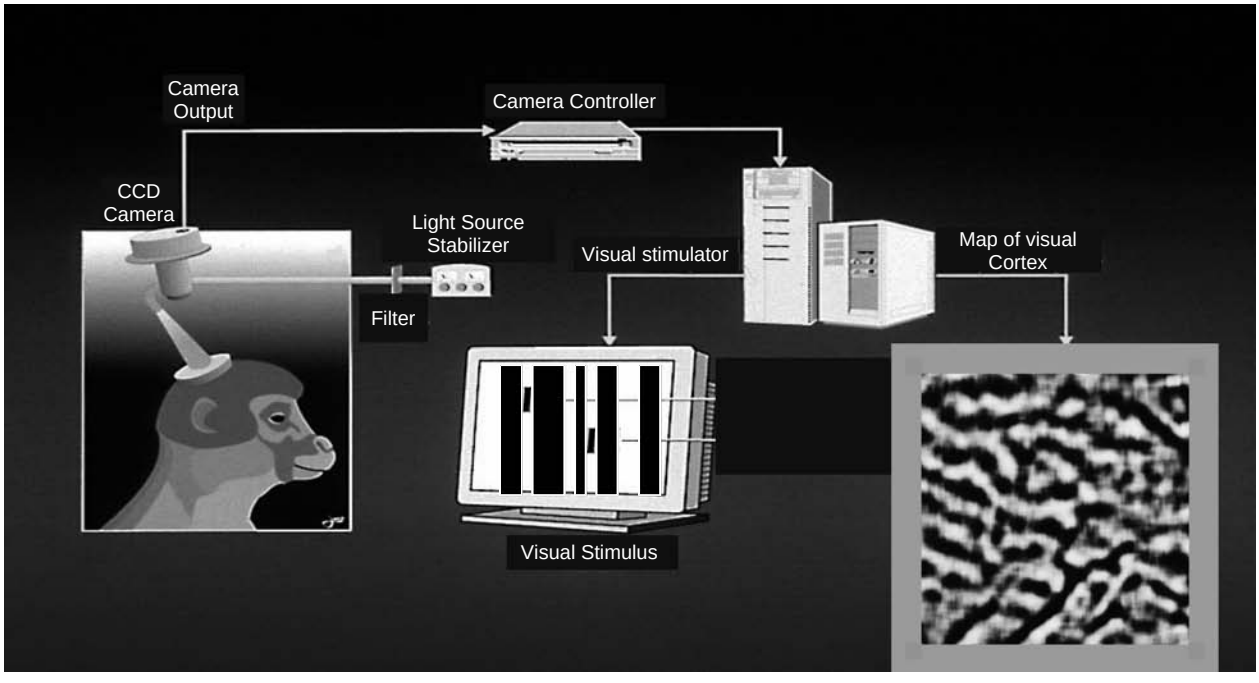

Figure 113b.2 Optical imaging of the functional organization of monkey visual cortex. The power of optical imaging was made apparent through studies on primate visual cortex published in the 1980s by two independent groups of researchers.[15,16] Those studies demonstrate that maps generated in single experiments with optical imaging could reveal patterns of cortical organization that were previously only made apparent through years of electrophysiological recordings from single neurons. Optical imaging is now a commonly used tool by visual cortex researchers. Illustrated here is a typical experiment, similar to the early pioneering studies. A cranial window is created over primary visual cortex and a CCD camera mounted to a microscope. A computer display is used as a 'visual stimulator' to display moving patterns to the monkey. Optical images of the visual cortex are acquired while each eye is stimulated independently while the other eye is closed. If left-eye images are subtracted from right-eye images, the ocular dominance columns become visible as zebra-striped patterns. Cortical neurons in each cortical column respond only to either left-eye or right-eye visual stimuli.

Previously, mapping of this cortical organization required data provided by hundreds of delicate electrophysiological experiments that involved recording the activity of single neurons one at a time, for which Hubel and Weisel were awarded a Nobel Prize.[17]

Motivated by the success in these primate studies, optical imaging techniques were finally adapted for use in the operating room in 1992.[18] These first human studies demonstrated that functional and epileptic activity could be mapped in patients undergoing surgical treatment for epilepsy.

Physiological mechanisms underlying generation of optical signal

It is known that there are at least three distinct physiological components that generate activity-evoked optical changes in cortex: (1) blood volume changes; (2) blood oxygenation changes; and (3) blood-independent changes likely involving activity-evoked swelling of glial cells.[4] It is hypothesized that it is possible to dissociate and map each of these types of changes independently by illuminating the cortex with light at the appropriate wavelength.[19]

Optical changes related to cortical hemodynamics: activity-evoked blood volume and blood oxygenation

Much of what is known about the responses of the cortical vascular network to increases in neuronal activity was elucidated by George Mchidlishvili and his co-workers through-out the 1970s and 1980s.[20,21] This work demonstrated that the microscopic pial arterioles lying on the surface of the cortex are entirely responsible for the redistribution of blood in the cortex during increases neuronal activity. The critical fact is that when neurons fire action potentials, the smallest pial arterioles near the firing neurons dilate. Work from the laboratory of H. R. Winn has shown that a pial arteriole typically dilates by approximately 30% from its resting diameter, and this vascular response is highly localized to within microns of firing neurons.[22] Such small dilations result in a tremendous amplification in blood flow, since flow is proportional to the fourth power of vessel diameter.[23] It is believed that only the terminal ramifications of the surface arterioles, prior to their penetration into the depth of the cortex, dilate. That is, the veins, larger arteries, and branches of vessels that penetrate into the cortex are thought not to respond to neuronal activation.

Two important consequences follow from the activity-evoked hemodynamic changes just described. First, since blood flow is dramatically increased by the dilating arterioles, the transit time of blood in active cortical tissue is sharply reduced, leading to an *increase* in blood oxygenation in the draining venous network. Indeed, this activity-related increase in blood oxygenation is the source of the signal measured by Bold fMRI.[24] Second, the localized increases in the diameter of the pial arterioles near firing neurons represent a localized *increase* in the blood volume of the cortical tissue. Since oxygenated (HbO_2) and deoxygenated (Hb) hemoglobin differ in the way the absorb light of various wavelengths, optical

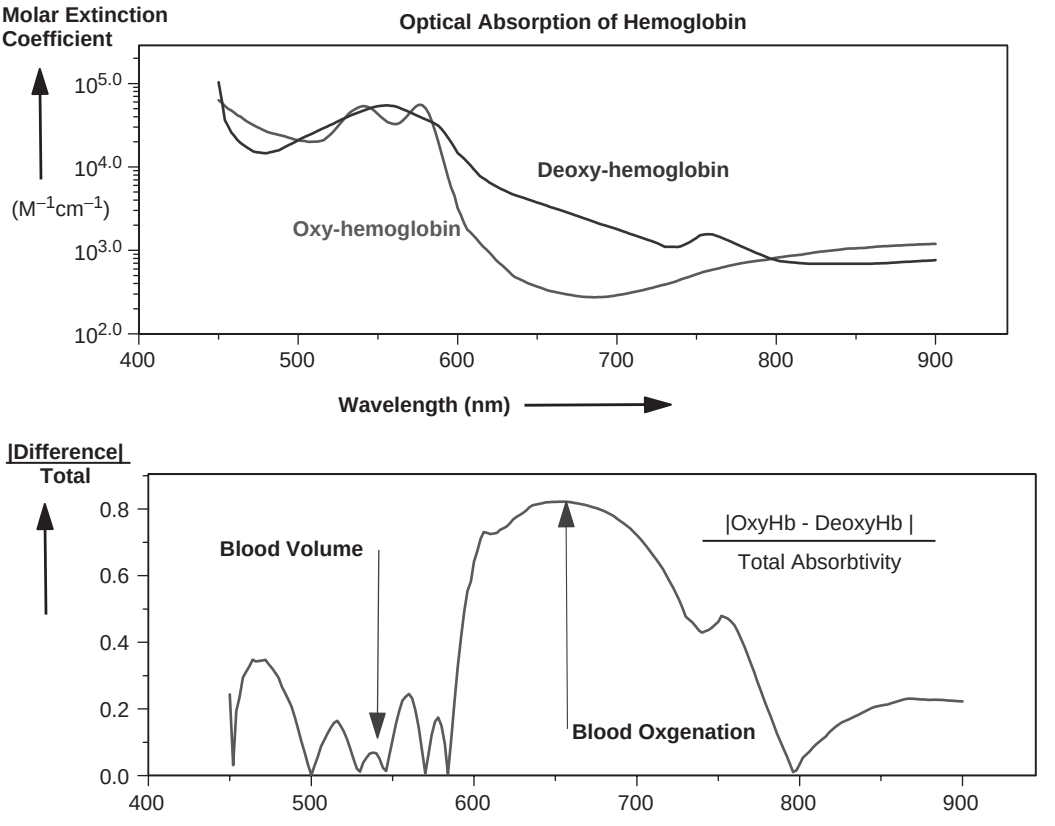

Figure 113b.3 Absorption spectra of oxy- and deoxyhemoglobin. These graphs show how much light is absorbed by hemoglobin at various wavelengths throughout the optical spectrum. The upper graph shows the spectra plotted logarithmically. The points where oxy- and deoxyhemoglobin intersect are called 'isobestic points', and represent wavelengths that are optimal for measuring changes in blood volume. Points on the graph that are maximally different are suited for mapping changes in the oxygenation state of hemoglobin. The bottom graph shows the normalized differences between oxy- and deoxyhemoglobin plotted on a linear scale.

imaging techniques can be applied to take advantage of these changes. Figure 113b.3 shows graphs of the optical properties of blood, where the upper plot shows the optical absorption spectra of Hb and HbO_2 (i.e., graphs of how much light Hb and HbO_2 absorb at each different pure wavelength); since they are plotted logarithmically, subtle features are difficult to distinguish. Hence the data has been re-plotted on the bottom as a single graph of the absolute differences between Hb and HbO_2 optical absorbances. Several features of these spectra are important to note. First, there are several 'isobestic points' – wavelengths at which the absorbances of both Hb and HbO_2 are indistinguishable (e.g., 530–535 nm and 800 nm). Since the absorption spectrum of hemoglobin at these wavelengths is independent of its oxygen state, and hence is only dependent upon the total number of hemoglobin molecules as consequence of Beer-Lambert law;[25] thus isobestic points represent ideal wavelengths to measure blood volume changes independently of blood oxygenation changes. Since Hb and HbO_2 have identical values at isobestic points, wavelengths representing isobestic points are located where their differences in light absorption vanish (i.e., where bottom graph touches the *x*-axis). Second, there are wavelengths at which Hb and HbO_2 are maximally distinguishable (660 nm and >900 nm). Consequently, these 'oxygen sensitive' wavelengths are ideal for optically monitoring changes in the oxygen state of blood, and are represented as maximal values in the bottom plot.

Imaging at blood volume wavelengths (530–535 nm) has been shown to reveal different patterns than imaging at blood oxygenation wavelengths (660 nm). For example, optical imaging of the human cortex during electrical stimulation shows that blood volume-selective wavelength are distributed diffusely throughout the tissue where the neurons are firing. However at the blood oxygenation-selective wavelength, the largest changes are restricted to the draining veins.[19] The significance of this is that optical imaging of blood volume (rather than blood oxygenation) provides the most accurate localization of neuronal activity.

Intraoperative localization of epileptic cortical activity

Ictal-like afterdischarge activity, as elicited by direct electrical stimulation of the cortex has been the most commonly mapped type of epileptiform activity mapped with optical imaging (Figure 113b.4). A more recent study suggests that IIOI may be useful for localizing tissue regions involved in the generation of spontaneous interictal activity.[19] Shown in Figure 113b.4 is data from an experiment in which the cortex of an awake patient was stimulated with a current set slightly above the afterdischarge threshold for triggering ictal seizure activity; recordings with EEG electrodes place on the cortical surface were acquired simultaneously for comparison to the optical maps (recording electrode marked as 'r' in the upper-left greyscale image). The image represents a 4 cm 4 cm area of cortex, where the distance between the bipolar stimulating

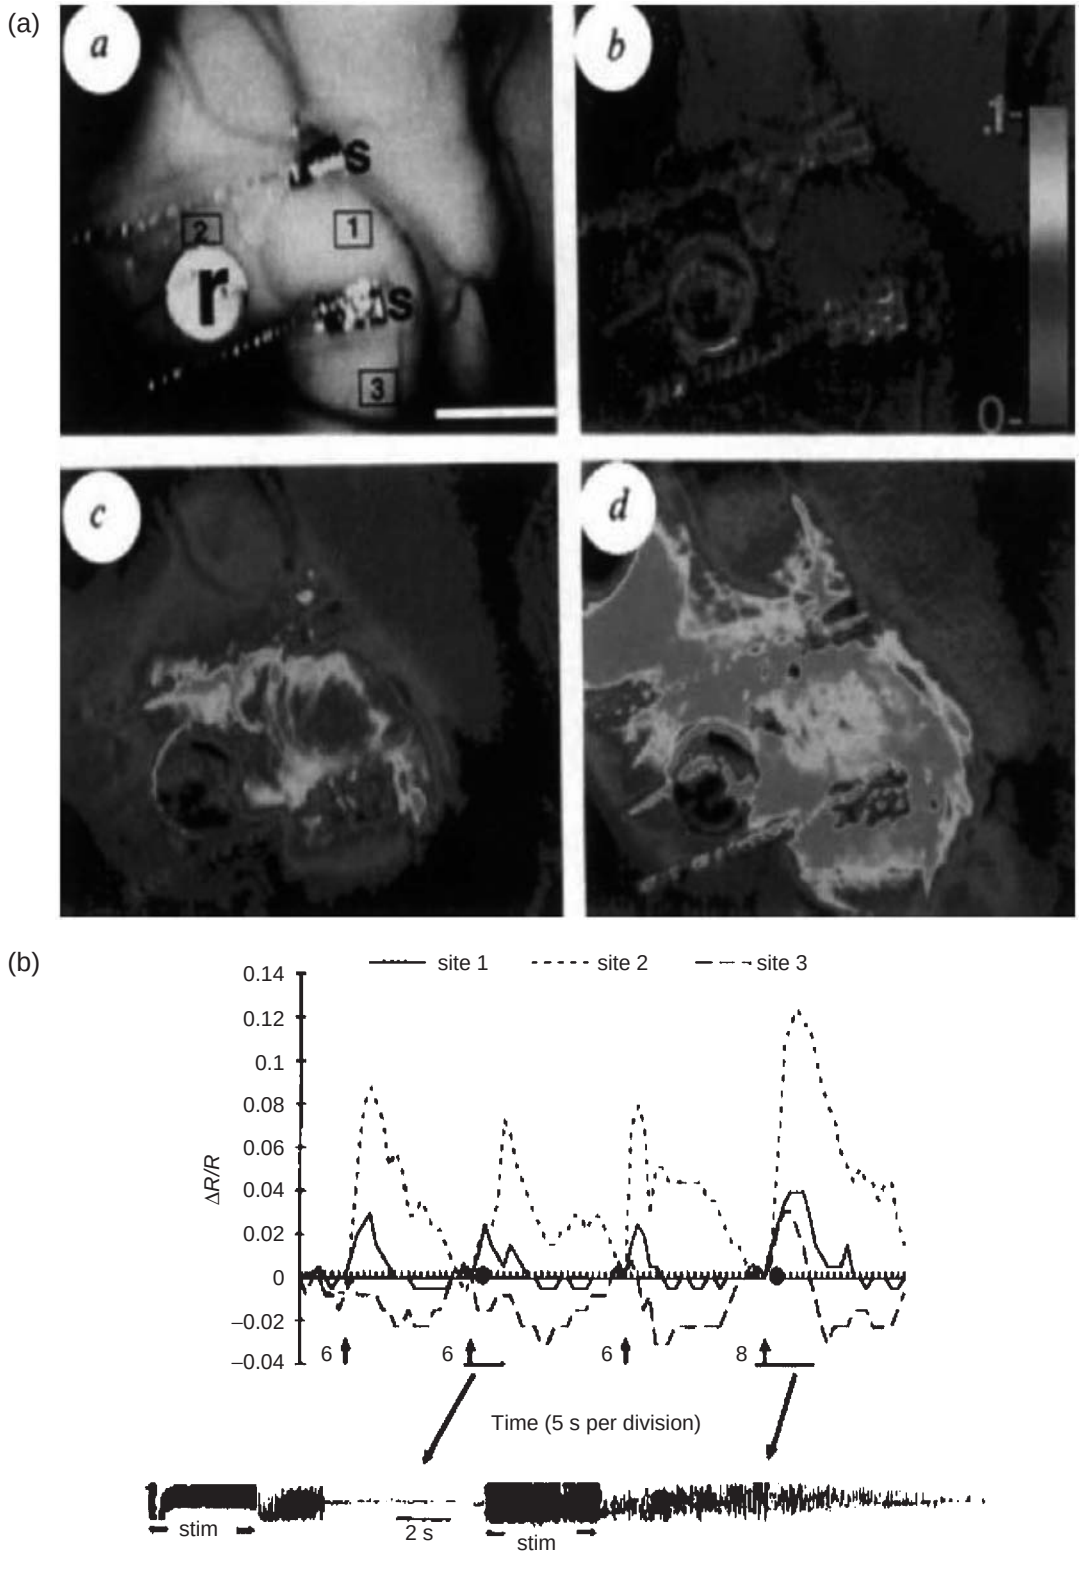

Figure 113b.4 Optical imaging of electrical stimulation-evoked ictal activity. Four consecutive afterdischarge episodes were elicited by direct electrical stimulation of the cortex with a bipolar stimulating electrode (marked 's' in the upper left a(a). a shows data acquired during two of the four episodes. Peak optical changes are represented as red. The first afterdischarge episode was less intense and of shorter duration than the second shown episode, as evidenced by the electrographic traces recorded by a surface electrode (marked 'r' in the upper gray-scale figure), shown as black traces on the bottom. Figure a(b) shows the optical image of baseline noise, and a(c) and a(d) show the peak optical changes evoked by each of the two afterdischarge episodes. Normalized optical changes from the three boxes labeled in a(a) are shown in b. The arrows represent stimulus application for four seconds and the number beside the arrow is the constant current stimulation intensity in mA. At the bottom of b are EEG traces from each of the four consecutive afterdischarge episodes. (Image adapted from previously published source).[18]

electrodes (marked 's') is approximately 1 cm. In this subject, different stimulation trials evoked afterdischarge episodes of varying durations and intensities, as the black and white electrographic recordings on the bottom of the figure demonstrate. In addition to representing data as pseudocolored difference-images, it is also possible to plot the absolute percentage change in the optical signal over time from various regions of interest. Optical changes from three different sites from the boxes labeled '1', '2', and '3', were plotted this way in the black and white plots immediately below the colored images. This quantitative analysis demonstrates that not only was a larger area of interest evoked involved in the spread of activity generated by longer-lasting afterdischarge episodes, but also the magnitude of the optical changes were large for more intense ictal activity.

Intraoperative mapping of sensory and evoked optical change

Other application of IIOS with significant practical potential is in the intraoperative localization mapping of sensory and language cortex. As an illustrative example applied to sensory localization, Figure 113b.5A shows an experiment where tongue and palate sensory cortex were first identified with electrical stimulation of the cortical surface of an awake

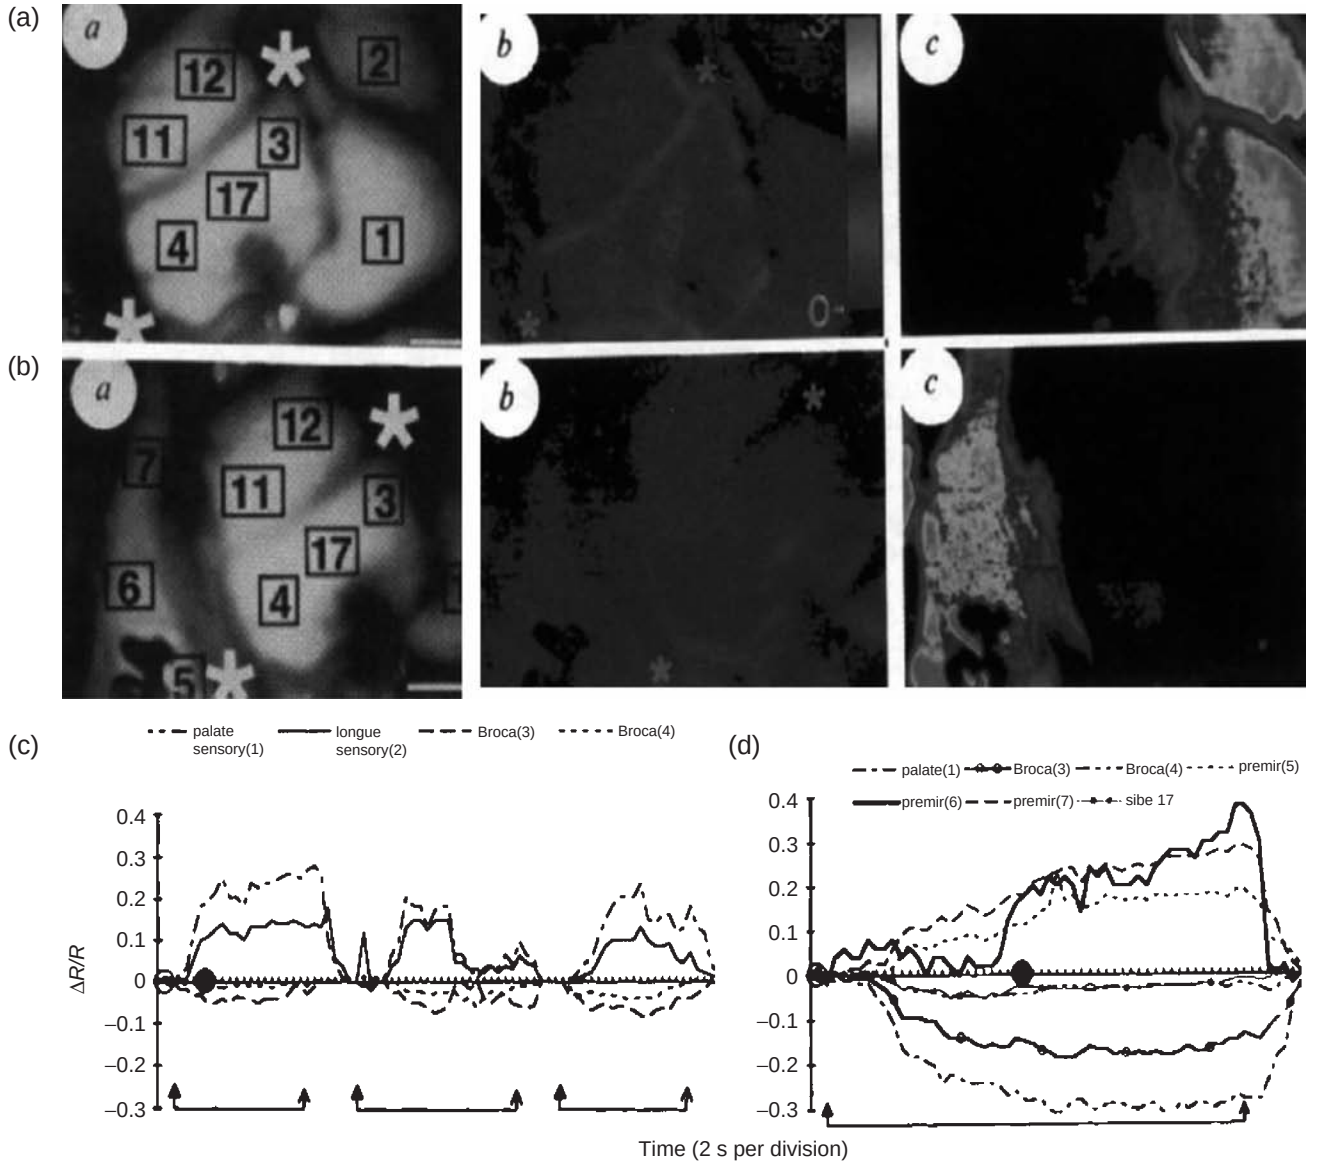

Figure 113b.5 Optical imaging of language and tongue motor sensory cortex. Anterior is to the left, posterior to the right, superior top and sylvian fissure bottom. Asterisks on the cortical surface are reference points a and b, where the field of view was slightly shifted forward. The numbered boxes in 4a(a) represent sites where electrical stimulation evoked palate tingling (1), tongue tingling (2), speech arrest-Broca's areas (3,4) and no response (5, 11,12,17). First the patient was instructed to move their tongue against their palate for 40 seconds and then allowed rest for several minutes; this tongue movement exercise was repeated three times. The solid circle in C indicates when tongue movement began. Next the field of view was shifted slightly forward to incorporate more of premotor cortex. After viewing several blank slides (control), the patient was then required to name pictures appearing every 2 seconds. b(c) shows optical changes acquired near the end of this naming exercise, showing that the maximal changes were located in the premotor region. The solid circle in the time axis in d shows when the naming began. Normalized optical changes acquired during tongue movement and naming are plotted in c and d. (Image adapted from previously published source).[18] (See Color plates.)

patient (i.e., stimulation at cortical sites marked '1' and '2' in the upper left grayscale image elicited a tingling sensation). Optical images were acquired while the patient moved their tongue from side to side against the roof of their palate. This is similar to the data shown in Figure 113b.1 though from a different patient.

Intraoperative mapping of different aspects of language function is currently a time consuming procedure. IIOS has yielded data suggesting it may be a valuable technique for localizing multiple language sites and functions in cortex. Data has been acquired from the language dominant hemispheres of awake patients in which imaging of the posterior inferior frontal and posterior temporal cortex was performed during that naming of common objects presented to the patients on a portable slide projector. Initially, essential naming sites were identified by electrical stimulation mapping. Optical maps were acquired during both overt and silent naming and compared to the maps of tongue motor and sensory cortex on the same patient (Figure 113b.5(b)). In posterior frontal cortex, optical changes occurred immediately in front of face motor cortex during overt naming, where no optical changes were observed during tongue sensory stimulation. The maximal optical changes occurred more frontally to sites at which electrical stimulation caused speech arrest. Graphical quantitative analysis of the optical changes revealed that the optical changes were initiated in the inferior frontal gyrus, and over time spread out form the site marked '6' towards the sites marked '5' and '7' (Figure 113b.5(c)). This demonstrates that optical imaging yields both spatial and temporal information of cortical language processing. Further investigation is required to determine which aspects of the optical maps provide the most reliable information for preservation of the patient's speech.

Optical imaging experiments over posterior temporal cortex also were correlated to sites of speech arrest during electrical stimulation, however in a more complex manner. Specifically, optical changes were observed in a wider area than had been identified by electrical stimulation, though no optical changes were observed in sites which naming was not interrupted by electrical stimulation (Figure 113b.6). These observations suggest that cortical areas critical for naming may extend to areas immediately surround those sites identified by electrical stimulation alone. During one experiment, the temporal resection was performed close to an electrical stimulation-identified posterior temporal language site. Naming exercises were performed by the patient during the procedure to help guide the resection, the resection being stopped when naming errors appeared, as identified by the solid line in Figure 113b.6. Experience has showed that resections stopped at that point do not lead to permanent language

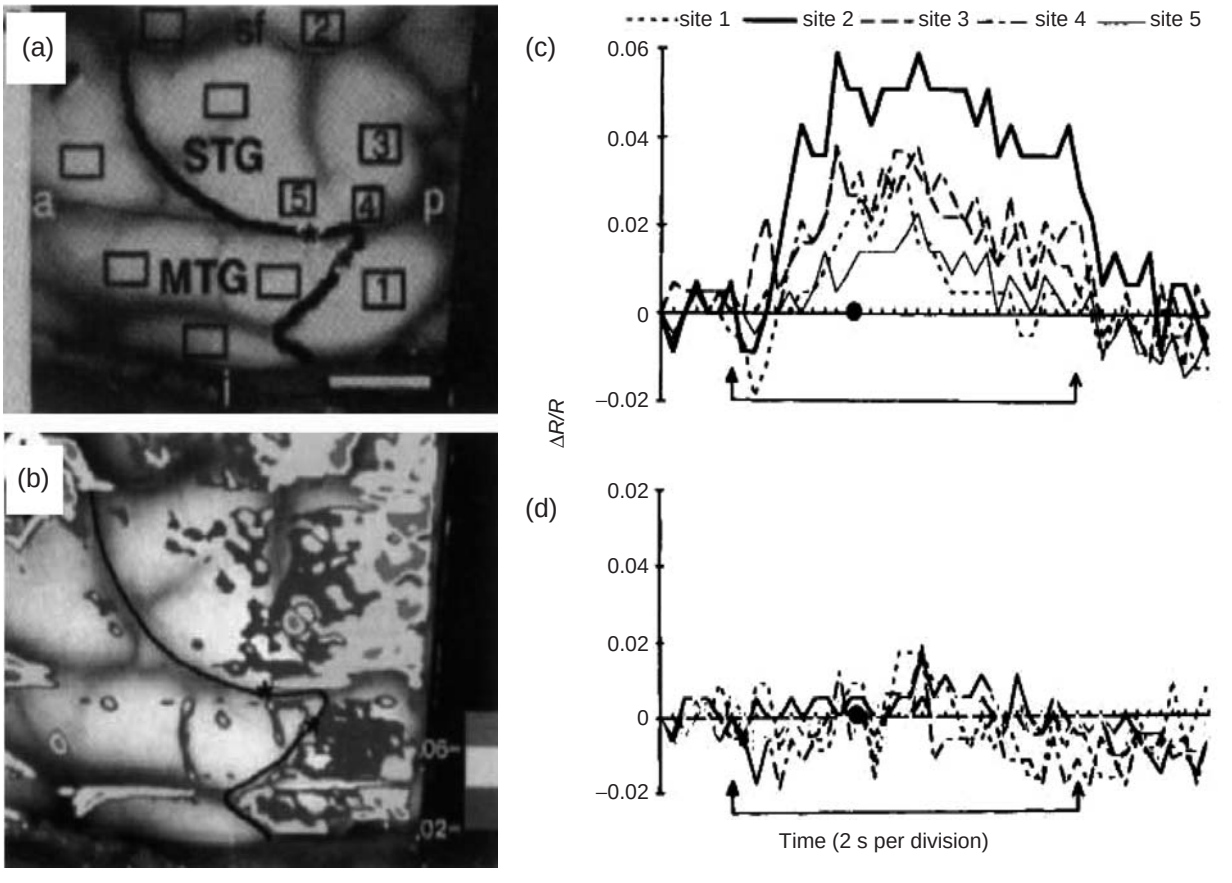

Figure 113b.6 Optical imaging of changes in Wernicke's area. a Shows dominant temporal lobe with sites 1, 2, 3, 4, and 5 representing sites where speech was identified with either electrical stimulation (sites 1, 2, and 3) or when the resection (thick black line) came from the anterior (a) to the posterior (p) in the temporal lobe (sites 4 and 5). Open boxes represent where electrical stimulation had no effect on naming objects. b shows the peak optical changes with the greatest changes localized in areas that were important for naming. c Shows optical changes during naming (arrows below axis show the start and end of the naming) at sites important for language. d shows optical changes at sites not found to be critical for naming. (Image adapted from previously published source).[18]

deficits, and this patient experienced no permanent problems. Optical imaging maps coincided exactly where the surgical resection was stopped. This provides strong evidence suggesting that IIOS can provide sufficient information for the mapping of language sites in a way that can used to guide cortical resections for the preservation of function.

Future prospects: optical imaging as a practical intraoperative tool

Although IIOS is still a research technique, it has considerable potential to be a practical intraoperative tool for the localization of epileptic and functional areas. In the authors' opinion, optical technologies and techniques have been developed to the point where it will soon be possible to take the next step of performing clinical trials aimed at validation and approval of IIOS for clinical applications. There are still several aspects of research and development which would help to further improve the IIOS technique. First, further research elucidating the relationships between the optical changes and neuronal activity will help establish the ultimate resolution of IIOS. Second, continuous improvements in computer and optoelectronic technologies are continuing to be more powerful and less expensive, and currently IIOS is the least expensive brain-mapping modality.

As described in this chapter, it has already been demonstrated that imaging of optical changes in the human cortex can provide dynamic, accurate maps of language, motor and sensory areas in human cortex. Further, the dynamic spread of epileptic activity throughout the cortex can be mapped. A further future development will be the use of noninvasive optical mapping techniques for preoperative evaluations, to support the intraoperative techniques. Such noninvasive methods are currently used in a number of academic laboratories.[26] These noninvasive techniques use longer wavelength near-infrared light which can monitor activity through the intact cranium. Although the noninvasive techniques have significantly reduced resolution by comparison to intraoperative techniques (i.e., centimeter resolution as opposed to micron resolution), these methods may supplant the need for current methods that are used for preoperative language localization and the mapping of seizure onset sites in patients suffering from neocortical epilepsy.

114 Functional localization of the cortex with depth electrodes

J-P Vignal and P Chauvel

The two objectives of intracranial recordings, electrocorticography (ECoG, subdural electrodes) and stereoelectroencelography (SEEG, depth electrodes) are to define the cortical region whose removal will result in complete cessation of seizures and to estimate the functionality of the cortical areas to be resected as well as related cortices. The cortical functions can be localized on the basis of the analysis of clinical signs and symptoms of the seizures themselves but more specifically from the results of electrical stimulations. If there are many publications on the mapping of the cortex on the basis of subdural electrodes, the publications based on the use of depth electrodes are rare. ECoG realizes a systematic but superficial exploration of the cortex. SEEG proceeds as a more targeted exploration of the cortical volume and its analysis is based above all on the spatio-temporal dynamics of spontaneous or evoked discharges. All the cortices can be explored, particularly in medial structures, but also the infolded cortex buried in the depth of intermediate sulci. The electrical stimulation is delivered in the cortex, or in the white matter, or in both. The obtained response can be the consequence of a local activation, or of a local activation triggering propagation through a neuronal network thus involving regions situated at some distance from the stimulated point. This underlies the way to interpret the stimulation effects according to the fact that it has provoked an afterdischarge or not. However, outside the primary sensory cortices and the motor cortices local afterdischarges often represent the condition to obtain cognitive or behavioural effects.

The functional localization of the cortex is constrained by the position of the electrodes. The position of the electrodes during SEEG is pre-established according to the hypothesis based on surface localization of the interictal paroxysms, of the recorded seizures and of the imaging data. The number and the position of the electrodes are optimized in order to achieve three goals: to localize the origin of seizures, to describe the ways of propagation, to identify the functions of the areas involved in the 'epileptogenic zone' and of the related areas. Bipolar stimulations were carried out between two adjacent electrode contacts. The stimulation frequency may vary from 1–50 Hz. Stimulation of the low threshold cortices (mainly the sensori-motor cortex) is performed through shock of short stimuli (~1 ms) at low frequency (1–5 Hz). In these cortices, 50 Hz stimulation provokes supra-threshold tonic responses, with a high risk of artificial tonico-clonic seizures. The associative and premotor regions have to be stimulated with a 50 Hz frequency. The stimulation intensity varies from 0.25–6 mA. The stimulus is a biphasic rectangular wave pulse, with each pulse lasting 1 ms.

The consequences of an electrical stimulation performed with depth electrodes differentiate themselves from a stimulation with subdural electrodes mainly on two points. With depth electrodes, the stimulation produces a more intense and focal perturbation. While with subdural electrodes, the motor cortex is stimulated with a 50-Hz frequency and with the intensity that can go up to 15 mA, it could be hazardous to stimulate the motor cortex with depth electrodes at 50 Hz, a single bipolar shock of 1 millisecond being enough to obtain a motor response. The sensitivity of this method is probably higher. We do not have any example where the motor cortex could not be identified, contrary to subdural stimulations.[1] The disadvantage of this very focal character of the stimulation is observed when it is necessary to synchronize a more extended cortical set to obtain a behavioural response like in language areas investigation. The second difference is the capacity to disturb neuronal networks by the stimulation of fibers underneath the cortex. The alterations imposed to cortical physiology can then be more complex and the interpretation in terms of deficit versus activation remains poorly understood.[2]

Localisation of somato-sensory and motor cortex

The localization of the somato-sensory and motor cortices has been established on the basis of subdural stimulations. Numerous maps which show the somatotopic organization of these areas along the central sulcus have been published.[3] This method, easy to implement, is the most widely used. It allows making a picture of the motor cortex from the surface. However, taking into consideration the complex convolutions of pre- and postcentral gyri, only a superficial part of the motor cortex can be stimulated, and the stimulation of the paracentral lobule is difficult. The functional maps obtained by stimulation of depth electrodes during SEEG represented, for their authors, localisations of fibers efferent from or afferent to the cortex.[4] Exploration of right parietal epilepsy. Electrodes P and L are placed to investigate the role of the sensori-motor cortex.

The stimulation of P by a 1 Hz shock at increasing intensities from 0.5–1 mA.

- P1–2: responses of left vastus lateralis
- P2–3: responses of left iliopsoas and vastus lateralis
- P3–4: no response
- P4–5: responses of left pectoralis major and deltoid
- P5–6: responses of left deltoid
- P6–7: responses of left deltoid
- P7–8: responses of left deltoid and triceps brachi
- P8–9: no response
- P9–10: tingling at the external side of the left wrist
- P10–11: tingling at the back side of the hand
- P11–12: idem
- P12–13: no effect

The stimulation of L is negative.

Interpretation: Taking into consideration the shape of the central sulcus, the electrode P explored along its trajectory the primary motor cortex of the leg and of the arm in their proximal parts and the primary sensory cortex of the hand. It crossed the central sulcus between leads 8 and 9, the latter in the upper limb distal representation in SI and the former in the proximal representation in MI, the two representations being not exactly facing each other. There is no need in this case to imply a relay of white matter stimulation to interpret this sequence.

Case 2. Exploration of epilepsy of the left operculo-temporal region. A cyst was evident in the left frontal opercular region. The etiology of this epilepsy was unknown. But seizures had been observed starting from the neonatal period. The perisylvian region showed a morphological change the consequences of which have to be cleared. He was a right-handed man but the Wada test showed the absence of speech arrest during injection into the left carotid. The objective of the electrodes P′ and S′ was to explore the motor cortex. The electrodes T′, H′ and J′ explored the superior temporal gyrus up to the junction with the parietal lobe. O′ was situated in the region of the Broca's area.

Stimulation of P′ at 1 hertz and 1 mA intensity:

- P′1–2: responses of the right deltoid
- P′2–3: responses of the right deltoid
- P′3–4: responses of the right deltoid
- P′4–5: responses of the wrist flexors
- P′5–6: responses of the wrist extensors
- P′6–7: numbness of the back side of the right hand, rhythmed by stimulation
- P′7–8: no response
- P′8–9: no response

Interpretation: Electrode P crosses the central sulcus as in the preceding case, thus the sensori-motor cortex; the stimulations activate the cortex, but possibly also the corticospinal fibres (after reconstruction of the electrode trajectory in Talairach's atlas).

Stimulations of S' at a frequency of 1 hertz and the intensity of 1 mA:

- S′1–2 and S′2–3: responses of the flexors muscles of the right wrist
- S′3–4: responses of the flexors muscles of the elbow
- S′4–5: responses of the thumb flexor
- S′4–5 to S′ 9–10: no response

Interpretation: The responses are the consequence of the stimulation of the corticospinal fibres.

The stimulations at 50 Hz for 5 seconds also provide data on the functional capacity of the explored cortex. No stimulation has provoked either phasic troubles or speech arrest. The stimulation of K′11–12 at 2.5 mA provoked an afterdischarge for 3 seconds on the external leads of K′ accompanied by a contraction of the right hemiface. The stimulation of K′10–11 provoked a sensation of swarming in the right cheek and a afterdischarge for 7 seconds on the external leads of K′ and on the external B′. The stimulation of J′8–9 at 2.5 mA provoked an afterdischarge for 3 seconds on external S′, external K′, external P′, external B′ and external J′ and a contraction of the right labial commissure followed by a clonic fall of the right arm. The interpretation of these responses is complex because of a local afterdischarge and, in one case, extended afterdischarge, and because the stimulations at 1 Hz of these electrodes had not evoked any response. However, it shows a reorganization of the sensori-motor opercular cortex.

The stimulation of H′2–3 at 1.5 mA evoked a sensation of painful heat in the right ear. During the stimulation of H′4–5 at 1.5 mA, the patient described an impression of turning with her bed in the room.

The excision of the cortex implied the region where electrodes S′, J′ and K′ were implanted. During the postoperative period no motor, sensitive or language deficit was observed.

The localization of the somato-sensory and motor cortex is based on the position of the electrodes correlated to the anatomic location reconstructed in three dimensions using angiography and stereotaxic MRI.

Localization of the supplementary motor area (SMA)

The stimulation of SMA with intracerebral electrodes allows provoking motor manifestations close to those observed during stimulations in corticography. To localize the SMA, stimulations at 50 Hz frequency and at 1–3 mA intensity have to be used. The stimulations by shock of 1 ms duration are inefficient. Talairach and Bancaud[4,5] localized the SMA at the medial aspect of supetior frontal gyrus using this method. The occurrence of diverse motor signs has been reported by Chauvel *et al.*[6] Speech arrest either accompanied or not by motor arrest was reported in 73% of positive stimulations. The tonic motor raising and abduction of the contralateral upper limb in 42% of the stimulations, deviation of head or eyes occurred in 31% of the stimulations of the medial cortex. The motor modifications of the arm were predominant over the proximal musculature realizing a movement of abduction and of rising of the shoulder. Deviation of head and eyes was tonic and contralateral to the side of the stimulation. Vocalizations were frequent (27% of the stimulations). A motor modification of the inferior limbs was rare and consisted of an extension associated with an abduction of the leg. Chauvel *et al.* insisted on the association of these signs. He remarked that speech arrest frequently occurred alone (50% of the total of positive stimulations) and with the weakest intensity values. A movement of the inferior limb or an adversion of the head rarely occurred in isolation (10.6% and 2.2% of the stimulations). These observations, an analysis of the

intensity values and of the plots on which these signs were obtained allowed Chauvel *et al.* to discuss the respective roles of the SMA and of the lateral cortex of areas 6 and 8. Only the coactivation of these two regions could explain the emergence of some signs such as the adversion and the postural tonic modifications of the superior limb.

Negative motor areas have been localized in the lateral and medial frontal cortex including SMA using high frequency cortical stimulations with subdural electrodes.[7] The stimulations by shock (1 Hz) at intensities from 0.4–3 mA provoke negative myoclonia. These negative myoclonias (more precisely a brief silent period at EMG) could be evoked in an extended cortical zone including the premotor cortex (including the SMA), the motor cortex and the somatosensory area.[8] Only the stimulations of the SMA provoke the periods of silence which do not depend on the intensity of stimulation suggesting a particular role of this structure in the organization of negative myoclonias.

Localization of Broca's area

The high frequency stimulation of Broca's area provokes speech arrest sometimes preceded by paraphasia.

Case 3. Exploration of epilepsy of left prefrontal regions in a right-handed patient aged 18. The Wada test confirmed dominance of the left hemisphere for language. MRI showed a dysplasia in the frontal interior gyrus. The purpose of the exploration is to study the relation between the lesion and the epileptogenic zone and to define the posterior limit of cortical excision in localizing Broca's area.

We sum up the main results of the stimulations. The stimulations of O′ at 50 Hz for 5 seconds at 2.5 mA and 3 mA had no effect.

Stimulation of P′ at 1 Hz at 3–6 mA:

- from P′2–3 to P′8–9 successively: periodical twitch of the right labial commissure, then of the right hemitongue, then of the superior lip or muscles of the chin.

Stimulation of R′ at 50 Hz for 5 seconds at 1.5 mA:

- from R′ 1–2 to 7–8: no effect
- from R′8–9 to R′11–12: speech arrest after some paraphasia

Stimulation of I′ at 50 Hz for 5 seconds at 1.5 mA:

- from I′1–2 to I′8–9: no effect

Stimulation of I′ at 50 Hz for 5 seconds at 2.5 or 2.8 mA:

- from I′ 1–2 to I′ 4–5: no response
- of I′5–6, I′ 6–7, I′ 7–8, I′8–9: each one of these stimulations provoked a seizure. These seizures started by speech arrest or by paraphasia with sometimes a start of jargonophasia. Then we observed a smile, face flushing, and gestural activity repeated twice: the patient crossed and uncrossed his legs, scratched his thorax with his left hand, hit his stomach with the right hand and then with his left hand. The discharge onset involved the lateral leads of O′, of R′, of A′ and the medial leads of F′. Then, the discharge spread to T′, H′. During the postictal period a language deficit was noted

These results allowed to conclude that P′ was situated in the face motor cortex, R' in Broca's area, while I′ was in the epileptogenic zone, but outside Broca's area. Excision of the lesion (DNET) and cortex around I′ and O′ did not provoke any language deficit. There is no study evaluating the reliability and the sensitivity of this method to localize Broca's area.

Localization of the sensory areas

The stimulations of the superior temporal gyrus provoke hallucinations and auditory illusions which allow localizing the auditory cortices.[9] De Graaf *et al.* showed that 76.7% of the electrodes in the temporal superior gyrus provoked auditory responses. The stimulations were delivered at 50 Hz for 5 seconds with intensity varying between 0.5 and 2.5 mA. There was no relation between the existence of a afterdischarge and obtention of an auditory response. The study of 180 stimulations of the superior temporal gyrus reported 32% of elementary hallucinations and 30% of illusions. The hallucinations were described as whistling, buzzing, and sizzling usually situated in the contralateral ear by the patient. Illusions were reported as modifications of intensity or tonality of the observer's voice or of the patient's own voice. The illusion of reverberation or echoing was also frequent. These illusions could be unilateral as well as bilateral. Complex auditory hallucinations were exceptional, contrary to the data obtained in electrocorticography by Penfield and Perot.[10] For de Graaf *et al.* this difference could be explained by the fact that Penfield and Perot stimulated with monopolar electrodes the surface of the cortex in patients who often presented seizures including auditory hallucinations. So, the hyperexcitability of the stimulated region, added to the technique of stimulation, allied to engage a larger cortical network as a result of stimulation. De Graaf *et al.* showed that it is possible with the stimulations to discriminate with precision between the primary and secondary auditory cortex and associative auditory areas in the superior temporal gyrus and temporal plane.

No auditory responses were provoked outside the superior temporal gyrus.

The localization of the gustatory cortex presents less interest for surgical planning, but is important for localizing seizure onset. The gustatory cortex is localized in the insula and in the frontal operculum. A secondary gustatory area is described in the orbito-frontal latero-caudal cortex. Hausser-Haw and Bancaud[11] described nine sites where the stimulation provoked a brief and isolated gustatory hallucination without an afterdischarge or with a local afterdischarge. They identified six different regions. In four cases the hallucination was provoked by the stimulation of the rolandic operculum and of the parietal operculum in one case. Two of these patients did not present any gustatory hallucination during their seizures. The other sites were amygdala in one case, the hippocampus in another one, the medial aspect of T1 in one patient and the anterior part of T2 in one patient. It must be observed that all the stimulations were right sided. All the stimulations had been delivered at 50 Hz with the exception of one case done at 2.5 Hz. These hallucinations were usually unpleasant. The opercular rolandic region plays a major role in the

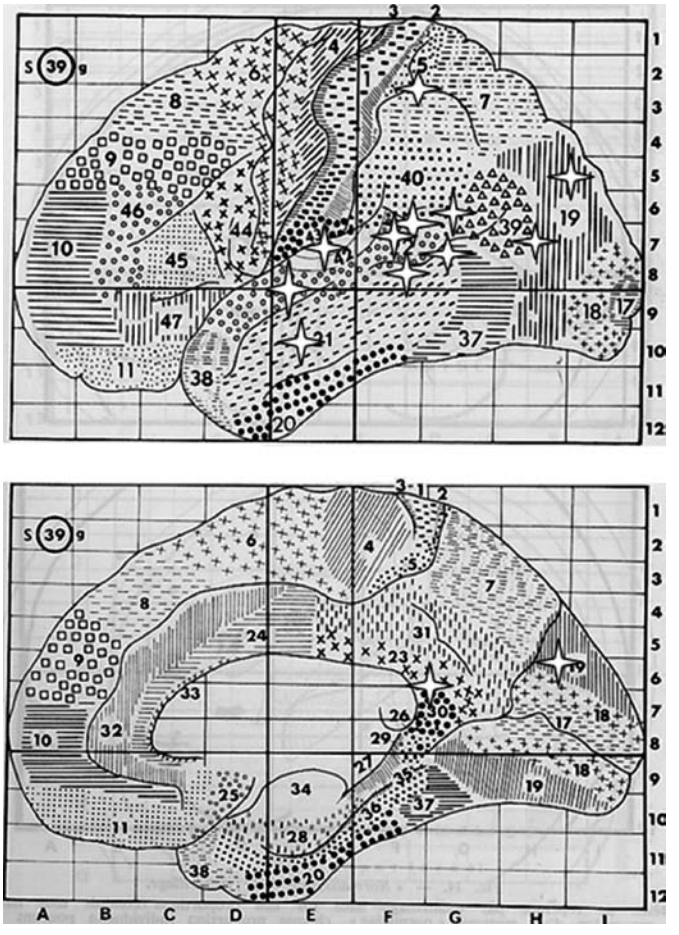

Figure 114.1 Location (✧) of 31 stimulations which evoked vertigos (19 patients).

emergence of gustatory hallucinations, either directly because of the location of the gustatory cortex or indirectly because of its connections with the temporal lobe, especially amygdala facilitated by the presence of an epileptogenic zone. Obtaining a gustatory hallucination by stimulation with subdural electrodes seems rare and has not been reported.

Vestibular projections are situated near the somatosensory face representation and the limit between the somesthaetic cortex and the motor cortex. Kahane *et al.*[12] defined vestibular manifestations as an illusion of rotation or of moving which concerns the patient himself or the environment. These authors showed that the sites the stimulation which induced a vestibular illusion were widely distributed in the lateral temporal and parietal cortex, with predominance in Brodmann areas 40, 21, and 22 of. The stimulations were delivered either at 50 or 1 Hz with intensities between 1 and 3 mA. A personal unpublished study (Figure 114.1–2) performed from 160 SEEG found this dispersion in the parietal and temporal lobes. This dispersion was even more extended, especially by existence of numerous responses in the posterior cingulate gyrus (areas 23, 31). Using these responses, Kahane *et al.* postulated the existence of a vestibular temporo-perisylvian cortex which would be the homologue of the vestibular parieto-insular cortex of the monkey. However, the clinical interest of these vestibular responses for surgery is limited but they have proven to be useful for understanding seizure organization, even though the anatomical significance is still lacking.

Localization of the insula

Insula is involved in visceral and autonomic functions, particularly control of digestive motility, taste and cardiovascular regulation, and pain. A change in heart rate and in blood pressure is provoked by the stimulation of the insula in man.[13] These stimulations have been realized during surgery and after the ablation of the superior temporal gyrus. Apart from surgery, only SEEG allows exploring the insula. The publications on the stimulations of insula using depth electrodes have not studied their effects on the cardiovascular system.

The stimulation of insular cortex provokes visceromotor and viscerosensitive responses and somesthetic manifestations.[14] The responses have been obtained by stimulating at high frequency (50 Hz for 5 seconds at intensities between 1 and 5 mA), and exceptionally by stimulating at low frequency. Viscerosensitive manifestations were nausea and a sense of abdominal and thoracic fullness. Visceromotor responses were movements of mastication and lip smacking. Somesthetic responses were usually contralateral to the side of stimulation, sometimes bilateral and painful or not. Viscerosensitive and visceromotor responses were provoked by stimulation of the anterior insula, while somesthetic manifestations were provoked by stimulation of the posterior insula. Ostrowsky *et al.* showed a somatotopic organization of somesthetic responses, painful in the superior part of the posterior insula and not painful in the posterior insula of both hemispheres. These authors have not studied changes in blood pressure and in heart rate.

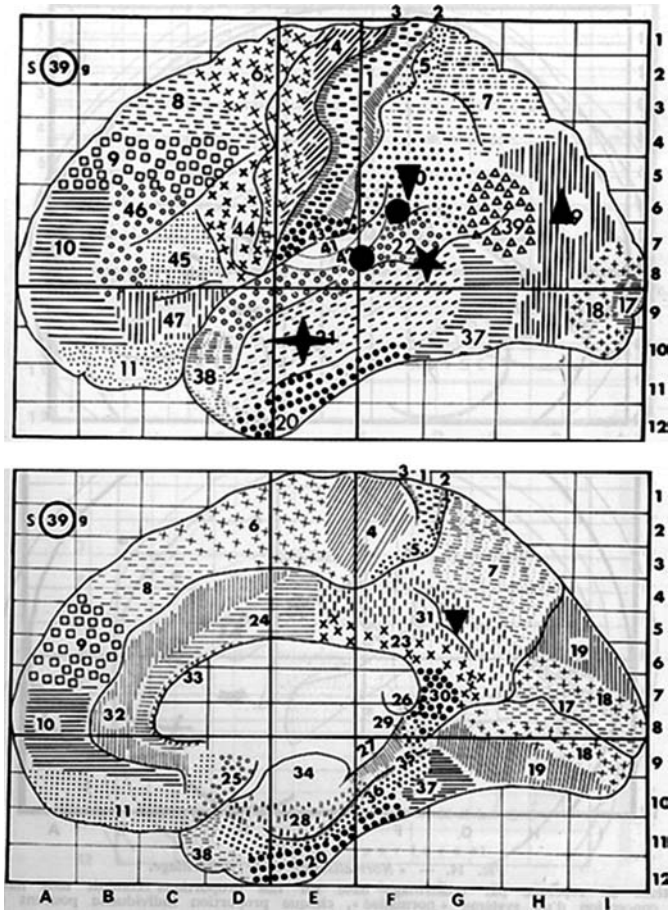

Figure 114.2 Responses to stimulation: 'gliding' (cross), 'falling' (star), 'environment turning from right to left' (triangle up), 'moving back' (triangle down), 'rolling sensation' (circle).

115 Intraoperative cortical mapping and intraoperative electrocorticography

DR Nair and I Najm

Introduction

It was Hans Berger who first pioneered the technique of electrocorticography (ECoG) in humans by studying a patient with a recent trephined skull.[1,2] The early investigations using ECoG were concentrated on proving the cortical origin to the electrical activity being recorded. The use of ECoG during surgical exposure was performed on patients with brain tumors and finding that the distortion of ECoG seen from brain tumors resulted from damage to adjacent cortex and did not emanate from the tumor itself.[3] The focus of ECoG shifting to the field of epilepsy occurred in Montreal in the late thirties with Wilder Penfield and Herbert Jasper at the Montreal Neurologic Institute. Electrocorticography was an established and integral part of epilepsy surgery for several years. It was through the use of ECoG that Penfield established the concept of epileptogenic anatomic lesion and the epileptogenic physiologic lesion.[4] It became recognized that convergence of these two regions was often necessary for a good post-surgical outcome. There are further subdivisions that one can use to differentiate regions associated with epileptogenicity. For example the epileptogenic lesion may be mesial temporal sclerosis; this area is surrounded by a fairly large area of interictal epileptiform activity described as the irritative zone. The area which represents the detected ictal onset is referred to as the ictal-onset zone. The area which when removed by surgery and results in rendering the patient seizure-free is referred to as the epileptogenic zone (Figure 115.1). The epileptogenic zone can only be inferred retrospectively after surgery. For epilepsy surgery to be a success, it is usually required that these various defined areas converge to one particular region.[5] Intraoperative ECoG has played an important role in the management of medically refractory focal epilepsy. It has been used to map epileptic tissue, monitor after-discharges during cortical stimulation, and for prognostication of surgical treatment of epilepsy. Despite these clinical usage there has been relatively few studies that have evaluated the efficacy of its use.[6]

With the onset of new technology, namely high-resolution MRI scan, positron emission tomography (PET), single photon emission computed tomography (SPECT), in addition to video-EEG monitoring data, convergence of data can be used to plan epilepsy surgery at times without the need for ECoG. There are, however, times during the evaluation of a patient for epilepsy surgery when ECoG can still be of benefit. This chapter will underscore some of the utility, methodology, limitations, and future directions for intraoperative ECoG.

Indications

Around the late 1940s and early 1950s, temporal lobe epilepsy became a well-recognized syndrome in patients with focal epilepsy. This introduced the therapy of temporal lobectomy as a surgical therapy in these patients. Many of the centers doing this surgery initially used ECoG to guide their surgical resections. It was through the use of ECoG that it became clear that mesial resection in including amgdala, hippocampus, and uncal regions were required to gain full benefit from this surgery for the patient. Once the surgery became standardized, the role of ECoG became progressively less used in a number of centers. For those centers that continue the use of ECoG in these surgeries, the use of this modality is aimed at either evaluating a possible extratemporal lobe involvement that was previously undetected by the extraoperative evaluation, for monitoring after-discharges during cortical stimulation for localizing language function, or for the detection of persistent epileptiform activity around the margins of the initial resection to determine if further extension of the margins of resection is needed.[7] The use of intraoperative ECoG in patients with extratemporal lobe epilepsy is more frequently used. These patients often represent a challenge to the neurosurgeon when either the anatomic abnormality may be subtle or a clear localization of the extraoperative physiology may not be available.

Various issues which remain unclear with regards to intraoperative ECoG include:[8]

- Is it important to include the irritative zone in all cases of epilepsy surgery, or is the epileptogenic zone encompassed by the irritative zone?
- Is there prognostic value in cases of residual interictal epileptiform activity in the postresection ECoG?
- Does activation of epileptiform pharmacologically provide useful data?
- Are there morphological or topographical criteria that can be used to predict prognosis or perhaps pathology?

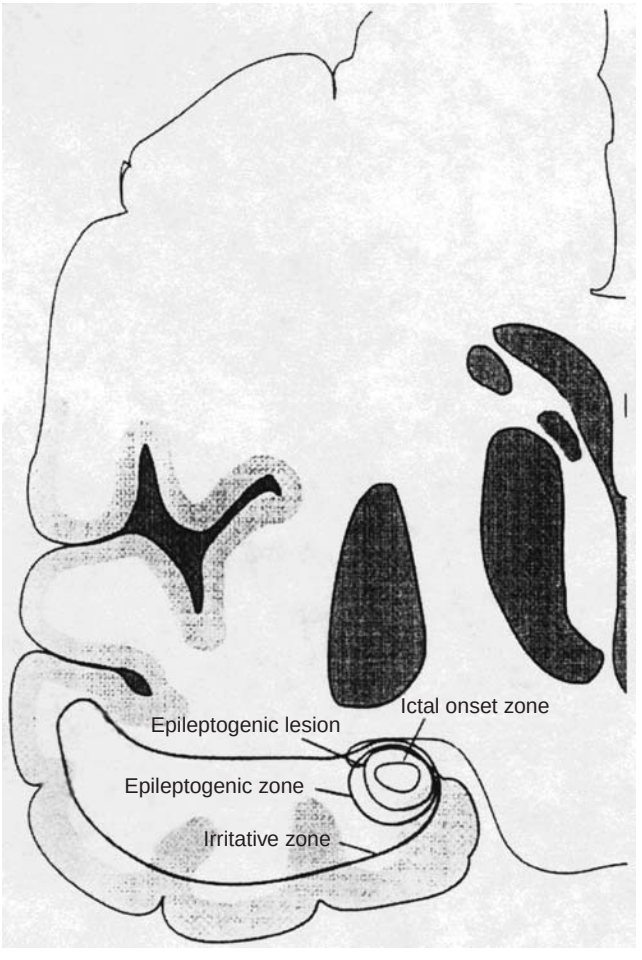

Figure 115.1 Outlining various regions converging to one particular cortical region. Taken from Dinner *et al.,* 1998.

Intraoperative ECoG is most often used as a guide in the operative management of patients with epilepsy to determine margins of resection. Intraoperative ECoG is also being used to address issues relating to prognosis for the patient as well as a research tool in the study of epilepsy.

Classification of abnormalities

There have been a variety of attempts proposed in order to create a systematic classification of ECoG abnormalities.

Interictal nonepileptic abnormalities

Spikes on the scalp-EEG are defined as a paroxysmal discharge lasting less than 80 msec with a mono- bi-, or polyphasic morphology followed by an aftergoing slow wave. Spikes recorded in the setting of use of subdural or depth recordings pose some unique challenges. For instance, it is not possible to differentiate various normal variants, such as small sharp spikes, in intracranial recordings.[9] This is due to the obvious lack of ability for recording ECoG in normal patients. Therefore, sharply contoured waveforms seen on ECoG have an unclear clinical significance. The requirements of amplitude, duration, morphology for intracranial recordings do not yet exist. In spite of this major limitation, most of the classifications have taken the aim of classifying spikes based on a quantification measure. Spikes were analyzed in one study by describing a *spike discharge rate*. This was defined as the percentage of spiking per unit time (seconds). The spike discharge rate was considered high frequency if greater than 50% and low frequency if lower than 50%.[10]

$$\text{Spike discharge rate} = \frac{\text{No. of seconds with any spikes}}{\text{Total seconds of recording}} \times 100$$

A number of continuous epileptiform discharges can be seen in ECoG. In a study of patients with cortical dysplasia, the frequency of spiking patterns appeared to be closely related to the outcomes of the patients, which will be described later in the chapter. In this study, three different patterns were discussed, one of which was essentially an ictal epileptiform pattern. The two other patterns may also represent an ictal pattern or a transition between ictal and interictal states due their very repetitive and rhythmic characteristics in three noted spiking patterns. *Continuous or quasicontinuous rhythmic spiking* consists of prolonged trains of spikes that occur rhythmic at 2–8 Hz and at times may be continuous or periodic (Figure 115.2). *Repetitive bursting patterns* refer to a high-frequency rhythmic polyspikes that appear suddenly and last from 5–10 seconds and then abruptly disappear. The frequency of these discharges varies from 10 to 20 Hz.[11]

Other classifications of interictal epileptiform activity differentiated spikes based on their frequency characteristics as well as their persistence. *Frequent spiking* was described as five or more spikes in 10 seconds. *Continuous frequent spiking* was described as *frequent spiking* defined above occurring every 30 seconds or more. *Very frequent spiking* was described as 20 or more spikes every 10 seconds. *Continuous very frequent spiking* was described as *very frequent spiking* as described above occurring in two bursts every 30 seconds or more. *Bursts of fast activity* was described as fast activity occurring at 10 Hz or higher in bursts lasting 2 seconds or more.[12]

Ictal epileptiform abnormalities

The presence of ictal recordings during intraoperative ECoG is a rare occurrence due to the time limitations of the recordings and perhaps due to anesthetic suppressive effects. In the study of Palmini *et al*., one of the three frequent spiking patterns were characterized as clear ictal events. *Repetitive electrographic seizures* refers to isolated spikes that progressively increase in their frequency and rhythmicity for several seconds and attain a frequency of 12–16 Hz that later may slow (Figure 115.3). This was followed by a focal slowing and attenuation of the recording.[11]

The use of intraoperative ECoG may be limited in the temporal and spatial resolution when compared with extraoperative ECoG, especially when it comes to the analysis of ictal epileptiform activity. This is particularly problematic when the ictal onset occurs at the edges of the plate. In this case, actual onset outside the margins of the plate cannot be ruled out.

Methodologic considerations

The technique of recording ECoG has remained essentially the same since its introduction. The machinery used to record ECoG does not differ substantially from that which is used to

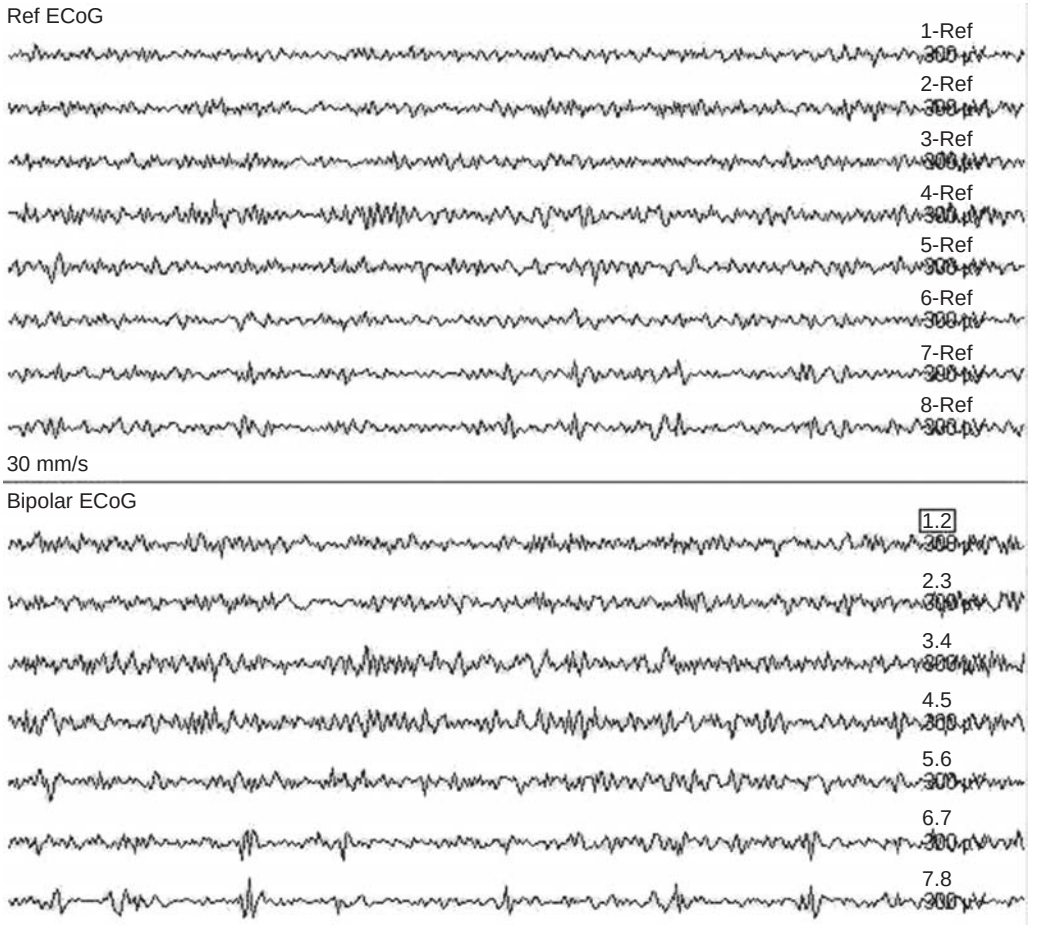

Figure 115.2 Continuous epileptiform discharges seen during intraoperative ECoG involving electrodes 7 and 8.

record standard EEG. There are a few considerations to note. The reference and ground can consist of needle electrodes placed into the surgical wound. The recording band pass filters can be 0.3 to 1.0 Hz to 70 Hz. Gain should be adjusted to prevent saturation of activity. A typical sensitivity range is 50–75 μvolts/mm.[13] The low-cut filter can be increased to 5 Hz if there are excessive slow waves obscuring the recognition of epileptiform activity. This filter setting will not allow for interpretation of focal slowing which is usually of little consequence when evaluating for epileptiform activity. Recordings can be made from 10 to 20 minutes in each position.

The recording is performed using a subdurally placed electrode array (Figure 115.4). The electrode sizes on these arrays can vary from 3 to 4 mm in diameter, embedded in medical-grade silicone plates, flexible Silatastic, or Teflon strips. The electrodes are made up of stainless steel or platinum (so that the electrodes are MRI compatible). The interelectrode distances is 1 mm and a variety of strips and grids can be made ranging from a 1 × 4, 1 × 8, 4 × 4, 8 × 8, etc.[5,14] These grids cannot be resterilized for use in another patient due to lack of adequate sterilization techniques. We tend to use larger arrays of electrode grids such as 4 × 4 intraoperatively, which allows for more spatial resolution and decreases time required for a more extensive coverage. For ease of recordings intraoperatively either 4 × 4 array over the lateral neocortical surface or strip electrodes for subtemporal regions are used. Several different positions/placements of the arrays are studied and regions of interest are marked on the cortex using sterile paper with numbers or letters or sterile marking pen. Previously electrode sets were used for recording. These sets were mounted in a holder attached to the patient's skull and were designed so that they were quickly moveable and were reusable. During the recordings immediate interpretation and communication of findings to the surgeon are required. Also, adjustments in sensitivities, filters, and time constants may be required. Total recording time is about 30–60 minutes, but can vary dependent on spike frequency and spatial distribution. Factors that may influence interictal spike frequency include inhalational anesthetic agents, opioids, antiepileptic medications, postictal state, and sleep.

Anesthetic requirements

Inhalational agents can have varying effects on epileptiform activity. There are some agents that have been known to activate epileptiform activity, such as enflurane. Other agents such as halothan, high-dose isoflurane or nitrous oxide can suppress epileptiform activity.[15] The effects of isoflurane on spike frequency may be dose-related and, based on varying reports in the literature, there appears to be a tendency to suppress spike frequency at concentrations of 0.5–1.5% but potentially increase spike frequency at a dose of 1.5%.[16,17] However, the study evaluating the higher dose of isoflurane was near the burst-suppression doses and brings up the question if these spikes have similar spatial relations and other characteristics to the patient's 'native epileptiform spikes.'

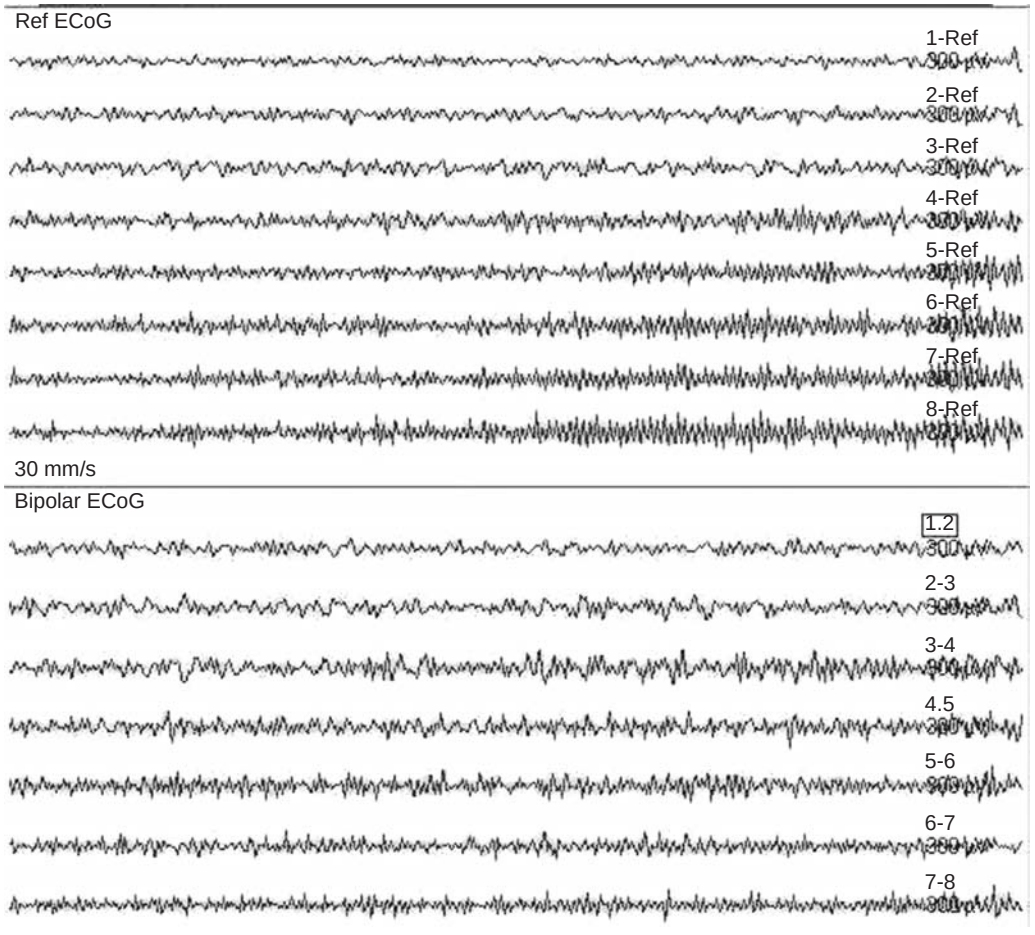

Figure 115.3 Electrographic seizure demonstrated during intraoperative ECoG beginning at electrode 8 and spreading to adjacent electrodes.

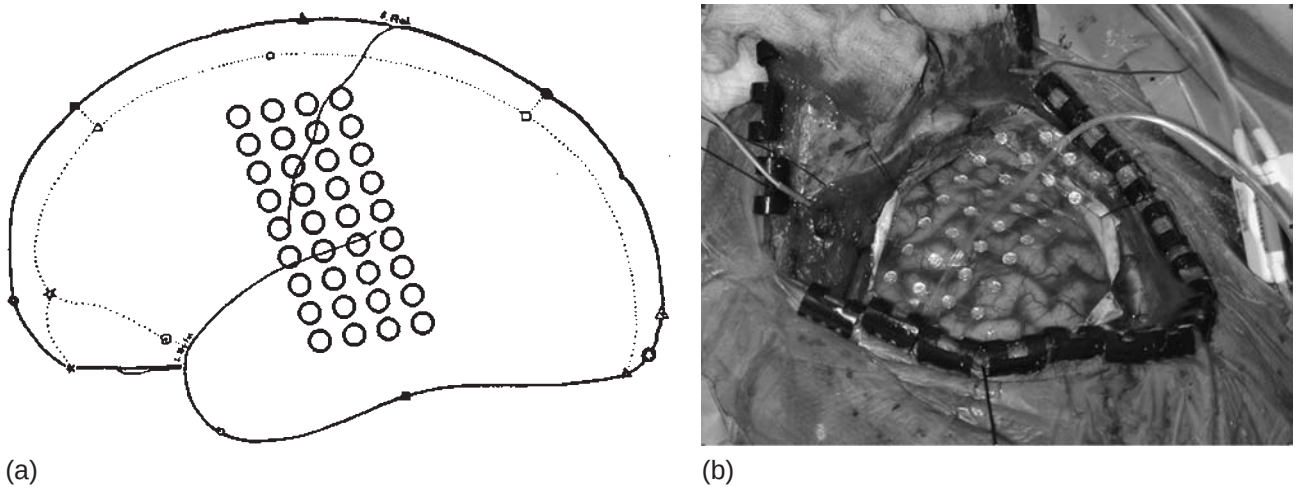
The role of nitrous oxide is also somewhat unclear in that a study evaluating spike frequency during intraoperative ECoG showed that there was no noticeable effect from nitrous oxide on epileptiform activity.[18] The use of light anesthesia such as using isoflurane with a narcotic drip is often selected for intraoperative ECoG. However, there is a higher risk for intraoperative awareness and recall for the patient. This method still has the potential for suppression of epileptiform activity as a result from anesthesia.

Opioids have the potential for proconvulsant properties. There is evidence to suggest that alfentanyl induces epileptiform activity. This is demonstrated by an increase in interictal epileptiform activity from the mesial temporal lobe as well as mesial temporal seizures associated with alfentanyl administration in one case.[19] There are various barbiturates, such as methohexital that are used to induce epileptiform discharges.[20–22] Again, the activation by methohexital may be inaccurate and demonstrate spikes not representative of the



(a) (b)

Figure 115.4 (a) Intraoperative map of subdural electrode 8 × 9 array placement. Diagram of photo shown. (b) Intraoperative photo showing subdural electrodes covering the left fronto-parieto-temporal cortex.

patient's native interictal epileptiform population.[23] Some authors suggest that it may be reasonable to consider the use of pharmacologic activation only in circumstances if the preexcision ECoG shows no interictal epileptiform activity.[23,24]

The use of three-dimensional MRI images with intraoperative stereotaxic guidance allows for the surgeon to locate the electrodes in relation to the patient's MRI anatomy as well as lesion (Figure 115.5). This modality offers additional reference to the surgeon beyond just visual inspection of the cortical structures.

Preexcision electrocorticography

The goal of localization of the epileptogenic zone is of primary importance in guiding epilepsy surgery. In cases where there is concordant data from noninvasive video EEG-monitoring, MRI data, other neuroimaging studies, the likelihood for further benefit from intraoperative ECoG becomes less likely. However, there are conflicting findings regarding the diagnostic yield and prognostic value of ECoG.[25–28]

Temporal lobe epilepsy

In a survey of several institutions, 68% of epilepsy centers showed that ECoG was being used during anterior temporal lobectomies, with 56% saying that the cortical resections were altered by the intraoperative ECoG data.[29] Some studies have shown that intraoperative epileptiform activity may have prognostic importance.[25–28] It is noted however that successful anterior temporal lobectomy has been preformed for epilepsy surgery without the use of intraoperative ECoG.[29,30] A study evaluating the predictive value of intraoperative ECoG in patients with unilateral hippocampal sclerosis undergoing selective amygdalohippocampectomy, showed that a greater percentage of patient with spikes recorded only in the mesiobasal temporal lobe remained seizure free more frequently than other patients studied.[31] A clear statement on prognostic significance for this finding requires the study of this issue with a large number of patients to verify these findings.

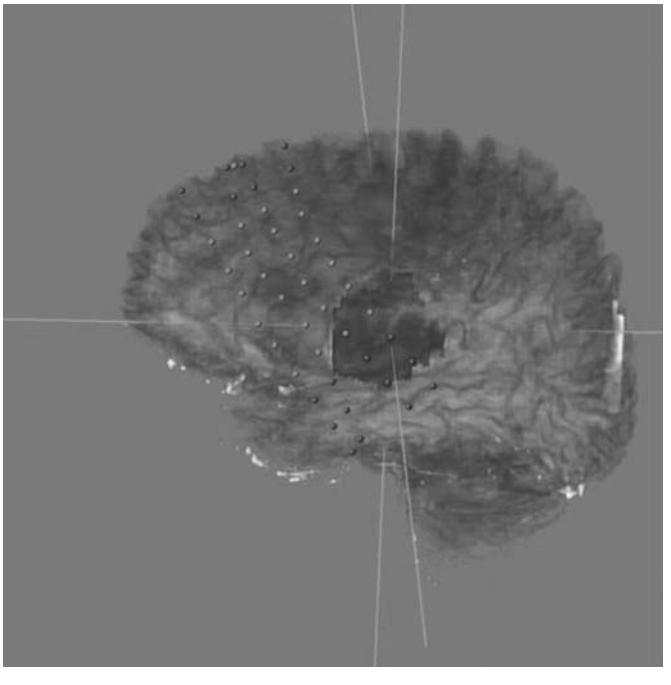


Figure 115.5 Intraoperative co-registered image of three-dimensional MRI scan of the brain with subdural grid shown in relation to the brain tumor.

Extratemporal lobe epilepsy

In one study, of patients with frontal lobe epilepsy, the distribution of the interictal epileptiform activity was focal in 15% of patients, lobar in 32%, and multilobar in 25%.[32] In this study patients who were seizure-free following surgery mostly demonstrated a regional distribution of interictal epileptiform activity. The multilobar distribution of interictal epileptiform activity was seen mostly in children.

A study of nontumoral intractable frontal lobe epilepsy, showed that interictal epileptiform activity from two or less gyri and absence of postexcision of was associated with a favorable outcome. This was in contrast to those with interictal epileptiform activity seen in three or with more gyri and the presence of postexcision, especially at a distance from the resection margin, where it was associated with a poor outcome.[33]

Postexcision electrocorticography

There is no general agreement in the ability of the postoperative ECoG findings to predict outcome. Some reports suggest that interictal epileptiform activity seen in the postexcision ECoG portends a poor prognosis as discussed in extratemporal lobe epilepsy. The use of intraoperative ECoG for standard temporal lobectomy is controversial. There are some who feel that it may be helpful in cases of temporal lobe epilepsy due to hippocampal sclerosis. In a case series that included 17 patients who underwent corticoamygdalohippocampectomy and underwent pre- and postresection ECoG found that in those cases with only isolated spikes as compared to those with high frequency or continuous discharges statistically tended toward good seizure control.[34] However there are many centers that perform standard temporal lobectomy without the use of intraoperative ECoG with excellent seizure-free outcomes.

Disadvantages

ECoG adds substantially to cost, personnel, and equipment. It also requires training of a specialized neurophysiologic team. It also increases the length of the surgical procedure by 30–60 minutes. The use of invasive extraoperative monitoring also made the use of intraoperative ECoG redundant in some circumstances. Due to the relatively short time available in the intraoperative setting, ictal ECoG findings are relatively infrequent occurrence. Therefore the clinical decisions are made by evaluating the interictal ECoG findings. The localizing significance of the irritative zone in the need to resect the epileptogenic zone is unclear.[5]

Special considerations

Isoflurane has been also shown to decrease spike frequency in children with neocortical epilepsy. It has been noted that the spatial pattern of spiking was similar in a study that looked at differences in the same children in the extraoperative to intraoperative settings. It was also found when comparing intraoperative spiking to ictal onset zones seen in during the extraoperative setting that spike frequency of <1 spike/minute was a poor indicator of the epileptogenic zone, whereas regions of cortex that should show a maximal spike frequency of more than one spike per minute were concordant with regions of ictal onset.[9] In the study of patients with cortical dysplasia, there appeared to be particular patterns of spiking that have prognostic value.[11] The three patterns described in this paper (see above for description) showed a high degree of spatial correlation with the anatomic extent of the dysplasia. This was in contrast to those patients in whom there was extensive lesion either visible or not on imaging studies, who tended to have a wider region of epileptogenicity. The focal-appearing lesions with focal or lobar electrocorticographic patterns correlated with a positive surgical outcome. Continuous spiking may be seen with other pathologies, such as with glioneuronal tumors, although these findings may be seen more commonly with focal cortical dysplasia.[35]

Future directions

Many of the studies of intraoperative ECoG in the literature are retrospective with small numbers of patients. There is a lack of large scale prospective studies looking at the efficacy of this modality.[6] Further studies that evaluate interictal epileptiform discharges seen in the postresection period are also need. Determining what types of postresective spikes suggest either a poor prognosis and potentially guiding in the extension resection margins would be a significant contribution to the literature. The determination of prognostic markers for intraoperative ECoG would likely influence the indication and make clearer the utility of this modality in various epilepsy syndromes. Currently the results from different centers of extending resection or ignoring postresection data is conflicting and often difficult to compare.[36,37] In patients with rare interictal abnormalities, the evaluation with ECoG may not help in prognostication as the absence of interictal abnormalities may be due to a number of different reasons and not a total elimination of the epileptogenic zone.[7] The use of ECoG in temporal lobectomy may become beneficial in cases undergoing selective removal of hippocampus and tailored temporal lobectomy in attempts to minimize memory outcomes. Various procedures such as multiple subplial transections maybe aided by the use of ECoG.[38]

The use of intraoperative ECoG is still a useful modality in circumstances where the exact localization of the epileptogenic zone is yet unclear despite a full pre-surgical evaluation and appears to be useful in guiding the surgeon in tailoring the resection, especially in some cases of extratemporal lobe epilepsy.

The use of combining modalities such as MEG, three-dimensional MRI, PET scan, and other neuroimaging data with intraoperative ECoG data may provide added understanding of the relationship with interictal epileptiform activity as it relates to lesions and also provide potential strategies for surgery when attempting to localize the epileptogenic zone. The relationship between spike frequency and prolonged seizure-free outcome has not been assessed across different epilepsy syndromes in large number of patients.

Cortical SSEP mapping

Somatosensory evoked potentials (SSEP) are electrical potentials generated in various parts of the somatosensory pathway in response to stimulation given to a peripheral nerve. The initial cortically generated potential appears in the primary somatosensory area contralateral to the stimulated side. These responses are closely related to the functional sensorimotor representation of the stimulated body part from the patient. So that, for example, the location of the SSEP after median nerve stimulation corresponds well to the 'hand area' in the primary somatosensory cortex. For the purpose of the definition of eloquent cortex, SSEP can be used as a localization tool of the primary sensory cortex. In this chapter, we will review the current understanding of SSEP, mainly those obtained from direct cortical recording.

Methodology

Standard settings for the scalp-recorded SSEP are well described. Generally, electrical stimulation is applied transcutaneously over the course of a peripheral nerve. Short monophasic electrical pulses (100–300 usec) are commonly used. The site of the stimulation can be any part of the body. Median nerve and stimulation at the wrist and posterior tibial nerve and stimulation at the ankle are the most popular sites, representing 'hand' and 'foot' areas, respectively. For trigeminal area SSEP, stimulation can be applied directly on the lip (mandibular branch of the trigeminal nerve), cheek, or chin, etc. The polarity of the stimuli can be alternated to minimize stimulus artifact, most typically done with the trigeminal SSEP, as the stimulus artifact is much larger using this technique due to the proximity of stimulation to the recording site. The intensity of electrical stimuli is usually set at the motor threshold, motor plus sensory threshold, or three to four times the sensory threshold. Stimulus rates of 1 to 10 per second are commonly used. To obtain the larger middle- to long-latency cortical responses or the secondary sensory responses, lower stimulus rates are recommended (<1 Hz). Averaging of 500 sweeps is usually enough to obtain sufficient signal-to-noise ratio in scalp-SSEP. A low number of sweeps is necessary in cortical-recorded SSEP, since the signal-to-noise ratio of the response is 5–8 times higher than in the scalp-EEG. A low-pass filter should be set at higher than 2000 Hz to avoid phase distortion. A high-pass filter is set at lower than 3 Hz to offset baseline. These settings are generally common to both scalp- and cortical-recorded SSEP.

Cortical SSEP with stimulation of the median nerve has been used to identify the central sulcus at the level of the hand sensorimotor area. Several studies have been reported about waveform characteristics of extraoperative cortical SSEP.

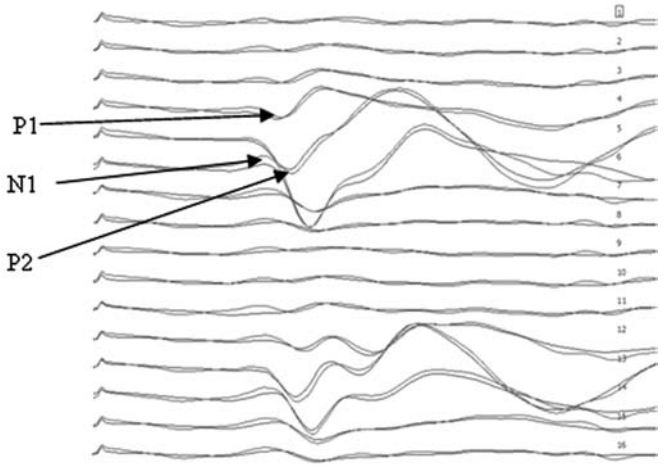

Figure 115.6 Phase reversal between the pre-central and post-central regions on a referential derivation, caused by two opposite polarities.

There are different terminologies that have been used to describe the various components seen in the median nerve cortical SSEP. One terminology uses the naming system of N1, P2, and N2, indicating their order of appearance among peaks of the same polarity. Another system uses the latency which is characteristic in between patients so that terms of N20, P20, and P25 are used. Though different terminology may confuse interpreters, some correspondence can be found in the early responses. Peak latencies of the responses later than P25 and P2 are highly variable between individuals. We will use both nomenclatures according to original investigators.

The initial cortical response is seen at a peak around a latency of 20 ms in adults. This component consists of negative polarity in the postcentral area the N1 response (also called N20) and smaller positive polarity in the precentral area (P20). The peak latency is same between these two maxima, or either peak, precedes the other by 2 ms. The two opposite polarities make a phase reversal between the pre-central and post-central regions on a referential derivation (Figure 115.6), which is one of the most reliable indicators for the central sulcus location.

Cortical stimulation

Cortical stimulation is typically performed in the useful patient, although some cortical function can still be evaluated in the setting of sedation, such as motor response. Cortical stimulation is used to evaluate the regions of brain termed eloquent cortex. The term eloquent cortex refers to those regions of brain which, when resected, would lead to significant neurologic disability. The method for analysis of these regions with cortical stimulation is performed by directly applying a series of electrical stimuli to the cortex to see what effect they have on functions such as sensation, motion, vision, language, etc. The electrical current consists of a series of repetitive square-wave electric currents of alternating polarity with a pulse width of 0.3 ms and a frequency of 50 Hz which were delivered for 2–5 seconds (Grass S-88 and SUI-7, Asro-Med Inc., R.I., USA). This stimulator is not FDA approved for human use, yet many institutions have fathered its use in patients due to its long history of use if the field of epilepsy and brain tumor patients requiring eloquent function mapping. The stimulus is typically delivered to the cortex via implanted subdural electrodes in the case of a patient undergoing long-term monitoring for epilepsy surgery. In the operative setting the stimulus can also be applied using a hand-held bipolar stimulator. During the delivery of cortical stimulation, simultaneous electrocorticography is typically being recorded in order to look for the presence of after-discharges that have been induced by the stimulation. After-discharges are epileptiform activity that has been generated following a cortical stimulus. If the after-discharges evolve either spontaneously or after repeated trials of cortical stimulation, it could result in a clinical seizure.

The subdural electrodes covering areas of functional interest were studied using cortical stimulation. Details of the methodology for cortical stimulation and the subsequent cortical mapping have been described elsewhere. Cortical areas were defined as language areas where stimulation produced an interruption of the ability to read aloud a sentence in the absence of the following: (1) positive tongue motor response

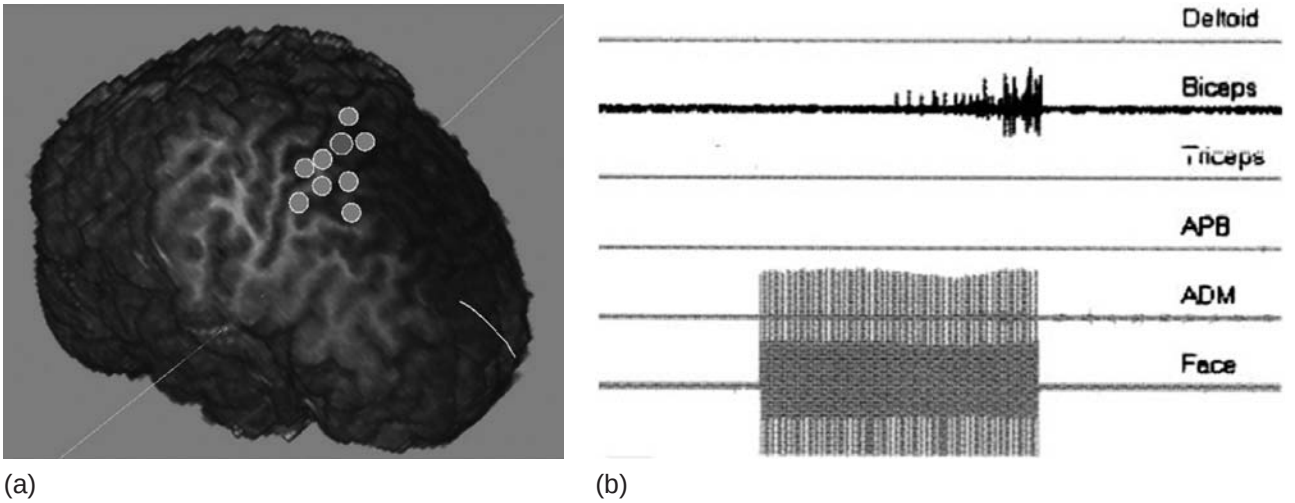

Figure 115.7 Cortical stimulation using hand held bipolar stimulation in the shaded position resulted in biceps contraction location one region of arm representation on the cortex.

(e.g., tonic tongue contraction), (2) negative tongue motor response (e.g., impairment of rapid alternating movements) and (3) after-discharges (ADs). Cortical stimulation of the location of motor representation can be done with direct observation of tonic, clonic, activity of limb or face, or by use of EMG electrodes (Figure 115.7). While testing of language function must be done under a wakeful setting, motor function can at times be tested with the patient lightly sedated or with low levels of general anesthesia. The motor thresholds will vary using this technique and may require higher levels of stimulus intensity or stimulus duration that used in the extraoperative setting. Stimulation testing for motor function under the influence of anesthesia is difficult in younger patients particularly in ages less than 10 years of age.

SECTION 15

Resective surgical procedures for epilepsy

116 Resective surgical techniques: mesial temporal lobe epilepsy

DK Binder and J Schramm

Introduction

In case after case, we found the cortex to be tough in the anterior and deep portion of the first temporal convolution. This abnormality extended into, and grew more marked in, the uncus and hippocampal gyrus. The tissue was tough, rubbery, and slightly yellow ... We have gradually realized the importance of this discovery, as the epileptogenic focus was often shown by electrocorticography to be situated here, and furthermore patients returned with continuing seizure when we had made anterior temporal removals without excision of this area.

Penfield and Jasper, Epilepsy and the Functional Anatomy of the Human Brain, p. 333 (1954).

Historical background

The earliest resections for epilepsy, from Macewen[1] and Horsley[2] to Krause[3] and Foerster,[4] were largely designed to remove cortical areas reflected in patients' ictal semiology. Following Hans Berger's discovery of the human electroencephalogram (EEG) in 1929,[5] EEG was adapted to identify and better localize epileptiform abnormalities, particularly in the temporal lobe. In the late 1930s, Wilder Penfield and Herbert Jasper at the Montreal Neurological Institute developed the use of EEG in combination with electrocorticography and functional mapping of 'eloquent' brain areas to tailor epilepsy resections.[6,7] The developing concept of 'psychomotor' or temporal lobe epilepsy and its surgical treatment[8–10] led to the advent of anatomically standardized *en bloc* temporal lobe resection.[11–13] Soon after, it became clear that pure lateral temporal cortical removal was associated with unsatisfactory seizure outcome, and removal of the deep structures including hippocampus and amygdala was required[6,14–18] (see quote above). Bilateral resections were abandoned early since they resulted in dense anterograde amnesia.[19]

Over the last half-century, many modifications to either 'tailored' or 'anatomic' temporal lobe resections have been adopted. Anatomically standardized resections rely on the concepts that resection of pathology seen on imaging studies will include the epileptogenic zone, and that resection of eloquent areas will be avoided by conforming to certain anatomic boundaries. In contrast, tailored resections emphasize altering degree of resection based on individual pathophysiology, functional mapping of eloquent cortex, and intraoperative electrocorticography. Of course, the goal of all epilepsy surgery remains extirpation of the epileptogenic zone without producing neurological or cognitive deficits.

This chapter reviews the various anatomic techniques of temporal lobe resection currently in use. There are three main differences among the techniques. The first is the relative extent of mesial temporal versus neocortical resection, from neocortical resection without mesial resection[20,21] to mesial resection without neocortical resection (selective amygdalohippocampectomy).[22–24] The second is the exact extent of mesial resection, with variations in amygdalar resection[25,26] and hippocampal and PHG resection.[25,27–31] The third difference is surgical approach (e.g., transsylvian[23,24] vs. transcortical[22] selective amygdalohippocampectomy). In this chapter, a step-by-step description of the most commonly-used surgical techniques will be presented. A detailed discussion of the tailored approach, including the use of intraoperative functional mapping and pre- and postresection electrocorticography, is beyond the scope of this chapter, and excellent reviews are available.[32–35] Patient selection, preoperative work-up, anesthesia,[36] outcome and complications will not be considered here. In addition, the reader is referred to other references that present detailed anatomic discussions of the intricate surgical and vascular anatomy of the temporal lobe.[37–51]

Classic anterior two-thirds lobectomy

Overview

There are many variations in the technique of anterior temporal lobectomy. Neocortical removal alone without removal of the mesial structures[20] has been largely abandoned in that it poorly controls seizures;[6,30] it is primarily used now in specific cases of neocortical lesionectomies (see below). Review of epilepsy programs participating in the second Palm Desert conference revealed that the median length of resection from the temporal tip was 5.5 cm in the nondominant temporal lobe, 4.5 cm in the dominant temporal lobe, and 3 cm of hippocampus.[52]

En bloc anterior temporal lobectomy was described by Falconer and colleagues[11] and subsequently used or adapted by others.[18,29] In this procedure, the neocortical and mesial temporal structures are removed together in one specimen. Alternatively, the temporal neocortex can be removed first followed by resection of the deep structures.[39] Most current temporal lobectomy procedures conform to the latter two-step procedure, and what follows is a step-by-step description of one method of performing such a two-step anterior temporal

lobectomy with staged resection of the neocortical block and deep structures.

Surgical procedure

The head is positioned so that the lateral surface of the temporal lobe is approximately horizontal. To prevent stress on the neck and minimize venous congestion, the patient is positioned supine with the shoulder elevated and the head turned, or in some cases the patient may be positioned in the full lateral position. The standard scalp incision is a 'question mark' shape extending from the superior border of the zygomatic arch just in front of the tragus above the auricle then superiorly and anteriorly to the hairline. This spares the frontalis branch of the facial nerve and can also be performed so as to preserve the superficial temporal artery. Following skin incision, the temporalis muscle is incised and reflected inferiorly leaving an appropriate cuff, or may be elevated together with the skin as a musculocutaneous flap. Next, a standard temporal craniotomy is fashioned with the superior margin just above the sylvian fissure (more frontal lobe is exposed if intraoperative electrocorticography will be performed). The inferior and anterior margins of the craniotomy are rongeured to reach closer to the floor of the middle fossa and temporal pole. The dura is opened and reflected anteriorly. A Cushing needle is used to measure the length of resection from the temporal pole (~4.5 cm on the dominant side, ~5.5 cm on the nondominant side) (Figure 116.1). The pia of the STG parallel to the sylvian fissure is coagulated, and also perpendicularly at the posterior resection margin down to the floor of the middle fossa. The plane between the STG and the sylvian fissure is dissected subpially with a Penfield dissector, protecting the MCA and its candelabra (Figure 116.2). This subpial dissection is carried down to the uncus inferomesially. A small amount of leptomeningeal hemorrhage is often seen following subpial dissection, which will cease with cottonoid packing or oxidized cellulose (Surgicel).

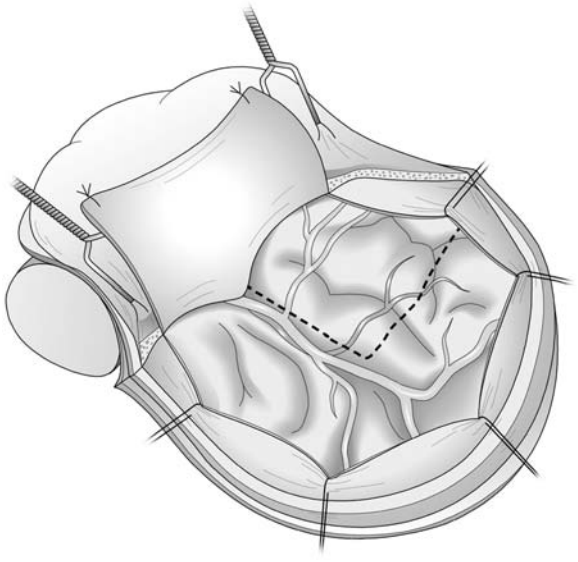

Figure 116.1 Exposure of the lateral temporal lobe (right side shown). The position of the cortical incision is indicated by the dashed line, extending from the STG parallel to the sylvian fissure perpendicularly at the posterior resection margin to the floor of the middle fossa. © 2006 Isabel Christensen and Johannes Schramm.

The next step is identification of the ventricle. This is done by incising the temporal stem at the inferior circular sulcus in the proper trajectory (Figure 116.3). An incision too medial may result in injury to the optic tract (producing a hemianopsia); an incision too lateral will result in missing the ventricle and arriving at the cortex over the floor of the middle fossa (Figure 116.3). Care must be taken at this step as the ventricular surface of the hippocampus may lie in close apposition to the white matter of the temporal stem, especially at the anterior margin of the temporal horn. Entry into the ventricle is confirmed by the appearance of bluish ependyma, choroid plexus, CSF, and/or view of the ventricular surface of the hippocampus. An alternative method of identifying the ventricle is to progressively deepen the posterior resection line through the white matter of the temporal stem in a coronal plane.[53]

Following identification of the level of the ventricle, disconnection of the neocortical block can be completed (Figure 116.4). First, a disconnection line is fashioned slightly oblique from the inferior circular sulcus and extended baso-laterally. This disconnection may further open the ventricle but not injure the hippocampus, and leaves the uncus in place. Second, the neocortical block can only be removed if the arachnoid at the base and alongside the pole is cut whereas it is left on the lateral neocortical gyri on the outer surface. Dissection down to the arachnoid deep to the lateral neocortical gyri is accomplished with the ultrasonic aspirator to approximately the level of the collateral sulcus. The posterior margin of the neocortical incision can then be extended to join with the prior disconnection to the ventricle. Vessels running obliquely and supplying cortex posterior to the resection line should be preserved. These steps can be performed in a number of different sequences.[18,53] The remaining arachnoid attachments of the neocortical block are cut, and it can be removed.

Next, attention is turned toward resection of the mesial structures (amygdala, uncus, hippocampus, PHG, entorhinal cortex). It is critical to recognize that the uncus and mesial aspect of the hippocampal formation lie over the tentorial hiatus, and therefore great care must be taken to use the ultrasonic aspirator on low settings to preserve the arachnoid protecting the important underlying structures (PCA, cranial nerve III, basal vein of Rosenthal, midbrain peduncle). First, the uncus can be emptied with the ultrasonic aspirator extending mesio-basally at the level of the limen insulae (working parallel to the ascending M1 segment), which includes removal of the most anterior portion of the amygdala. The next step is further opening of the temporal horn extending to the anterior tip. In view within the ventricle will be the choroid plexus, choroidal fissure, head and anterior body of the hippocampus, and amygdala. The hippocampus lies within the floor of the temporal horn (Figure 116.5) while the amygdala forms the roof of the anterior portion of the temporal horn and extends superomesially. Now comes the classic step of connecting the choroidal point with the limen insulae along the CP-LI line (Figure 116.6). Identified intraoperatively, the choroidal point is the anterior limit of the choroid plexus in the choroidal fissure (at the joining of the fimbria with the stria terminalis). The portion of the amygdala inferolateral to the CP-LI line can now be removed with ultrasonic aspiration. Care must be taken not to extend the

amygdala resection superomedially into the globus pallidus. During this step, the entorhinal cortex (anterior portion of PHG) will be transected and removed.

Next, the fimbria hippocampi, which forms the medial border of the hippocampus and the lateral boundary of the choroidal fissure, can be loosened from its attachments (taenia fimbriae) mediolaterally. This reveals the hippocampal sulcus (hippocampal fissure), a duplicate layer of arachnoid containing the arterial branches (Ammon's horn arteries) from the P2 segment of the PCA and anterior choroidal artery (Figure 116.7). Next, the arachnoid of the PHG is identified and sectioned, allowing the subpial elevation of the PHG out of its arachnoid bed in parallel to the choroidal fissure and the hippocampal sulcus. At this stage, the small perforating vessels entering the hippocampal sulcus are identified and divided close to the substance of the hippocampus (i.e., working preferably within the hippocampal sulcus) (Figure 116.8), allowing the mobilization of the combined block of PHG and hippocampus. Thus, the four steps of hippocampal removal are as follows. The first step was lateral disconnection, already done by removal of the neocortical block. The anterior disconnection was done when the uncus and temporal pole were removed by suction. The mesial disconnection was done by opening the choroidal fissure and dissecting along the CP-LI line which leaves only the posterior disconnection, which is done with the ultrasonic aspirator. In this way, the hippocampus-PHG block can be removed (*en bloc* if desired) by

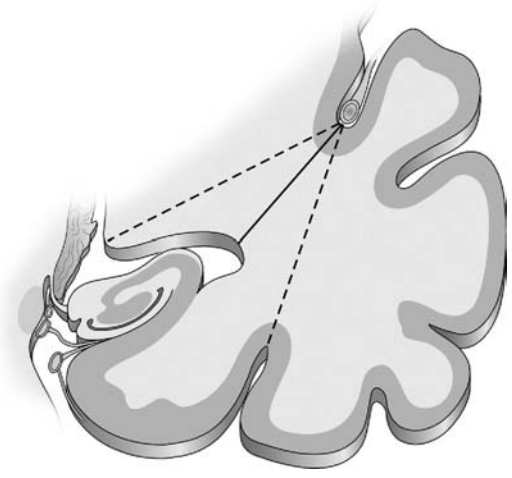

Figure 116.3 Identification of the ventricle. The ventricle is reached by making an incision through the temporal stem. The ideal trajectory is illustrated by the solid line (center). An incision too medial (medial dashed line) may miss the ventricle and result in injury to the optic tract; an incision too lateral (lateral dashed line) may miss the ventricle and arrive at the cortex over the floor of the middle fossa (pictured, over the collateral sulcus between PHG and fusiform gyri). Aiming a bit too lateral and then turning medially is a good technique. © 2006 Isabel Christensen and Johannes Schramm.

careful subpial dissection, taking care to protect the structures in the tentorial hiatus. Variations of these steps have been described.[53]

At the conclusion of the resection, the arachnoid has ideally been left intact and through it the tentorial hiatus, cranial nerve III, basal vein of Rosenthal, PCA, and anterior choroidal artery, and smaller branches and the midbrain peduncle can usually be appreciated. Use of bipolar cautery in the arachnoidal bed is mostly unnecessary and can be dangerous; oxidized cellulose (Surgicel) is sufficient for hemostasis in the majority of cases. Following adequate hemostasis, the craniotomy is closed in standard fashion.

Anterior one-third lobectomy combined with amygdalohippocampectomy

Overview

Based on the observation that some patients explored with depth electrodes had seizure onset that was quite posterior in the hippocampus, Spencer developed a technique in which limited cortical removal was followed by extended hippocampal resection.[54] This has also been termed *anteromedial temporal lobectomy* or *radical hippocampectomy*.[31,41] The rationale is to preserve functional lateral temporal neocortex while providing access for removal of mesial structures that reaches far more posterior than the neocortical resection.

(c) 2006 Isabel Christensen and Johannes Schramm.

Operative procedure

The patient is positioned supine with the head placed in pin fixation and turned laterally so that the zygoma is at an angle of ~10° to the floor, enabling a line of sight along the temporal horn and hippocampus. A temporal craniotomy is performed, exposing ~5–6 cm of temporal lobe and the sylvian fissure and orbitofrontal region (or up to 9 cm in another description).[31] A cortical incision is made in the superior margin of the MTG 3–3.5 cm from the temporal tip which then curves inferiorly across the MTG and ITG. The superior margin is the arachnoid of the STG, which is spared. A lateral neocortical block is removed extending to a depth of ~3 cm, approaching but not entering the temporal horn.

The second step is dissection of the medial structures. Self-retaining retractors are placed on the STG and the posterior aspect of the resection bed, and the ultrasonic aspirator is used to enter into the temporal horn. An incision is made anteromedially to the amygdala and then inferiorly to the tentorial incisura, at which time the uncus is gently removed with ultrasonic aspiration. Next, an incision is made through the temporal horn and the occipitotemporal (inferior longitudinal) fasciculus to the floor of the middle fossa, and extended posteriorly to the arachnoid margin over the fusiform gyrus, at the point where the hippocampus curves medially posterior to the brainstem. The lateral temporal cortex is continuously retracted and slightly elevated with a retractor. The removal of the mesial structures is then accomplished. Proceeding in an anterior to posterior direction, the incision is carried from uncus and amygdala along the choroidal fissure. Attention is now turned toward resection of the hippocampus. The small vessels lying in the hippocampal fissure are identified, coagulated, and divided, allowing mobilization of the hippocampus, and the fimbria hippocampi is freed from its arachnoid attachment. Lastly, the incision from the middle fossa floor is joined to the incision of the posterior body of the hippocampus, and the hippocampus and PHG are removed *en bloc*. Structures identifiable in the resection cavity include choroid plexus, arachnoid overlying optic tract and midbrain, medial edge of the tentorium, cranial nerve III, and occasionally cranial nerve IV.[31] Following meticulous hemostasis, the wound is closed in standard fashion.

Transsylvian selective amygdalohippocampectomy

Overview

The term *selective amygdalohippocampectomy* refers to that group of procedures aimed at resection of mesial structures only without neocortical resection. Strictly speaking, it is not 'selective' as the PHG is usually included in the removal, as are the uncus and part of the amygdala. This would amount to an unco-amygdalo-hippocampo-parahippocampectomy but the initial terminology is more practical and accepted. Indications include patients with clear evidence of mesial temporal lobe seizure foci or lesions and lack of involvement of lateral temporal neocortex (i.e., typical cases of mesial temporal sclerosis). The *transsylvian* approach was pioneered by Yaşargil and Wieser.[23,24,37] Among the original proposed advantages are the lack of a neocortical incision as required by the transcortical approach, and the lack of temporal lobe retraction necessitated by the subtemporal approach (see below).

Operative procedure

The patient is positioned either in a lateral decubitus position or supine with the shoulder elevated. Unlike the position for standard temporal lobectomy or transcortical selective amygdalohippocampectomy, the head is turned so that the malar eminence is the highest point, making the sylvian fissure approximately vertical. The head is placed in pin fixation. A semilunar incision is used, and a craniotomy is fashioned that extends superior to the sylvian fissure by ~1.5 cm. The craniotomy can be smaller than that used for a standard temporal lobectomy. Next, the sphenoid ridge is flattened with the drill down to the anterior clinoid process to allow optimal dural

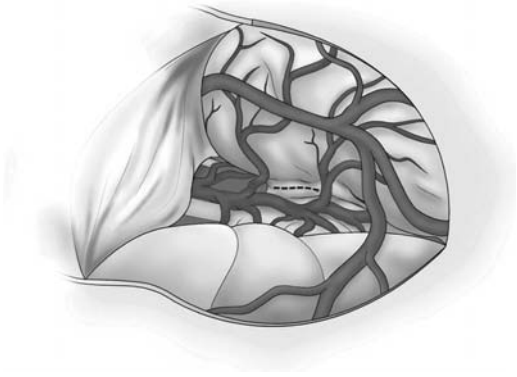

Figure 116.9 View following opening of the right sylvian fissure demonstrating temporal and frontal opercula, anterior insular cortex, limen insulae, and associated vascular anatomy. Dashed line demonstrates site for 10–15 mm incision into the anterior temporal stem for access into the temporal horn. Modified from Yasargil MG. Figure 116.11 Intraoperative view of the hippocampus (left transsylvian approach). The temporal stem has been incised, the temporal horn has been opened, and the shiny ventricular surface of the hippocampus (alveus) can be seen along with the choroid plexus in the choroidal fissure mesially.

retraction. The dura is opened in semicircular fashion and reflected toward the sphenoid ridge and orbit. The sylvian fissure is opened from the carotid bifurcation through the MCA bifurcation and ~2 cm more distally, exposing the ascending M1 branch, the limen insulae, the anterior third of the insular cortex and associated M2 branches, and the mesial surface of the uncus and temporal pole (Figure 116.9). The positions of the lateral M2 branches – including temporopolar and anterior temporal arteries – are noted. The inferior circular sulcus is identified which separates the temporal operculum from the insular cortex.

Next, a ~10–15-mm incision into the anterior temporal stem is made at the level of the limen insulae (Figure 116.9). Opening of the temporal horn is accomplished by carrying this incision down to the uncus parallel to the M1 segment.

Uncoamygdalohippocampectomy is then performed as follows (Figure 116.10). The uncus is emptied with the ultrasonic aspirator, taking care to set low values for suction and amplitude to leave the arachnoid intact. The bulging portion of the amygdala (identified grossly by its speckled brown color) along the CP-LI line can then be resected with the ultrasonic aspirator or dissector. Together with this the entorhinal cortex (anterior extent of PHG) is resected. Next, the temporal horn is opened further to better visualize the choroid plexus and choroidal fissure marking the mesial boundary of the hippocampal dissection (Figure 116.11). A disconnection is then made lateral to the hippocampus along the ventricular border lateral to the collateral eminence, using a dissector or the aspirator in the anterior-posterior direction, aiming approximately to the level of the collateral sulcus. The fimbria hippocampi is disconnected mesially by gentle dissection of the taenia fimbriae attaching to the choroidal fissure, and the medial aspect of the parahippocampal gyrus (subiculum) can then be subpially elevated with a dissector. Identification, coagulation, and transection of the hippocampal vessels (Ammon's horn arteries) in the hippocampal fissure is performed, with great care taken to preserve the larger trunks of the anterior choroidal artery and

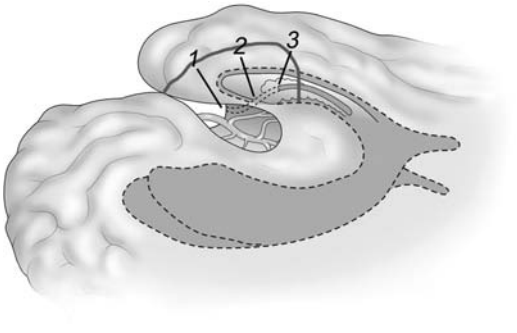

Figure 116.10 Extent of resection in selective amygdalohippocampectomy. 1, limen insulae; 2, CP-LI line; 3, choroidal point. Red Line demonstrates extent of temporomesial resection in transsylvian selective amygdalohippocampectomy (includes portions of hippocampus and amygdala, entorhinal cortex, uncus, parahippocampal gyrus). © 2006 Isabel Christensen and Johannes Schramm. (See Color plates.)

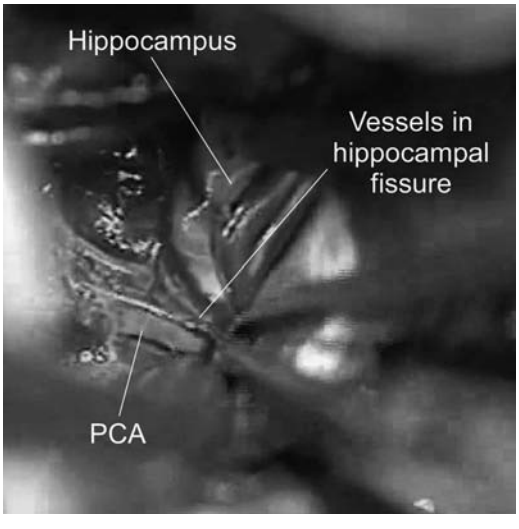

Figure 116.12 The hippocampal-parahippocampal tissue block is elevated out of its arachnoid bed by the Penfield dissector to the right, demonstrating the basal vessels in the hippocampal fissure. Careful microsurgical identification, coagulation, and transection of vessels in the hippocampal fissure arising from the P2 segment of the PCA (shown) and the anterior choroidal artery is the key to successful hippocampal resection.

P2 segment of the PCA (Figure 116.12). This is safely achieved by transecting the hippocampal vessels within the hippocampal fissure. Finally, the combined hippocampus/PHG can be disconnected posteriorly by mediolateral transverse section with the ultrasonic aspirator, and can be freed from its arachnoidal cover either by rolling it from mesial to lateral or vice versa (Figure 116.13). The specimen can be removed *en bloc* if desired (Figure 116.14). Hemostasis is accomplished with oxidized cellulose (Surgicel) and the wound is closed in standard fashion.

Transcortical selective amygdalohippocampectomy

Overview

In 1958, Niemeyer introduced the *transventricular amygdalohippocampectomy*,[22] which has been subsequently termed transcortical selective amygdalohippocampectomy. He used this in patients thought to have mesial pathology but normal lateral temporal neocortex. Niemeyer described an approach through an incision in the MTG, providing access to the temporal horn of the lateral ventricle. The hippocampus (~3 cm), amygdala and PHG were then removed with subpial dissection. In 1969, Niemeyer and Bello reported on a microsurgical route to these structures.[55]

Olivier subsequently described a modification of this technique through an incision in the STG.[27,56] In this variation, the anterior 2 cm of the STG are resected to allow access to the amygdala, which is resected, the temporal horn is opened, and the anterior 1–2 cm of hippocampus are removed. Olivier and others have also used the superior temporal sulcus[57] although it should be noted that Olivier has since reverted to the original Niemeyer approach through the MTG, terming the STG approach 'more tedious and less satisfactory'.[39]

Operative procedure

The position of the head is similar to that used for a standard temporal lobectomy approach. A linear or slightly curved incision in front of the tragus may be used. Neuronavigation is extremely helpful in planning both the craniotomy (which can either correspond to the standard pterional approach or be much smaller 'keyhole' craniotomy centered over the MTG).[56] Furthermore, neuronavigation can be subsequently used to plan the trajectory to the ventricle, hippocampus and amygdala.

Figure 116.13 Intraoperative view of the hippocampus (left transsylvian approach) following lateral, medial, and posterior disconnection.

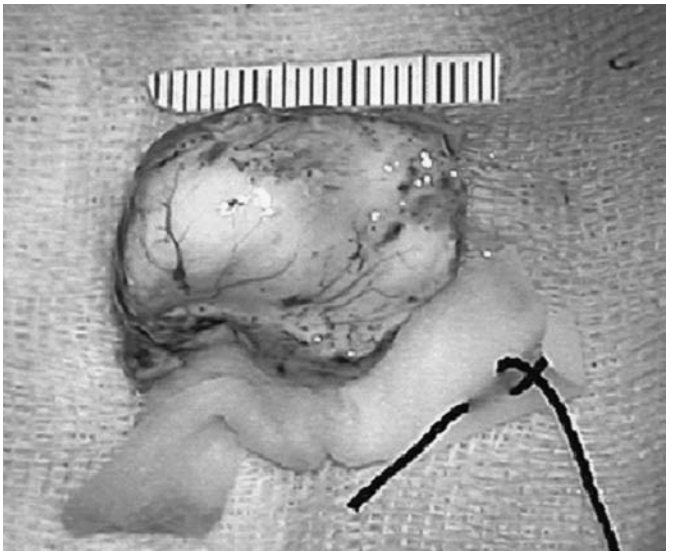

Figure 116.14 Resected *en bloc* hippocampal specimen (~3.5 cm).

At the Montreal Neurological Institute, all of these procedures since 1992 have been performed using MRI-based frameless stereotaxy.[56] The pial surface of the MTG just inferior to the superior temporal sulcus is coagulated, and a 2–3 cm anteroposterior incision is made. On the nondominant side, Olivier places the incision anterior to the central sulcus; on the dominant side, it lies anterior to the precentral sulcus.[56] Dissection down to the temporal horn is performed via slit-like transection of the white matter in the anterior-posterior direction. Retractors are then inserted to provide an unobstructed view of the hippocampus within the temporal horn. The ependyma must be opened sufficiently to see the bulge of the amygdala and the tip of the temporal horn anteriorly. Resection of the hippocampus is initiated by entering the PHG by transecting laterally at the ventricular sulcus between the hippocampus proper and the collateral eminence. Thus an endopial intragyral removal of the PHG is performed along its longitudinal extent. Care is taken not to injure the P2 segment of the PCA which runs under the pia near the medial border of the PHG. Dissection is carried forward into the PHG and the anterior portion of the uncus is entered. The hippocampus proper can then be mobilized laterally and the fimbria hippocampi resected longitudinally revealing the hippocampal sulcus. Posteriorly, the hippocampus proper can be transected at the junction of the body and tail, enabling it to be lifted gradually off the hippocampal sulcus. Careful dissection, coagulation, and division of hippocampal vessels in the hippocampal sulcus is performed, and the hippocampal specimen may be progressively mobilized and ultimately removed. It should be noted that large *en bloc* removal of the hippocampus is difficult with this approach. Subpial resection is then carried forward to the apex of the uncus (intralimbic gyrus), and then the anterior uncus is also emptied with careful aspiration. Next comes the resection of the amygdala. The amygdala is resected as far and as high anteriorly as the horizontal (M1) segment of the MCA. In this approach, in contrast to the transsylvian approach, the amygdala is visualized and resected following the main hippocampal resection. Finally, if more posterior resection of the hippocampus and PHG is desired, this can be accomplished

with endopial aspiration back to the level of the superior colliculus.[39,56,58] After careful hemostasis, the wound is closed in standard fashion.

In our center, we prefer the transsylvian to the transcortical approach to selective amygdalohippocampectomy. One of the supposed advantages of the transcortical approach is the sparing of fiber tracts running through the temporal stem; however, our results suggest a greater chance of inducing a homonymous hemianopia compared with the transsylvian approach (Clusmann et al., unpublished data), a result which is supported by anatomic studies.[47] When we perform the transcortical approach, we make an incision in the MTG. Furthermore, we typically work underneath the PHG and reach the fimbria hippocampi transventricularly. In this way, the hippocampus-PHG may be removed *en bloc* together, albeit in shorter segments than using the transsylvian approach.

Furthermore, the transcortical approach gives a more mesially pointed direction of view, making it more difficult to gauge the extent of resection of the amygdala toward its mesial border.

Subtemporal and other approaches

In addition to the above-mentioned transcortical and transsylvian approaches to selective amygdalohippocampectomy, several authors have reported subtemporal approaches and variants. Hori et al. initially described the subtemporal approach to amygdalohippocampectomy in 4 patients.[59] The approach involved cutting the tentorium to reduce temporal lobe retraction and *en bloc* excision of the fusiform gyrus to provide access to the temporal horn. A subsequent variation by the same authors is the retrolabyrinthine presigmoid transpetrosal approach to subtemporal amygdalohippocampectomy.[60] In 1989, Shimizu et al. described access to mesial temporal structures via a subtemporal 'zygomatic' approach in five patients, involving removal of the zygomatic arch and access to the mesial structures via limited resection of the ITG.[61] Later, Shimizu et al. reported on a lateral temporal polar approach to mesial temporal lesions in 25 patients.[62] Park and colleagues describe a subtemporal transparahippocampal approach to amygdalohippocampectomy in eight patients, allowing preservation of the fusiform gyrus and the lateral temporal lobe.[63,64] Recently, Miyamoto et al. have described a combination of the subtemporal and transventricular/transchoroidal approaches.[65]

The primary rationale for subtemporal approaches is that they spare temporal neocortex and do not involve incision of the temporal stem. However, drawbacks include temporal lobe retraction, venous anatomy, surgical orientation and access, and the potential importance of basal temporal language areas in some patients.[66,67] Temporal lobe retraction places the vein of Labbé at risk. Exactly where to enter the temporal lobe on its inferior surface, either through the PHG, collateral sulcus, fusiform gyrus, or ITG may be unclear or may require intraoperative neuronavigation. Thus, orientation may be difficult, beginning with patient positioning; and variations in venous anatomy may make retraction of the basal surface of the temporal lobe difficult or impossible. Furthermore, while exposure of the hippocampus may be adequate, exposure and removal of the uncus and amygdala are difficult from this operative trajectory. It is probably best limited to lesionectomies of the posterior hippocampal/mesial temporal region.

Several other approaches to exposure or ablation of the mesial temporal structures have also been described. Vajkoczy et al. describe a modification of the transsylvian approach, termed the transsylvian-transcisternal approach,[68] which involves opening the arachnoid of the basal cisterns and *en bloc* resection of the mesial structures. Stereotactic removal or ablation of the amygdala and hippocampus has been reported,[69–74] although no large modern series are available for outcome comparisons. Gamma knife radiosurgery for mesial temporal lobe epilepsy is under investigation[75–77] and is the topic of an ongoing multicenter US trial.

Combined amygdalohippocampectomy and lesionectomy

The majority of cases of temporal lobe epilepsy are associated with hippocampal pathology, most often 'mesial temporal sclerosis' characterized by neuronal loss and gliosis and specific imaging findings.[78–82] In such cases, resection of the mesial structures appears critical for seizure-free outcome.

Another group of patients, however, present with lesional temporal lobe epilepsy.[83–85] Smaller temporal lobe lesions are being increasingly diagnosed with the advent of modern MRI imaging.[86,87] These may include glial or glioneuronal tumors, cortical dysplasias, or vascular malformations. It is clear that lesionectomy is necessary for adequate seizure control.[85] However, experience has shown that lesionectomy alone may not be sufficient for seizure control.[88,89] Depending on preoperative workup, lesion size and location, and electrophysiology, the recommendation may be for lesionectomy with or without concurrent mesial resection. For example, small tumors or cavernous malformations in the temporal pole, amygdala, and head of the hippocampus may be seen. With these the presurgical evaluation frequently leads to the recommendation to remove only the adjoining part of the hippocampus as opposed to a classic hippocampectomy. The combination of lesionectomy and amygdalohippocampectomy may also be performed from a posterolateral or subtemporal approach, usually for small tumors or cavernous malformations in the dorsal parahippocampal or fusiform gyri.

A final group of patients presents with dual pathology, i.e., the coexistence of two lesions such as MTS and an extrahippocampal lesion such as a neuronal migration disorder.[90,91] The presence of dual pathology or extrahippocampal pathology may be a poor prognostic factor for seizure outcome, unless both pathologies can be excised completely.[92–94]

Summary

The diversity of surgical approaches developed for temporal lobe resection has reflected the history of concepts of temporal lobe epilepsy, the diversity of lesions found within the temporal lobe, and also the progressive innovations in neurosurgical techniques and approaches. All of the approaches share the philosophy of minimal but efficacious removal of pathologic tissue with preservation of cognitive and neurologic function to the greatest degree

possible. Selective amygdalohippocampectomy without lateral cortical resection has shown excellent results in cases of solitary mesial temporal lobe pathology (e.g., MTS). Over the last 15 years, there has been a trend toward reducing the extent of neocortical resection and increasing the extent of resection of mesial structures. Nevertheless, presence of lateral pathology or dual pathology clearly requires either standard temporal lobectomy or tailored approaches. Mass lesions should be treated with lesionectomy possibly including resection of adjacent or involved mesial structures. Further clinical studies are required to determine the relative role of anatomic *vs*. tailored resections, better delineate epileptogenic *vs*. normal tissue,[95] and assess long-term seizure, neuropsychological, cognitive, and functional outcomes.

117 Resective neocortical techniques in adults

EO Richter and SN Roper

Introduction

In contrast to medial temporal lobe epilepsy, which is a fairly consistent epilepsy syndrome associated with a specific pathologic substrate, neocortical epilepsy is a heterogeneous group of disorders which arises from a variety of pathologies and whose clinical manifestation and treatment options are determined more by the precise location of the focus than by the pathology. In addition, the eloquence of various neocortical areas may limit surgical options. The various methods of localizing the focus, including history and physical examination, seizure semiology, EEG, long-term video monitoring, neuropsychological testing, MEG, advanced imaging, and invasive and intraoperative electrophysiology recordings have been discussed extensively in other chapters. In this chapter we will discuss briefly the overall decision-making process before proceeding to operative techniques of neocortical resections and the eloquence of various neocortical regions, or what deficits may be expected from resections of these areas.

A major consideration in planning for extratemporal seizure surgery is the presence of a lesion on neuroimaging (Table 117.1). As discussed more fully elsewhere in this text, the success rates in lesional epilepsy surgery are considerably better than those in which no lesion can be identified where electrophysiological evidence is the only means of guiding the resection. This decision algorithm is depicted in Figure 117.1 for nontemporal neocortical epilepsy. In patients with complex partial seizures and electrophysiological evidence of lateral (neocortical) temporal onset, dual pathology (additional involvement of mesial temporal structures) is not uncommon, and requires consideration. Our suggestion for a rational approach to these cases is depicted in Figure 117.2.

Surgical technique

General techniques for neocortical resections

The fundamental principles of topectomy are a careful subpial resection of the gray matter in the defined region of epileptogenisis with careful preservation of the vasculature and avoidance of injury to adjacent cortex, as such injury may in itself be epileptogenic.

The pia overlying the top of the gyrus to be resected is carefully coagulated with bipolar electrocautery and incised (Figure 117.3). The pial flap is then gently elevated and the underlying gray matter gently suctioned off. Intermittent bipolar coagulation may be necessary at a low setting. Some centers use an ultrasonic aspirator at a low suction and vibration setting for this process. The sulci are not disturbed, and any significant vessels passing over the gyrus may be skeletonized and left in situ (Figure 117.4). The subpial resection is carried to the base of the sulcus. The dissection should not be taken deeper, because removal of underlying white matter will not improve seizure control and risks injury to underlying projection fibers.

Particular attention must be given to preservation of the ascending veins to the superior sagittal sinus. This is important during resections of the dominant midline and parietal lobes, or when preoperative vascular studies have indicated a paucity of drainage to the superficial sylvian system. Venous compromise may lead to increased postoperative edema or even venous infarction.

Dural reflection, while not usually considered a major step in brain surgery, can be a time consuming and important phase in these procedures. Extratemporal seizure foci are often associated with areas of prior injury or surgery and may have extensive dural scar and adhesion formation. In some cases, safely separating the dura without risk of vascular injury may require microsurgical techniques.

Frontal resection

Deficits after frontal resections, provided they are unilateral, generally fall into the broad categories of cognitive dysfunction

Table 117.1 A list of some potentially epileptogenic lesions that may be demonstrated with MRI scanning

Some potentially epileptogenic lesions	
Developmental:	Cortical dysplasia Hamartoma Hetrotopia
Tumors:	Low-grade glioma Ganglioglioma DNET
Vascular:	AVM Cavernous malformation
Injury:	Gliosis (trauma, CVA)
Infectious:	Granuloma Parasitic cyst

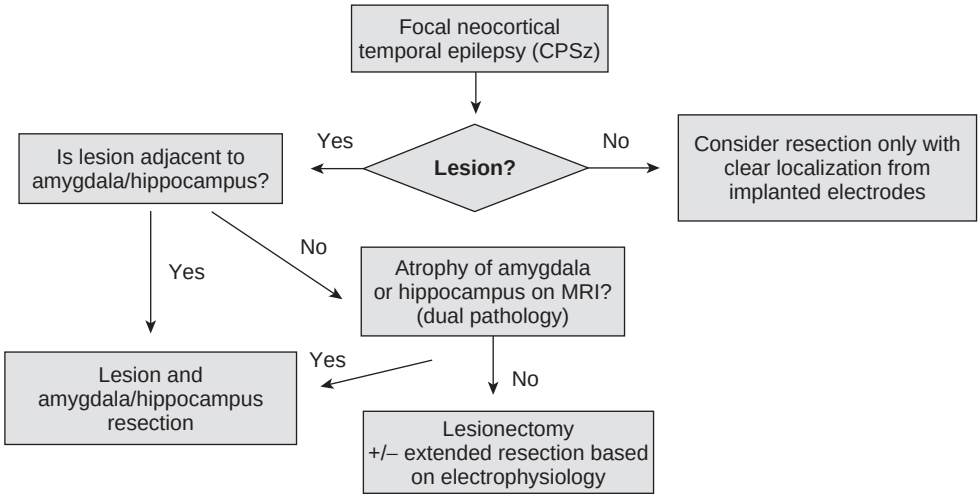

Figure 117.1 Treatment algorithm for patients with neocortical temporal origin. CPSz = complex partial seizures.

(which is usually so mild as to be clinically inconsequential, though demonstrable on sophisticated testing),[1] motor, and language deficits.

The frontal area most associated with language is Broca's area, situated in the pars opercularis of the inferior frontal gyrus. When performed under general anesthesia, it has generally been regarded as safe to spare the posterior 2.5 cm of the gyrus.[2] However, variable localization of language function has been demonstrated in the frontal lobe,[3–5] and awake mapping, either intraoperative or extraoperative, is preferable. Cortical stimulation has demonstrated reproducible effects on language in the superior and middle gyrus, as well as the parasagittal cortex. Resection of accessory motor language areas (superolateral or parasagittal frontal cortex) can produce a dramatic postoperative mutism that clears gradually over weeks.[6]

Conversely, if the area that anatomically would be expected to be Broca's area shows no speech deficit with stimulation testing, it can be safely resected, provided such function has been localized elsewhere in the frontal lobe. Transient motor dysphasia is common whenever the resection is carried within a centimeter or two of areas in which stimulation has caused consistent errors. This usually clears completely within a few weeks.[7]

To avoid motor deficit, it is crucial to carefully preserve the vascular supply to the precentral gyrus, skeletonizing vessels as necessary. Given meticulous vascular preservation, it is safe to resect up to the precentral sulcus if stimulation testing has been negative.[7]

Temporal resection

Neocortical temporal resections, as alluded to above, have been associated with considerable controversy. Some consider these poor surgical candidates, while others recommend resections tailored completely by intraoperative corticography. The presence of a lesion and the possibility of dual pathology are primary considerations in surgical planning. In addition, the location of eloquent areas in the temporal lobe is extremely variable.[8] The primary concern is language, and it seems clear that the more posteriorly the caudal cortical incision is made during a standardized resection, the more likely a postoperation language deficit. In general, 3 cm from the temporal tip in dominant cortex (4 cm in nondominant cortex) avoids postoperative aphasia.

Mapping studies have demonstrated that language localization is extremely variable, and no landmark provides reliable

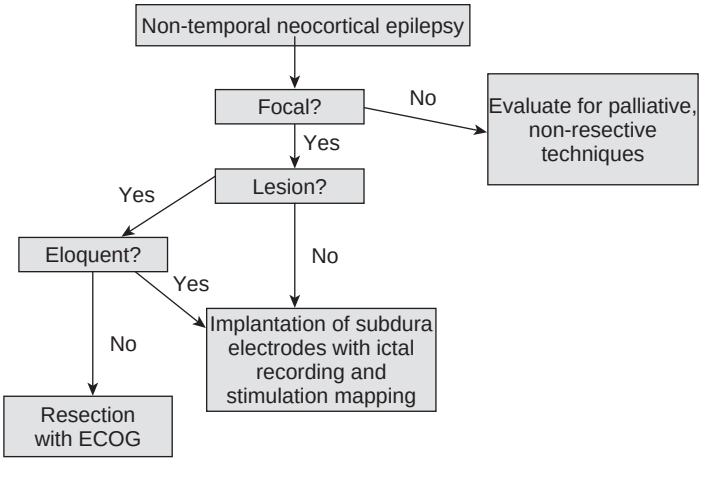

Figure 117.2 Treatment algorithm for patients with nontemporal epilepsy.

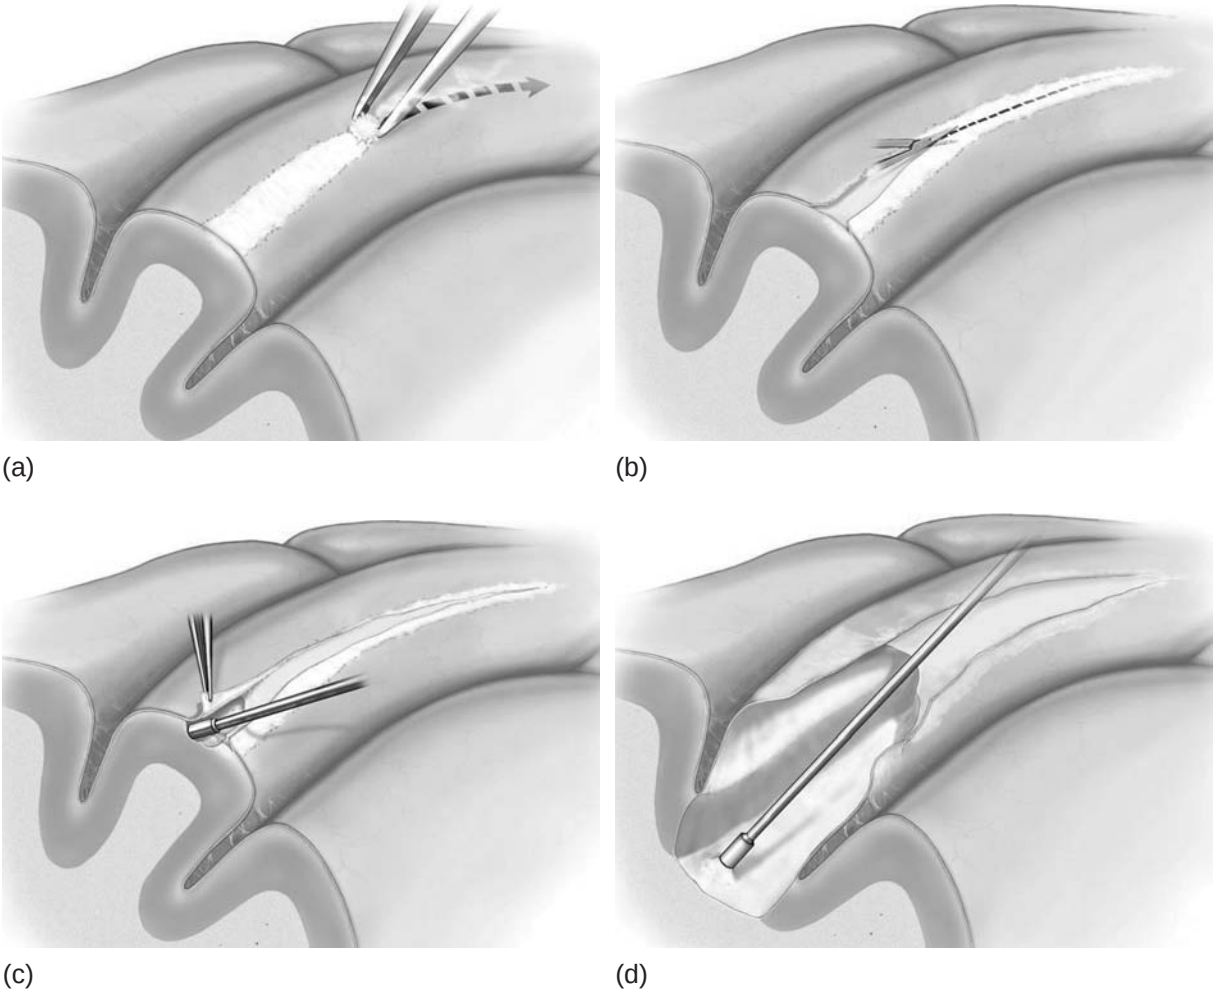

Figure 117.3 Technique for topectomy. (a) The pia over the center line of the gyrus is coagulated with bipolar electrocautery a nd (b) divided with microscissors. (c) The pial flap is then elevated and the gray matter evacuated with gentle suction. Bipolar electrocautery is used for small vessel hemostasis, and occasionally to disrupt tissue that is not easily suctioned. (d) The resection is carried down to the bottom of the gray matter of the sulcus. White matter in the gyrus may be resected to this level, but not further.

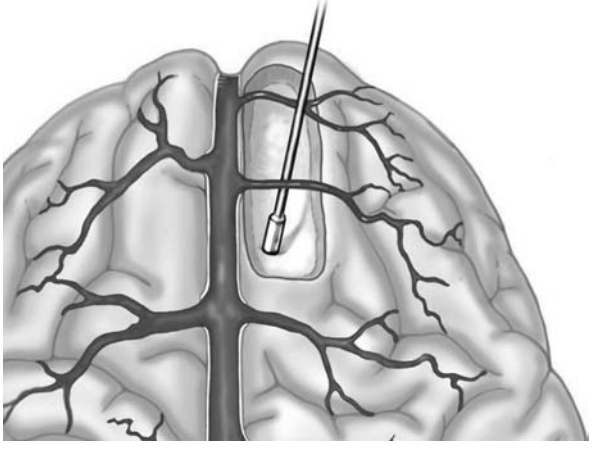

Figure 117.4 Preservation of vessels in topectomy. Respect for the vasculature is of the utmost importance, as sacrifice of en-passage arteries or bridging veins may result in infarction of adjacent, functional cortex, leading to loss of function or a new epileptogenic focus. In this representation, a parasagittal gyrus is resected, skeletonizing the bridging veins.

guidance for anatomic resection.[8] Speech areas are not necessarily confined to the superior temporal gyrus, and in some, no temporoparietal language site can be identified at all.[9] It is thought that unusually located essential language areas may be responsible for aphasia after standardized resection.[10] When such sites are identified, no deficit is likely if the resection spares a 2-cm margin along the gyrus.[8] Despite these concerns, large series of standard ATLs have not reported an increased incidence of aphasia.

Most commonly, language is tested using a naming task, and areas that repeatedly cause anomia with stimulation testing are considered essential language cortex. It is clear that other language functions can be delineated with specific testing and are discretely localized, such as naming in a second language[10,11] or reading.[12,13] In patients for whom these are vital functions, it may be best to map them independently. Other studies have demonstrated that some areas that produce aphasia with stimulation mapping may be safely resected with only occasional and mild lasting language deficit.[14–16]

The localization of memory function within the temporal lobe is also controversial. Most data suggests that postoperative

memory decline is based on resection of a functional hippocampus especially in the language dominant temporal lobe. Memory function is generally assessed preoperatively with the sodium amytal (Wada) test. When the patient suffers profound transient memory deficits with this test, it is expected they would have a high morbidity in terms of short term memory with a standard ATL. Various approaches to this situation have included surgical exclusion or minimizing the extent of mesial resection.[17,18]

Ojemann espouses a different conception of the role of the temporal lobe in memory function, and emphasizes the role of a tailored neocortical resection guided by stimulation testing.[18] He points out that significant work demonstrates that certain sites in the temporal neocortex cause acute disturbances in recent verbal memory during stimulation testing,[13,19,20] and that these are independent of language effects. The technique is time consuming because normal individuals will make memory errors without stimulation, and memory testing involves three phases (input, storage, and output) compared to the simple task of naming in language mapping. The baseline error rate in memory testing means that more testing cycles per stimulation site are required for a statistically significant difference between essential memory cortex and nonessential cortex. Thus he suggests that when the sodium amytal test indicates a major role of the epileptogemic temporal lobe in memory function, rather than denying the patient surgery or limiting the mesial resection, it may be best to tailor the lateral resection with stimulation memory mapping. They have presented two patients[17,18] in whom Wada testing suggested complete dependence of memory on the side of the resection, but had no postoperative decline in verbal memory after such resections. He also points out that dominant temporal resection patients with postoperative verbal memory deficits had large lateral rather than medial resections, and suggests that this is due to resection of lateral cortex essential for the input or storage phases of verbal memory.

Finally, in the posterior temporal lobe, care must be taken to avoid resection below the sulci, as the visual field fibers may be interrupted. The deficit from resection of the temporal pole is very mild and well tolerated, but that obtained by too deep a resection in a posterior temporal corticectomy can be much more profound and disabling.

Central cortex

The deficits associated with resection of face cortex vary both with the extent of resection and with the side. Generally, partial resection of nondominant face cortex will leave no permanent deficit, only a transient facial asymmetry. Complete nondominant resection leaves permanent perioral weakness in half,[21] but generally is not severe if the resection stays at least 2 mm below the lowest site of thumb activation with stimulation.[22] Of course, the stimulation of face, throat or tongue motor cortex on either side may interfere with the movements required for speech and so interfere with language function. Usually, these motor manifestations are clear and be easily distinguished from true language effects. On the dominant side, resection of face cortex can lead to a dysarthria or dysphasia, particularly if there has been any manipulation of surrounding cortex.[7] Rasmussen[21] has successfully resected dominant face cortex without these problems. Care must also be taken in resections in this area not to go too deep, as the underlying white matter includes the projection fibers of the adjacent hand area en route to the internal capsule.

Resection in the hand primary motor cortex will always leave a permanent fine motor deficit and should be reserved for patients without useful hand function. Removal of primary leg cortex results in a postoperative flaccid paralysis that partially[21] recovers if the remainder of the primary cortex is intact. In general, white matter can be removed in the gyri, but it is important not to undercut adjacent cortex. When necessary, white matter stimulation mapping can warn of important subcortical white matter motor tracts and avoid damage.[23]

Removal of the leg portion of the post-central gyrus results in long-term deficits of proprioception and joint sense. Resection of the face portion leads to long-term loss of two-point discrimination. Both of these deficits are well tolerated.[24] Removal of the hand cortex, however, is much more poorly tolerated, with 70% having severe multimodality sensory complaints and 40% having ipsilateral complaints.[24]

Parietal resection

Similar to frontal resection, the side of resection is important in parietal resections. The entire nondominant parietal lobe posterior to the post central sulcus may be relatively safely removed with a 0.5% risk of hemiparesis. Visual field defects may be encountered after parietal resections, usually contralateral lower quadrant defects, the counterpart of the superior quadrantanopsia of temporal resections. They are generally more poorly tolerated than their temporal counterparts[25,26] and are usually associated with too aggressive a resection of underlying white matter.

The major additional consideration in the dominant parietal lobe is the language cortex. The location of Wernicke's area cannot be reliably predicted by anatomic criteria.[3,4,25] Therefore, mapping is essential. Reading and other more complex language functions may be more broadly localized than simple naming.[3,4]

Occipital resection

Occipital foci are relatively uncommon, and often become symptomatic only after spread to the temporal lobe. Given the high risk of visual deficit, it is important to have an accurate assessment of the patient's preoperative visual status (normally including formal visual fields) and usually to obtain very precise intracranial localization of the seizure onset. In cases of documented occipital onset seizures that do not become symptomatic until temporal spread, some recommend a temporal resection for symptom control, rather than risk primary visual cortex.[27] However, as this has been demonstrated to yield poor long-term seizure control, most recommend either resection of the epileptogenic tissue, or nonsurgical therapy. If such a resection is attempted, the anterior limits of resection are into the parietal and parietotemporal areas, with the most important emphasis on preservation of calcarine cortex and optic radiations.

Summary

A variety of methods exist for determining the precise location of neocortical epileptogenic foci. The most crucial of these are imaging and electrophysiologic methods. Once localized, these foci can be resected with a careful subpial technique, taking care to preserve the vasculature and underlying white matter. Careful attention to the location of eloquent cortex in each lobe, using both anatomic criteria and awake mapping, can minimize the risk of a postoperative neurological deficit.

118 Epilepsy and vascular malformations: spectrum of lesions and strategies for management

P Jabbour and I Awad

Spectrum of cerebral vascular malformations

Cerebral vascular malformations are known to affect 2–4 % of the population, predisposing their host to a lifetime risk of hemorrhagic stroke and epilepsy. These are a hetregeneous group of lesions, with distinct angioarchitecture, and also biologic mechanisms of lesion genesis and progression. Risk and mechanisms of epilepsy are also variable among different lesion types, and treatment decisions often consider not only their epileptogenicity, but also the prospective risk and potential sequelae of hemorrhage.

Arteriovenous malformations

The arteriovenous malformations (AVMs) exhibit mature vessel wall elements with direct communications between arteries and veins, and a high flow profile predisposing to vascular recruitment, arterialization of venous structures and gliosis of intervening and adjacent brain tissue (Figure 118.1). They have three major components: arterial feeders, nidus, and venous outflow. The AVMs are associated with significant gliosis in the nidus and in adjacent brain, thought to result from ischemia caused by arteriovenous shunting and venous hypertension.[1–5] AVMs are prone to apoplectic hemorrhage by rupture of nidal vessels or associated aneurysms, or by venous outflow obstruction.[6–8]

The AVMs have a distinct phenotypic profile, recognizeable on magnetic resonance (MR) imaging and angiography, and these can reveal nidus size and major arterial feeders and draining veins. The MRI also reveals parenchymal ischemia and gliosis in adjacent brain, and areas of encephalomalacia related to previous hemorrhage.

The AVMs typically present as solitary lesions, except in the rare setting of Hereditary Hemorrhagic Telangiectasia (HHT), or disease of Osler-Weber-Rendu, which includes multifocal AVMs, including tiny lesions in skin and mucosa, and multiple organs in addition to brain. The lesions all represent direct arteriovenous shunts, with lack of capillary bed in the nidus, and secondary changes of arterial recruitment and venous engorgement. HHT disease has recently mapped to the endoglin gene (a TGFβ binding protein expressed on endothelial cells) on 9q, or the activin receptor-like kinase gene on chromosome 12q, also expressed on endothelial cells and related to the TGFβ receptor system. The genetic heterogeneity in HHT is associated with apparent differences in disease manifestations, with more frequent cerebral and pulmonary AVMs in association with endoglin mutations. A third gene locus Smad4 on Chromosome 5 has recently been associated with familial colon polyposis in addition to manifestations of HHT.[9]

Cerebral cavernous malformations

Cerebral cavernous malformations (CCMs) represent clusters of dilated sinusoids filled with blood and lined with endothelium without intervening parenchyma (Figure 118.2). They appear to grow by a process of vascular cavern proliferation in the setting of repetitive lesional hemorrhages. The CCMs exhibit brittle vascular morphology devoid of mature vessel wall elements.[10,11] They do not exhibit the high-flow features of AVMs and are less commonly associated with apoplectic hemorrhage.[12–15]

The CCM lesion are commonly missed or misdiagnosed on computed tomographic scans of the brain, because of small size and often isodense appearance related ot subacute hemorrhage or microcalcifications. They are angiographically occult. However, the CCM lesions are easily detected on MR imaging, and manifests a specific appearance of mixed signal in the lesion itself on T1 and T2 sequences, surrounded by a ring of T2 hypointensity from leakage of hemosiderin. Smaller CCM lesions may only be seen on gradient echo MR images because of tell tale hemorrhagic signals.

Solitary CCM lesions occur in 40–60% of cases, with remaining cases manifesting multiple lesions and familial inheritance in autosomal dominant pattern. Familial CCMs have been linked to one of three gene foci on chromosomes 7q, 7p, or 3q.[16] The identified proteins encoded by CCM genes appear to interact with endothelial cytoskleton during angiogenesis,[16,17] and are expressed in neural tissue, hence potentially explaining propensity of lesion genesis in the central nervous system.[16,17] A hallmark of familial disease is the presence of multiple lesions, some of which may only be appreciated on gradient echo MR imaging (Figure 118.3). Solitary sporadic (nonfamilial) CCMs are frequently associated with venous anomalies as noted below, and

these can easily be recognized on contrast enhanced T1 MR sequences.

Capillary malformations

Capillary vascular malformations, also known as capillary telangiectasiae are vascular malformations that consist of a collection of dilated capillaries with normal intervening brain parenchyma.[18–21] They are most commonly located in the pons. They are typically and incidental finding at autopsy, but some cases of symptomatic capillary malformations have been visualized on MRI as vague patches of punctate contrast enhancement[19,22–24] (Figure 118.4). They may also be found in association with more clinically overt lesions, such as CCMs or venous malformations. Microscopically, the vessel walls appear similar to normal capillaries, lined with a single layer

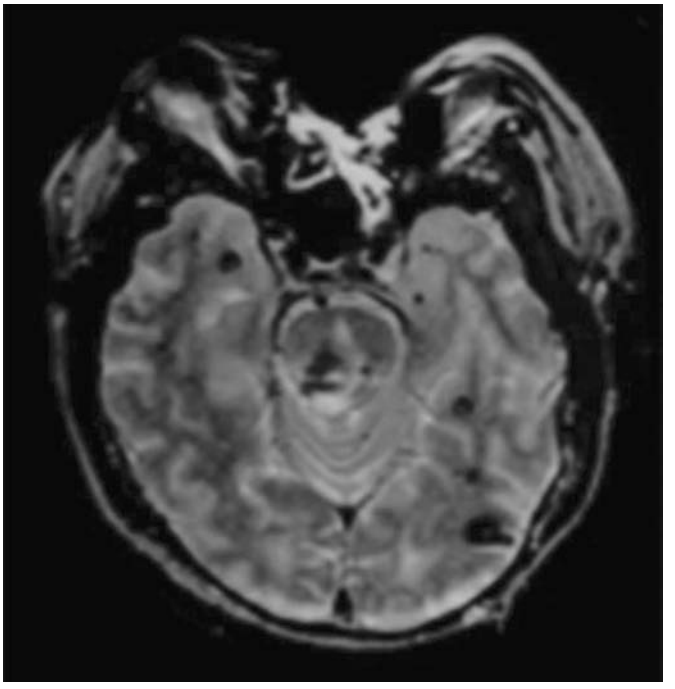
of vascular endothelium. While both capillary telangiectasiae and CCMs represent dilated capillaries, the presence of hemorrhage (on MR imaging or histopathology) is a cardinal difference that clearly distinguishes CCMs from capillary malformations.

Venous malformations

A fourth and the most common form of cerebral vascular malformation is the venous malformation (VM), also known as venous angioma or venous developmental anomaly (Figure 118.5). The VM rarely bleeds except when associated with a CCM lesion [25,26] (Figure 118.6). It is composed of abnormally enlarged venous channels separated by normal neural parenchyma.[27, 28] These vessels are arranged in a radial pattern extending from a dilated central venous trunk, which itself drains into either a deep or superficial venous sinus.[19,27,29,30]

Mixed and dural vascular malformations

Despite the apparently distinct clinical-radiologic-pathologic profiles of the various cerebral vascular malformations, some lesions exhibit mixed or transitional features implying related pathobiologic mechanisms.[23,31–34] Portions of CCMs may exhibit partial or complete mature vessel wall elements akin to AVMs (Figure 118.6), and many CCMs appear to arise in close proximity to venous malformations (Figure 118.7).[1,4]



Firgure 118.3 Gradient echo MRI showing the hemosiderin of multiple CCMs.

It is not known if mixed vascular malformations with CCM component occur in the setting of genetic predisposition to CCM. Both CCMs and AVMs may rarely be associated with skin lesions (even in the absence of HHT) although such skin pathology has not been carefully characterized in association with various lesion types. Rare metameric vascular malformations have also been associated with complex abnormalities and AVM extension into adjacent skull, face and skin.[35–37]

Dural AVMs are another category of vascular malformations with arteriovenous shunting involving the pachymeninges, but may manifest retrograde letpomeningeal venous drainage into the cerebral circulation. This feature may result in venous hypertension in brain parenchyma, and has been associated with seizures and focal neurologic deficits [38–41] (Figure 118.8).

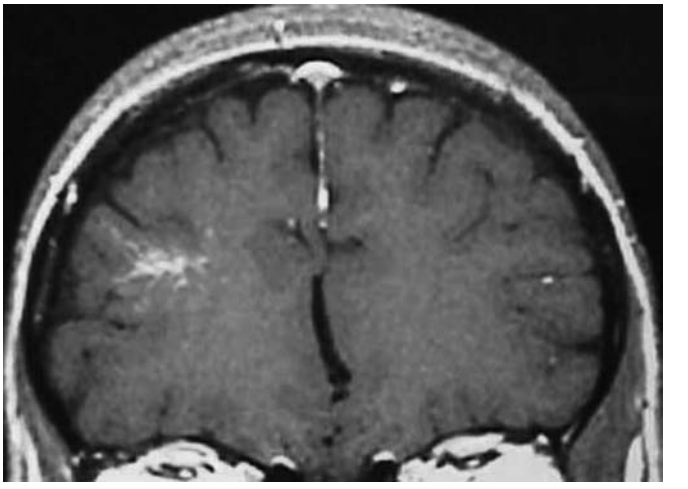

Figure 118.5 T1-weighted MRI with contrast, showing venous developmental anomaly or VM, characterized by large transmeduallry vein with caput medusae morphology, and no other abnormality in adjacent brain. T2-weighed and gradient echo images would not typically reveal any evidence of bleeding.

Mechanisms of epilepsy

Both diagnosis and treatment of localization-related epilepsy have been greatly improved by modern neuroimaging methods. This has led to the reclassification of many 'cryptogenic seizures' into lesional epilepsies, many of these epilepsies are amenable to surgical treatment with the potential for cure or significant reduction in seizure frequency with lesion resection. Lesional epilepsy is thought to be a direct consequence of a focal brain lesion that could be neoplastic, vascular, dysgenetic, traumatic or ischemic.

Localization-related epilepsy is also likely affected by host predisposition, as identical lesions (type, size and location) may cause varying manifestations in different patients, including a spectrum of severity of seizure disorder. Host predisposition may also affect seizure intractability, propensity for pharmacologic seizure control, and the cure or recurrence of epilepsy after lesion excision.

Epileptogenesis in adjacent brain

The vascular malformations are malformed blood vessels and do not typically include funtioning neural tissue. Hence they are not intrinsically epileptogenic, but induce seizures by their effect on the surrounding brain tissue. These may include ischemia, venous hypertension, gliosis, deposits of blood breakdown products, and/or cellular and humoral inflammatory response. Epilepsy in association with vascular malformations has been shown to induce different firing patterns in adjacent hippocampal slices than epilepsy associated with neoplasia.[42]

These alterations may induce epileptic activity that is dependant on the presence of the vascular malformation, and may not support ongoing epileptogenic activity in the absence of that primary lesion. Other changes in adjacent brain may represent permanent (independent) epilep-togenic foci. In these cases selective resection of the MRI-visible lesion may not be sufficient to abolish all the seizures.[42] There is thought to be a spectrum of such maturation of independent epileptogenicity, and time course is thought to be important in the establishment of independent seizure foci. Hence, lesion-related epilepsy is postulated to be more likely permanent or independent of the instigating pathology, after longer duration of epileptogenicity.

Overt hemorrhage from AVMs and CCMs may create encephalomalacia and cortical scars that may be independently epileptogenic. These are often noted on MR imaging and may be associated with correlative focal neurologic deficits. Chronic deposition of blood breakdown products is characteristic of CCMs, where gliotic hemosiderin-stained brain adjacent to the lesion is thought to be the source of epileptogenic activity. In contrast, AVMs may induce gliosis from ischemia in adjacent brain or vasogenic edema form venous hypertension, both related to arteriovenous shunting. Venous angiomas, may rarely cause venous hypertension in adjacent brain, or may reflect regional gyral dysmorphism, itself responsible for seizure activity.

Epileptogenesis in remote brain regions

Lesions may induce changes in the brain tissue located at a significant distance from the primary epileptogenic lesion, and this may contribute to epilepsy syndrome, and even to independent distant foci of epileptogenicity. The limbic structures, and to a lesser extent neocortex, may 'learn' to generate seizures independently and, may become secondarily epileptogenic, after constant exposure to the repetitive seizures caused by an epileptogenic lesion. Over time this may alter network relationships in such a way as to lead to secondary epileptogenesis in these remote regions.[44] This has been most frequently demonstrated in mesial temporal structures adjacent to structural lesions, and much less likely in human neocortex.

Another form of remote epileptogenicity is commonly seen in association with venous hypertension from AVMs, or more commonly dural AVMs, where arteriovenous shunting in the vascular lesion causes alterations of circulation and neurologic manifestations in remote brain. This can often be gleaned from careful analysis of lesion angiodynamics and 'vasogenic edema' signals on MRI.

The demonstration of dual epileptogenic activity in association with a single vascular malformation does not necessarily imply that the second focus, more remote from the lesion, will remain active after lesion excision. In fact, this seems to be uncommon in the setting of single vascular malformation-associated seizure disorder. Often, this dictates a staged approach, with excision of lesion and surrounding epileptogenic brain, at first stage, and more extensive investigations of remaining epileptogenicity only in those uncommon cases where seizures persist after lesion excision. The more frequent the seizures, the more likely a secondary focus to become permanent. This raise the question of early surgical intervention when medical therapy fails.[45]

Multiple lesions

Dual and multifocal pathologies are important for the understanding of the pathogenesis of epilepsy and also for surgical planning. Patients who preoperatively demonstrate multiple structural lesions require more extensive preoperative investigations and tailoring of interventions for control of epilepsy.[46–48]

The CCMs are frequently, and AVMs more rarely, associated with multifocal vascular lesions, any one of which may contributing to epileptogenesis. While the larger lesion, or one with most recent bleeding or other clinical manifestations, is more likely the source of seizures, this cannot be taken for granted. Resection of the wrong lesion will not only fail at controlling seizures, but may result in catastrophic functional sequelae when the remaining epileptogenic lesion resides in contralateral temporal or frontal lobes.

The most sensitive imaging studies must be evaluated in the setting of cerebral vascular malformations to demonstrate or exclude multifocal structural pathology, that may be contributing to epileptogenicity. In cases of CCMs or venous malformations, gradient echo MR images must be performed to demonstrate or exclude multiple foci of occult hemorrhage. In cases of HHT, formal cerebral angiography may demonstrate exceptional multiplicity of cerebral AVMs not evident on MRI,[49] while MR imaging may reveal areas of previous ischemia from paradoxical embolism caused by pulmonary AVMs.

Treatment options

Medical therapies

The first line treatment of seizures associated with a vascular malformation is always medical. Different anticonvulsant agents are associated with varying effectiveness in different seizure types. And several newer drugs are associated with fewer side effects, or may be safer in potential pregnancy. These drugs will be reviewed in detail in different sections in this book.

After a first seizure, the decision to start anticonvulsant medication is based on the risk of seizure recurrence and on the potential risks associated with chronic antiepileptic therapy. Whenever a structural lesion is identified on imaging studies, decision must be made about its likely relation of the lesion to the seizure disorder. In the setting of cortical CCM, AVM, and certainly where seizure semiology is clearly related

to the lesion locale, this relationship is easy to establish. In other instances, such as with infratentorial or subcortical vascular anomalies, or seizure precipitated by alcohol, drugs or trauma, the possibility of incidental lesion may be considered. Venous malformations are extremely common in the general populations and are often incidental to various neurologic symptoms, including seizures, especially when seizure semiology does not suggest appropriate localization. Electrophysiologic studies may be helpful in this regard, especially when positive and with appropriate lateralization or focality, but a normal electroencephalogram does not rule out epileptogenicity.

If a vascular malformation is thought to be the cause of seizure, long-term anticonvulsants are indicated, as seizures likely will recur and may progress toward intractability. A drug is chosen based on the type of seizure, and on potential side-effects in the particular patient. When the drug of first choice has been selected this drug almost always is used in monotherapy. Only when seizures recur despite verified compliance and therapeutic doses of monotherapy is a second agent added.

Patients with vascular anomalies in cortical locations are subject to a prospective lifetime risk of new seizures. This is greatest with CCMs located in temporal, frontal, and perilimbic locations, and may affect occupational clearance for pilots and other professions. Clinical history is important in such patients, to elicit possible auras or other stereotyped symptoms that may represent seizure activity. However, prophylactic treatment is rarely indicated in these instances unless epileptic activity has been established.

Lesionectomy

Surgical resection of vascular malformation may be undertaken to prevent future hemorrhage, and/or to assist in seizure control. This can involve resection of the lesion alone known as lesionectomy, which is associated with an excellent postoperative control of seizure activity in many patients.[12] The likelihood of postoperative seizure control following simple lesion excision is greater in patients with less intractable preoperative epilepsy, and also in patients with extratemporal lesions. Unlike temporal lobectomy there are no anatomically standard operations for performing a simple lesionectomy. These procedures are divided in temporal lesionectomy and extratemporal lesionectomy. In patients with temporal lesions and intractable epilepsy, studies of lesionectomy alone without resection of mesial structures showed a low seizure control rate ranging from 20 to 45%.[50–52] In extratemporal lesional epilepsy, lesional resection alone has provided favorable results with seizure control rate varying from 65 to 95%.[50–53]

Most patients achieving postoperative seizure control will still require long term anticonvulsants, often with fewer agents and at lower doses. The decision to taper or discontinue anticonvulsant therapy is often performed very cautiously to avoid precipitating new or recurrent seizures. In the setting of new onset localization-related seizures and single cerebrovascular anomaly, especially CCM, up to half of cases that are seizure free after lesion excision may successfully taper off all anticonvulsant medications.[54–57] This promising outcome, and its associated positive impact on quality of life, may play a role in decision to excise a solitary accessible cerbrovascular anomaly, especially a cortical CCM, even when seizures are not truly intractable to medical therapy.

Lesionectomy and cortisectomy

Surgical resection of structural lesions can involve resection of the lesion alone or resection of the lesion and epileptogenic cortex. A tailored resection may be performed to avoid the eloquent cortex. Many studies have compared lesionectomy and lesionectomy with cortisectomy,[51,53,58,59] with controversial results. A meta-analysis evaluating seizure outcome following lesionectomy or lesionectomy and cortisectomy concluded that at 2-year follow-up, the percentage of patients with persistent seizures following lesionectomy ranged from 1.4 to 4 times that following lesionectomy and cortisectomy. Low grade gliomas, gangliogliomas, and vascular malformations were most successfully treated with lesionectomy and cortisectomy.[60] On the other hand patients with fewer seizures before presentation, shorter preoperative seizure history, or seizures that responded to antiepileptic medications are more likely to be seizure free following lesionectomy alone.[61–67]

Several studies have shown that complete lesion excision is necessary for seizure control in the majority of patients where the lesion is shown to be responsible for the seizure disorder.[53] It also is well documented that lesion excision alone may not always sufficient for seizure control, especially in patients with truly intractable epilepsy. Many patients with persistent intractable seizures following lesion excision have involved lesions in the temporal lobe.[50] Some of these patients were rendered seizure free by additional resection of epileptogenic brain in the same region.

Resection at first operation of epileptogenic brain in addition to the lesion may accomplish seizure control, sparing the patient a second surgical intervention. But the functional impact of resection of additional brain must be considered in this decision. This is especially important when considering resection of mesial structures in the presence of high or normal material specific neuropsychologic function, or in other eloquent areas (such as dominant temporal neocortex). Intraoperative electrocortigoraphy is sometimes performed to further delineate the extent of the cortical epileptogenic zone. This technique may provide prognostic information by indicating the areas of residual discharges after the resection of the vascular malformation or what was thought to be the seizure focus.[68–72] However, residual spikes in adjacent brain areas do not reliably predict residual epileptogenicity, nor does their absence guarantee postoperative seizure control.

Disconnection surgery

Multiple subpial transections are mainly used to treat partial epilepsies that reside within eloquent cortical regions.[73] The technique involves disconnecting the gray matter columns that lie in eloquent cortex. This can inhibit synchronization and spread of seizure activity with less drastic effect on eloquent function.[74–77] Most patients who have multiple subpial transections in eloquent brain have subtle transient deficits corresponding to the area transected most pronounced in the first week after surgery.[78–82]

Corpus callosotomy is another potential palliative treatment in patients with multiple or poorly lateralized epileptogenic foci, secondarily generalized tonic-clonic seizures, and injurious drop attacks due to tonic or atonic seizures with resultant falls and injury[83–86] In 70% of patients, elimination or more than 80% reduction of seizures has

been reported.[84,85,87] Complications specific to this procedure consist of acute disconnection syndromes more common with total callosotomy.[88,89]

Neuroaugmentative surgery

Vagus nerve stimulation is a palliative treatment for intractable seizures, with data in the literature showing a seizure reduction rate varying from 35%–75% in the setting of various seizure types, with most patients remaining on anticonvulsants. Specific results in seizure disorder associated with cerebrovacular malformations have not been reported to our knowledge. The side-effects can include voice alteration, hoarseness, throat or neck pain, headache, cough, dyspnea, vocal cord paralysis, and aspiration.[90–93] It is a relatively simple procedure technically, but discussion with the patients about their expectations after such procedure is very important.

Deep brain stimulation has been attempted for the modulation of seizure activity, with electrode stimulation targets in the cerebellum; in anterior, centromedian, and ventralis intermedius thalamic nuclei; and in the caudate nucleus has.[94,95] Stimulation of the hippocampus in an attempt to block temporal lobe seizures has recently been used.[96] The stimulation of the subthalamic nucleus reduced daytime seizures by 80%.[94]

Management strategies

First seizure

The surgical option is rarely considered for the goal of seizure control in patients with a first seizure in association with known or newly diagnosed vascular malformation. Lesion excision may be performed for the purpose of preventing hemorrhage, and in rare cases, especially with solitary and accessible CCM, to allow a chance at discontinuing anticonvulsant medications. Medical treatment is typically initiated to try to classify the patient in the well controlled or uncontrolled seizure group.

Arteriovenous malformations

The cause of epileptogenesis from cerebral AVMs is not always evident. A number of different hypotheses have been proposed,[57, 97–102] including focal cerebral ischemia attributable to a 'steal' phenomenon resulting from neighboring arteriovenous shunting. Gliosis, neuronal degradation, demyelination, and hemosiderin deposits lining the AVM bed have been suggested. And there have been noted secondary epileptogenesis at a distant site attributable to a 'kindling' phenomenon, in which epileptic discharges are enhanced by excitatory synaptic connections from the AVM.

Cerebral cavernous malformations

The CCMs are known to be more epileptogenic than other cerebrovascular anomalies, as they are more frequently associated with seizures and with intractability of epilepsy. The exact mechanisms by which CCMs cause seizures are unknown although a number of electrophysiologic and pathophysiologic theories have been proposed. These include changes in altered neurotransmitter levels (GABA and somatostatin), free radical formation and altered second messenger physiology.[103] Morphological changes have also been identified such as alterations in vascular supply, neuronal cell loss, glial proliferation and subtle subcortical disconnections.[57] Most investigators suspect that the breakdown products caused by repeated small microhemorrhages deposit ferric ions into the surrounding cortex which are known to be highly epileptogenic. In animals, the injection of ferric ions into the cortex and subcortical regions creates a potent and reproducible model of recurrent and intractable seizures.[104] These different pathophysiologic mechanisms my present unique opportunities for developing specific anticonvulsant strategies better suited to such mechanisms.

CCMs in the Rolandic or peri-Rolandic cortex, as well as near limbic areas (temporal lobe and cingulate gyrus lesions) tend to be the most epileptogenic. Lesion size may represent an additional factor in epileptogenicity. A final issue that must be considered is the possibility that the CCM identified on imaging may represent an incidental finding and not playing any role in seizure onset. This may be the situation in up to 6% of cases of patients with cavernous angiomas and epilepsy.[105] It is also possible that the CCM represents a structural lesion coexistent with mesial temporal sclerosis.

Capillary and venous malformations

The risk of hemorrhage of capillary telangiectasia is extremely minimal, there are some reports in the literature decribing the association of capillary malformations with seizures and hemorrhage.[106,107] Seizures can occur as a direct result of the hemorrhage caused by the capillary malformation, a transformation likely converting the lesion into a CCM.

Venous angiomas are rarely associated with seizures. Moreover these lesions are often difficult to relate causally and topographically to the epileptogenic zone.[108–110] More often they are occasionally observed during the diagnosic evaluation of different incidental clinical scenarioss. These lesions are often associated with cavernous malformations or AVMs and in this setting the seizures are probably due to the associated malformation rather than the venous angioma itself.[108–111] Rarely, brain dysmorphism (gyral or lobar developmental anomalies) are associated with regional venous dysmorphism. In those instances, the venous anomaly is an index or associated dysmorphic brain that may be epileptogenic. Careful electrophysiologic studies and interictal and ictal functional imaging are indicated in these cases to clearly associate the lesion with epileptogenic zone.

Controlled seizures

Regardless of the type of vascular malformation, the risk of surgical intervention for any vascular malformation is not typically warranted in the setting of well-controlled epilepsy unless there exists another indication for lesion excision. Often, lesion excision is considered to prevent future hemorrhage, but not necessarily to assist with seizure control.

Some patients not compliant with their antiseizure medications but otherwise with medically-controlled seizures would be candidate for resection of the vascular malformation for seizure control purposes, or patients that do not want to be on antiseizure medications because of adverse effects or other reasons, may also benefit from a surgical resection. In these cases it is very important to take into account the location of the malformation and the feasibility of the procedure, weighting

the risks and benefits, and enhanced seizure control or discontinuation of medicatiosn cannot be guaranteed.

Patients with controlled seizures harboring an AVM may need their lesion treated for reasons different than seizures, mainly for the purpose of avoiding a risk of hemorrhage from the AVM which varies between 2–4% per year.[112] Different treatment modalities are available depending on the grade of the AVM: surgery, endovascular embolisation, or stereotactic radiosurgery. These considerations are beyond the scope of this chapter.

Cavernous malformations have a lower risk of apoplectic hemorrhage compared to AVMs, but lesions with prior overt hemorrhage or demonstrated lesion growth are often considered for lesion excision to prevent further neurologic sequelae.

Intractable seizures: prognosis and outcome

The presence of a vascular malformation in association with intractable seizures is a challenging situation. Surgical intervention for resection of the malformation is usually performed in an attempt to control the seizures.

Arteriovenous malformations

In the majority of AVM patients with seizures, the emphasis of surgical intervention is the elimination of the risk of intracerebral hemorrhage rather than seizure control.[97] Most seizure disorders associated with AVMs can be well controlled with anticonvulsant medication. Seizures might improve, remain unchanged, or worsen after any therapeutic intervention for an AVM.[66, 97,113–117] De novo seizures have also been described after AVM resection. Intractable seizures often become much easier to control after AVM excision, and in a few cases anticonvulsants may be discontinued altogether after a seizure-free period. There is no evidence that extensive monitoring, mapping, and excision of epileptogenic brain is necessary, cost effective, or achieves a better overall outcome relative to seizure control than the primary treatment of AVMs. In cases of persistent intratctable seizures after AVMs excision, formal mapping and excision of epileptogenic zones can achieve seizure control.[118]

Some factors are implicated in the likelihood of postoperative seizures: age at seizure onset <30, duration of preoperative seizures >12 months, AVM size >3 cm, location of the AVM in the vicinity of mesial temporal or peri-Rolandic cortex, prior hemorrhage and gliosis surrounding an AVM.[57,66,97,98,114,119]

Cerebral cavernous malformations

Patients with solitary CCMs and uncontrolled epilepsy with semiology related to lesion location are candidates for surgical excision of the CCM to improve seizure control. Overall analysis of the data demonstrates improvement of symptoms in the majority of patients.[12–14, 120,121] Of patients treated with surgical resection of the offending lesion, 50%–90% were postoperatively seizure free with or without anticonvulsant therapy.[13,14,120] Persistent seizures have been reported in conjunction with incomplete lesion resection. In order to maximize the likelihood of seizure control, excision of the CCM should be accompanied, whenever possible (i.e., in noneloquent brain regions), by resection of the gliotic hemosiderin-stained brain surrounding the lesion.[12,13,55,110]

As with AVMs, there is no evidence that extensive preoperative mapping or additional brain excision at initial surgery will improve seizure outcome beyond that of lesionectomy and perilesional gliotic brain in cases with solitary CCMs and intractable epilepsy. The rare cases with residual or recurrent seizures after lesionectomy may be considered for resection of residual lesion, adjacent or remote epileptogenic brain at the second operation. Such reoperations require comprehensive preoperative and intraoperative mapping and functional studies as in other localization-related epilepsies.

In patients where there is any question whatsoever about relationship of a CCM to the intractable seizure disorder, the patient should not undergo empiric lesion resection with the remote hope that intractable epilepsy might resolve, instead, detailed preoperative mapping and recording should be performed. This is particularly true in cases with mutiple CCMs, where the single offending lesion is not always easy ot define. In these cases, careful preoperative mapping and other diagnostic studies must be undertyaken before preoposing the resection of one of the lesions for seizure control.

Conclusion

The direct relationship between structural vascular malformations and seizures, is not always clear cut. Prolonged preoperative mapping and careful recording are mandatory in clarifying cases in which the lesion may not be the primary epileptogenic drive, may simply be incidental or unrelated to the seizure disorder, or in cases with multifocal pathologies. Complete resection of a solitary AVM or CCM is the best approach to optimize seizure control if the lesion is indeed believed to be epileptogenic. Thresholds for considering lesion excision are dictated by the projected natural history of the lesion, and its surgical accessibility. In the different senarios families and patients should be aware of all expectations from different procedures.

119 Resective neocortical techniques in children

F Villarejo

Definition

Resective surgery can be used to treat any epilepsy that originates in the neocortex outside the medial structures of the temporal lobe.

Introduction

Cortical resection to treat refractory epilepsy was first described by Victor Hosley in 1886.[1] His classic paper on the subject described a young adolescent with numerous daily crises who was completely cured after the surgery. Despite the efforts of this pioneer neurosurgeon, surgery for refractory epilepsy was only accepted after the work of Penfield and Jasper[2] from the Montreal Neurological Institute. They described the role of electroencephalography, or EEG, and confirmed that a good prognosis depended on multidisciplinary teamwork among epileptologists, radiologists, neuropsychologists, neurosurgeons and anesthetists. The series published by these authors and other institutions in the second half of the twentieth century included mostly adults and only a few young people.

Papers by Rasmussen[3] and Goldring[4] demonstrated that this surgery was safe in a developing brain. Various factors have lead to more widespread greater acceptance of surgical treatment for refractory epilepsy in children in recent years. The most important is the awareness of the natural history of some pediatric syndromes that only have surgical treatment. Although the intensity and frequency of the crises should decrease with time, the patient's intelligence decreases progressively if the seizures persist. What is more, spontaneous remission of the crises is very rare. And, some anticonvulsants are known to have a negative effect on intellectual development.

Second, the advances in neuroradiology, metabolic studies, and functional MRI have improved our identification of the structural lesions that are responsible for the epilepsy as well as the relations between the lesions and important functional areas.

Third, we would note that the development of techniques to map brain function has enormously improved the surgical prognosis in pediatric patients. The safety of these procedures has also been helped by the new neuroanesthetic techniques.

Differences between adults and children's refractory epilepsy

The epilepsy of adults and children presents many similarities but there are also differences. First, a developing brain has a low crisis threshold and this means that catastrophic epilepsy is frequent. It is characterized by a type of malign epilepsy that associates multiple crises with a severe psychomotor developmental retardation.

The pathological substrate is also similar in adults and children. Lesional epilepsy, particularly, and anomalies in cortical development are much more common among the pediatric population while medial temporal epilepsy or temporal medial sclerosis is quite common in adults and very rare in children. The symptoms and EEG of the pediatric syndromes that are curable with surgery are also different. The auras and temporal manifestations of a seizure are frequently overlooked in children while in adults these auras are a common clue or factor that can help locate the origin of the focus of the crisis. These symptoms are frequently interpreted as a generalized epilepsy in children.

These differences motivate important differences in the pre-surgical study of refractory epilepsy in children.

Pre-surgical evaluation

The most important part of a pre-surgical evaluation is to identify the epileptogenic zone or the area of abnormal cerebral tissue that is responsible for the seizures and to determine its relation with the eloquent cortex. Before now, this identification was only based on the ictal and interictal EEGs. High-definition MRI has been an important advance, especially the 1.5 and 3 Tesla functions that have made it possible to identify very small lesions during pre-surgical evaluation. After identification of the pathological substrate, the patient's response to anticonvulsants, the frequency of the seizures, and also the prognosis for psychomotor development are primordial. The family history and the family members' description of the seizures help to identify the type of seizure while frequency must be documented through careful neurological examination. Often the neurological examination is what allows us to focalize the seizures.

Neuroradiological study

The brain anatomy and lesions that may be located are fundamental for pre-surgical evaluation and for guiding the electrophysiologist in determining whether there is any correlation between the MRI image and the alterations that may be found on the EEG study. The MRI study is performed following the existing protocols for neocortical study.

Use of the high definition MRI allows the identification of a pathological substrate in 80 % of pediatric patients.

Metabolic imaging

The introduction of positron emission tomography or PET into the treatment of childhood refractory epilepsy has been very important. It is an extremely helpful study in patients with demonstrated lesions on the MRI because it measures the relation between the hypermetabolic area identified by the PET and the epileptogenic area, if this has been determined with the EEG. If the focus has not been identified, PET can help determine the lateralization, and this is fundamental when the MRI is normal. However, SPECT, or single photon emission computed tomography, is problematic in children because their seizures are usually short and this test has low anatomical resolution. Generally it is performed after a seizure and more than locate the lesion itself, it helps to lateralize the lesion.

Video-EEG

A recording or registry of one or more seizures is very important in confirming the epilepsy diagnosis in a child as well as to help lateralize and localize the epileptogenic area. The most important factor of the video-EEG is identifying the irritative zone and the interictal spikes, as well as the ictal area or area that is triggering the seizures. Generally, several seizures are registered and their symptoms are analyzed together with the ictal EEG registry. The ideal is to be able to locate both the interictal zone and the ictal zone during the video-EEG.

However, this ideal is very difficult to realize in children with refractory epilepsy, even in tumoral pathologies, since their interictal activity can be quite widespread or it may not be possible to lateralize the seizure onset. These are the most significant differences in epilepsy between adults and children.

Invasive registries

When it has not been possible to define the ictal zone adequately by noninvasive studies, invasive techniques employing electrodes must be used. There are three main types of electrodes: foramen oval electrodes; deep electrodes, and lastly, subdural electrodes.

Subdural electrodes are the most widely used electrodes in children. Employing strips or grids of electrodes makes it possible to cover wide areas of the cerebral cortex when performing an EEG registry or a cortical map. The drawback is that placing a strip or grid requires a very large craniotomy, and this implies a significant blood loss and increased risk of infection for the child. Placed as strips, subdural electrodes can be placed through a burr hole, but the difficulty is that children's brain tissue is very soft, more so in very small children, and they do not have a well-developed subarachnoid space, so that it is possible to produce cortical lesions while placing this type of electrode.

At this time, subdural electrodes are not commonly placed under stereotaxic guidance.

Another important point in pre-surgical localization of the dominant hemisphere and memory evaluation is the Wada test, although it is not commonly applied in small patients. Generally, most epilepsy services are more commonly employing functional MR and the Wada test is only used in our own service in patients over 12 years of age.

Neuropsychology

The epileptogenic zone is characterized by an area of persistent dysfunction. The neuropsychological evaluation will attempt to identify specific deficits associated with the area where the cortical dysfunction is occurring. Unfortunately, the information supplied by the children, despite our use of specific tests, very rarely allows us to lateralize the lesion.

Functional mapping

When the lesion or epileptogenic zone affects or is adjacent to eloquent cortex, it is necessary to perform functional mapping in order to achieve maximum safety during resection. Mapping is mostly done when the resections will be close to the central area, in the dominant hemisphere in the frontal lobe, inferior in the dominant hemisphere or in the posterior part of the temporal lobe, as well as in the precentral surcus and in the dominant parietal lobe or the occipital lobe. Different methods exist to map these functional areas including modern technologies like functional MRI and magnetoencephalography.

Craneotomy in the conscious patient

This technique has advanced with the introduction of propofol in anesthesia. The patient must be an older child who can cooperate with an anesthesiologist familiar with this technique. The technique keeps the patient awake while areas adjacent to the language area are being resected. It should only be done in patients over 13 years of age and requires the placement of an electrode grid for pre-surgical mapping of the language area.

Incidence

The Neurological Institute of Montreal study reported that, of the 2,167 epilepsy surgeries they performed, between 1929 and 1980, 56% were temporal lobe surgeries.[5] In March 1987, Olivier presented his own series of 525 patients, and temporal lobe was affected in 74% of the patients in this series, the frontal lobe in 11%, the central area in 1%, the parietal area in 9% and the occipital lobe in 8%. Multilobal and/or total or partial hemispherectomies were performed in 2.5% of the patients and callosotomies in 9.5%.[6]

However, the proportions are completely the reverse in the pediatric population[7] and 60% of epilepsy surgeries affect extratemporal areas in children. Of 86 children operated in the Hospital Garrahan in Buenos Aires, Argentina, between

1988 and 1997, 63 were children and 23 were adults. The temporal lobe was affected in 73.9% of the surgeries in adults and in 42.8% of the children.

Differences between temporal and extratemporal lobe surgery

Professor Rasmussen published his famous triad for rationalizing procedures for epilepsy surgery in 1987.[8] The triad consists of three queries:

(a) Where does the seizure begin?
(b) How much of the cerebral volume is involved for the seizure to be triggered?
(c) How much tissue must be extirpated to stop this seizure?

These three basic questions are quite difficult to answer in the context of extra temporal epilepsy.

In his work, Rasmussen suggests that epileptogenic lesions in the extra temporal areas are much more variable in extension and configuration than in the temporal lobe.[9,10] In addition, differences in the triggering threshold between the cerebral cortex and other cerebral areas are notable. For example, the triggering threshold in the postcentral area is lower than in the precentral area so that stimulation of the latter has a smaller risk of producing a seizure during intraoperative cerebral mapping than stimulation of the post central area.[11]

This is particularly important if surgery is being done on a conscious patient, given the high risk associated with a seizure occurring during surgery. If the patient is unconscious, it is quite difficult to provoke a symptom of the patient's epilepsy through cortical stimulation when the patient is asleep, since, for example, stimulating the motor area that corresponds to the hand will not easily obtain hand movement. This is particularly true in children, in whom the process of cerebral maturation or myelinization is incomplete.

Classification of extratemporal resections

There are three patient groups:

1. Patients with organic lesions.
2. Patient who show no correlation between their existing lesion and their epilepsy.
3. Patients without an identifiable organic lesion.

Patients with organic lesions

The first step is obtaining a clinical and neurological diagnosis of the type of crises that the patient has. First, one attempts to correlate the MRI lesion with the clinical expression of the seizures. The next step is to correlate the clinical symptoms of the seizure with the EEG. This is done by performing a normal EEG placing electrodes on the scalp surface and then recording a seizure. Obviously, this is difficult, so generally, one performs a video-EEG. The patient is admitted to the Epilepsy Unit and the symptoms of the seizure are recorded simultaneously with the alterations in the EEG. Depending on the site of the lesion, if it is in an eloquent area, and, depending on the patient's age, it would be very helpful to perform an ictal and interictal registry placing an electrode grid to perfectly delimit the eloquent areas. If it is not an eloquent area, and the MRI and video-EEG findings correlate with one another, one can go directly to surgery during which an intra operative electrocorticography can be performed to confirm the relation between the lesion, its periphery and the EEG alterations.

Patients who show no relation between their lesion and their epilepsy

If there is no clinical correlation between the lesion and the patient's epilepsy, despite the MRI clearly showing a lesion, it is important to demonstrate the relation with the epileptogenic focus that is producing the convulsive seizures before surgery. In these cases it is absolutely necessary to place a subdural grid of as many as 24 or 32 electrodes and correlate the ictal alterations with the lesions that are visible on the MRI. The time in which the subdural electrodes are in place and the video-EEG is being performed is used not only to locate the original focus of the seizures, which would be the primary epileptogenic area and its propagation route, but also to make a cerebral map of the areas on which the electrodes are placed; this process should provide a significant safety margin for the actual surgery. Once the focus has been mapped, the second surgical time can be planned in which the epileptogenic area or zone will be resected. An electrocorticography is done during surgery to corroborate the site of the epileptogenic focus and to be sure that surgery does not leave potentially epileptogenic areas. An adequate surgical technique would employ microsurgical techniques, bipolar coagulation and an ultrasonic sucker.

Persistence of points that are distant from the site of the resection is an indication that the resection should be enlarged to completely extirpate any residual focus. The value of the points close to the border of the corticectomy is under discussion in the literature with no clear criteria at this time as to how to treat them.[12,13]

In our own series of resections in children we always finished with a normal electrocorticography, although this did not always coincide with a cure or normalization in the postsurgical EEG.

Patients with no organic lesion

We apply the above method, but with extreme caution. Since the CT and MRI are normal and thus there is no anatomical orientation, it is absolutely necessary to have a symptomatic diagnosis of the patient's epilepsy that can locate the focus from a clinical and electroencephalographic angle. Without this minimum information it is impossible to plan surgery in this group of patients.

Normally the lesions in this third group without a visible lesion on their MRI and with refractory epilepsy are extratemporal and the epileptogenic area is also extra temporal.[14] These patients make up about 20–30% of all patients who are evaluated for surgery in the centers dedicated to epilepsy surgery.[15–17] The percentage that can become seizure free after resection in between 30–50%,[18] reflecting the difficulty in identifying the epileptogenic area without a visible lesion on the MRI.

Histopathologically, most authors think that there is an undetected organic focus that provokes this partial epilepsy in children. Histological study of many of these patients with a normal MR has found small areas of cortical dysplasia, small vascular malformations and even small tumors. Even the tissues that appear to be normal or do not present any of these alterations, do often show a proliferation of astrocytes, and neuronal or myelin loss.[19]

In 1984 Meencke and Janz [20] defined the term microdysgenesis to describe minor histological alterations with a congenital origin during cerebral development but that do not reach a size large enough for them to be included among the parameters of a cortical dysplasia. These changes consist in aberrant neurons in the pia mater and white matter, alterations in cortical neurons and Purkinje cells as well as in the granular and molecular layer and the white matter. One must also note that these changes are found in patients who have no history of epilepsy. The neurophysiological study of the video-EEG of patients without an MRI lesion can reveal ictal and interictal anomalies that, although they do not identify the epileptogenic area, do lateralize it. In these pre-identified patients, a PET and SPECT can locate the hypermetabolic area or area of increased blood flow in specific cortical areas, which if it coincides with the EEG alterations, will also allow us to lateralize the location of the epileptogenic area. The proportion of patients without MRI alterations but with PET hypermetabolism, whose alterations coincide with the EEG is one-third of the cases in which it is possible to locate the epileptogenic area, and this proportion is similar for the ictal SPECT sequences.

Returning to group 1, patients with a focal lesion on the MRI, the lesions should be subdivided among:

(a) Tumoral lesions (gangliogliomas, DNTS and gliomas)
(b) Developmental disorders (cortical dysplasia, hamartomas and phacomatosis)
(c) Vascular lesions (cavernomas and arteriovenous malformations)
(d) Infectious lesions (tuberculomas, neurocysticercosis)
(e) Ischemic or hypoxic lesions
(f) Traumatic lesions.

Tumoral lesions

The incidence of seizures among patients with cerebral tumors is related with the pathology and location of the tumor.[21] It is important to note that 50% of patients with a cerebral tumor have epileptic seizures.[22] Within tumoral pathology, the only symptoms produced by gangliogliomas and dysembrioplastic neuroepithelial tumors in most cases are the epileptic crises, while gliomas can produce a syndrome of intracranial hypertension, anf focal deficits as well as seizures, although, differently from DNTS, gangliogliomas can also sometimes produce a syndrome of neurological deficit, basically of cerebral edema.

Depending on their location, tumors located in the central parietal region and in the temporal lobe are the ones that most frequently produce seizures.

The diagnosis of these tumors is basically done with MRI. (Figures 119.1 and 119.2) The problem is how to manage a patient with refractory crises and a cerebral tumor. To the author, the answer is clear: any and all cerebral tumors must be surgically removed, even in eloquent areas since with modern surgical methods (stereotaxis, ultrasound, surgical microscope, ultrasound sucker, cortical stimulation of the conscious patient, etc.) the resulting cerebral damage is minimal. Also, with surgery it is possible to identify the histology and thereby avoid growth or hemorrhage, and what is more, in most cases we can solve the problem of the seizures. Once we identify the histology, it is possible to administer coadjuvant therapy (radio or chemotherapy), if necessary.

If the epilepsy is chronic and the image on the MRI seems to show a benign tumor like a ganglioglioma, DNT or benign astrocytoma, we would advise surgical resection.

Vascular lesions

The two types of vascular lesion that most frequently cause epilepsy are cavernomas and arteriovenous malformations. The difficulty is that the surgical indication is completely different in both types.

Cavernomas make up 5–6% of all intracranial vascular malformations;[23] a third present with seizures, another third with intracranial hemorrhages and the last third produce a compression syndrome because of their size. We would firmly

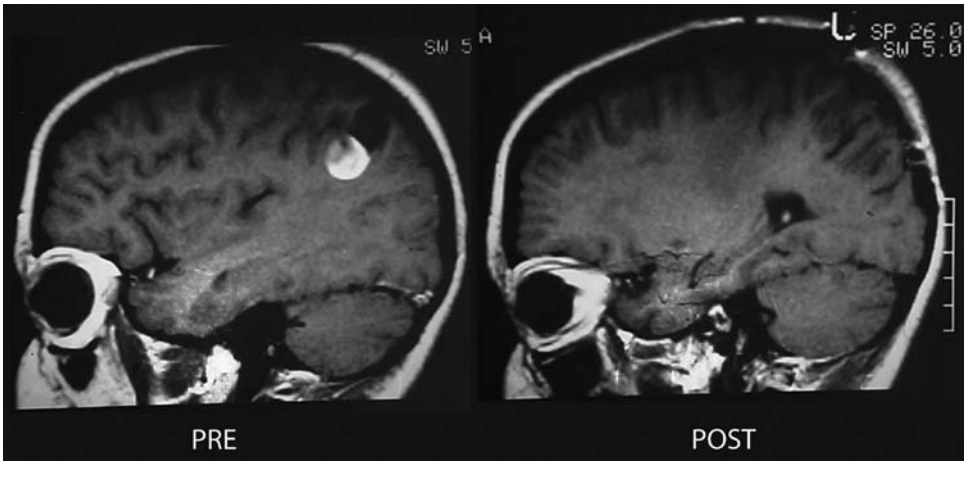

Figure 119.1 Sagital MRI shows parietal DNT before and after surgery.

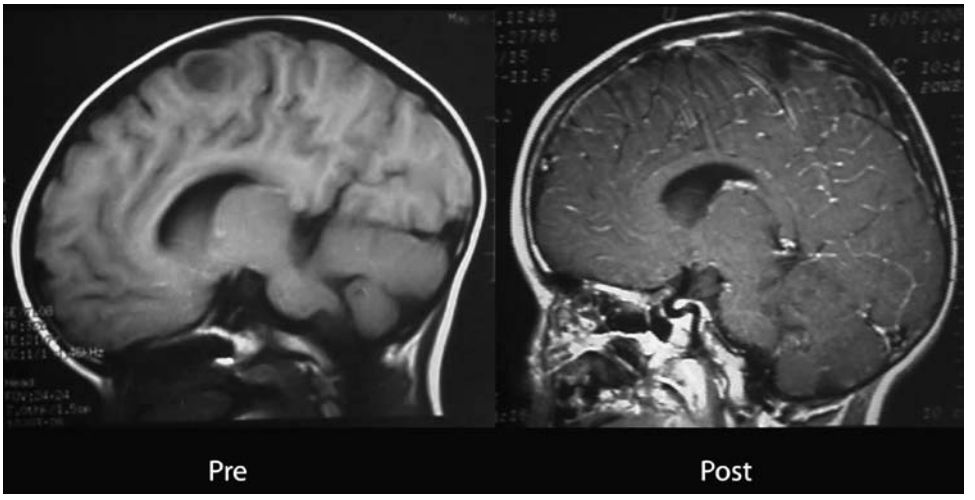

Figure 119.2 Sagital MRI shows central ganglioglioma before and after surgery.

advise surgery for any supratentorial or infratentorial cavernoma, except for those located in the brain stem if they do not cause symptoms.

On the other hand, arteriovenous malformations may present with hemorrhages or seizures (20%).[24] When these malformations are diagnosed, the surgical indication is largely influenced by the size of the malformation. The treatment of very large malformations located in eloquent areas and that only produce seizures is still controversial. We believe that the first step is to control the seizures with medical treatment. If the malformations are small, less than 3 cm, and in eloquent areas, radiosurgery should be attempted. When they are not located in eloquent areas the treatment *of choice* is surgery.

Developmental lesions

Cortical dysplasia is produced by an anomalous development in the formation of the intracranial sulcus and gyrus with disorders in cerebral cortex cell organization; the most severe forms are schizencephalia, polymicrogiria, pachygyria and lysencephalia. These dsysplasias may be limited to certain surci and therefore produce clinical seizures, or there may be some migratory disorder that produces isolated cortical heterotopias in the white matter that may be isolated or quite wide. These seizure-producing smaller cortical dysplasias and isolated heterotopias can be treated by extirpating the malformed area. (Figures 119.3, 119.4, 119.5, 119.6)

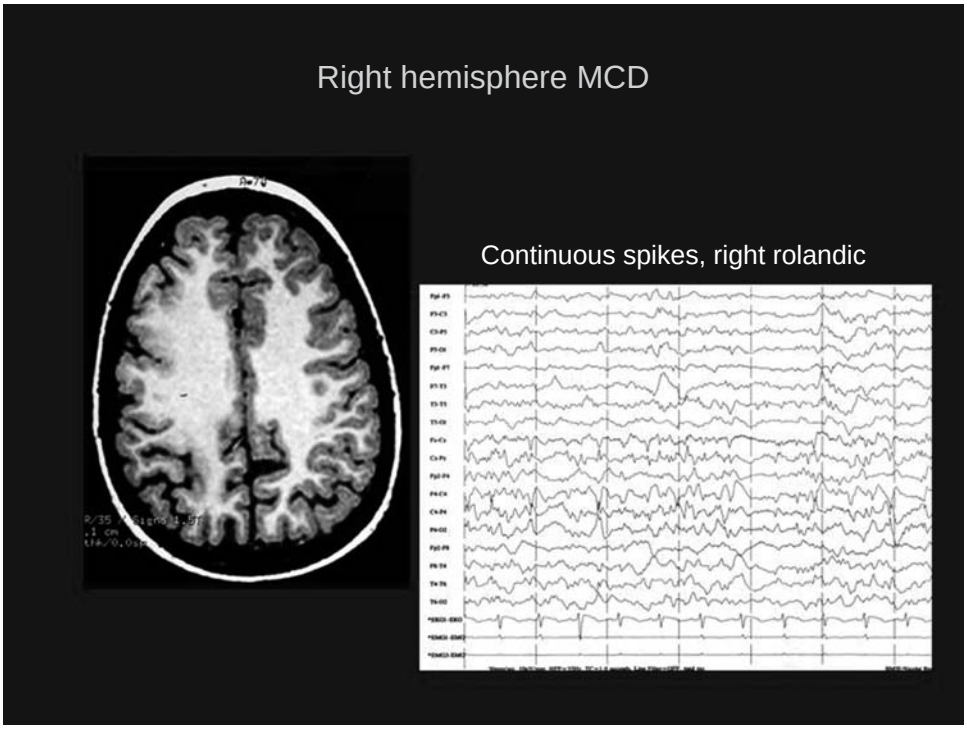

Figure 119.3 MRI and EEG right hemisphere malformation cortical development.

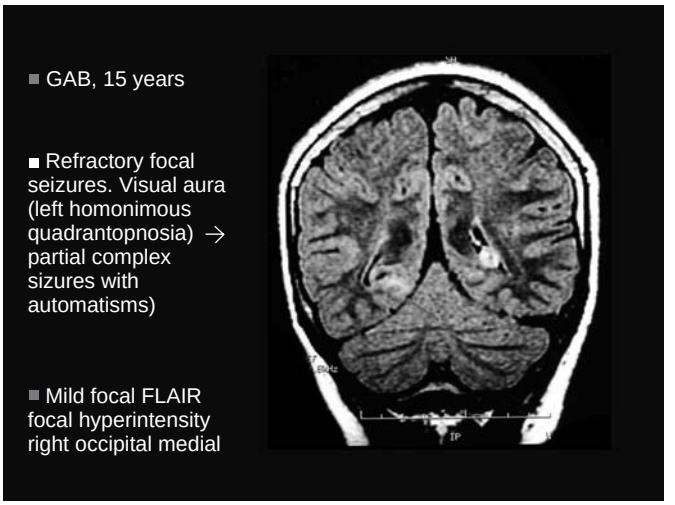

Figure 119.4 MRI coronal view shows occipital displasia.

A larger disorder would be a hemimegalencephalia, (Figure 119.7) with a dysmorphic hemisphere with pachygyria, heteroptopia, polymicrogyria and the loss of the union between white and gray matter. Other cases may present lysencephalia or agyria. These patients usually present multifocal crises and the best treatment is a functional hemispherectomy.

Hamartomas can be considered tumors, but in reality they are a developmental anomaly which results in the formation of small masses of diverse cell types, usually in the temporal lobe. They are treated by surgery.

A phacomatosis is made up of neurofibromatosis, tuberous sclerosis and Stuger-Weber syndrome. In the first two types, epilepsy is related with the cortical tumors that are characteristic of these processes, so that in some cases extirpating the processes would treat the epilepsy. However, in Sturge-Weber syndrome the malformation occupies almost the entire hemispheric cortex and the treatment would be a hemispherectomy.

Infectious lesions

Nowadays it is very difficult to encounter a seizure-producing tuberculoma. Medical treatment can dissolve the mass, but if the process continues to grow and clinically produce seizures or there is an expansive process, the appropriate treatment is surgical extirpation.

Intracranial cysticercosis is more frequent, and between 50 – 70% debut with epilepsy. When the epilepsy is not medically controllable, the indicated treatment is surgery. Rasmussen encephalitis is an encephalopathy of possible viral origin that was first described in 1958 by Rasmussen. (Figure 119.8)

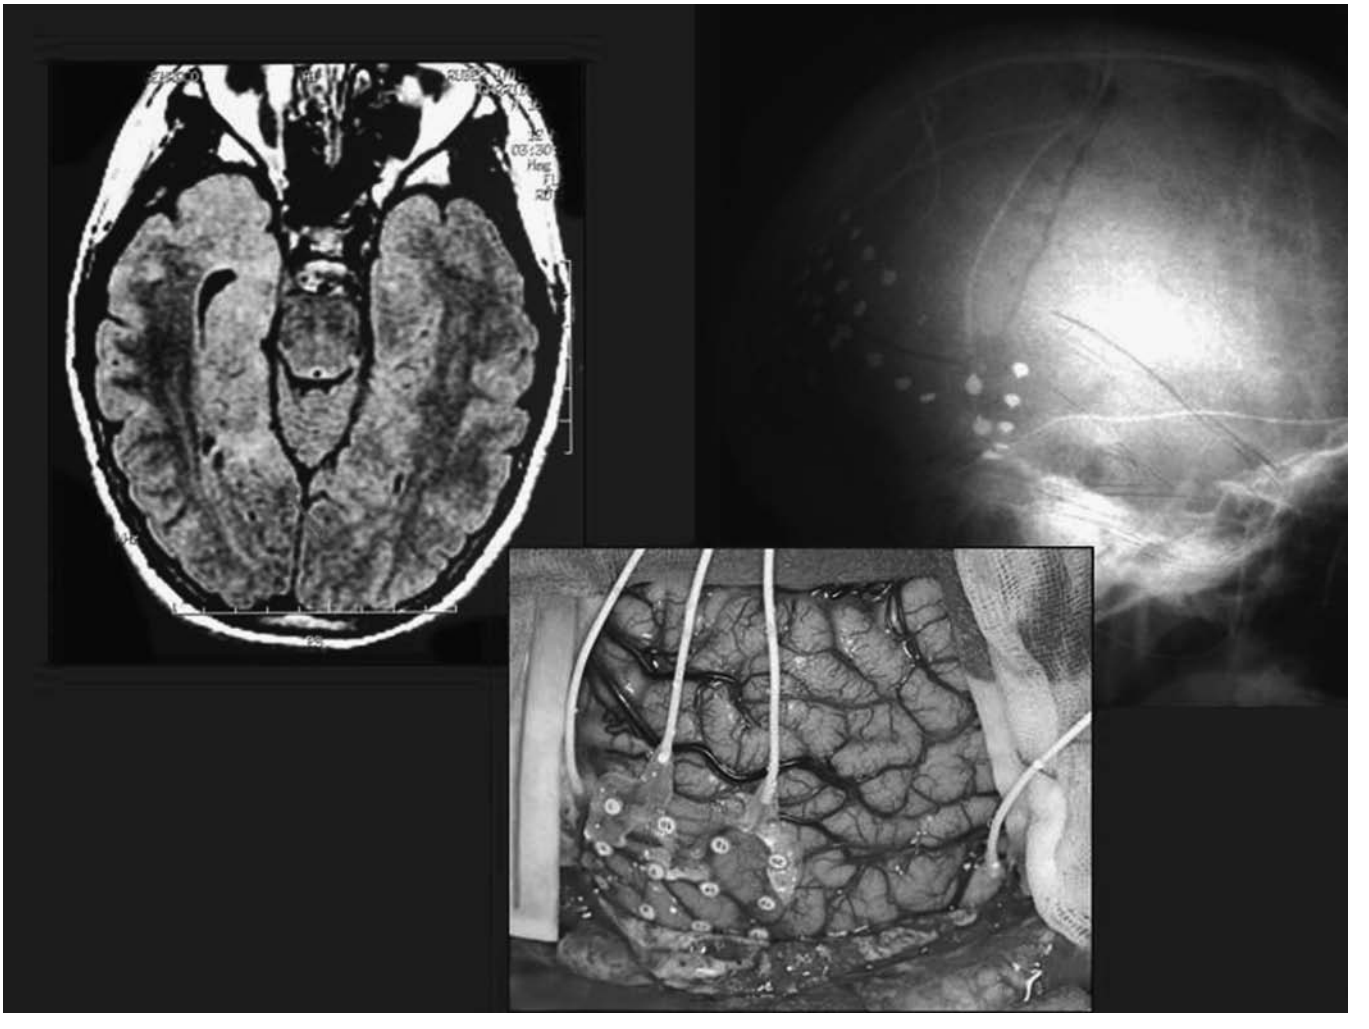

Figure 119.5 MRI sagital view, same case, craniotomy and subdural electrodes placement skull X-ray to see location of electrodes.

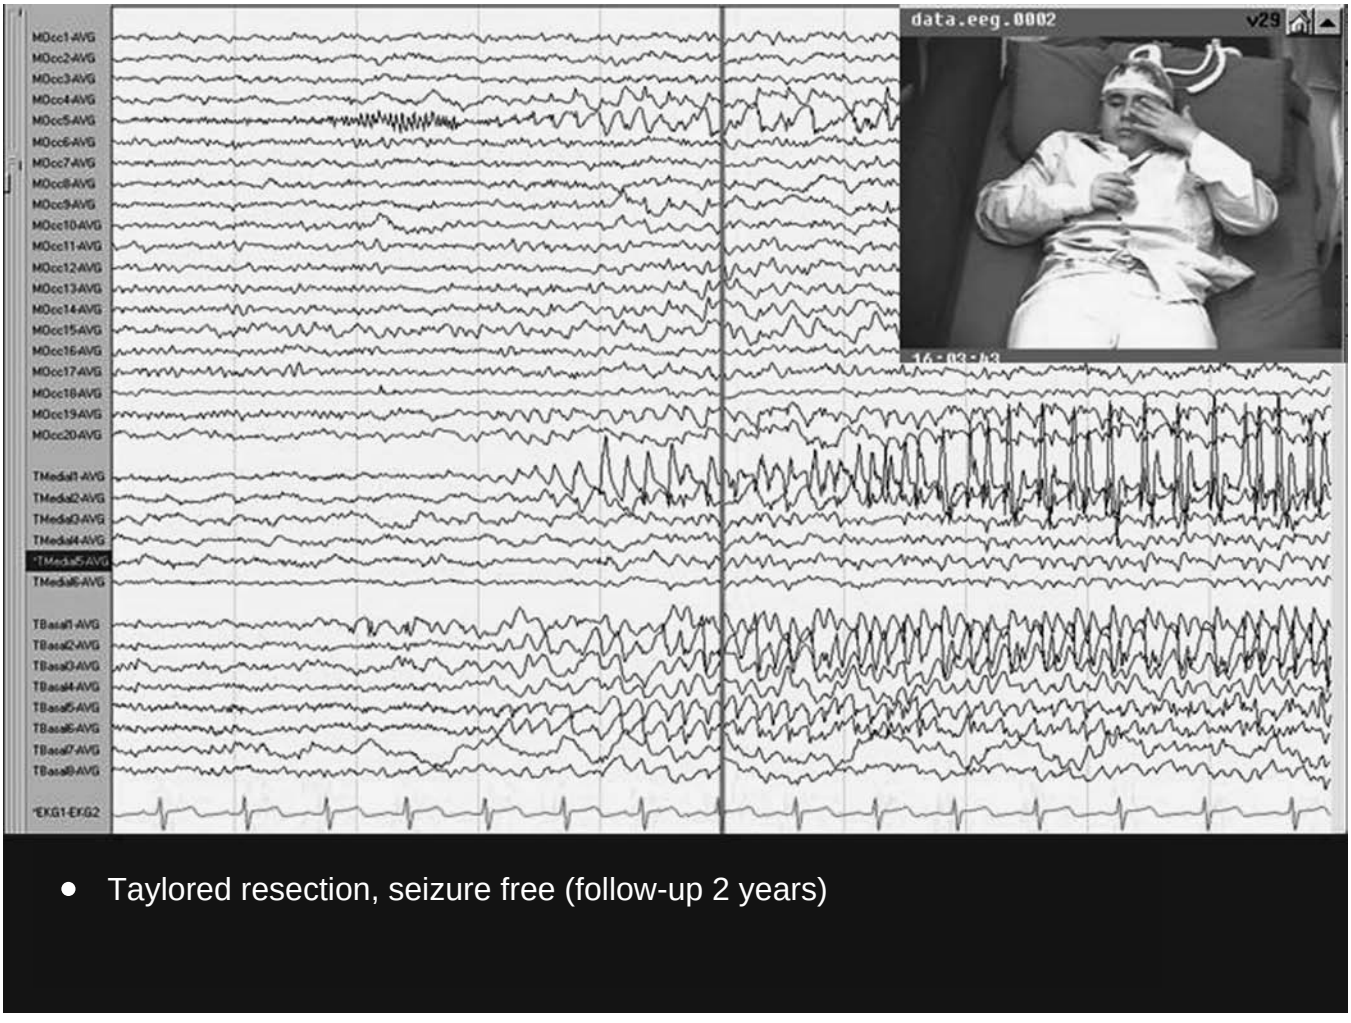

Figure 119.6 EEG after tailored resection.

It produces a syndrome of progressive unilateral motor deficit accompanied by focal seizures that can become generalized as well as progressive mental deterioration. Treatment consists in hemispherectomy.

Herpes simplex can also produce an encephalitis that usually mostly affects the temporal lobe and the indicated treatment is surgery if produce refractory epilepsy.

Hypoxic or ischemic lesions

Hypoxia or ischemia during pregnancy or birth can produce small or larger infarcts with later atrophias, gliosis and cyst formation. These can occasionally produce seizures and their treatment is the same as for a focal cortical dysplasia. (Figure 119.9)

Traumatic and post-traumatic lesions

Head injuries can induce seizures in the acute period, that is, shortly after the trauma, or in a more chronic manner, several months after the trauma. In the first early period the only surgical indication would be to treat any hematoma, if it existed. Later, if the patient had seizures it becomes necessary to investigate their origin. There may be small scars in the cortex at the level of the cerebral contusion or the site of the hematoma. Surgery is indicated in only a very few cases since most are pharmacologically controllable; the incidence is very low (4–7%).[25]

Surgical techniques in neocortical epilepsy in children

Frontal resection (Figure 119.10)

This can be divided into:

Total frontal lobectomy

The frontal lobe is resected in two steps during the same surgical approach from its pole until the precentral gyrus. We generally locate these structures under general anesthesia using evoked potential cerebral mapping. Once the postcentral area (primary of the brain) is located, we know that the central surcus is immediately in front of it and in front of that the motor area. The latter is the posterior limit of the resection. The first stage of the surgery is to do an en bloc resection of the three frontal gyrus (in the nondominant hemisphere), which would correspond to the convexity of the frontal lobe, and the second step is to resect the cingulum. Neither the posterior orbitofrontal cortex nor the subcallosum gyrus are resected.

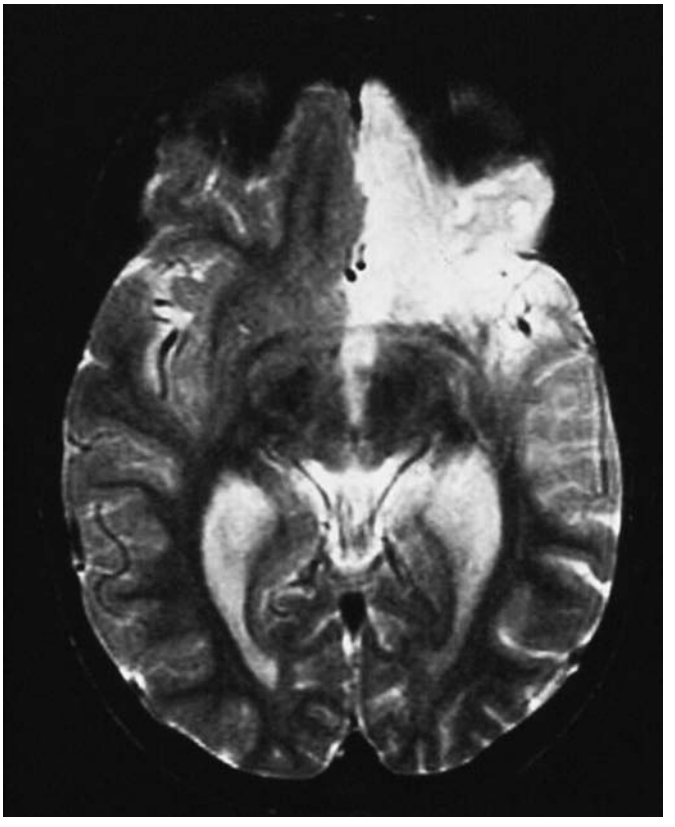

Figure 119.7 MRG axial view shows hemimegalencephaly.

Figure 119.8 MRI axial view of Rasmussen's encephalitis.

In the dominant hemisphere, one does a resection from the second frontal gyrus until the midline respecting the third gyrus. Olivier[26] believes that a resection of the dominant hemisphere has more of an anatomical than neurophysiological base. That is to say, the surgeon preferentially refers to the area limits determined in the angiography or MRI rather than to neurophysiological findings or cerebral mapping of eloquent areas. It is extremely important to respect the venous circulation in order to avoid aphasic sequelae. The avascular area between the cerebral media and the cerebral anterior corresponds to the second frontal circumvolution, the posterior limit to the resection in the dominant hemisphere. Veins that flow toward the superior longitudinal sinus must not be sacrificed unless you are certain that they can be replaced by veins that drain into the sylvian system.

Paramedian resections

One begins at the crista galli apophysis and continues towards the precentral gyrus and laterally toward the middle of the second circumvolution. The gyrus cinguly should preferentially be resected employing an ultrasound sucker and respecting the norms of subpial resection so as not to lesion the arteries and veins, which would lead to sequelae of edema and ischemia. It must be remembered that the vessels run in the depth of the pericallosum and marginal callosum sulcus. Vein coagulation will be done at the end of the procedure to avoid congestion and edema in the brain that would make ending the surgery difficult.

Frontopolar resection

This resection should go from the crista galli apophysis to the middle part of the frontal lobe. This the most frequent type of posttraumatic epilepsy.

Central area resections

Resections of the pre- and post central area can reach as far as 3 cm from the sylvian fissure. The seizures that can originate in them can be motor or sensitive and they can be surgically treated, even in the dominant hemisphere.[27] It must be remembered that the limit of the resection is obtained in an unconscious patient, placing stimulation electrodes on the tongue, thumb and lips and then registering the arrival of the stimulus at the cerebral cortex; that is to say the areas that, if damaged will produce dysarthrias, which, given their location would be equivalent to forms of aphasia, are mapped. In the central area it is more important than in any other area to respect the basic norms of surgery epilepsy: bipolar coagulation and low intensity ultrasound sucking to respect the arteries and veins in the area affected by subpial dissections.

Lateral convexity resection

This resection can include a small part of the frontal lobe in the convexity, depending on the location of the structural lesion.

Parietal resections

As in temporal lobe surgery, surgery of the frontal lobe undoubtedly requires the anatomic and neurophysiologic identification of the central area and basic to this is identifying the precentral gyrus. The inferior portion of the post central gyrus can be resected as far as 3 cm from the sylvian fissure.

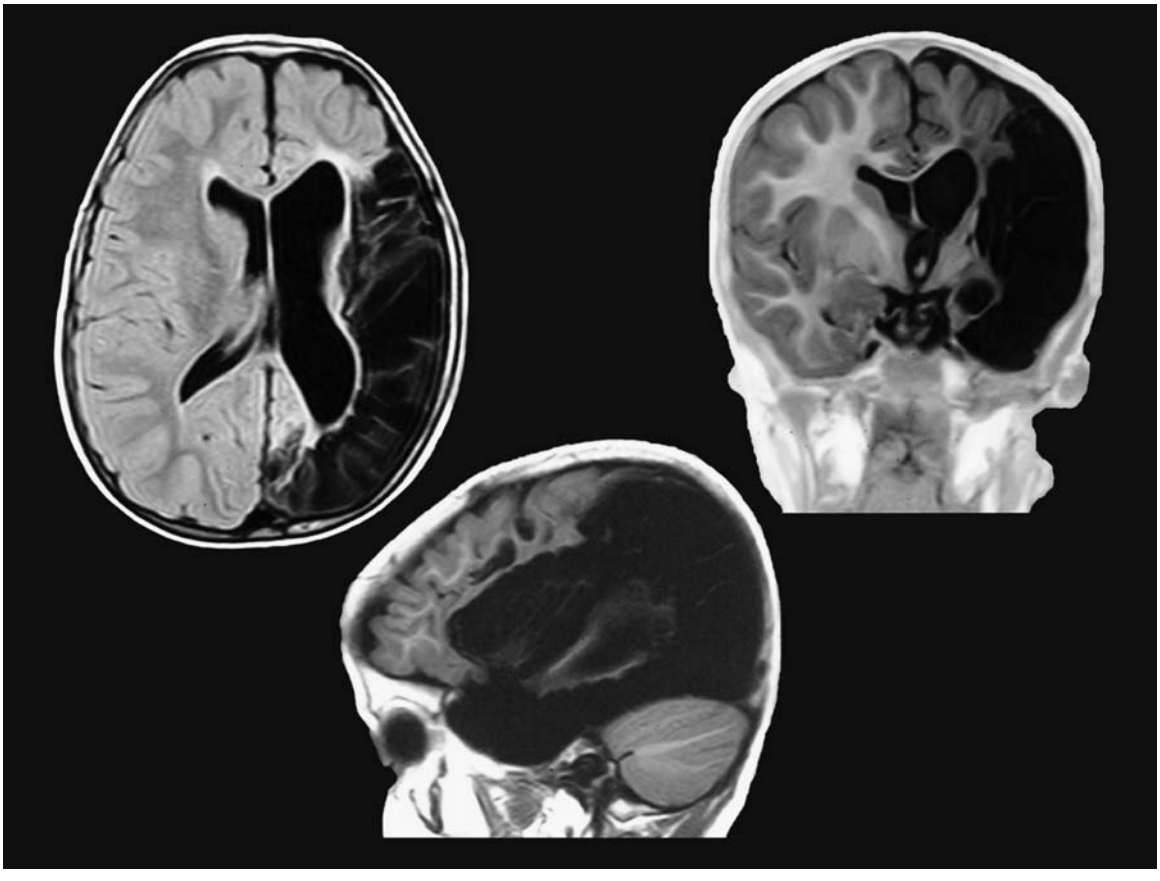

Figure 119.9 MRI axial view shows a large hemisphere infarct.

A larger resection could leave sequelae of a severe sensi-tive deficit. Campimetric alterations may also result. The superior limit of resection in the dominant hemisphere is the superior parietal lobe. The deep and inferior limits are the interparietal surcus and the anterior limit is the postcentral surcus.

Occipital resections

The symptoms produced by visual seizures–hallucinations, transitory loss, flash, shines, colors or unorganized geometric shapes–may evolve into a contralateral sensitivomotor seizure with head and eye turning. Obviously, with such vague symptoms, surgery can only be planned if there is a focus that is demonstrated by subdural electrodes and an electrocorticography. Occipital lobe seizures can spread to the temporal lobe or the central area.[28] Epilepsies that are generated by occipital foci can be treated with a deconnection or lobectomy of the temporal lobe, which will avoid the campimetric deficit that is produced by a complete resection of the occipital lobe.

Multilobar resections

These resections are performed when there are very wide and large destructive lesions that affect more than one lobe in the affected hemisphere and they consist in resecting small regions of several lobes in one hemisphere.

Lesionectomies

In 1993 Fried and Cascino[29] proposed four possible surgical strategies. The first was the lesionectomy or an extirpation of the lesion (Figures 119.11 and 119.12); the second, extirpation of the lesion with its margins; the third, extirpating the lesion and the secondary epileptogenic lesion that is usually elsewhere; and the fourth consisted in resecting the second-ary epileptogenic lesion without extirpating the primary lesion.

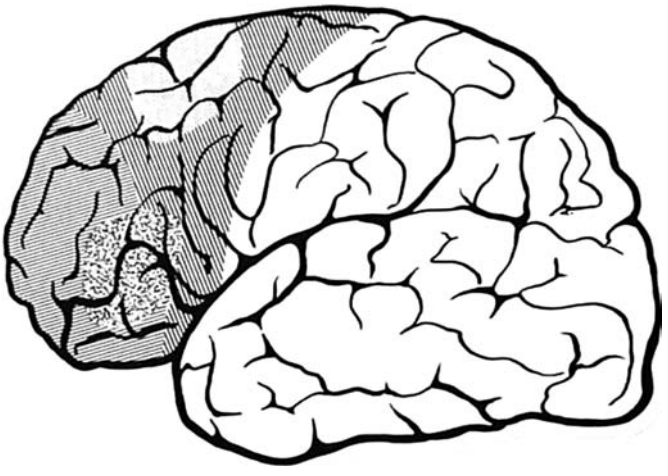

Figure 119.10 Types of frontal resections.

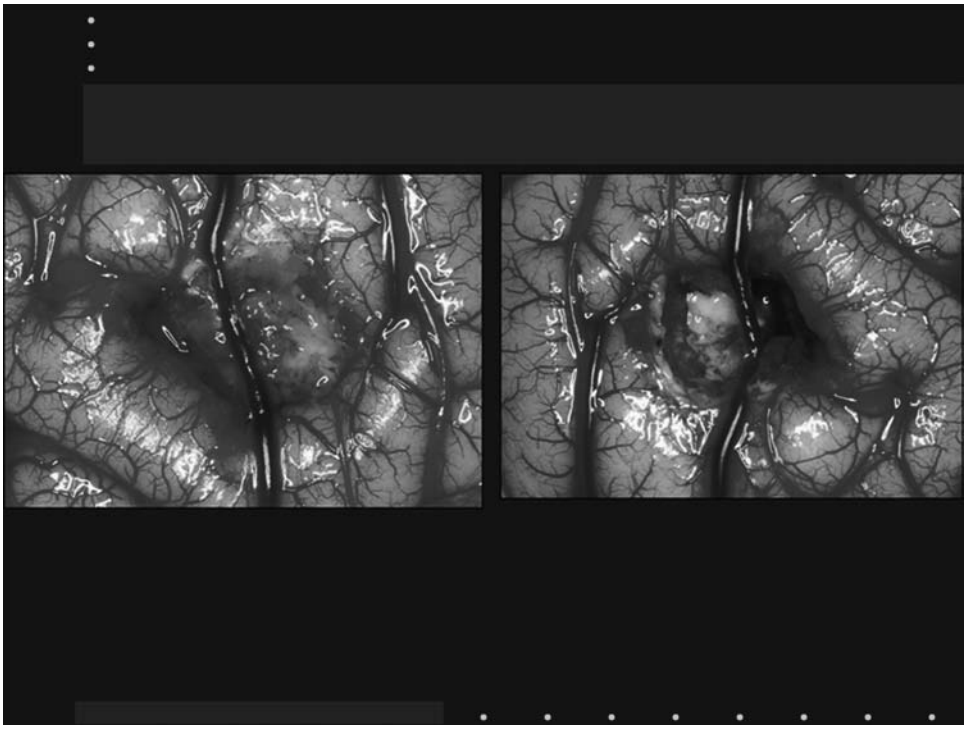

Figures 119.11 and 119.12 Lesionectimy of a parietal DNT.

The first strategy is quite clear and most authors agree, ourselves included. With the second strategy, when the images of the lesion produce clear alterations in the elecrocorticography, one can resect as much as 2 cm beyond the borders, but only in non eloquent areas. Awad[30] did not find a notable difference in the prognosis for the seizures if one included the lesion borders in the resection. With regard to the third strategy, the technique is quite controversial and the prognosis and indications have not been clearly defined.[31,32] Last, series employing the fourth strategy are too short to allow conclusions.

Conclusions

Epilepsy surgery began with extratemporal resections; however, it only became an accepted therapeutic possibility with the success obtained in temporal lobe epilepsy. Large series of prestigious centers report a percentage of cure or significant improvement of not less than 75%. Seven out of ten patients with temporal epilepsy, whether it is medial or neocortical, may be cured with surgery. Nevertheless, surgery for extratemporal epilepsy offers more uncertain results. The large extension of the brain, the existence of eloquent areas that increase the risk of neurological sequelae, the difficulty of precisely determining the primary epileptogenic area, even with invasive techniques like subdural or even intraparenchymatous electrodes, explain why the results for cures or improvement are no better than 50% in patients with extratemporal lobe epilepsy. More patients are improved than cured, differently from what can be achieved in temporal lobe epilepsy surgery.

In this context one must emphasize the great advantage for surgical treatment of extratemporal epilepsy brought about by the so-called 'imaging revolution', particularly the development in the middle of the 1980s of the MRI and also the PET and SPECT.

Today there is no doubt that detecting the origin, which is the orienting substrate of extratemporal epilepsies, has substantially improved the prognosis of their surgical treatment.

120 Hemispherectomy techniques

SJ Nagel, SK Elbabaa, EJ Hadar, and WE Bingaman

Introduction

Hemispherectomy offers selected patients with unilateral hemispheric epilepsy a surgical cure. Common etiologies include congenital neurodevelopmental disorders, ischemic/anoxic brain injury, Sturge-Weber disease, and Rasmussen's encephalitis. Clinical manifestations include intractable seizures and contralateral motor and visual field deficits, often with developmental delay. Early control of catastrophic epilepsy is desirable as seizures arising from the diseased hemisphere suppress and limit the neurodevelopmental potential of the undamaged brain.[1,2]

During the last 75 years, surgical approaches to hemispheric epilepsy have evolved to address concerns reported in some patients after anatomic hemispherectomy.[3,4] Perhaps as valuable in contributing to the care of these patients was the evolution of neuroimaging during the last two decades, coupled with improved microneurosurgical techniques. Prior to this, the physician relied on limited imaging data to recommend patients for operation. Currently, the spectrum of disease to which these techniques are applicable has expanded, and, conversely, the age of the patient at operation has decreased.[5–7]

History of hemispherectomy

The hemispherectomy operation has evolved over several decades. The surgical technique was first described by Walter Dandy in 1928. He reported on the use of hemispherectomy for the treatment of glioma in five patients involving the right hemisphere.[8] Hemishperectomy was first utilized for epilepsy surgery in Toronto by McKenzie in 1938 when he performed hemispherectomies on patients with infantile hemiplegia.[9] Krynauw popularized the procedure in 1951 after reporting hemispherectomy on 12 children with infantile hemiplegia resulting in good seizure control.[10] After Krynauw's report, the procedure became recognized as valuable and effective in controlling not only seizures, but also improving cognitive outcome. Robert White published multiple experimental animal studies on hemispherectomy between 1957 and 1962 detailing surgical techniques, physiologic consequences, and clinical implications of hemispherectomy on the monkey.[11–13]

Between 1952 and 1960, multiple minor modifications of the classic anatomic resection were introduced.[14–21] By 1961, HH White had collected 267 operated cases in many neurosurgical centers, with a mean postoperative follow-up of only 16 months. He concluded that hemispherectomy was safe and effective.[22]

The procedure continued to gain popularity until early signs of trouble were reported by Laine, *et al* in 1964 including three catastrophic late complications of unknown etiology in a series of 20 hemispherectomies.[17] Oppenheimer and Griffith in 1966 reported their observations made in three autopsies of patients who died many years after hemispherectomy for control of seizures associated with infantile hemiplegia.[23] All of the patients enjoyed a trouble-free period lasting many years after surgery before they died from gradual neurological decline. Their major autopsy findings included hemorrhagic subdural membranes extending into the ventricular system, hydrocephalus, obstructive granular ependymitis, and superficial cerebral hemosiderosis (SCH). Brett in 1969, Falconer and Wilson in 1970, and Rasmussen in 1973 reported a high incidence of SCH in anatomical hemispherectomy series ranging from 22 to 34% in patients followed longer than five years with a mortality reaching 33%.[24] After these reports, the popularity of the procedure declined and the procedure was effectively abandoned for several years until new hemispherectomy techniques emerged aiming at eliminating these late complications.

In 1970, Wilson performed the first modified anatomical hemispherectomy.[24] Functional hemispherectomy was first described by Rasmussen in 1974 as a subtotal anatomical resection with complete physiological hemispherectomy.[4] Rasmussen reported excellent results after functional hemispherectomy in the Montreal Neurological Hospital's series from 1937–1971. Other modifications included the Oxford modification by Adams in 1983 aimed at reduction of the subdural space by a dural plication technique after anatomic hemispherectomy and the shunted hemispherectomy modification by the UCLA group.[1,25]

Hemicorticectomy (or hemidecortication) was first described by Ignelzi and Bucy in 1968.[25] Hoffman at Toronto (1979) reported a good seizure outcome in infants with Sturge-Weber syndrome treated by hemicorticectomy but with preservation of basal ganglia.[26] Carson, at Johns Hopkins, reported a 96% seizure-free outcome after hemidecortication in 52 patients and emphasized the importance of anesthetic management and blood replacement during surgery.[27] In order to further improve on perioperative safety, functional hemispherectomy has been further modified to a less invasive method termed hemispherotomy. Delalande, in 1992, described hemispherotomy as a safe disconnective procedure aimed at disconnecting the epileptogenic hemisphere from the

subcortical centers via parasagittal hemispherotomy.[28] Villemure, in 1995, reported a seizure control rate reaching 80% via peri-insular hemispherotomy. He described the peri-insular approach as a radical hemispheric tractotomy, resulting in a completely disconnected hemisphere with advantages that include shorter operative times, a less stormy postoperative course, and better anatomic preservation of the operated hemisphere, thus presumably reducing long-term complications.[29–31]

Hemispheric deafferentation, another form of functional hemispherectomy, was first described by Schramm in 1995 as a less-invasive microsurgical procedure, followed by a 2001 report describing a transsylvian keyhole approach to further reduce the operative time and need for blood replacement.[32,33]

As described above, the hemispherectomy procedure has followed an interesting evolution over several decades. The early reports of SCH lead to the loss of confidence in the anatomic procedure. Hemispherectomy regained its popularity after technique modifications lead to similar seizure control rates, but with decreased complication rates. The most recent modifications concentrated on making the procedure less-invasive but with equally good seizure control and low complication rates.

Patient selection and evaluation

Selecting a patient for hemispherectomy requires multidisciplinary evaluation. The onset of seizures should localize to one hemisphere on electroencephalography (EEG). Seizure semiology should be concordant with the EEG findings. Magnetic resonance imaging (MRI) and positron emission tomography (PET) should confirm structural and functional abnormalities in the diseased hemisphere and the relative integrity of the other hemisphere. Ideally, the patient should have a preexisting hemiparesis and hemianopsia opposite the diseased hemisphere.

Infantile hemiplegia with seizures secondary to perinatal stroke was the first epilepsy associated disease to be treated with hemispherectomy.[10] This diagnosis was the most common cause of seizures in patients treated by hemispherectomy for several decades. A contemporary series of 115 patients operated on between 1986 and 2002 at UCLA reflects the current etiology of seizures in patients treated with hemispherectomy (Table 120.1).[5,6] In a comparable study of 111 patients who underwent hemispherectomy between 1975 and 2002, Rasmussen's syndrome was the most common etiology reflecting institutional referral patterns. (Table 120.2).[7] Cortical dysplasia when hemimegalencephaly is included is likely the most common etiology however. Refractory status epilepticus has also been successfully controlled with hemispherectomy.[34]

History and physical exam

A detailed medical history which includes the perinatal period and family history and a thorough physical exam is an essential component of the preoperative evaluation. Specifically, the patient and/or family should be queried on seizure onset, any inciting event, and changes in type, frequency or location of seizures. A medication history should reflect seizures refractory to dosage adjustments and prescription changes.

Table 120.1 Etiology of seizures in a 115 patients treated with hemispherectomy at UCLA between 1986–2001[5,6]

Assessing motor and sensory deficit in infants and young children can be difficult.[35] Most patients will be hemiparetic or hemiplegic; contralateral muscle atrophy is often present. In the first year of life, motor findings can be subtle. Children with only a mild hemiparesis often have diminished motor function following surgery and are usually left with a 'helper hand'.[36] Hemianopsia is always present post-operatively. A formal ophthalmology exam can sometimes verify a visual field defect preoperatively depending on the age of the patient. Absent or partial hemianopsia preoperatively should not deter the patient and/or surgeon from proceeding. After surgery, the hemianopsia may preclude driving if the patient is seizure free. It is important to ascertain parental and patient expectations and offer realistic goals prior to surgery.

Neuroimaging: functional and structural

Magnetic resonance imaging (MRI) is the structural imaging technique of choice for all candidates and should include T1- and T2-weighted, proton density, and fluid attenuated inversion recovery (FLAIR) sequences. High-resolution volumetric acquisition with very thin (1.5 mm) contiguous slices and 3-dimensional reconstructions detect more subtle abnormalities than conventional spin-echo imaging.[37,38] Contrasted studies are valuable in select cases such as Sturge-Weber.[39] The role of MRI is to establish a diagnosis, evaluate the normal

Table 120.2 Etiology for seizures in 111 patients treated with hemispherectomy at Johns Hopkins between 1975–2002[7]

hemisphere, and aid in surgical technique selection. When evaluating the MRI, the surgeon should identify areas of deep dysplasia and pay careful attention to ventricular size, which may influence surgical technique. An atrophied or hypertrophied cortical mantle may influence the decision to proceed with an anatomic or functional hemispherectomy. Abnormalities within the contralateral hemisphere should be investigated as an active or potential source for epileptic activity.

Functional imaging using single photon emission computed tomography (SPECT) or [18F]fluoro-2-deoxyglucose([18F]FDG) PET can be used to verify hemispheric pathology and confirm lateralization of seizures. Patients with hemispheric epilepsy typically show widespread decreased glucose consumption with [18F]FDG PET in the epileptogenic hemisphere and normal glucose metabolism on the opposite side.[35,40]

Electroencephalography and adjunctive tests

All candidates for hemispherectomy should undergo inpatient continuous video EEG monitoring of ictal and interictal activity to document epilepsy and identify the region of ictal onset. Lateralization of diffuse hemispheric discharges confirms the site of pathology and is of prognostic value.[39] This is especially true when imaging, clinical findings, and EEG are concordant.

Wada test (intracarotid sodium amytal) is indicated to assess language and memory localization in older patients when the transfer of these processes to the contralateral hemisphere remains uncertain. All age appropriate patients should be tested on verbal and nonverbal communication and undergo neuropsychological testing pre and postoperatively.

Surgical techniques

In theory and in practice there are only three ways to surgically eradicate a diffuse unilateral hemispheric seizure focus, inhibit impulse transmission to the contralateral hemisphere, and impede its materialization in the body through the brainstem:

1. Resect the hemisphere in its entirety
2. Disrupt the fiber tracts projecting from the cortex

or *anatomic hemispherectomy*, *functional hemispherectomy* and *hemidecortication respectively* (Table 120.3).

Table 120.3 Operative techniques used in the treatment of unilateral hemispheric seizures

III. Hemicorticectomy (hemidecortication) Ultrasound-tailored functional hemispherectomy

General concepts

The surgeon's recognition of the anatomic relationships within the hemisphere is of paramount importance and cannot be overestimated. This ensures not only the success of the operation but also the patient's safety. Very often, the disease process has distorted the hemisphere challenging even the experienced surgeon. It is instructive to begin the dissection of the cerebral hemisphere with a survey of the surface landmarks which delimit the operation and project over the deeper structures. Retraction or resection of the fronto-parietal operculum exposes the insular cortex and the C-shaped cortical association fibers of the superior and inferior longitudinal fasciculus. (SLF/ILF) The SLF is divided until reaching the projections of the internal capsule which form the corona radiata. This white matter is opened to expose the lateral ventricle. The pericallosal artery travels in the pericallosal cistern superior to the ventricle. The course of the pericallosal artery is useful to direct the surgeon with callosotomy from genu to splenium (Figure 120.1).

To disconnect the mesial temporo-parietal structures, the fornix is divided just anterior to the splenium and the mesial gyri enveloped by the temporal lobe are resected through the temporal horn. The frontal horizontal fibers, which include the uncinate and occipitofrontal fasciculus are cut anterior to the frontal horn, following the course of the anterior cerebral artery in the mesial frontal pia back to its junction with the internal cerebral artery (Table 120.4).

Preoperative care

Dexamethasone and antibiotics are administered before induction. Antiepileptic medications are taken the morning of surgery and continued postoperatively in conjunction with an epileptologist. An anesthesiologist dedicated to pediatric neuroanesthesia should be routinely used in such patients. The surgical site is confirmed, an arterial line and bladder catheter placed, and central venous access is obtained.

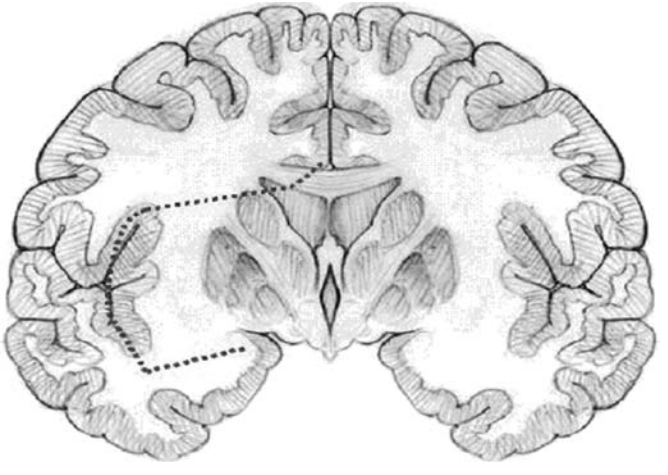

Figure 120.1 Schematic representation of an anatomic hemispherectomy including callosotomy, resection of the mesial temporal structures and sparing of insula and basal ganglia.

Table 120.4 Intra and inter hemispheric connections sacrificed during functional hemispherectomy and hemispherotomy[56]

Callosal fibers	
Rostrum and genu	Frontal lobes
Truncus (rostral)	Premotor and supplementary
Truncus (middle)	Prencentral
Fasciculi	
Superior longitudinal fasciculus	Connects the frontal, parietal, occipital and temporal lobes
Anterior limb	Connects speech areas (Wernicke, Broca) with Area 8 (frontal eye fields)
Posterior limb	Connects Areas 18 (secondary visual area) and 19 (tertiary visual area) and middle temporal Area with Area 8 (frontal eye fields)
Uncinate fasciculus	Connects temporal pole and amygdale with orbitofrontal cortex
Occipito-frontal fasciculus:	Projections from Area 22 (rostral auditory association cortex), Area 20,21 (visual fields below the superior temporal sulcus) and sulcal cortex of the prefrontal cortex.

All patients are typed and crossed for expected blood and plasma transfusions.

Anatomic hemispherectomy

In recent years, there has been renewed interest in this operation; seizure control is excellent and the safety profile has improved. It is the surgery of choice at our institution for hemimegalencephaly, select cortical malformations, and reoperation after failed functional hemispherectomy.[35]

The patient is positioned supine on the operative table with an ipsilateral shoulder role. The head is turned 30∞ to the side and positioned with the vertex slightly down to allow adequate visualization of the mesial temporal structures. A 'T' incision is marked to allow access to the entire hemisphere (sagittal sinus to floor of middle fossa). The operative field is prepped and draped widely. Local anesthetic is injected along the planned incision which is opened with the scalpel. Every effort should be made to optimize hemostasis. The scalp flaps are mobilized to expose the temporalis muscle. This is reflected to expose the zygomatic root and the anatomic keyhole for placement of burr holes. The craniotomy is performed to allow exposure from the floor of the middle fossa to the parasagittal cortex just off the midline. The length of the sylvian fissure is exposed. The bone flap is carefully elevated and dura tacked up to the skull. The dura is opened in H-fashion and reflected back on the sagittal sinus (Figure 120.2).

The sylvian fissure is opened using microdissection and the middle cerebral artery exposed. It is subsequently ligated distal to the lenticulostriates but proximal to its bifurcation. The insula and surrounding superior and inferior circular sulci are identified. Once the sylvian fissure is widely opened and the MCA ligated, the infrasylvian portion proceeds with removal of the temporal lobe in stepwise fashion. First the lateral temporal lobe is removed by a posterior line of resection at the level of the posterior sylvian fissure. This line of dissection involves coagulation and division over the lateral and basal temporal lobe mesially to the collateral sulcus. From here the collateral sulcus is followed up to the temporal white matter and the temporal horn is entered. From the inferior circular sulcus, the white matter of the temporal horn is aspirated to open the temporal horn along its entire length. The lateral ventricular sulcus is identified and opened, following it down through the fusiform gyrus to the pia along the tentorium. This is coagulated and divided and the lateral temporal lobe including the temporal pole is removed, leaving behind the amygdala, hippocampus, and parahippocampal gyrus.

Figure 120.2 Intraoperative photograph illustrating the cerebral hemisphere in a patient with hemimegalencephaly prior to anatomic resection.

The suprasylvian stage begins with exposure of the superior circular sulcus and division of the MCA branches supplying the fronto-parietal cortex. The superior circular sulcus is used as a template to divide the corona radiata and facilitate the opening of the length of the lateral ventricle. The foramen of Monroe is exposed and plugged with a cotton ball to limit blood and cellular debris from accumulating in the contralateral ventricle. From within the lateral ventricle, a complete callosotomy is performed. The ventricular roof is incised at its junction with the septum pellucidum. This exposes the pericallosal cistern and traversing arteries. A parasagittal sectioning of the callosum ensues from the rostrum to the splenium disrupting the mesial fronto-parietal commissural fibers and ipsilateral cingulate gyrus. The dissection is carried posteriorly along the falx with removal of the ipsilateral cingulate gyrus until the previously exposed tentorium is brought into view below the sylvian fissure. The fornix is subsequently divided at the hippocampal tail adjacent to the atrium and just anterior to the splenium. Care should be taken to insure that the splenium is completely disrupted. The posterior branches of the MCA irrigating the parietal and occipital cortex are divided so that the entire lateral ventricle is opened.

Finally the pia along the edge of the falx is coagulated and divided following the falx and tentorium mesially and inferiorly towards the mesial temporal lobe. The cingulate gyrus transitions to the parahippocampal gyrus and these structures are removed as the pia is dissected along the edge of the tentorium. During this phase, the posterior cerebral artery will be encountered and divided as it crosses the tentorium on its way to the occipital lobe.

Anteriorly, at the level of the genu, the mesial frontal lobe is slowly aspirated and branches of the ACA ligated as they are encountered. The pia along the edge of the falx is coagulated and divided down to the anterior aspect of the anterior cranial fossa. Here, the olfactory nerve is encountered. Care should be taken to skeletonize it as the ipsilateral gyrus rectus is aspirated and the contralateral mesial frontal lobe is visualized. Both pericallosal arteries and anterior cerebral arteries should be identified and protected to avoid inadvertent injury to the arterial supply to the other hemisphere. Dissection along the mesiobasal frontal lobe should continue back to the level of the internal carotid artery and optic nerve. Ultrasonic dissection is useful for the subpial dissection required at this stage.

Prior to removing the hemisphere, the large draining veins to the sagittal sinus and transverse sinus must be coagulated and divided. Once this is accomplished, the hemisphere is removed en bloc and sent to pathology. The remaining tissue to be removed includes the amygdala, hippocampus, insular cortex, and perhaps some residual parahippocampal tissue. This is done by identification of several anatomic landmarks including the choriodal point, M1 trunk of the MCA, choroid plexus, lateral geniculate body, and edge of the tentorium. The bulk of the amygdala is resected below a line connecting the M1 trunk and the choroidal point. Care is taken to stop below this line to avoid injury to the basal ganglia. The hippocampus is resected by cutting the tail at the trigone and aspirating the fornix just below the choroid plexus to expose the hippocampal sulcus. The hippocampal sulcus is coagulated, divided and the hippocampus is removed by subpial aspiration being careful to avoid injuring the mesial pia overlying the brainstem and the perimesencephalic structures (posterior cerebral artery, basal vein of Rosenthal, oculomotor nerve, posterior communicating artery, and anterior choroidal artery). Finally, any residual parahippocampal gyrus is subpially aspirated including the uncus back to the level of the trigone where the dissection from above will be encountered. The insular cortex may be aspirated when indicated (Figure 120.3) by careful aspiration of the long and short gyri underneath the pia of the sylvian fissure.

The cavity is irrigated and bleeding controlled (Figure 120.4). A ventricular catheter is placed in the cavity and tunneled out through the skin. The dura is sutured closed and the bone flap secured with a microplating system or sutures depending on the patients age. The muscle fascia is closed and the incision sewn in two layers after insertion of a subgaleal drain.

Figure 120.3 Intraoperative photograph demonstrates the resection cavity.

Figure 120.4 En bloc specimen of the left cerebral hemisphere after anatomic hemispherectomy.

Oxford modification

Adams devised a modification of the standard anatomic hemispherectomy to prevent SCH. This method was first attempted by Gibbs and Wilson in 1968.[24] By plicating the excess dura to the exposed falx, tent, and floor of the empty hemispheric cavity, he shrunk the subdural space and expanded the extradural cavity isolating it from the ventricles. Adams also occluded the ipsilateral foramen of Monroe with a muscle plug to prevent the contents of the subdural space from spilling over into the third ventricle.[3] Other attempts to curb the late complications of anatomic hemispherectomy included duraplasty and implantation of space-occupying material such as omentum, silicone prosthesis and Zenoderm graft on-lay.[31,41–43] Although of historic note, this modification is no longer in use today.

Functional hemispherectomy

Although Oppenheimer and Griffith proposed disconnecting the abnormal hemisphere, it was not until Rasmussen that the concept and practice of functional hemispherectomy ushered in the modern era of surgical treatment for hemispheric epilepsy.[23] This operation consists of a temporal lobectomy, central resection, corpus callosotomy and disconnection of the mesial parietal-occipital and frontal lobes, which are left in situ.

After satisfactory general endotracheal anesthesia, the patient is positioned supine with the head turned to the appropriate side and rigidly fixed with the vertex angled slightly down. The hemicalvarium is shaved and a pterional reverse question-mark incision 1 cm anterior to the tragus reaching medial to the superior temporal line is marked out. The temporalis muscle is elevated to gain wide exposure to the cranial floor. A fronto-parietal-temporal bone flap is turned to expose the sylvian fissure (Figure 120.5). The infrasylvian phase is then performed as in the anatomic operation. This includes a large temporo-parietal resection to the posterior exstent of the sylvian fissure with resection of the mesial structures.

The suprasylvian phase is designed to preserve the anterior frontal lobe and the posterior parietal and occipital lobes. Care must be taken to preserve the arterial and venous supply to these areas (anterior frontal and parieto-occipital MCA branches, PCA, and ACA supply).

A central segment of the hemisphere (fronto-parietal operculum) is resected beginning at the superior margin of the sylvian fissure through the frontal operculum and extending anteriorly to the rostrum of the corpus callosum and posteriorly to the splenium. This window typically includes the inferior and middle frontal gyri as well as a portion of the inferior parietal lobe. The dissection is directed medially and superiorly to the superior circular sulcus of the insula and then continues through the corona radiata toward the ventricle. Branches of the MCA supplying the resected tissue are ligated and divided however care must be taken to spare the large posterior parietal branches and some of the anterior frontal branches to avoid postoperative infarction of the cortex left disconnected but in situ. The lateral ventricle is accessed and this block of tissue removed. The entire ventricular system is opened by aspirating the corona radiata to connect the frontal, temporal and occipital horns.

The corpus callosum is disconnected via the ultrasonic aspirator from the genu to the splenium, as is the adjacent ipsilateral cingulate gyrus. Again, it must be emphasized to carefully look for residual splenium or genu that could lead to postoperative seizure recurrence. The white matter projections to and from the anterior frontal lobe are then disrupted to the pia medially through the frontal horn and caudate nucleus. Posteriorly, the mesial parietal-occipital fiber tracts are sectioned in a similar fashion. The remaining brain is irrigated and hemostasis achieved (Figure 120.6). A ventricular catheter is placed in the cavity. The dura closed and the bone

Figure 120.5 Intraoperative photograph taken after removal of bone flap and opening of the dura in a patient with a history of perinatal stroke and epilepsy.

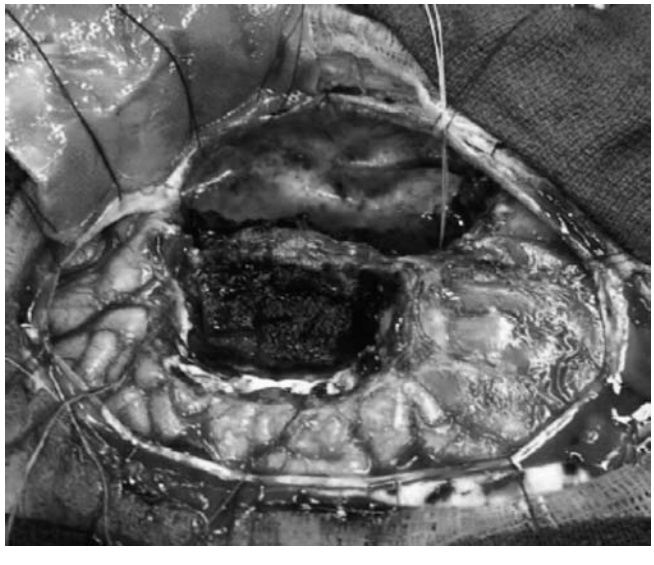

Figure 120.6 Intrapoperative photograph illustrating the preservation of the anterior frontal lobe and posterior parietal-occipitial lobes following resection of the frontal-parietal operculum.

flap secured with a microplating system. A second drain is inserted in the subgaleal space. The muscle fascia is reapproximated and the skin sutured in 2 layers. These steps constitute the functionally complete but anatomically subtotal hemispherectomy. (In his original lecture, Rasmussen stressed preservation of the posterior third of the hemisphere in patients without a homonymous hemianopsia.[4]

Peri-insular hemispherotomy

Hemispherotomy as defined by Villemure is the 'surgical procedure that requires the smallest brain volume removal to accomplish a complete hemispheric disconnection.'[29] Based on this definition, the following surgical goals were advanced: division of the internal capsule, transventricular callosotomy through a suprasylvian window, transection of the frontal horizontal fibers, and resection of mesial temporal lobe structures through an infrasylvian window. This technique, described in 1995, takes maximum advantage of the orientation of the cortical projections on the approach to the corpus callosum.[29] Perinsular hemispherotomy has the theoretical benefits of reduced operative time, minimal blood loss, and fewer postoperative complications with equivalent seizure control when performed correctly. The landmarks are better appreciated in patients with enlarged lateral ventricles, although peri-insular hemispherotomy has been successfully performed in patients without ventriculomegaly.[44]

Hemispheric deafferentation

In the same year that Villemure and Mascott published their description of the peri-insular hemispherotomy, Schramm *et al* published the technique 'hemispheric deafferentation'.[32] These techniques are almost identical in principal but vary in sequence of disconnection. In the hemispheric deafferentation, a standard temporal lobectomy is performed first to gain access to the temporal horn. From within the temporal horn, the ventricle is followed to guide entrance into the lateral ventricle. There were three modifications included in the original report. Modification 1 included selective temporal lobe resection of the first 4 cm of superior temporal gyrus along with amygdalohippocampectomy. Modification 2 describes what is essentially the creation of a perisylvian window as used by Villemure. In modification 3, the keyhole hemispherectomy, outlined below, is discussed.

Keyhole hemispherectomy

Schramm *et al*. refined the hemispherotomy technique with the advent of the transylvian keyhole, functional hemispherectomy or transylvian, transulcal technique.[33] This method goes further to limit the craniotomy to an area directly over the sylvian fissure. Favorable anatomy for this approach include; hemispheric atrophy, enlarged ventricles, porencephalic cysts and an atrophic basal ganglia and insula.[45]

Transopercular hemispherotomy

In 2000, Schimizu and Maehara published their modification of the original hemispherotomy technique, the 'transopercular hemispherotomy'. In this technique, the mesial temporal structures are approached from the medial aspect of the insula. This maneuver facilitates insular fiber resection during access to the hippocampus and amygdala and obviates the need for insular cortex aspiration. The balance of the operation proceeds similarly to the standard hemispherotomy.[46]

Vertical hemispherotomy

The vertical hemispherectomy originally described by Delalande in 1992 is a unique disconnective operation.[28] Nearly the entire operation is carried out in the white matter and dissection is subpial. In 2000, Danielpour *et al*. further described this alternative, minimally invasive, disconnective operation. In comparison to the small hemicorticectomy used to access the ventricular roof by Delalande, their method involves no cortical resection. The surgery is summarized below.[47]

A midline bone flap is turned to encompass the length of the corpus callosum. The dura is incised and the hemisphere retracted laterally. The ventricle is unroofed by dividing the callosum to reveal the entire lateral ventricle. Dissection is carried down to the temporal horn in an inferior-lateral fashion. This serves two purposes: 1) disconnection of afferent and efferent fibers from the internal capsule; 2) establishes a corridor for the resection of the amygdala and anterior hippocampus. Finally, 3) to finish the hippocampectomy, the posterior pillar of the fornix is sectioned.

Hemidecortication (hemicorticectomy)

Hemidecortication, first brought to attention by Ignelzi and Bucy in the treatment of infantile cerebral hemiatrophy in 1968, has maintained a foothold in the therapeutic strategies for diffuse hemispheric epilepsies since its inception. It was popularized in the 1970s when it was instituted by Winston and Hoffman independently.[48] The Johns Hopkins experience includes the largest modern, published series of hemidecortications (n = 111).[7] The operation is best understood as a 'degloving' of the cortex from the supporting white matter. Its theoretical advantage is to minimize entry into the ventricle. However, the operation cannot be accomplished without entering the temporal horn which still exposes the ventricular system to blood and cellular debris. Other drawbacks of this technique include the obliteration of ipsilateral arachnoid granulations which would normally resorb CSF as well as the challenges associated with detecting dysplastic foci buried in the white matter. Blood loss, hydrocephalus, and incomplete disconnection may be more common.[45] The use of ultrasound guidance to characterize the shape of the ventricles and relative location beneath the cortex has been described by Kanev *et al*.[49]

Postoperative care

After functional or anatomic hemispherectomy, patients are usually extubated in the operating room. They are transferred to the intensive care unit with frequent lab assessment, serial neurological exams, and monitoring of fluid status. Careful transfer of the patient and orientation of the patient with remaining hemisphere down may be of value in preventing brainstem hemorrhage.[36] Coagulopathy during the first 48 hours is common and prompt correction with blood products is essential. The external ventricular catheter removes CSF contaminated with blood and surgical debris for 48 to 72 hours. The subgaleal drain is discontinued in 1–3 days.

Antibiotics are continued until the ventricular catheter is pulled. A 1-week course of steroids is usually prescribed. Fevers, often secondary to aseptic meningitis occur frequently and are tolerated for up to one week following surgery before consideration of an infectious cause. A baseline MRI is obtained the morning after surgery. Diet is advanced, fluids weaned, and physical and occupational therapy resumed expectantly.

Technique selection

Recent modifications have focused on minimizing the amount of tissue removed in favor of cortical disconnection. The proposed benefits of the newer approaches are a smaller craniotomy, reduced operative time and blood loss, decreased risk of infection, and prevention of hydrocephalus. In a recent retrospective review comparing hemidecortication to peri-insular hemispherotomy, a reduction in blood loss, transfusion, fever, intraoperative hypotension, recovery time, and hydrocephalus necessitating shunting was observed in patients treated with peri-insular hemispherectomy.[44] However, many of these adverse events depend on the surgical skill, and comfort level of the surgeon with a given operation. Furthermore, functional hemispherectomy and hemispherotomy have a steep learning curve and may be suboptimal surgical approaches for selected hemispheric pathologies. This contributes to the higher reoperation rate observed with functional hemispherectomies.[6]

Cook *et al*. retrospectively reviewed the UCLA case series of 115 patients treated with either anatomic hemispherectomy, functional hemispherectomy, or a modified lateral hemispherotomy.[6] None of the patients required reoperation for seizure control in the anatomic hemispherectomy cohort. A total of 12 patients underwent reoperation for seizure control when using the other techniques (functional hemispherectomy = 8; modified lateral hemispherotomy = 4).[6] The improved rates of seizure control in some recent reports using newer techniques may reflect improved patient selection.

Reoperation

Seizures may persist or recur even with thorough preoperative planning and perfect execution. Postoperative ictal and interictal epileptic discharges arising from both hemispheres are not uncommon and should be carefully analyzed. For example, of 51 patients available for follow-up after vertical hemispherectomy, 80% were seizure free. Nine of the remaining 10 had a 90% reduction in seizure frequency. In each of these cases, epileptic discharges where recorded in the nonoperated hemisphere.[30]

When seizure control is unsatisfactory, surgical failure may also be the culprit. Reoperation may be indicated to complete the disconnection of white matter tracts which have only been partially divided as demonstrated on postoperative imaging. Unfortunately, postoperative MRI and EEG can be difficult to interpret and re-operation with anatomic removal of the hemisphere is sometimes carried out as a compassionate treatment to reduce seizure burden. In other cases, residual tissue will be identified on postoperative imaging and re-operation is indicated. In our experience, problematic areas to be carefully analyzed on MRI include the corpus callosal disconnection, the insula, and the posterior mesiobasal frontal lobe. These are all potential sources of residual epileptic tissue, especially in cases of hemimegalencephaly.

Following the Shimizu perinsular hemispherotomy, reoperation was warranted in 3 out of 34 patients. In each patient, the corpus callosum was incompletely sectioned.[46] Residual epileptic cortex has also been identified after hemidecortication and should be resected when appropriate.[44]

Technique selection: Rasmussen's encephalitis

The symptoms of Rasmussen's encephalitis often consist of epilepsia partialis continua, progressive hemiparesis, and eventual mental deterioration. Increased signal on MRI often heralds the onset of hemispheric atrophy later. When to proceed with surgery is controversial. Peacock has advocated delaying surgery until digital dexterity in the hemiparetic arm is restricted, however, early intervention may limit the cognitive impairment of the disease despite worsening the hemiparesis.[1] This may facilitate the early transfer of function and reduce the overall burden of this disease.[36] Complete disconnection of the affected hemisphere including insular removal is the surgical goal and can generally be accomplished by the functional techniques.

Technique selection: hemimegalencephaly

Hemimegalencephaly is a functionally incapacitating neuronal migrational disorder of unknown etiology. Infants with this malformation demonstrate psychomotor delay, encephalopathy, and refractory seizures. There is overt hemispheric asymmetry and the cortex is diffusely hypertrophic often with enlargement of the ipsilateral ventricle. Gross specimens may show hyperplastic frontal and occipital lobes surrounding a hypoplastic temporal lobe with lissencephalic cortex.[50] Subcortical heterotopia and calcification are usually seen. The microscopic findings reveal the complete absence of normal cortical cytoarchitecture.[39] Hemispherectomy is routinely offered to patients with this condition based on the devastating epilepsy and improved outcomes achieved with surgery in the past.[51,52] Contralateral, independent seizure spikes should not be a contraindication to surgery although this may portend poorer seizure control postoperatively.[52] In these situations, Wada testing may help extract information regarding expected seizure suppression with surgery.[52]

Applying the disconnective techniques to hemimegalencephaly is hampered by the enlargement of the hemisphere and the presence of subcortical dysplastic tissue. The midline often is displaced by the anomalous gyri further obscuring the anatomic landmarks. Thus, anatomic hemispherectomy is the preferred operation for hemimegalencephaly at our institution.[2,35] Sparing parasagittal cortical tissue with anomalous draining veins adjacent to the sagittal sinus may reduce bleeding during resection. [27,51] If a disconnective operation is chosen, resection of the temporal lobe and the frontal operculum is recommended. This is a necessary step to allow for adequate visualization of the hemisphere and reduce the chances of postoperative brain swelling.[33,53] (Figure 120.7).

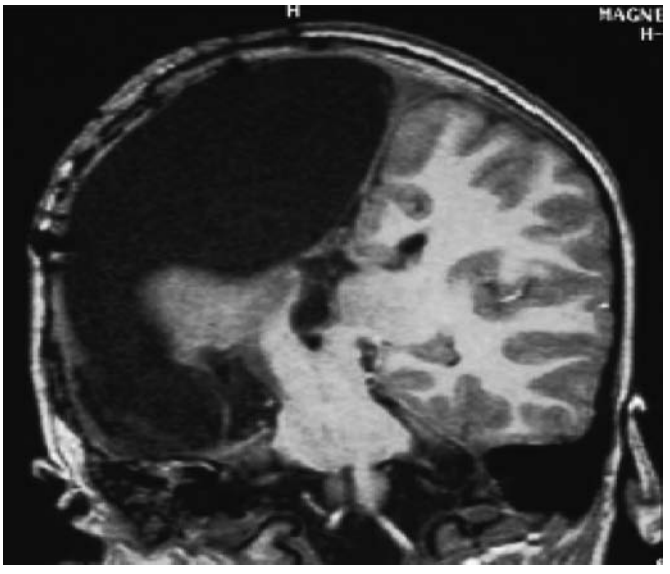

Figure 120.7 Postoperative coronal magnetic resonance imaging following anatomic hemispherectomy for hemimegalencephaly.

Technique selection: Sturge-Weber disease

Sturge-Weber disease or encephalofacial angiomatosis is characterized by the presence of a port wine nevus in the distribution of one or more trigeminal divisions and ipsilateral leptomeningeal venous malformation. Patients are often plagued by seizures with onset in infancy and debilitating hemiplegia. Functional imaging with PET or SPECT may better delineate the extent of the pial angiomatosis than MRI.[39] The description of hemispherectomy as a promising therapeutic option in reducing seizures in patients with Sturge-Weber disease was first published in 1952.[26,54] Falconer later elaborated on his experience in his report of five patients, all of whom had relief from seizures.[26,55] They supported early intervention in patients with diffuse hemispheric disease as the majority had a normal IQ and minimal hemiparesis when operated on in infancy.[26]

Special precautions should be taken in patients with Sturge-Weber who have holohemispheric leptomeningial angiomas throughout the operation. In infants, a staged operation may prevent the complications associated with potential blood loss.[44] Uncontrollable bleeding was encountered after drilling burr holes in one patient because of enlarged diploic veins resulting in the patients death.[27] Hoffman *et al.* published their case series of seven patients in 1979 and recommended en bloc rather than piecemeal removal because this technique limited blood loss from the pial vascular malformation.

Summary

The principle behind hemispherectomy has not changed in 75 years; isolation of the diseased hemisphere from normal brain. The versatile surgeon should opt for a technique tailored to the patient taking into account age, pathology, and anatomy. These surgical approaches are remarkably successful in the treatment of hemispheric epilepsy and hemispherectomy remains one of our most successful operations.

SECTION 16

Nonresective surgical procedures and electrical or magnetic stimulation for epilepsy treatment

121 Experimental multiple subpial transection: is it still indicated?

T Tanaka, A Hodozuka, K Hashizume, M Kunimoto, and S Takebayashi

Introduction

Multiple subpial transection (MST) is an effective procedure for suppressing focal epileptic seizures and is associated with minimal neurological deficits.[1,2] The rationale of their findings is based upon basic researches.[3–7] It is the method of choice for patients with uncontrollable epileptic lesions situated in unresectable eloquent cortex regions. However, adverse effects of MST following surgery have recently been reported.[8]

In the present study, the postoperative effects of MST were studied in an experimental model of focal cortical seizures induced by an intracortical microinjection of kainic acid (KA) in cats and in rats developed in our institution.[10–11] Electroencephalographic and autoradiographic analyses were carried out in surgically treated animals with and without MST, and the effectiveness and the after-effects of MST were assessed.

Methods and materials

Kainic acid injection into the sensorimotor cortex of cats (8–80 μg) or rats (2–20 μg) under mild pentobarbital anesthesia resulted in a transient focal motor seizure status for a period of 5–10 hours. On EEG, focal seizures lasting for about 30 seconds were repeated every 5–8 minutes at the injected site of the sensorimotor cortex with occasional secondary generalized seizures. An autoradiogram taken during the partial seizures demonstrated three major propagation pathways from the epileptogenic cortical focus: ipsilateral cortico-cortical propagation, contralateral cortical propagation via corpus callosum, and propagations to subcortical structures such as basal ganglia and thalamus. Using this focal cortical seizure model, the following studies were carried out.

1. *Experiment I*: Neurophysiological approach to MST in an experimental cat model. Under mild pentobarbital anesthesia, animals were placed on a stereotaxic frame and a fronto-parietal craniectomy was performed using a surgical microdrill. A cannula was inserted into the unilateral sensorimotor cortex, and EEG electrodes were placed on the dura. An injection needle was inserted into the cannula and KA solution was injected. One hour after focal seizures induction, unilateral craniectomy was performed at the frontal region. In control cats (without MST), the wound was closed with nylon stitches. In the MST group, two parasagittal MSTs were performed to either side of the KA focus. After MST, 5 hours of EEG recording was carried out. The wounds were closed with nylon stitches and the animals were intensively cared for with warm blankets, intraperitoneal water, and electrolyte administration. After recovery from the surgery, the animals resumed their normal condition without any seizure activity in both control and MST groups. Animals were deeply anesthetized with intraperitoneal pentobarbital and processed for pathological analysis 1 week or 1 month after surgery.
2. *^{14}C-deoxyglucose autoradiography in rats with or without MST.* In control rats, unilateral craniectomy was done and only MST was performed. The rats were processed for autoradiographic imaging with ^{14}C-deoxyglucose, as described previously.[11] In KA-group rats, after induction of focal cortical seizures, two parasagittal MSTs were performed at the focus area, and the animals processed for autoradiography. The local cerebral glucose utilization (LCGU) was measured using an image analyzer.

Results

Kainic acid injection into the unilateral sensorimotor cortex resulted in focal cortical seizure status in all cats. In control cats, induced seizure status persisted about 10 hours after KA injection. In the MST group, two parasagittal MSTs immediately arrested the seizure at the KA focus on EEG. Seizures did not propagate to the contralateral frontal cortex. However, high-amplitude beta activities remained in the cortex caudal to the MSTs (Figure 121.1, arrow).

The postoperative course after MST was uneventful without neurological deficit. Seizures did not recur in cats injected with a low dose of KA solution. However, in cats injected with a high dose of KA, transient myoclonic jerk contralateral to the KA injection was observed. In both cases, motor deficits were not induced following MST.

Pathological studies in cats with MST revealed intracortical and subpial hemorrhages at one week after the MST (Figure 121.2). Mild subarachnoid hemorrhage was noted adjacent to the MST area. At 1 month after surgery, gliosis with hemosiderin doposits and microvacuolations were noted along the MST track.

Autoradiography with ^{14}C-deoxyglucose was performed in rats after MST with or without KA-induced focal seizure

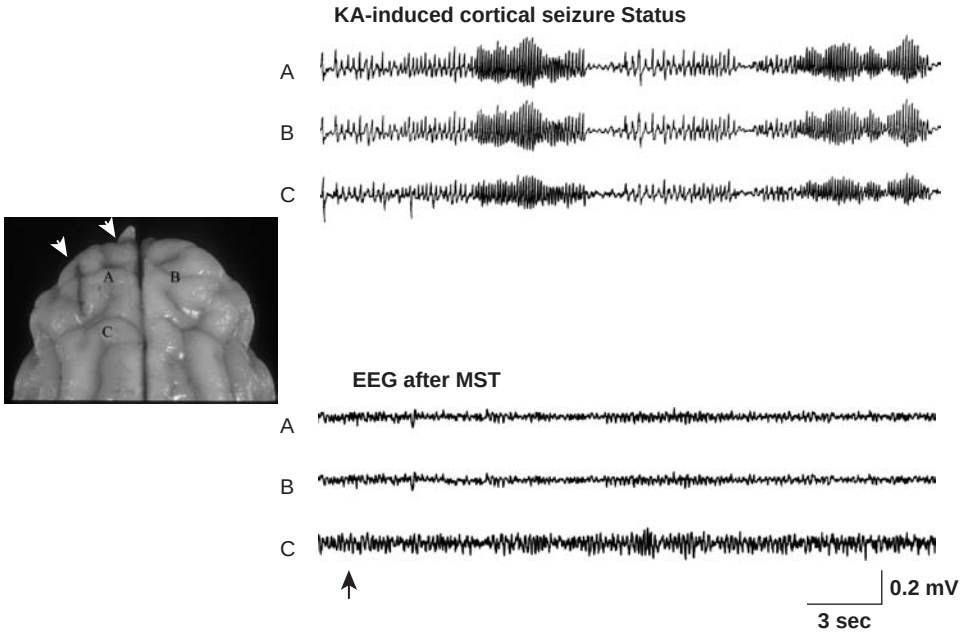

Figure 121.1 Intracortical KA injection resulted in focal cortical seizure status (top). EEG after MST demonstrated seizure suppression in electrodes A and B (bottom). However, high-amplitude beta activities remained in the ipsilateral parietal cortex (arrow).

status. In rats without KA, normal local cerebral glucose utilization (LCGU) was observed even after two MSTs had been performed (Figure 121.3). In rats with KA and MST, suppression of LCGU was noted at the epileptogenic focus in the transected cortex, especially between the two MST sites. However, LCGU of the ipsilateral cortex posterior to the MST, and in the superior part of the caudate nucleus, thalamus, hippocampus and contralateral cortex remained hypermetabolic even after the MST.

Discussion

In refractory extratemporal cortical epilepsy, when the epileptic focus is situated in unresectable cortex such as the speech centers of Broca or Wernicke, visual cortex, or sensori-motor cortex, radical resection therapy is not indicated, since serious functional deficits may result. MST is a relatively new surgical technique for treating intractable epilepsy arising from the eloquent cortex. The aim of the procedure is to transect

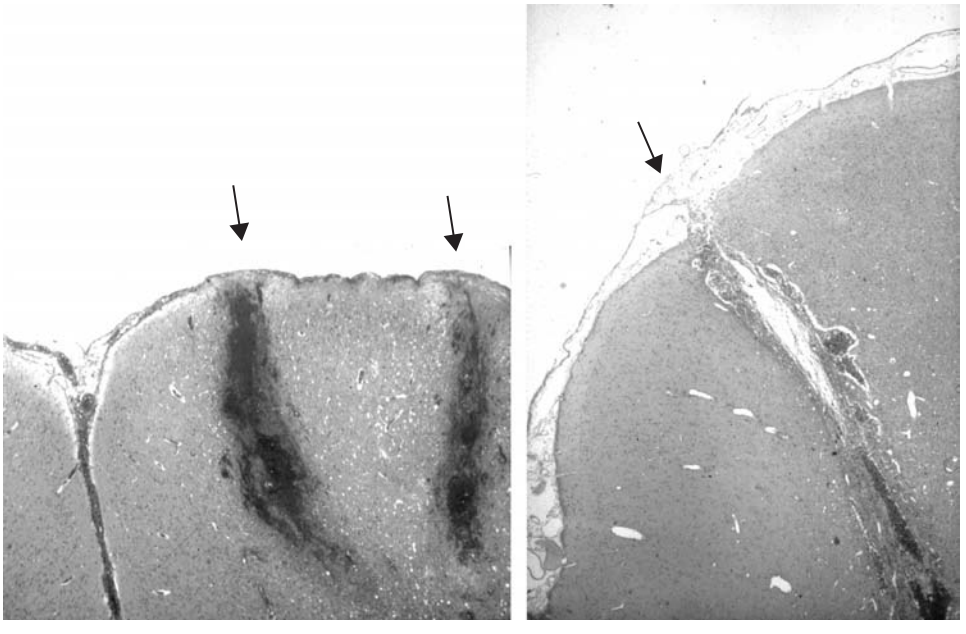

Figure 121.2 Photomicrograph demonstrating hemorrhage at the MST track one week after surgery (a, arrows). Subpial and subarachnoid hemorrhaging were also observed (a). One month after the MST, gliosis and hyalinization were observed along the MST track (b, arrow). Hemosidelin deposits were also observed.

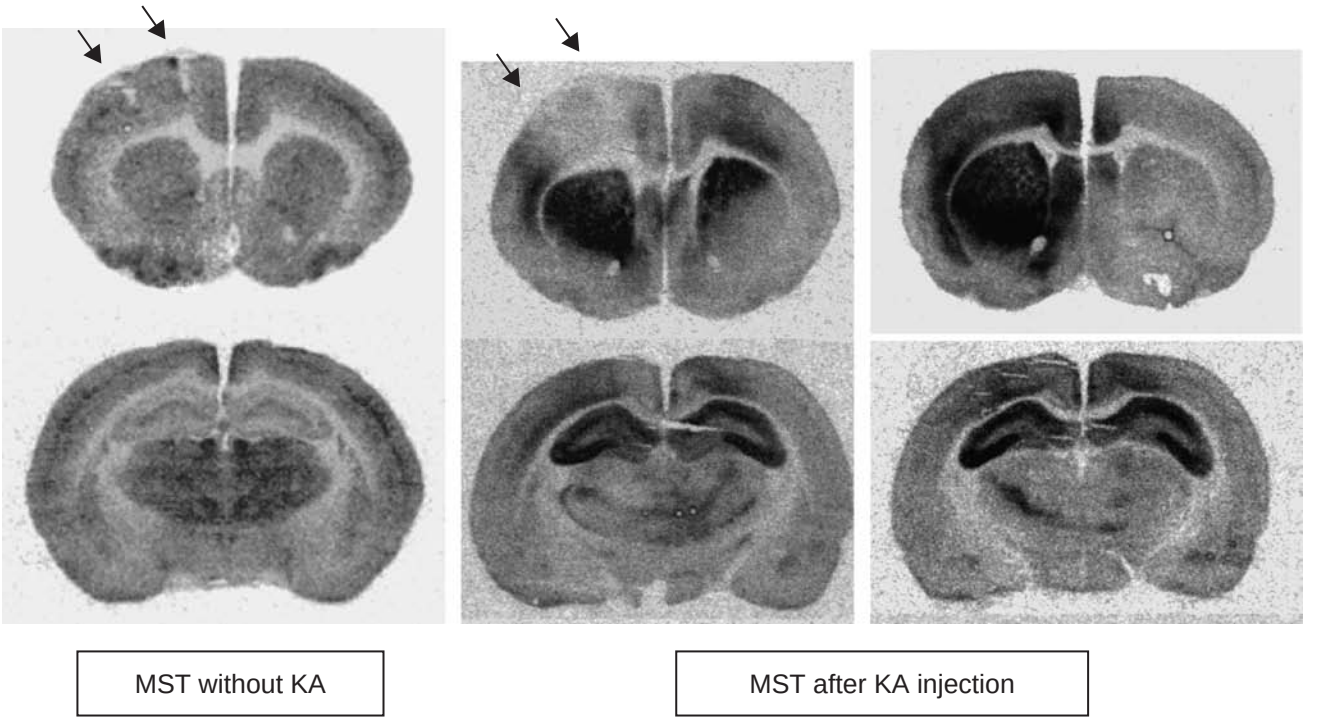

Figure 121.3 Autoradiograms with ^{14}C-deoxyglucose demonstrating normal local cerebral glucose utilization (LCGU) in rats without KA even after two MSTs had been performed (left, arrows). In rats with KA and MST, suppression of LCGU was noted at the epileptogenic focus in the transected cortex, especially at the cortex between two MSTs (middle, top). However, LCGU of the ipsilateral cortex posterior to the MST (left, top), superior part of the caudate nucleus, thalamus, hippocampus and contralateral cortex remained hypermetabolic even after the MST (middle and left, bottom).

horizontally coursing intracortical fibers, which play an important role in seizure spread, while preserving the vertically-oriented cortical columns that are related to normal cortical function.[2] In this study, unilateral KA injection into the sensorimotor cortex in cats resulted in a transient focal motor seizure status with occasional secondary generalizations for a period of 5–10 hours. This KA-induced seizure model is extremely useful for the experimental study of MST as the primary epileptogenic focus is localized within the site of the KA-injected cortical layer. MSTs performed in this study actually suppressed the seizure activities of the sandwiched area of the cortex between the MST sites. Cortical seizure propagations in the horizontal plane on EEG were clearly inhibited by the MST because the cortical seizure did not propagate beyond that focal area of MST.[12–16] In a limbic seizure status model, Imamura *et al.* studied effects of orthogonal transection between the dorsal and ventral hippocampus upon kainic acid-induced amygdalar seizures.[17] Seizures subsided within 24 h, showing no ictal manifestations except for aggressiveness. Overall, seizures were weak and transient compared with those in controls. Histologically, hippocampal neuronal damage was slight. These results indicated that connections between the dorsal and ventral hippocampus are important for full development of KA-induced amygdalar seizures. However, this method is palliative and not curative.

Autoradiographic studies with ^{14}C-deoxyglucose were analyzed precisely in rats with or without KA focus and revealed that the LCGU between the two MSTs was normal. This indicated that the MSTs did not interfere with cortex metabolism even in the surgically sandwiched cortex.

In rats with KA and MST, suppression of LCGU was noted at the epileptogenic cortex between the two MSTs. However, LCGU of the parietal cortex posterior to the parasagittal MSTs, deep cortical layer, superior part of the caudate nucleus, thalamus and contralateral cortex remained hypermetabolic even after the MSTs. This result shows that MST is a good surgical alternative only when the MSTs can sandwich the small epileptic focus in the cerebral cortex, but seizure propagation via vertically oriented cortical columns to the basal ganglia and thalamus remained after MST.

Subacute and chronic pathological analysis revealed a scar formation in the cortex after MST indicating that MST may be an alternative for controlling electrophysiological focal cortical seizures in the eloquent cortex. However, chronic pathological changes should be monitored over long-term follow-up of the procedure.

In clinical cases, bleeding can occur at the site of the transection, but the procedure has been generally well tolerated, with no major complications.[18–28] Spencer *et al.*[29] studied 211 patients from six large epilepsy centers who had undergone either surgical lesionectomy with MST (158/211) or MST only (53/211). In the MST and resection patients, a >95% seizure reduction was obtained in 68% of cases for simple partial seizures. For the patients undergoing MST only, the results were not as good, with a >95% seizure reduction obtained for simple partial seizures in 63% of cases. Surgery-related neurological

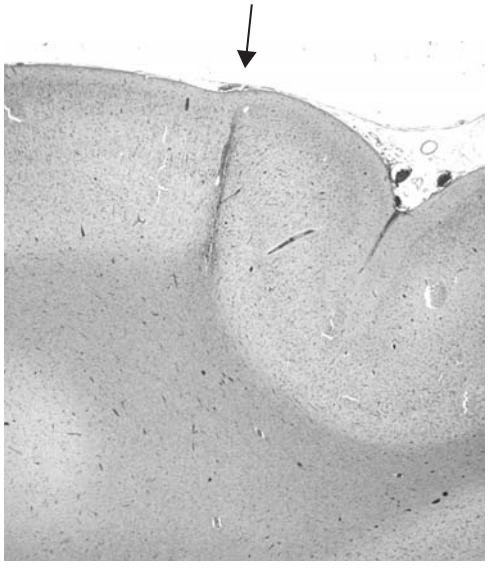

Figure 121.4 Photomicrograph of 9 year-old boy demonstrating a cortical scar by MST 6 months after the surgery (arrow). Along the track of the cortical MST, thin gliotic tissues were observed. Moreover, degenerative process such as micro-vacuolation and hyalinization with hemosiderin deposits were observed.

deficits were present in 47 out of the 211 patients, in 23% of the lesionectomy and MST group, and in 19% of those who had MST only (19%). This study highlighted that the possible neurological deficits from these procedures must be considered.

In our institution, 11 patients underwent MST from 1995 to 2003. In ten patients, lesionectomy with MST was performed. Only one patient who had focal cortical dysplasia over Broca's area underwent MST only. Six patients became seizure-free and three patients achieved 90% seizure reduction after surgery. One patient in the lesionectomy with MST group and one patient with MST only did not show improvement (Engel's Class III). Neurological deficits were not observed in this series of MST patients. In our institution, MST is performed only in areas where remarkable residual spikes are observed on postresection ECG. Damage to arteries and veins over the surface of the cortex are avoided if possible during the MST procedure. Consequently, the distance between the MSTs is variable and not always within 5 mm. This method is not the MST procedure originally described, but the modifications introduced appear to reduce the postoperative adverse effects.

We encountered a 9-year-old boy suffering from intractable complex partial seizure due to focal cortical dysplasia in the caudal part of the left inferior temporal gyrus. Based on the presurgical evaluation, lesionectomy with MST of the temporal cortex was preformed. Postoperatively, seizure recurred 3 months after the surgery. Further evaluation was made and mesial temporal focus was diagnosed. Six months after the first surgery, an antero-medial temporal resection was performed, after which the patient was seizure free. The final diagnosis indicated a dual pathology. Photomicrography of the resected temporal lobe contained a previous MST in the temporal cortex. Along the trace of the cortical MST, thin gliotic tissue was observed. In addition, degenerative processes such as microvacuolation and hyalinization were apparent, as were numerous hemosiderin deposits.

MST has been generally well tolerated, with no major complications reported. Our experimental study in cats clearly demonstrated the possibility of intracerebral hemorrhage along the track of the MST, subarachnoid hemorrhage one week after the MST, and scar formation one month after the MST. Our case with re-operation 6 months after the MST also demonstrated scar formation in the cortex. Late seizure recurrence after MST was recently reported.[8] The recurrence late was ten out of 54 patients (18.5%). Long-term follow-up is necessary after MST due to the potential for scaring of the most vulnerable cortex for epilptogenesis. Additional studies are needed to better define the risks and benefits of this procedure.

Summary

MST was evaluated in animals with KA-induced experimental partial epilepsy.

MST around the epileptic cortical focus suppressed the seizure activities of the cortex on EEG. However, seizure propagations in the subcortical structures remained even after the MST. The postoperative clinical course was uneventful, and subsequent motor deficit was not observed. However, pathological analysis indicated acute hemorrhage and chronic scar formation around the MST track. These results suggested that MST may provide a palliative method to suppress epileptic activity. Long-term studies are needed to fully define the risk-effectiveness of this surgical technique.

122a Multiple subpial transections

W Harkness

To improve human health, scientific discoveries must be translated into practical applications. Such discoveries typically begin at 'the bench' with basic research — in which scientists study disease at a molecular or cellular level — then progress to the clinical level, or the patient's 'bedside'.

Office of Portfolio Analysis and Strategic Initiatives
National Institutes of Health 2007

Although the phrase 'translational research' may be perceived as relatively recent concept, there are examples in the history of medicine where the inspirational step from the laboratory to the bedside has led to a dramatic change in the management of disease to the benefit of patients. Such an example is the introduction of multiple subpial transections (MST) into the surgical management of epilepsy by Prof. Frank Morrell, a scientist physician with the almost unique distinction of having a surgical procedure and instruments eponymously named after him. Morrell was a most distinguished basic scientist and was one of the 26 founder members of the Society for Neuroscience whose first mission statement is to 'advance the understanding of the brain and nervous system by bringing together scientists of diverse backgrounds, by facilitating the integration of research directed at all levels of biological organization, and by encouraging translational research and the application of new scientific knowledge to develop improved disease treatments and cures'.

The scientific basis to MST

The initial studies to demonstrate the efficacy of multiple subpial transections were carried out by Professor Frank Morrell using an animal model.[1] The scientific premise upon which the hypothesis was based was developed from previous anatomical observations upon the vertical orientation of the cerebral cortex function,[2,3] combined with his own observations on the epileptic spike and it's anatomical orientation,[1] the need for horizontal propagation and the area of cortex required for seizure propagation and spread.[4]

Prior to his work, other authors had described procedures used in animals to demonstrate how tangential connectivity could be disrupted without loss of function.[5,6] These experiments carried out in the visual cortex of the cat demonstrated no change in visual perception and in addition that horizontal cortical cuts did not damage the blood supply to the cortex, thus ensuring preservation of vertically orientated cortical function. Morrells' laboratory work demonstrated that the minimum contiguous cortex necessary to sustain synchronous spiking was 12.5 mm^2 whilst cortical islands greater than 5 mm in width can support paroxysmal discharge with tangential spread occurring at a rate of 0.05 mm/s. In 1989, Morrell and Whistler described their initial experience of the procedure in human subjects,[7] and this has subsequently led to papers exploring the effects of the technique, both clinically and pathologically as well as its use in specific clinical scenarios. Despite the fact that the initial description of the clinical studies was now almost 20 years ago, remarkably few papers have been published describing clinical outcome and those studies that are reported are confounded by the fact that MST is frequently combined with resective or disconnective procedures. A recent multivariant analysis of outcome from a number of major epilepsy centers[8] was able to give some insight into the results but as yet little explanation appears to have been given to the relatively poor uptake of the procedure. This chapter will explore the original surgical technique and subsequent modifications, the histological features following MST as well as postoperative radiological features and finally clinical outcome in terms of morbidity, seizure status, and where possible quality of life improvement.

The surgical technique and its evolution

In the original animal experiments carried out by Morrell, he described a technique whereby intragriseal incisions spaced at 5 mm intervals were placed over the crown of the cortical gyri. This same surgical technique was applied by Morrell and Whisler in their human clinical studies.[7] Whisler has described and demonstrated the surgical technique involving a small pial incision at the edge of the gyral crown and then insertion of specially designed knives to divide the gray matter in a vertical orientation. The knives are modifications of those used in the animal experiments and consist of a single piece of stainless steel with a flexible shaft ending in a flattened tip at 105° to the shaft (modified from the original 90° to reduce the risk of snagging the arachnoid and vessels). The tip is 4 mm in height and 0.3 mm wide and rounded so that when it is drawn horizontally across the gyral crown beneath the pia, the tip of the knife does not breach the pia.

The initial description of the surgical technique involved placing an incision in the pia with a fine blade or needle as far down into the sulcus as the vessels allow. Should bleeding occur, hemostasis is achieved by gentle pressure with or without the application of a hemostatic agent. The end of the knife is then introduced into the breach in the arachnoid and passed

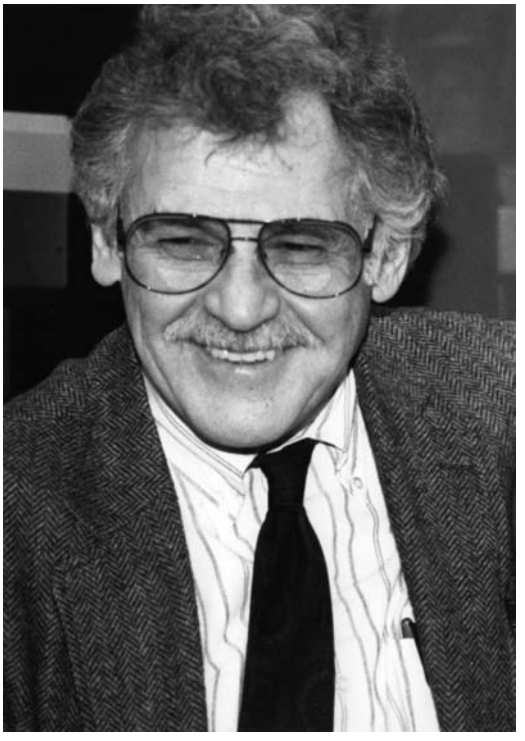

Figure 122a.1 Prof Frank Morrell 1926–1996

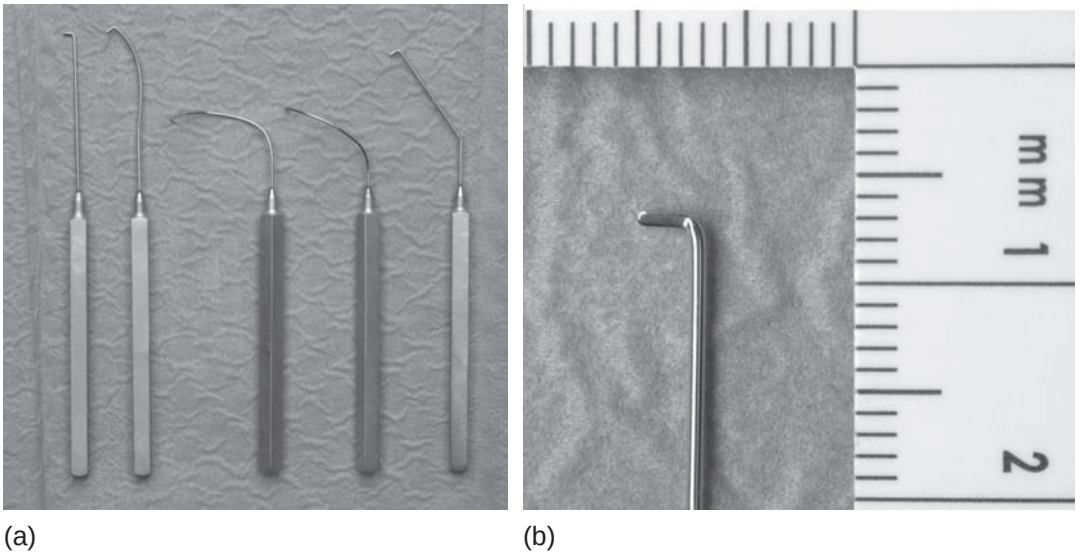
across to the other side of the gyrus, keeping the tip in view at all times. Gentle upwards pressure on the arachnoid will ensure that an incision of the correct depth is placed in the gray matter of the crown of the gyrus. Once the knife is removed and hemostasis achieved, a further breach in the arachnoid is made at 5 mm distance and the process repeated parallel to the first transection and thereby the gyrus becomes marked by a series of thin red lines perpendicular to the long axis of the gyrus.[9] As the gyrus turns the transections should be fashioned in such a way as to ensure that the 5 mm spacing is not exceeded and so a 'fan-like' pattern to the transections may be produced.

In order to determine the area that is to undergo MST, intraoperative electrocorticography is required. Areas showing evidence of epileptiform discharges are then transected prior to the corticography being repeated to ensure that the discharges are ablated. Should discharges persist, it should be considered as to whether the cortical sulci should be opened to allow transection of deeper areas of cortex. In order that an adequate exploration of the cortical surface can be carried out, a wide surgical exposure is necessary. In addition, in the anesthetized patient, it may be necessary to perform SEEPs in order to demonstrate eloquent cortex or alternatively direct cortical stimulation may be carried out in the absence of neuromuscular blockade. Whislers' original cases were performed with the patient awake with direct observation of the effects of cortical stimulation.[7]

One of the theoretical disadvantages of this technique is that a wide area of the anatomical and physiological target does not in fact become transected. Cortex in the vertical plane adjacent to sulci, microgyri, and gyri buried beneath the surface do not undergo transection. For this reason, a number of authors[10–12] have described a modification of the technique in which the knives are passed in a vertical orientation to transect some of this cortex and more than one pial incision made to ensure both sulci can be safely reached.[11] Great care needs to be taken when passing the knife tip downwards to prevent snagging of the arachnoid or vessels deep in the sulcus, as it is not in view unless the sulcus is opened. This is where the 'feel' of the knives becomes so important, that is the tactile feedback afforded by the flexible shafts of the knives. A number of instruments with different angulation and orientation of the knife point facilitates this aspect of the surgery. This modification of Morrell and Whisler's initial technique appears to have adopted more widespread use. A further practical adaptation is in the use of a micropoint diathermy at very low setting to make the pial incision and thus reduce bleeding from the surface vessels.

Pathological changes

Limited attention seems to have been paid to the pathological changes and the microscopical appearances of MST and this is probably due to the paucity of pathological material. One study



(a) (b)

looked at the acute changes brought on by MST in patients who were in fact undergoing temporal lobe cortical resection.[13] MSTs were carried out immediately prior to the cortex being removed and the results analyzed histologically. The orientation of the transections was appraised, as well as the histological appearances. The authors concluded that in many cases, the orientation of the gyri meant that the transections themselves very often did not comply with the intended vertical orientation, whilst the histological appearances were of an acute hemorrhagic reaction. An abstract from the AES proceedings of 1993[14] described two patients in whom more chronic specimens were obtained, at 8 and 12 months following transection. Personal experience of the morphological consequences of Morrell procedure is confined to one functional hemispherectomy specimen from a 13-year old girl whose management for Rasmussen's encephalitis had included multiple subpial resections carried out on the right motor-sensory strip 4 months earlier. A number of narrow gliotic scars were noted over the crowns of the gyri running perpendicularly to the surface pia; these reach mid-cortical level but in some cases cut right through the cortical ribbon to reach the white matter. Hemosiderin-laden macrophages were noted in such scars. The anatomy of these lesions closely resembles the acute lesions described by Kaufmann *et al* (1996). While the surrounding neural parenchyma appeared unaffected, some scars were adjacent to long strips of cystic cortical destruction running from the gyral crest into the depth of sulci. These changes could correspond to incisions made vertically in the orientation of the sulci as described above but since such cortical destruction could not be distinguished from the burnt-out lesions of Rasmussen's disease, its relationship to the surgical lesions cannot presently be determined. These changes appear to differ from those described by the team from Rush Presbyterian in terms of their orientation but again may be explained by the slight difference in surgical technique (Figure 122a.4).

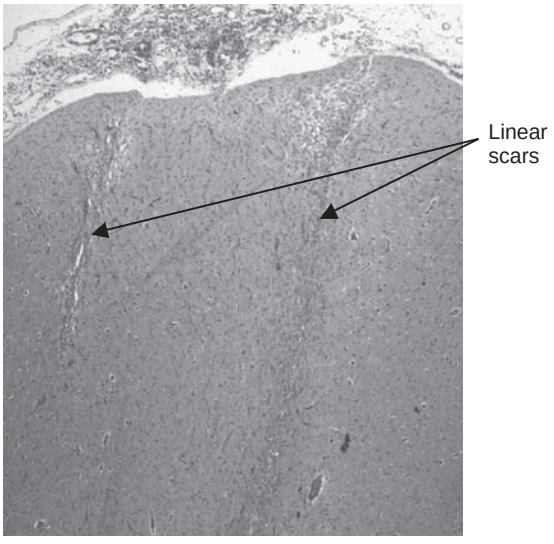

Figure 122a.4 Linear scars.

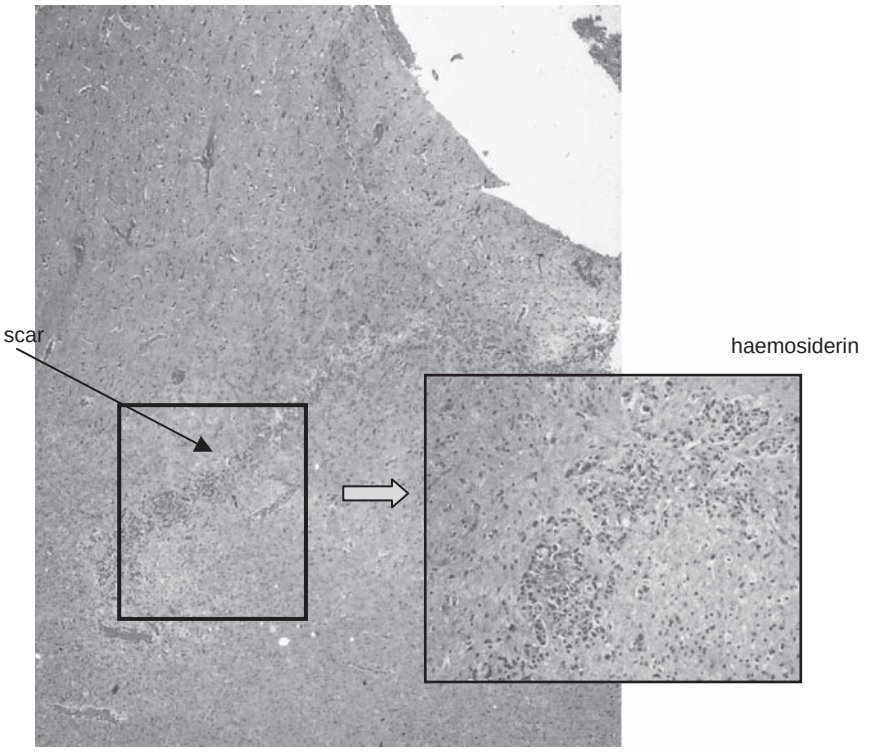

Figure 122a.5

These histological appearances would be consistent with the changes seen on MRI scanning. In the acute phase, there may be evidence of edema and hemorrhage in the superficial cortex and in the longer term, there maybe gliosis and evidence of ischemic change. The long term MRI appearances may also be limited to some mild atrophy, with the transections clearly seen on the T1 imaging. The imaging appearances may be confounded by any progressive changes that may be attributable to the underlying pathological process such as Rasmussen's disease.

Clinical indications and outcomes

The aim of MST is to impair the capacity of cortical tissue to develop sufficient neuronal synchrony to produce epileptiform discharges, without interfering with it's capability to mediate normal physiologic transactions.

Morrell Advances in Neurology 1990;81 259–69

The aim of MST as described by Morrell shows that the primary indication for the procedure is in functionally critical

cortex, with or without evidence of pathology. Four anatomical groupings of patients were treated:

a) pre-central gyrus
b) post-central gyrus
c) Broca's area
d) Wernicke's area involving angular and supramarginal gyri.

In all these patients the procedures were performed awake and with cortical stimulation to confirm functionality. In a chapter published in 1996 Morrell and Whisler reported their accumulated experience of 172 areas of transection in 97 patients up until June 1994.[15] The results of these procedures were described by Morrell with respect to function as well as seizure outcome.

There were 52 transections in the precentral gyrus and in seven of these who had transections in the leg area; two experienced a foot drop, attributed to subcortical venous haemorrhage. In none of the 44 cases in whom the procedure was carried out in the face or hand area was there an ensuing weakness. Two patients subsequently underwent resection of the previously transected areas, due to persistent seizures or progressive pathology and in both cases a profound weakness developed, supporting the underlying thesis of the procedure.

There were 57 cases of transection in the post central gyrus and in none of these was there any discernible postoperative sensory deficit. In 29 out of 57 (51%) there was an unexpected and unexplained deterioration in rapid fine finger movement.

In 23 cases transections were performed in Broca's area with only three showing evidence of decreased verbal fluency. In 45 cases transections were performed in Wernicke's area and the supramarginal and angular gyri and, apart from four cases, all are reported to have retained ability to 'understand, speak, read, write and copy'. In the earlier initial report from Morrell[7] of five patients all had some demonstrable difficulties in naming and word substitution but we do not have similar detail for the later, larger series. One patient who had undergone two previous procedures in the same anatomical location sustained an irreversible deterioration of her speech deficit following a deep subcortical hemorrhage.

Morrell and Whisler report seizure outcome for these patients undergoing purely MST according to the Engel Classification[16] with 53% Engel Class I; 11% Engel Class II; 20% Engel Class III; and 16% Class IV. Bearing in mind the refractory nature of the seizures and the location of the Epileptogenic Zone in eloquent cortex these results are impressive. There was no reported mortality but morbidity that was either procedure specific (e.g., subcortical hemorrhage) or procedure non-specific (e.g., osteomyelitis of bone flap) occurred in 18% of cases.

Subsequently Morrell and other authors went on to describe applications in other areas and in the presence of specific pathologies or clinical seizure syndromes, although the majority of cases reported in the literature are concentrated anatomically in frontal and temporal cortex.

The multi-centric meta-analysis carried out by Spencer *et al.* in 2002 reported standardized data of a total of 211 cases of MST from six centers.[8] The length of follow up and when the cases were accrued is not included in the chapter, implying that this was the total experience over an approximately 20 year period for these major centers. In 53 cases MST was carried out alone; whilst in the remainder MST was performed in conjunction with either resection or disconnection. Of the pure MST 10 cases (19%) developed new neurological deficits which is a figure very similar to the Morrell and Whisler series. Four patients had memory decline, whilst four experienced hemiparesis and one a visual field loss. Interestingly none had a deficit of sensation or speech as a consequence of MST alone, again supporting Morrell's findings. With regards seizure outcome this study did not use Engel's classification but rather a scale wherein an 'excellent outcome' was >95% reduction of monthly seizure frequency. 62% of patients undergoing pure MST fell into this 'excellent' category for simple and partial seizures and 71% had an excellent response as regards generalized seizures. Simple partial seizures were seen to increase in 15–20% of the total group of patients and outcome was better in the presence of focal lesions and worse in progressive or diffuse pathologies.

This analysis is a worthy attempt to bring together the sporadic and sometimes anecdotal reports of MST in the surgical

treatment of epilepsy but sadly can draw no significant conclusions other than MST 'can be considered a viable and effective approach to uncontrolled seizures arising in functionally critical cortical areas'.

Because of the interest in patients with Landau–Kleffner syndrome, which is discussed below, there has been much interest in the application of MST to the pediatric population. Blount *et al*. have reported the results in 30 cases accrued over a four year period, in whom 26 had MST combined with resection and four had MST alone.[17] The surgical strategy applied was to resect the epileptogenic zone and therefore invasive recordings were performed in 23. Outcome was 42% of patients who had resection and MST were Engel Class I and a further 42% Engel II and III. In all there was evidence of motor impairment when primary motor cortex was transected but there was no evidence of any permanent deficits. This outcome is very similar to a comparable adult series although the functional recovery appears superior in the pediatric group.[18,19]

Specific seizure types

Epilepsia partialis continua

When epilepsia partialis continua (EPC) affects the sensori-motor cortex the effects can be disabling and painful and severely affect quality of life. When distinct structural lesions are present it may be possible to carry out a successful resection using a combination of pre- and intra-operative functional information. This is not, however, possible in all cases and therefore when the pathology is diffuse or progressive with as yet little or no neurological deficit then MST may be the only realistic option. There have been five descriptions in the literature of MST being used for EPC in a total of five clinical cases. In one case MST was used in conjunction with resection;[20] another with disconnection[21] while in another[22] it was used as a prelude to invasive recording and focal resection. Molyneux *et al*.[23] have reported a patient with life-threatening complications due to medical treatment of EPC was significantly improved with MST. Despite a negative 0.5 T MRI the underlying pathology from a biopsy taken at the time of surgery was found to be cortical dysplasia. Follow up at eleven years following MST finds the patient had three seizures in the previous year and is working, whilst there have been several years completely free from seizures. A further unreported case from the same institution involves a patient with Rasmussen's encephalitis who had painful sensori-motor EPC with no neurological deficit in whom MST in primary sensori-motor cortex produced a dramatic clinical improvement and at 11 years follow up is having approximately four seizures per year.

Infantile spasms

There has been increasing recognition that infantile spasms may be associated with underlying focal pathology which may be surgical remediable, with associated improvement in developmental progress.[24–26] Chuang *et al*. have described two children (22 months and three years) in whom MST was carried out over an area localized by intraoperative electrocorticography.[27] There was an appreciable reduction in spasms in both cases but neither became seizure free. In one case cortical dysplasia was seen on biopsy and in the other the picture was strongly suggestive of dysplasia due to the asymmetric spasms and localized epileptogenic zone. It could be therefore argued that these cases would have been suitable for a potentially curative resective or disconnective procedure. Patil in describing his series of MST performed on both hemispheres included two patients with infantile spasms, one of whom was seizure free whilst the other was not improved.[28]

Specific syndromes and clinical settings

Landau–Kleffner syndrome with or without autistic features

Landau–Kleffner syndrome is an acquired epileptic aphasia with female predominance following previously normal development and the clinical picture is one of a progressive deterioration of speech, which may be associated with clinical seizures but more typically clinical seizures are less prevalent but EEG abnormalities exist most commonly in the temporal lobe. The neurophysiological findings may include electrical status epilepticus in sleep (ESES).

The severity of the clinical syndrome and the natural history of the disorder can vary considerably and the classical picture may be complicated by other features such as autism.[29] Although the condition may remit spontaneously within 2–3 years, there is evidence that continuing ESES lasting longer than 36 months and a younger age at onset are associated with poorer long term outcome. In addition, even when speech does return there is frequent evidence of impairment both of speech and memory.

Morrell[30] described his experience with 14 children with LKS who underwent MST in Wernicke's area, lateralization being achieved by EEG, methohexitone suppression test, sodium amytal test, and dipole mapping. All surgically treated subjects were developmentally normal prior to the acquisition of LKS and had the condition for a minimum of 2 years. Unilateral MST was carried out under electrocorticographic control with the Sylvian fissure being opened where deemed necessary and in two cases an additional anterior temporal resection was performed.

In seven cases 'normal' speech returned, in five there was a marked improvement in speech whilst in the remaining three there was no change. Changes in speech were usually seen progressively over the first six months following surgery and other gains seen with longer follow up. The presence of persistent EEG abnormality following MST was associated with a poorer outcome.

Grote *et al*.[31]subsequently reported the outcome of a further series of surgically treated patients from a total of 80 patients with LKS. Eighteen patients were operated upon of whom 14 were available for follow up. This study included 10 of the patients from Morrell's original group, four having been excluded on the basis of progressive or bilateral problem. A much more detailed analysis of outcome was available with two patients suffering significant peri-operative morbidity, one child showing a significant decline expressive and receptive language function and only 4 of 14 patients were recorded as returning to normal school. Nonetheless 50% showed a significant improvement in one or other domain tested following surgery.

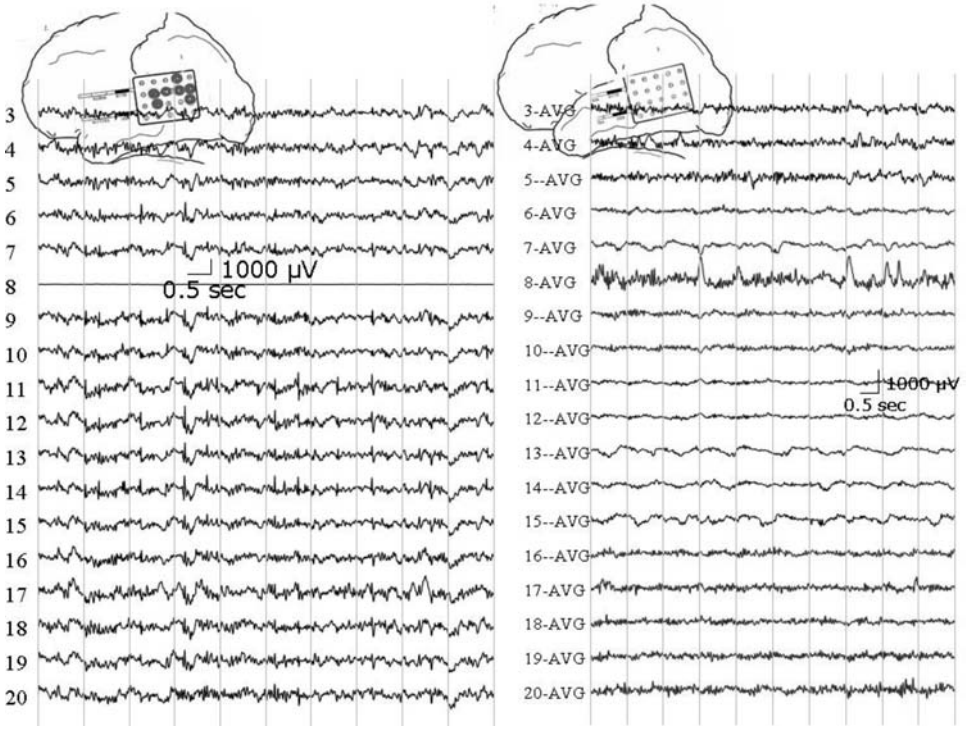

Figure 122a.8 Intra-operative electrocorticography recordings in patient with Landau–Kleffner syndrome before and after MST.

Irwin *et al.*[32] have described five patients with LKS treated with MST over an eight year period. Despite what appears to be an identical surgical procedure the outcome with respect to language was poor with no patient recovering age appropriate language. There was however, a significant reduction in clinical seizures and also an improvement in behavior, with loss of defiant aggressive behavior, improvement in attention span and reduction in hyperactivity. No child had a return of fluent speech but in two patients there was a significant improvement in behavior. This experience is shared in the series from Toronto[17] and in our own series of 10 patients undergoing MST for LKS in whom three showed an improvement of receptive language function and two an improvement of expressive language function.

It is not clear why the results described by Morrell and Grote have not been replicated in these two further studies. In Morrell's original paper children with autistic regression in association with LKS were not included. Certainly other authors have recognized a great deal of variability of the clinical picture with many patients either showing signs of delayed language before regression or failure to acquire language.[33–35] There are also clear links with features of autistic regression as one third of autistic patients undergo language regression under the age of three years and surgical series show evidence of lesions particularly in the right temporal lobe in patients with seizures and autism.[36] Nass *et al.*[37] have described seven cases in whom there were improvements in receptive language and also behavior although these were not always sustained. Neville *et al*[38] have described the response following surgical treatment in two patients with autistic regression one treated with temporal lobectomy and the other with MST, both of whom showed improvements in communication. Patil has reported five cases who showed apparent post operative improvement but this outcome was not quantified objectively.[39] Szabo *et al.*[40] have described five cases of epilepsy surgery in autistic regression with improvement but not relief of the autistic features. Finally, early onset of seizures has been linked with autistic regression and this might support the argument for early referral to surgical centers and the as yet unproven hypothesis that early surgery might minimize the development of autistic regression.[41]

Whilst clearly MST remains a surgical option in the management of LKS,[42] the families of patients need to be carefully counselled as to the expected outcome on the basis of the clinical information available. The outstanding questions of the timing of the procedure in the clinical course of the syndrome and its true clinical efficacy remain unanswered and will require a prospective audit of cases with careful pre- and post- operative evaluation both electroclinically and from the language and behavioral standpoint. The relationship between LKS, autistic regression, and epileptiform activity is a complex one[35] and thus the effect of MST on autistic regression also requires further evidence and remains the subject of discussion.[39]

Rasmussen's encephalitis

Due to the preservation of cortical function afforded by MST it is a surgical option when there is little or no neurological deficit, particularly for the dominant hemisphere.[43] Despite the likely palliative nature of the procedure in the presence of progressive pathology, it may have a role in the management of Rasmussen's encephalitis and has been described as such by a number of authors. Reviewing the major published series it appears that a approximately 19 patients with Rasmussen's encephalitis have undergone MST,[11,15,19,43–45] although two reports from the same center may duplicate cases. Whilst the long-term results are inevitably poor the temporary palliation

afforded may improve quality of life significantly and obviate the need for a hemispherectomy both in the short and long term.

Bilateral independent seizure foci

Patil *et al*. have described their experience of 61 patients in whom they have performed MST to multiple areas in both hemispheres.[28] Seventeen of these patients had an additional resection carried out, although these tended to be small and indicated only when there were persistent discharges detected on intraoperative electrocorticography after extensive MST had been performed. Each procedure lasted for between 10 and 12 hours and there was an interval of between 5 and 7 days between the surgeries to each hemisphere. The clinical seizure types consisted most of complex partial seizures (50 cases) but included Lennox–Gastaut (3 cases) infantile spasms (2 cases), and myoclonic seizures (2 cases). The number of lobes of the brain operated upon ranged from two to eight. Although transient hemiparesis and dysphasia were observed in one patient and there were two peri-operative complications and one patient died from a massive post operative GI bleed, no lasting neurological deficits were seen. Seizure outcome was Engel Grade I in 52% and Grade II in a further 8%. There was no further clinical detail of functional or neuropsychological outcome. This is obviously an apparently impressive response to MST but further outcome data is required before such a procedure could be widely adopted although the authors have demonstrated the safety of this procedure in a potentially difficult to treat patient group.

Focal pathologies

One of the confounding factors in being able to gauge the efficacy of MST has been its frequent use in combination with cortical resection. The rationale has usually been that either the structural abnormality or neurophysiological abnormality extends into eloquent cortex rendering complete excision of either focus impossible. Even when eloquent cortex is not encroached upon it has been argued that MST to the neurophysiological abnormality beyond the structural abnormality may improve seizure outcome. Certainly there is scientific evidence that the tissue surrounding structural lesions such as dysembryoplastic neuroepithelial tumours and gangliogliomas may be abnormal and epileptogenic.[46] In addition as we learn more about the patterns of abnormality of cortical migration and the abnormal circuitry that lies within and around these lesions, it is increasingly apparent that the epileptogenic zone may extend beyond the structural abnormality, supporting the hypothesis for additional MST.[47]

There is reported evidence that resecting the epileptogenic zone in addition to the anatomically evident pathology improves seizure outcome[48] but similarly in the current era of MRI and intraoperative guidance excellent results can be achieved without careful intraoperative neurophysiological guidance.[49] A series from the Toronto group appears to show no additional benefit in 16 cases where MST was applied in conjunction with focal resection in cases of focal cortical dysplasia.[50] In order to prove the additional benefit of MST a large prospective study would be required with considerable funding to support it.

Current questions concerning MST

Because of the fragmented and sometimes repetitive data presented for MST it is difficult to draw firm conclusions as to its role and efficacy. There is no doubt that it remains an immensely innovative procedure and there is evidence that seizures are reduced following surgery in many patients who would otherwise not be considered to be surgical candidates. However, like other palliative procedures such as callosotomy and vagal nerve stimulation it is not possible to accurately predict preoperatively who is likely to benefit from surgery. There are currently a number of questions that need to be asked of MST.

Does MST achieve its anatomical goal?

If the gyral folding of the cerebral cortex were to be smoothed out, then the incisions made over the crowns of the gyri would provide a very incomplete isolation of the cortex into discrete islands of the desired volume; a fundamental thesis of the procedure cannot therefore be achievable. Even with the addition of transections down into the sulci and opening of the major gyri a significant portion of the cortex will remain anatomically and neurophysiologically connected. In addition the thickness of the cortex varies according to anatomical location, varying from 2 mm in the calcarine cortex to 4 mm in the precentral region and also tending to be thinned towards the depths of a sulcus.[51] Furthermore a number of pathological conditions may result in either thickening[52] or thinning of the cortical mantle and therefore the intragriseal transections may either incompletely cut through thickened cortex or extend into the white matter when the cortex is atrophic, resulting in either incomplete disconnection or damage to white matter tracts. Whilst the former may be rectified by further transections if the intraoperative electrocorticography shows persistent electrical abnormality, the latter will be irreversible and may explain some unexpected post operative functional deficits.

Does MST achieve its physiological goal?

When transections are carried out in eloquent cortex the functional results strongly support the hypothesis of preservation of function. Whilst the results are not free of morbidity such morbidity as does occur is frequently linked to a clear explanation such as the presence of subcortical hemorrhage and others may be explained by the variation in cortical thickness as explained above.[51] A single post operative functional PET study has demonstrated functional activity in an area in which MST had previously been carried out.[53] There was also suggestion of recruitment of other areas and this would be supported by the prospective study of functional motor recovery following MST.[54]

Similarly the results with respect seizure outcome are also supportive of the hypothesis of the critical area required for seizure propagation and support the animal data. Nonetheless the increasing understanding of the aberrant physiological circuits present in certain pathologies such as focal dysplasias[55,56] and the very rapid spread of seizures, suggest that the physiology of this pathology is significantly different from normal cortex and therefore the underlying thesis may not apply.[57]

Is there a place for MST in addition to resection?

In certain pathologies the outcomes for anatomical resection are excellent and therefore determining the added efficacy of MST is extremely difficult. Morrell himself suggested that in dominant temporal lobe resections improved outcome could be achieved by combining MST with resection.[15] This approach may be justified when there is a structural lesion rather than mesial temporal sclerosis due to the possibility of incomplete lesional resection or more widespread pathology. Examination of the pathological specimens from 'en bloc' temporal resections from the Maudsley group revealed concomitant 'dual pathology' in the form of mesial temporal sclerosis in 33% and evidence of dysplasia in 25%; although outcome did not appear to be dependent upon extent of resection.[58]

MST as a procedure was conceived in the era prior to the consistent MRI detection of mesial temporal pathology and in view of the excellent results of a Spencer type procedure this approach does not seem to be justified, unless its addition might result in broadening the numbers of patients suitable for surgery.

Why has MST not been more widely applied?

MST was conceived in an era of epilepsy surgery when many structural lesions causing epilepsy could not be identified. In addition much weight was placed on pre- and intra-operative electrophysiological studies, with a great deal of experience of the latter being available. In the MRI era, targeted resections of pathology causing epilepsy is now both feasible and followed with excellent results. In addition, whilst the major epilepsy centers continue to have experience of intraoperative electrocorticography, the field of epilepsy surgery and the numbers of centers performing it have increased dramatically. The emphasis on neurophysiology in many centers has reduced and the availability of intraoperative electrocorticography is not widespread. The debate over the 'structural' or 'functional' approach to the investigation and management of epilepsy has, at times, been a heated one[59] but there is little doubt that the increasing impact of structural imaging has broadened the scope and availability of epilepsy surgery considerably. It is likely that MST will remain a procedure for complex epilepsy centers and indeed experience should be concentrated in major centers so that the appropriate studies can be performed.

Can a multi-center study of the efficacy of MST be carried out?

On review of the data on MST there is a lamentable lack of consistent data that can be compared in an objective way. This is because of the combination of MST with resections and disconnections, the varied pathologies treated, an inconsistent approach to reporting outcome and the lack of any quality of life data. The only way in which a multi-centre trial will be effective is if a distinct entity, such as pure Landau–Kleffner syndrome, is looked at and if MST is assessed on its own merits in the absence of resection or disconnection. The ILAE subcommission for pediatric epilepsy surgery in its Appendix 1 has indicated that MST is the surgical treatment of choice for Landau–Kleffner but the evidence to support this appears confused.[42] The commissions' main document stresses the importance of a careful pre- and post- operative assessment of all pediatric cases so that outcome data can be standardized. However, even in major centers such cases as are suitable for MST are rare and the accumulation of cases may simply be an impossible task.

Does MST have a future?

The introduction of any new surgical procedure is usually followed by a period of increased usage and then a decline, when the indications, outcome and complications become clearer. Due to its very limited clinical application the period of accrual for MST has taken longer than most and the surge of interest in surgery for epilepsy based on anatomical imaging has done nothing to help its cause. The excellent results of focal resection without additional MST make its role in focal pathology very limited. In true MRI negative cases when the epileptogenic focus appears well localized to eloquent cortex and the deficit offered by resection is unacceptable, then MST clearly does still have a role.

A recent paper from Japan has put forward a new innovative role for MST in the management of seizures of hippocampal origin.[60] Twenty-one patients underwent a minimally invasive procedure in which access was obtained into the temporal horn through the temporal stem and then transections carried out in the hippocampal formation, using a modified ring-type transector. The objective of this approach was to reduce neuropsychological deficits in patients who were highly functioning. Seizure outcome was reported in 17 cases with 82% seizure free at one year, comparable with resective techniques. Neuropsychological data

Figure 122a.9

was only available in eight patients and only in one of these was there evidence of deficit in post-operative testing which resolved at six month follow up. It is not clear whether all of these cases were in the dominant hemisphere (12 of the total series had dominant temporal resections) but in any event the neuropsychological outcome is encouraging and further results in term of seizure outcome and neuropsychology are now needed to see if this technique has a role in the surgical armamentarium.

The description of this final innovative surgical application for MST brings us full circle to Prof. Morrell once more. Much of his laboratory and clinical research was directed to the concepts of secondary epileptogenesis in man and the possibility of mirror foci.[61] The intriguing possibility now arises for bilateral temporal surgery to be possible, for if bilateral mesial temporal foci can be targeted without neuropsychological deficit, then a whole group of patients will potentially become suitable surgical candidates.

Summary

Multiple subpial transection is a technique whose role has yet to be clarified. The surgical series reported present a confused picture due to the widely disparate subjects, pathologies and methods of reporting outcome. There is evidence that it does cure seizures in some cases and give good palliation in others. Without careful multi-center trials it will be difficult in the future to establish clearly its clinical indications. It remains an inspired piece of translational science and is likely to remain in the armamentarium of the epilepsy surgeon for the foreseeable future.

122b Nonresective surgical procedures and electrical or magnetic stimulation for epilepsy treatment mutiple hippocampal transection

H Shmizu

Introduction

Temporal lobe epilepsy is known to be one of the most drug resistant epilepsy in adulthood. However, surgical treatment of temporal lobectomy is very effective in seizure control with around 70% success rate.[1] Temporal lobectomy was established in the 1950s[2–4] and has been widely applied to intractable temporal lobe epilepsy. In spite of good seizure outcome, postoperative memory impairment has been a long-standing unresolved problem.[5–7] If the epileptic focus exists in the left medial temporal area and the preoperative MRI demonstrates no atrophy of the hippocampus, resection of the hippocampus brings about worsening of verbal memory in most cases.[8] This ominous complication cannot be avoided even if the most selective resection of the medial structures, selective amygdalohippocampectomy, is employed.[9]

To cope with this complication, we applied the principle of multiple subpial transection (MST)[10] to the hippocampus. The neuronal structure of the hippocampus is significantly different from that of the cerebral cortex.[11] However, the rationale of MST, disrupting the horizontal interneuronal connections and preserving vertical connection fibers, can be also applicable to the pyramidal layer of the hippocampus.

We applied this new method, multiple hippocampal transection, to patients with intractable temporal lobe epilepsy without hippocampal atrophy on preoperative MRI. We have so far obtained excellent surgical results with regard to preservation of verbal memory and control of seizures.[12]

Rationale for this method

Multiple subpial transection is an established surgical method to surgically treat eloquent areas, particularly as the motor or speech area, with preservation of cortical functions. The basic concept of MST is to interrupt interneuronal connections, most important for genesis of epileptic discharges, and to preserve vertical projecting fibers, critical connections for cortical functions. We hypothesized that if the pyramidal layer of the hippocampus can be treated in the same way as in MST, epileptogenic discharges from the hippocampus might be eliminated.

For this purpose, an adequate access route to the hippocampus without disrupting the memory circuit must be found. There are two neuronal pathways important for the hippocampus: the polysynaptic intrahippocampal pathway and the direct intrahippocampal pathway. The latter is the most important connection for verbal memory in humans.[11] The input fibers of the direct hippocampal pathway mainly originate from the inferior temporal association cortex (area 37) and reach the entorhinal cortex through the perirhinal cortex. Therefore, access routes to the hippocampus through the temporal basal area will disrupt this pathway.

Experimental data from monkeys, using a behavioral test known to most relevantly represent human amnesia, indicated that bilateral section of the temporal stem does not impair the memory function.[13] Based on this experimental data, we developed the following surgical route to the hippocampus, which can preserve the neuronal connections to memory function. A small corticotomy is placed on the superior temporal gyrus within 4.5 cm from the temporal tip and the gray matter is aspirated along the sylvian fissure to reach the temporal stem. As the temporal stem constitutes the roof of the inferior ventricle, the hippocampus can be easily accessed by sectioning the temporal stem (Figure 122b.1).

Although the temporal stem can be also accessed by directly dissecting the sylvian fissure and aspirating the lower part of the superior temporal gyrus as employed in selective amygdalohippocampectomy, the visual field thus obtained is too narrow and too deep to perform very subtle manipulation of hippocampus transection.

As the pyramidal cell layer of the hippocampus is within 2 mm from the surface, we devised a ring transector 2 mm in diameter. To transect the CA4 and the dentate gyrus, deeper transection is necessary. As the pyramidal cell layer descends into the subiculum at the lateral corner of the hippocampus, deep transection is also necessary to transect this CA1 area (Figure 122b.2). Based on these anatomical relations, a ring

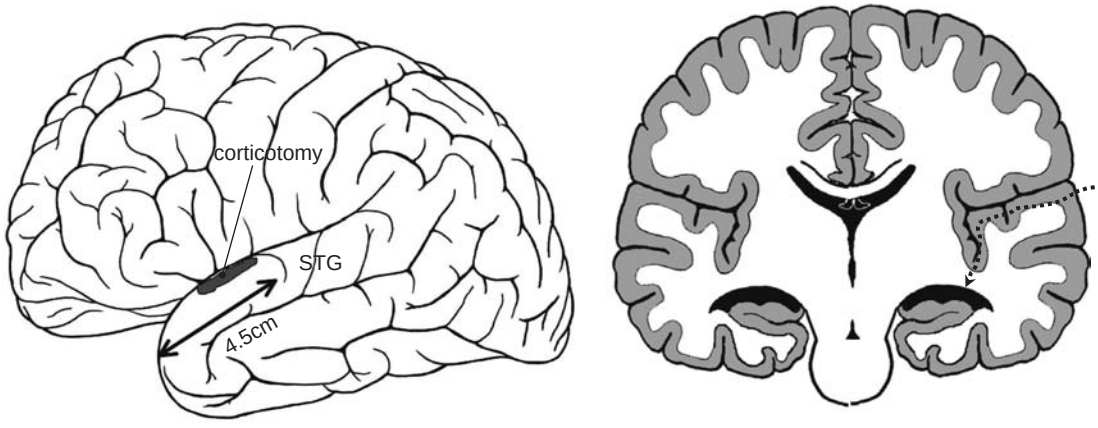

Figure 122b.1

transector 4mm in diameter is designed for transection of the bilateral corners of the hippocampus. At the posterior part of the hippocampus, the transverse diameter becomes smaller, so an oval-shaped transector with 4×2mm diameter is applied to transect the lateral corners without intruding the mid portion of the hippocampus (Figure 122b.3).

Surgical procedure

Under general anesthesia, the patient is placed supine on the operating table with the head tilted almost horizontal to the opposite side. Skin incision and the extent of craniotomy are the same as for ordinary anterior temporal lobectomy. The bone window is widened as much as possible to expose the temporal pole and basal areas. After dural incision, around 2 cm corticotomy is placed on the superior temporal gyrus along the superior sylvian veins. The posterior end of the corticotomy is confined within 4.5 cm from the temporal tip to prevent postoperative speech disturbance. If moderate size arteries cross the corticotomy line, the arachnoid membrane around the arteries and their small branches are dissected or severed and the main arteries are translocated out of the corticotomy area to keep normal cerebral circulation of the left temporal pole.

It is very important to precisely open the inferior ventricle without injuring the hippocampal surface. The optimal point of the ventricular opening is the medial posterior portion of the ventricle, just above the choroid plexus around the hippocampal body. For this purpose, the operating table is adjusted as the patient's head is up and rotated to the opposite side. The ideal trajectory of the temporal stem suction is directed at 45° inward from the center of middle fossa (Figure 122b.4).

Three types of electrodes (Figure 122b.5) are applied to the amygdala, the hippocampal head and the posterior part of the hippocampus to record electrocorticography (ECoG) over these areas and determine the extent of surgical procedure. If the amygdala does not show any independent epileptic discharges, only its surface is pared off to obtain am ample space for manipulating the hippocampal head. If ECoG otherwise documented active independent epileptic discharges from the amygdala, it is resected in the same way as in anterior temporal lobectomy. Generally, the hippocampus shows very active spike discharges. They are sometimes confined to the head or observed throughout over the entire hippocampus (Figure 122b.6).

Based on ECoG data, the extent of hippocampal transection is determined. The alveus, white fiber bundle covering the hippocampal surface, is extremely tough and should be incised with microscissors for inserting a ring transector. The incisions lines are designed 5mm apart as in MST and parallel to the hippocampal digitation marks at the hippocampal head (Figure 122b.7). If vessels (usually small veins) cross the incision lines, they are electrically coagulated with bipolar forceps.

To transect the pyramidal cell layer, which is within 2mm from the surface, a ring transector 2mm in diameter is inserted through the incision lines of the alveus. At both lateral ends of the hippocampus, a larger ring transector 4mm in diameter is employed to completely transect the end folium at the medial portion and the CA1 pyramidal cell layer descending to the subiculum at the lateral border. In the posterior part of the hippocampus, the transverse diameter is smaller and a 4 × 2 mm oval-shaped ring transector is used for transection of the bilateral corners.

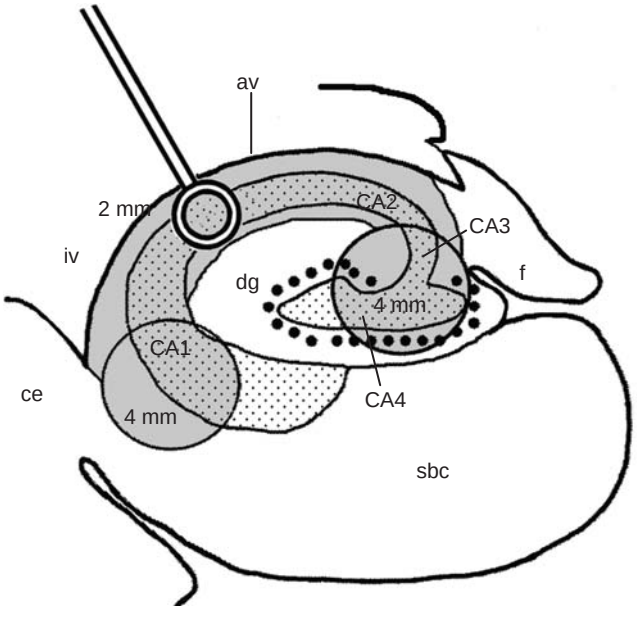

Figure 122b.2

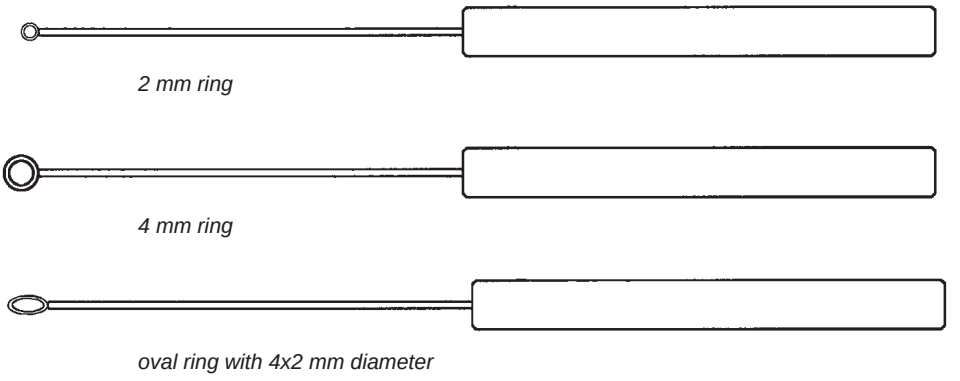

Figure 122b.3

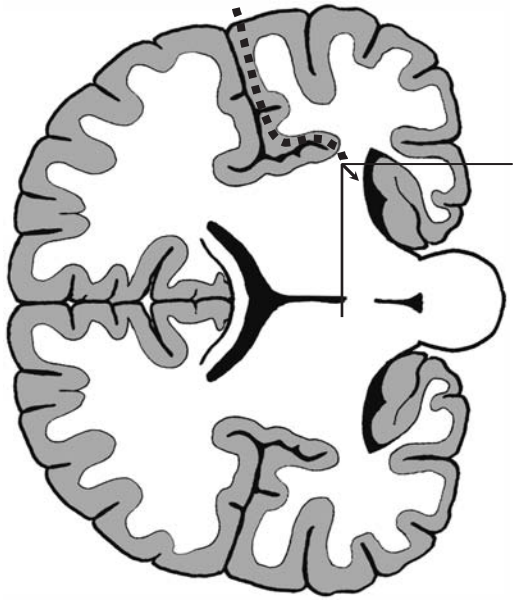

Figure 122b.4

Once hippocampal transection is accomplished, ECoG is repeated over the entire hippocampus. This time, an amygdala electrode is also placed over the hippocampal head and residual spikes are carefully examined. Generally, active epileptic discharges from the hippocampus beautifully disappear as far as transection covers entire epileptic areas (Figure 122b.8). If residual spikes are detected in an untreated posterior part, transection is extended posteriorly. When spikes do not disappear over transected areas, each transection line is carefully examined to check whether they cover the full length of the hippocampal surface. If all of the transection lines are complete and yet synchronized small spikes or sharp waves are still observed over a wide area of the hippocampus, spread of epileptic discharges from the basal temporal area or the temporal cortical surface should be suspected.

After completion of the hippocampal transection, ECoG is further recorded over the basal and superficial temporal surface. When epileptic discharges are detected in the anterior basal area, this area can be approached through the anterior end of the opened inferior ventricle and resected without damaging the surface temporal area. The epileptic discharges in the posterior basal area and the superficial temporal surface area are generally treated by MST without compromising brain functions. With combining hippocampal transection and MST, all epileptic discharges in the temporal lobe are surgically treatable with preservation of brain functions.

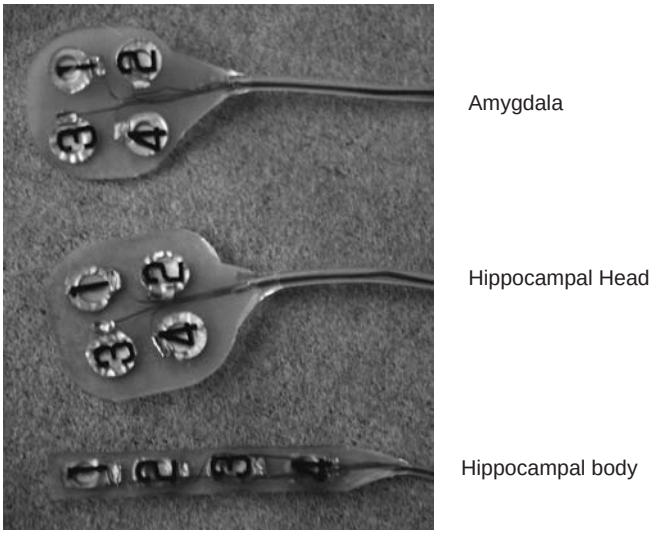

Figure 122b.5

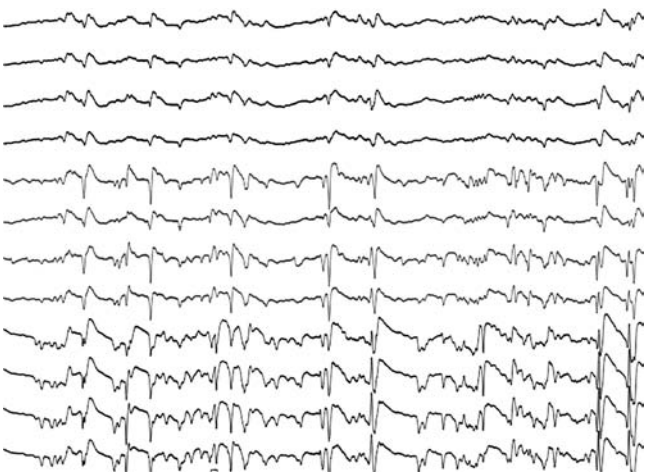

Figure 122b.6

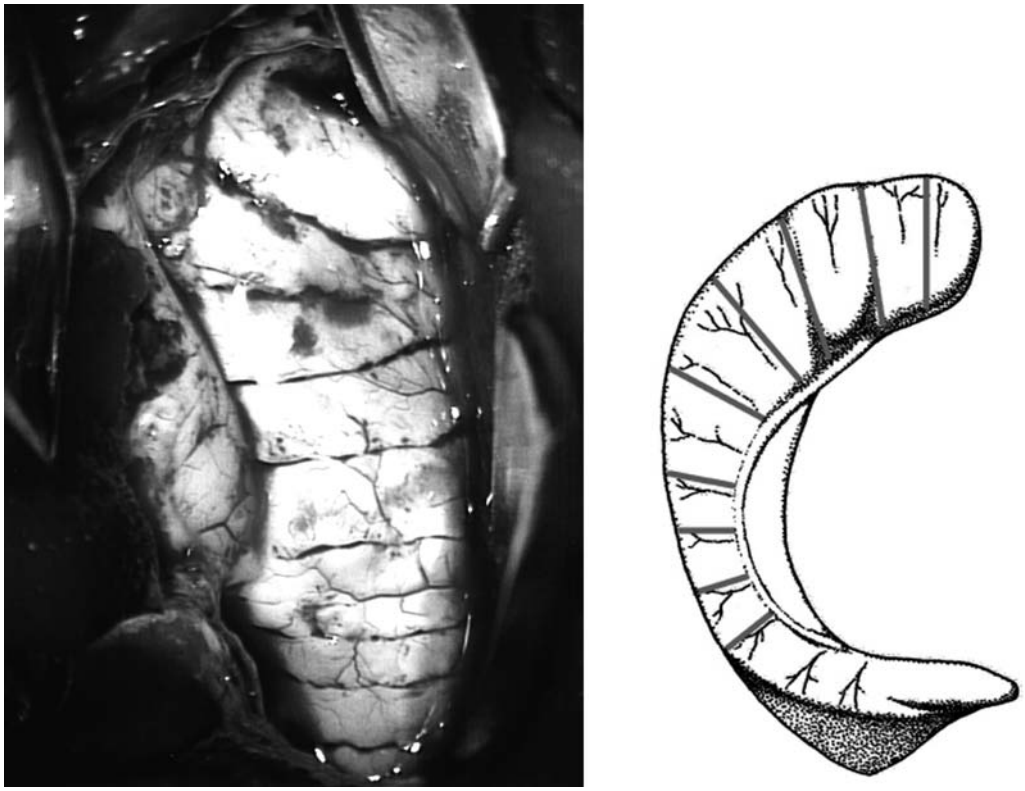

Figure 122b.7

Surgical outcome

Between January 2001 and March 2006, 35 cases of intractable temporal lobe epilepsy without hippocampal atrophy on preoperative MRI and unilaterally diagnosed focus were operated on by hippocampal transection. They consisted of 20 males and 15 females, ranging in age from 2.9 to 48 years with a mean age of 27 years. Left side hippocampal transection was performed in 22 cases and right side in 23 cases.

Postoperative MRI demonstrated the access route from the superior temporal gyrus to the inferior ventricle. However, transected hippocampus did not show any deformity or transected lines when studied six months after surgery (Figure 122b.9).

As evaluation of pre- and postoperative verbal memory, auditory verbal learning test (AVLT)[14] was performed immediately (3–4 weeks) and 6 months after surgery. Seizure outcome was evaluated only in cases with more than one year follow-up.

Verbal memory

In 13 eligible cases undergoing left hippocampal transection, AVLT was performed for evaluation of verbal memory function. If immediate postoperative test demonstrated decline of AVLT score, the test was repeated 6 months after surgery. In all of the cases except one, the scores of AVLT did not become worse at the point of 6 months after surgery

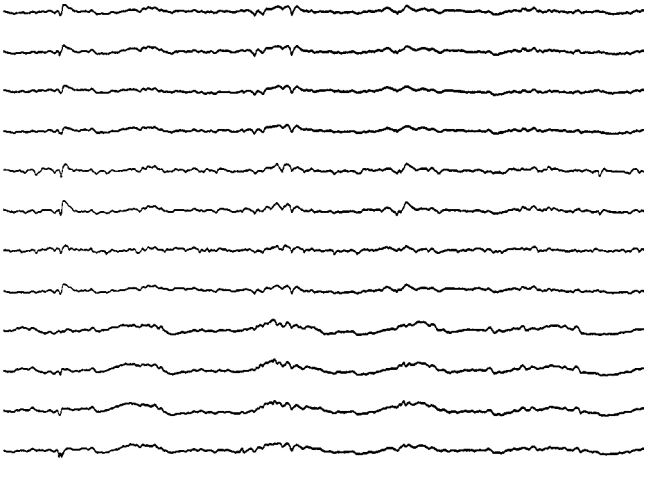

Figure 122b.8

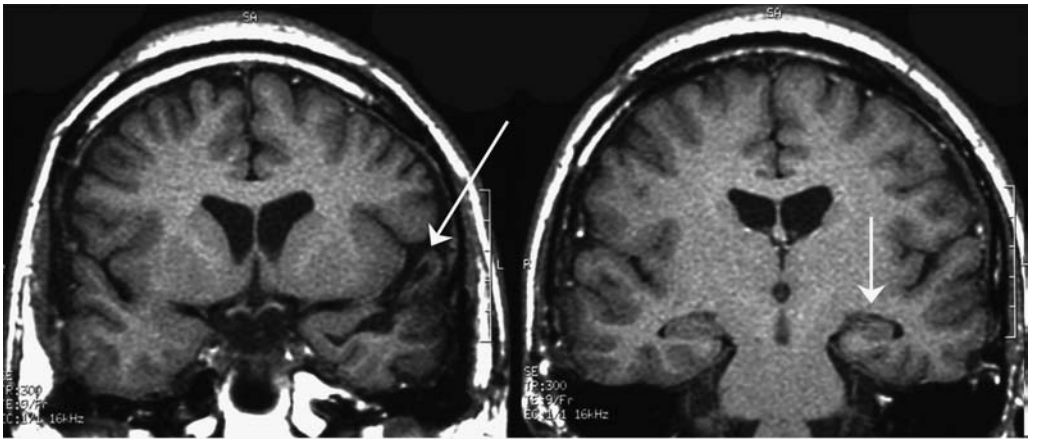

Figure 122b.9

(Figure 122b.10). In one case, the AVLT score worsened after surgery and did not improve even after 6 months follow-up. However, this 33-year-old male did not complain of amnestic symptoms and returned to the preoperative workplace.

Seizure outcome

Seizure outcome was extremely good. In 23 cases with more than 1-year follow-up, 28 cases are seizure free (Engle class IA) and four have rare seizures (Figure 122b.11). In one cases, preoperative seizures have dramatically reduced in frequency and severity, but still has several seizures per month.

Bilateral temporal lobe epilepsy

If the left hippocampus can be surgically treated without postoperative neurological complications, the possibility of surgical treatment of bilateral temporal lobe epilepsy will arise. This possibility is a sea change when we remember the tragic result of H.M., who underwent resection of bilateral mesial temporal structures and suffered an almost compete loss of anterograde memory functions.[15,16]

However, bilateral cases have proved not as simple in distribution of epileptic foci as unilateral ones. Even when transection of bilateral hippocampi was successfully performed in two stages, hidden epileptic foci appeared and caused new types of seizures. These complex patterns of focus distribution were particularly prominent in epilepsy caused by late-onset encephalitis.

We have so far performed bilateral hippocampal transection in ten cases and followed them up for more than 1 year. Good surgical outcome was obtained only in four cases (one: free, three: rare), and the remaining six patients showed poor results. In one case with bilateral hippocampal atrophy, postoperative memory deficit was very severe (after left hippocampal transection) and has not recovered even 3 years after surgery.

Based on the above experience, we now restrict application of hippocampal transection only to unilateral temporal lobe epilepsy. However, taking account of many disabled patients with bilateral temporal lobe foci, future effort is strongly demanded to solve this long-standing problem.

Abstract:

Temporal lobe epilepsy (TLE) is the most common form of medically intractable partial epilepsy in adults, and surgery (temporal lobectomy or amygdalo-hippocampectomy) is effective in the majority of patients. In extratemporal lobe epilepsy (mainly frontal and multi lobar epilepsy) these results are less favourable but are highly depending on the presurgical evaluation and the possibility to delineate the epileptogenic zone (EZ). However, in the majority of cases, the surgical option usually applied is the removal of the epileptic tissue We report here the method, preliminary results and safety of a new procedure for non lesional TLE and extratemporal lobe epilepsy which consists in disconnecting the EZ without removing it.

Between 1998 and 2004, 62 patients suffering from temporal or extratemporal lobe epilepsy have been treated by surgical disconnection of the epileptogenic zone. 45 TLE patients (35±10 years mean, duration 24±10 years, 16 males and 29 females, handedness 12 left and 33 right) have undergone temporal disconnection (20 left, 25 right) and 17 patients underwent extratemporal disconnection (one frontal, one occipital, seven temporal lobectomy + extratemporal disconnection, and eight multilobar disconnection). Among the patients suffering from TLE, 16 patients (35%) underwent additional presurgical evaluation with depth electrodes (SEEG). while this number reached up to 100% of cases in extratemporal lobe epilepsy cases After the surgical disconnection, all patients underwent a postoperative MRI, neuropsychological testing, and repeated scalp EEG and visual field examination. Postoperative outcome was assessed using Engel's classification. Temporal disconnection was performed under neuronavigation and consisted in disconnecting the lateral temporal neocortex, the whole hippocampus, parahippocampus and the amygdala from the rest of the brain in cases of TLE. Veins and arteries were spared in order to avoid postoperative temporal lobe ischemia and subsequent temporal lobe swelling.

Results in temporal disconnections, 38 patients out of 45 (84.4%) were seizure free (Engel's I) at 2-years follow-up, among which 26 were class Ia (58%). Four patients were class II and three class IV. Postoperative clinical morbidity was as follows: persistent mild hemiparesia (n=1), persistent mild facial paresia ($n=1$), definitive quadranopia (n=23), hemianopia ($n=1$). When the dominant temporal lobe was disconnected, verbal memory was worsened in about 69%.

In extratemporal lobe epilepsy, 75% of patients who received a multilobar disconnection and 85% of of patients who received a temporal lobectomy associated with an extratemporal disconnection were Engel's class 1. One patient who was operated for a frontal epilepsy was Engel's class 2.

Radiological postoperative morbidity was as follows: two patients exhibited asymptomatic thalamic or pallidal limited ischemia, two patients exhibited temporal horn cystic dilatation among which one requested surgical reoperation without clinical consequences. General morbidity was represented by a single case of postoperative phlebitis.

For TLE, scalp EEG performed at 6 months post-op showed temporal spikes in 27% of patients with postoperative seizures compared to 8.5% of patients seizure free. At 1-year follow-up, scalp-EEG showed temporal spikes respectively in 19 and 6% of patients.

In the multilobar disconnected group, 75 % of patients were Engel's class 1.

In conclusion, this technique, in experienced hands, appears to be as effective and safe as cortectomy or lobectomy. The main advantage is that disconnection prevents brain shift and subsequent subdural collections, shortens the duration of the surgery and allows a smaller craniotomy. On the other hand, disconnections do not allow complete histological examination of the epileptogenic tissue but provide only samples. Studies in the future will have to assess the prognosis value of interictal spikes seen on postoperative EEG in order to help predicting seizure outcome during the following period.

Introduction

Resective surgery such as lobectomy, or amygdalo-hippocampectomy, is the major surgical option for intractable pharmacoresistent epilepsy. The global outcome reaches nearly 90% of Engel Class I in temporal lobectomy, 1–3 except when foci are multiple, located remotely from the temporal lobe and bilateral. They however have complications, as they create a large empty volume, which can induce bleeding, brain shifts, and subdural collections (Figure 122c.1). The purpose of this work is to provide an alternative approach by disconnecting the epileptic zone, without removing the brain tissue. Advantages are simpler surgery, reduced operating time, and reduced complications (brain shift and subdural collections).

The rationale of this approach was based on the following considerations:

- Disconnection procedures are effective in children treated by hemispherotomy 4–7 and in cases of hypothalamic hamartomas 7–9.
- Removal of the cortex is not mandatory in nonlesional TLE, when there is no potentially evolutive mass lesion, or no diffuse dysplastic cortex.
- Disconnection might minimize the risk of brain shift, especially in large temporal lobectomy, where the large parenchymal defect favors displacement of the surrounding lobes.
- Disconnection can be performed with a standardized minimally invasive craniotomy, making large craniotomy not mandatory.

Material and methods

Surgical procedure

- Under neuronavigation (Surgiscope, ISIS, Grenoble, France), in dorso-lateral decubitus, a circular craniotomy is performed using a trephine (50 mm in diameter) the center of the craniotomy being positioned at the level of the superior temporal sulcus.

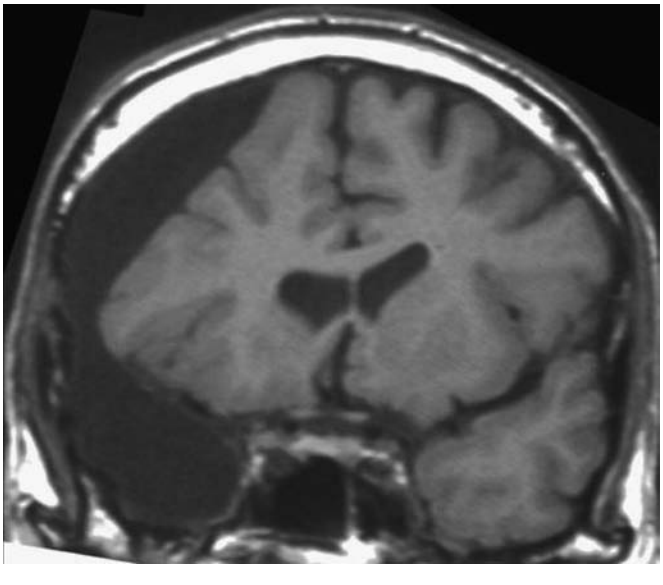

Figure 122c.1 Brain shift and extra cerebral fluid collection following large parenchymal resection.

Presurgical definition of the epileptic zone (Figure 122c.3).

It is basically similar to what is done for lobectomies, as only the technical aspects vary, the indications, basic principles, area to be removed or disconnected being the same.

Video-EEG alone without depth recordings is applied to patients in whom the clinical examination, the natural history of the patients' epilepsy as well as the specific clinical, ictal and interictal electrical features of the seizures have been extensively investigated, are all concordant and point to the same epileptogenic zone (EZ). This leads to a predefinition of the area involved, from the irritative zone where the epileptic discharge is generated to the full field of its propagations, defining the epileptic zone (EZ). Following the currently admitted principles, originating from Talairach's approach to the concepts developed by Lüders, Engel, etc, the video-EEG, associating continuous EEG recording and behavioral videotaping, provides informations on which will depend the necessity or not to be resected.

Stereoelectroencephalography (SEEG), (or subdural grids in other institutions), is performed if additional informations are needed about the precise involvement of deep structures (which is more easily provided by SEEG rather than by subdural grids), or when the presurgical evaluation based on noninvasive tools are not concordant. Similarly to what has been done during video-EEG, and according to the SEEG methodology developed by Talairach and Bancaud,[10] the correlation between the temporo-spatial organization of the discharge and the symptoms, allow to delineate the ictal onset zone and the epileptic zone according to the definition recently released by Nair and Luders[11].

In addition to the electrical and clinical analysis of the seizures, high resolution MRI is performed in all cases to detect any mass lesion, hippocampal sclerosis or dysplasia.

Neuronavigation planning of the disconnection (Figure 122c.3).

It is basically based on a volumetric 3D MRI performed with markers screwed to the skull and the images fed into the Neuronavigation software of the robotized microscope ISS Surgicope®

Using the features of the Neuronavigation software, the first step consists in reporting on MRI the synthetic scheme of the epileptic zone, taking into account the specific anatomy of the patients, following the sulci and avoiding the vessels. One may therefore draw on each adjacent slice from the surface to the depth, the contours of the disconnection.

Delineation of the limits of disconnection

One may take the decision of additional resection of the first temporal gyrus, depending on the morphology of the insula: when the angle between the sylvian valley and the insular plane is close to 90°, it is quite often difficult to dissect the superior temporal gyrus and recline it without damaging it to access to the bottom limit of the insula. Therefore, it happens to be easier to resect by suction, or using a dissectron, the upper lip of the superior temporal gyrus. On the contrary,

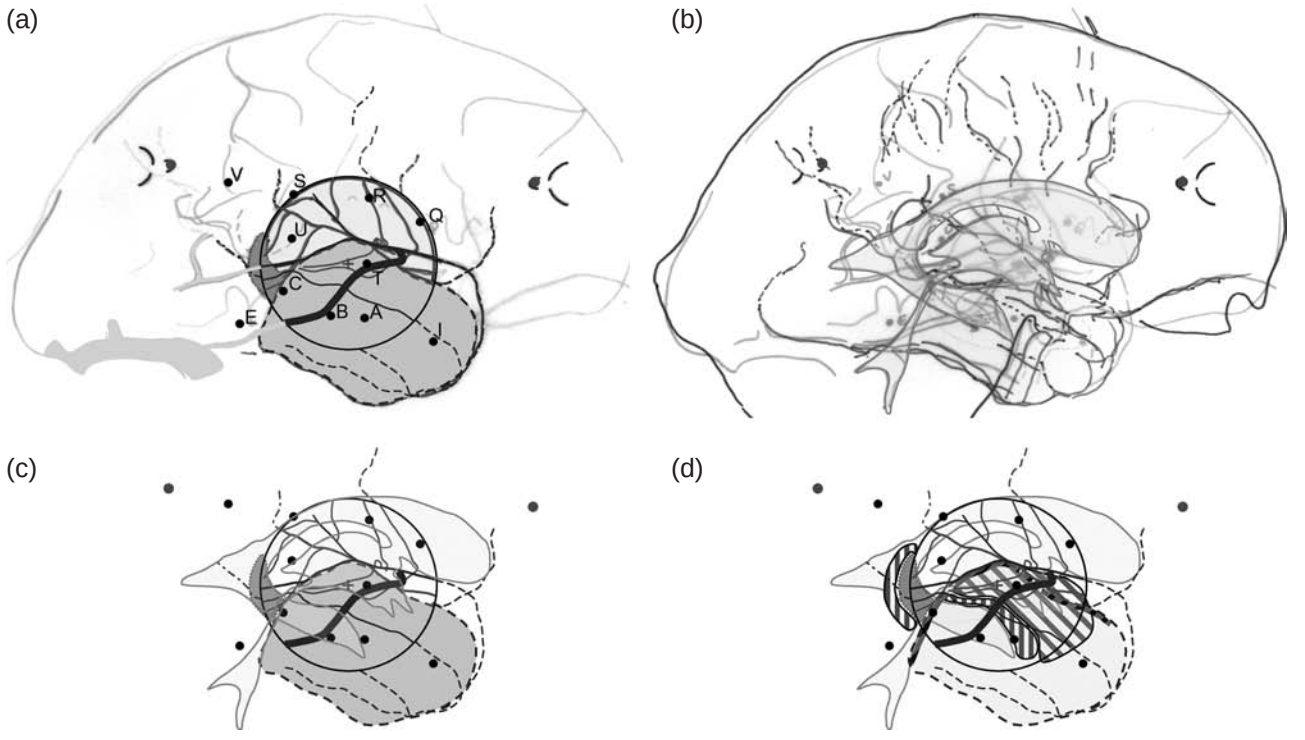

Figure 122c.2 Programming a disconnection of the right temporal lobe. a: synthetic drawing of vessels (arteries and veins), contours of the hemisphere, position of the deep recording electrodes, circular craniotomy (centre marked by the red cross), b: superimposition of the drawing of the sulci and of the ventricular system visualized by ventriculography, (yellow) c: superimposition of the ventricular system (yellow) and of the epileptogenic zone (right temporal lobe in green, tail of the hippocampus in pink), d: steps of the disconnection. Striped grey: windows of disconnection of the cortical convexity of the temporal lobe, sparing the vessels. Oblique stripes in green: subarachnoidal dissection from the sylvian valley of the mesial side of the first temporal gyrus. Vertical stripes in red: section of the white matter from the inferior boarder of the insula to the ceiling of the temporal horn, and posterior inferior disconnection by section of the white matter and cortex surrounding the tail of the hippocampus. (See Color plates.)

when this angle is around 120° or more, the sylvian valley provides a convenient approach to the ceiling of the lateral ventricle. At this stage, it is also important to recognize the particular morphology of the superior temporal gyrus, which is sometimes hidden by the middle temporal gyrus which might be overlapping the superior temporal gyrus. This is misleading, particularly when one has to start a disconnection between the gyrus T1 and T2.

The placement of the center of the trephine is crucial, in order to provide a direct view in the anterior-posterior plane of disconnection, parallel to the sylvian valley as well as in the cranio-caudal plane of the posterior temporal lobe section: most often, the trephine should be centered on the superior temporal sulcus, and not more than one centimeter ahead of the plane of the posterior section of the temporal lobe (Figure 126c.2A):

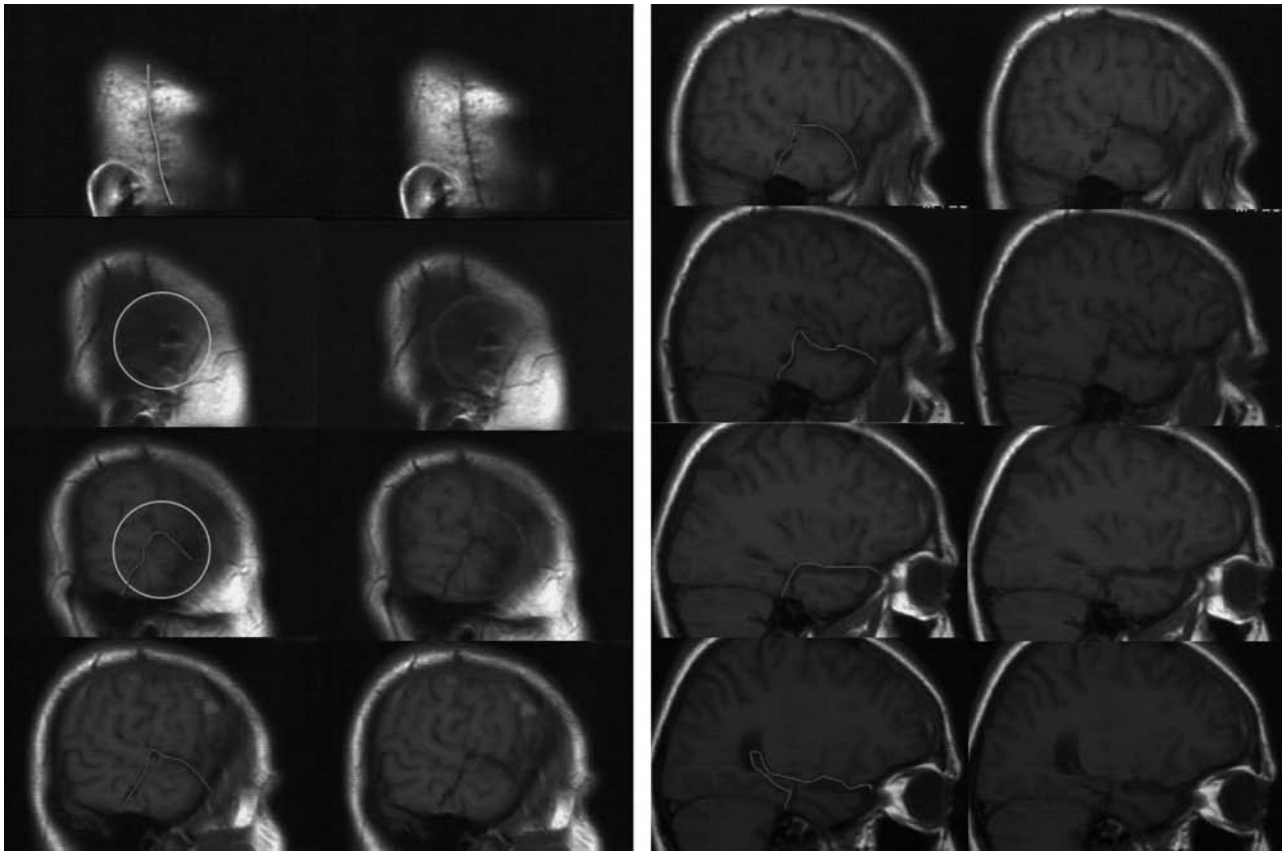
Surgical disconnection

Typical right temporal disconnection

Under general anesthesia, semi-sitting position, the head is fixed on a Mayfield clamp in lateral position. Correspondence between Neuronavigation, Surgiscope, and patient's head (fiducials) is performed, using a pointer which is observed by the camera of the tracking system. Skin incision and trephine are centred on the basis of the Neuronavigation program.

Cruciform opening of dura is performed, its diameter aligned along the superior temporal sulcus, allowing recognition in the visible area of the elements of the brain (arteries, veins, sulci) displayed on the MRI images of the planning (Figure 122c.3A).

1. After tracing on the cortex the posterior limit of the disconnection, which often corresponds to the plane of the acqueduct of Sylvius (Figures 122c.2b and 122c.2c), the temporal lobe is sectioned along this line, using spatula, coagulation and section, down to the base, then to the tentorium and up, where one opens the lateral temporal horn. The arachnoid is cut only on the convexity, while it is not necessary to cut it on the base and on the mesial side, as this provides a security layer against the vessels of the midline and the brainstem
2. Incision of the arachnoid along the sylvian valley is performed carefully, sparing all vessels (veins and arteries), to preserve the vascularization of the temporal lobe which will be left in place and also the vascularization of the basal temporo-occipital cortex which receives branches of the mid-cerebral artery, most often the medial temporal artery (Figure 122c.2D).



(a) (b)

Figure 122c.3 MRI control of a temporal lobe disconnection. The different planes of imaging from the skin to the depth are presented with the MRI images on the left-hand side of each column and on the right-hand side the drawing in green of the craniotomy and in red outline the parenchymal section. Column a: from the skin incision to the convexity cortical section. Column b: parenchymal section from the subcortical planes to the disconnection of the hippocampal formation into the ventricle. (See Color plates.)

3. Using a spatula and a small smooth curette, the superior gyrus is peeled subarachnoidally, and reflected downward, almost perpendicularly, until the plane of the insula. This provides the visibility, through the arachnoid which protects them, of the insular elements, (arterial branches of the mid cerebral artery and veins, and the insula itself, until the reflection of the cortex at the bottom line of the insula), from the posterior section to the anterior part of the insula (Figure 122c.3b). One sees there that the inner surface of the superior temporal gyrus turns, along with the middle cerebral artery, around the fronto-temporal stem, which has to be carefully identified and separated from the frontal lobe (to which it is often adherent) until the pericarotid cistern, where a cotton might be inserted to mark the place, is reached.
4. Back to the posterior section of the temporal lobe, in the lateral ventricle, a cotton is inserted along the sphenoidal horn in the anterior direction, to protect the choroid plexus which is reclined upward, therefore protecting the anterior choroidal artery and its upper anatomical neighbour, the optical tract. The white matter of the insulo-temporal stem, along the inferior limit of the insula, is severed from back to anterior (one must take care to see permanently the ventricular cavity in order not to go medially and above the ventricular horn, where one could end up in the base of the putamen), until the anterior recess of the horn, where the choroid plexus emerges, along with the anterior choroid artery from the arachnoidal veil which separates the ventricle from the Bichat fissure, where the choroidal vein goes.
5. Dissociation of this arachnoidal veil gives access to the pericarotid cistern, where the cotton previously inserted into the cistern from the sylvian dissection is seen. This makes it easy to section the fronto-temporal white matter stem which has been fully circumscribed, and which is, at this moment, the only remaining anterior connection of the temporal lobe. The amygdalo-hippocampic formation has been therefore disconnected from its anterior connections. As this formation has no mesial connections with the extratemporal brain, (the Bichat fissure is obliterated only by an arachnoidal veil which does not need to be severed), its only remaining connection is posterior at the level of the tail of the hippocampus.
6. Going back to the posterior section of the temporal lobe and into the ventricular cavity, using the spatula, the white matter of the temporo-occipital junction is severed along the hippocampal formation, until the spatula touches the arachnoid and, through it, the dura of the tentorium. This section is prolonged backward, following the volume of the hippocampus tail, which turns around the posterior

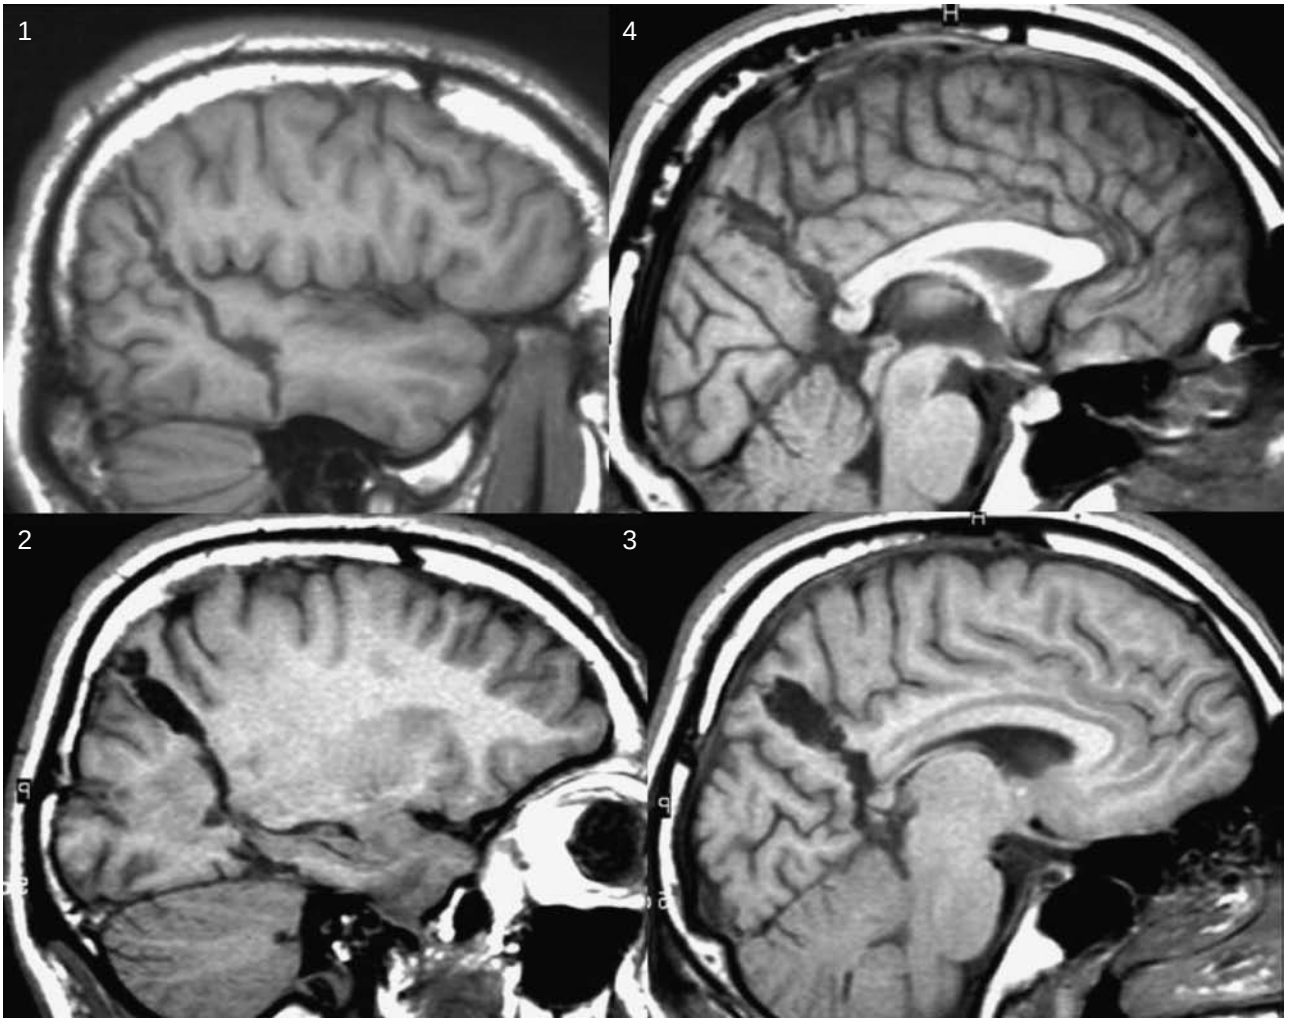


Figure 122c.4 MRI control of an occipito-temporal disconnection. The plane of disconnection is visible from the cortical surface to the mesial face of the hemisphere. In the MRI slices 2 and 3, suction associated to spatula section has created a larger gap in the separation between the disconnected temporo-occipital part from the rest of the brain. The ablation of the disconnected part would have created a large cavity, and possibly a brain shift.

pole of the thalamus, by direct viewing into the ventricular cavity. The posterior part of the Bichat fissure is dissected by sectioning the arachnoidal veil up to the level of the white matter disconnection. At this level, the tail of the hippocampus is sectioned, carefully preserving the vascular lamina which runs in the thin intrahippocampal sulcus. Sometimes, removal of the posterior part of the hippocampus can be also performed as it can be easier and offers the possibility for histological examination to confirm hippocampal sclerosis, which is known to be of good prognosis. (Figure 122c.2D).

Care must be taken not to confound the volume of the hippocampus with the volume of the anterior part of the calcarine formation, which would lead to an hemianopic deficit, less tolerated than the upper lateral homonymous quadranopia which is almost always created by the interruption of the Meyer geniculo-calcarine fibers at the level of the posterior section of the temporal lobe.

When this is achieved, the temporal lobe has no more neural connections with the rest of the hemisphere: the amygdalo-hippocampic formation has been separated from its frontobasal connections at the level of the fronto-temporal stem, and from its posterior limbic connections at the level of its tail, behind the thalamus. The temporal neocortex has been severed from the insula all along the roof of the temporal horn, form the anterior fronto temporal stem, to join the vertical posterior section which disconnects the temporal lobe from all its projections to the parieto-occipital area.

Specific variations

Sparing of the superior temporal gyrus can be indicated when the recording has not proven any electrical involvement of the structure. Therefore, instead of making the incision of the arachnoid along the sylvian valley, one makes it along the superior temporal gyrus, on the upper border of the second temporal gyrus. This makes easier the undercutting of the white matter at the depth of the T1-T2 sulcus (as it is practically in front of the temporal horn), which can be made without significant tissue resection.

On the left side, however, usually the dominant side for language, the superior temporal gyrus has to be spared in its

two posterior thirds. The anterior limit is marked usually by crossing of the anterior temporal artery, which is also at the level of the junction with the sylvian valley of the precentral gyrus on the MRI.

Besides this temporal disconnection and its variations, disconnection can be used also, in different various areas such as the frontal lobe or the occipital lobe, where the duration of the surgery is strongly reduced, as the transhemispherical section, once the midline has been reached, is sufficient and one does not need to ablate the tissue represented by those disconnected lobes.

Different examples are given in Figures 122c.3 (temporal disconnections) and 122c.4 (extratemporal disconnections).

Patients' population

Patient's selection

Indications are the same as for lobectomies: limited epileptic zone, no involvement of functional (motor, sensitive, or visual) cortical areas, absence of potentially evolutive lesion (cavernomas, gangliogliomas, dysplasia? and DNEs), pharmaco resistance, no surgical contraindications.

Fourty-five patients were operated for TLE (16 males, 29 females, mean age 35 ± 10 years, 4 children aged 3–10 years). The mean duration of epilepsy was 24 ± 10 years, 12 patients were left-handed. The TLE involved 20 left and 25 temporal lobes

Pre-op MRI confirmed that the TLE was nonlesional (no mass lesion), hippocampal sclerosis was observed in 83% of the cases, and anterior temporal abnormalities in 37% of the cases

Presurgical evaluation involved in all cases video-EEG, neuropsychological testing, and high-resolution MRI. PET scan was performed in 13 patients, SPECT in 17 patients, and depth recording (SEEG) in 16 cases.

Postoperative follow up (mean follow up is 3 years) comprised in all cases postoperative MRI at 3 and 12 months, postoperative EEG at 3, 6, 12, and 24 months. The postoperative outcome was rated according to Engel's classification.

Seventeen patients were operated for extratemporal epilepsies (six females, 11 males, mean age 27 ± 10, two children, aged 8–16 years old). Two patients out of 17 were left-handed, and one had bilateral representation of language. One patient suffered from frontal lobe epilepsy, one from occipital epilepsy and 15 from multilobar epilepsy (either fronto-temporal or temporo-occipital).

Among these patients, one had a frontal disconnection, one had occipital disconnection, eight had multilobar disconnection and seven had a temporal lobectomy associated with a frontal or parietal disconnection.

Results

Seizure suppression

In the 45 TLE

Thirty-eight patients out of 45 (84.4%) were seizure free (Engel's I), among which 26 were Ia (58%). Four patients were class II and 3 class IV.

Among the seven non-cured patients, one case was related to an incomplete hippocampal disconnection, as seen in the post-op MRI scan, one patient suffered from insular seizure documented by a second SEEG, three patients had late recurrences of seizure (3 years after) for unknown reasons, and two patients had a running up phenomenon related to withdrawal of AED

In the 17 extratemporal epilepsies

In the multilobar disconnected group, 75% of patients were Engel's class 1. The patients operated on the occipital lobe were Engel's class 1 and the one operated on frontal lobe was Engel's class 2. Among the patients which were treated by a disconnection + lobectomy, 86% of them were Engel's class 1.

MRI evolution

In the 45 TLE

There were two temporal horn cysts (one required reintervention), two asymptomatic thalamic or pallidal small ischemia, one incomplete disconnection (posterior hippocampal disconnection), no temporal swelling, and no brain shift.

In the 17 extra temporal lobe epilepsy

In the unique frontal disconnection case, the cortex was atrophic at the 1-year post-op MRI and among the patients operated with multilobar disconnection, the post-op MRI showed an asymptomatic frontal ischemia located in the frontal disconnected tissue in one case and in another case, a severe controlateral ischemia of the perisylvian cortex due to a carotide dissection.

EEG evolution

In the 45 TLE

Of post operative EEG, 70% were available at 2-years post-op. At 3 months post-op, about 75% of patients presented with interictal EEG abnormalities. In the group of patients seizure free after surgery, only one-third of patients did not have any electrical interictal abnormalities. Interestingly, 60% of patients who are not seizure free after surgery had diffuse interictal abnormalities, located outside the temporal region compared to 20% of patients who were seizure free and in whom interictal spikes could be recorded outside the temporal region. The presence of interictal electrical abnormalities outside the temporal region seems to be of bad prognosis when recorded 1 or 2 years after surgery. A patient, seizure free at 2-years follow-up after a left temporal disconnection, exhibited anterior fronto-temporal focal spikes, and electrical, asymptomatic seizures within the disconnected temporal cortex.

Postoperative interictal activity was observed 2 years after surgery in a non-cured patient with left temporal epilepsy, with interictal and independent diffused spikes overlapping in the posterior temporal region (T5 –O1).

In the 17 extratemporal epilepsies: all the patients exhibited interictal electrical abnormalities (mainly spikes and slow waves) usually recorded on scalp-EEG electrodes located in front of the disconnected tissue and this was seen in cured or

non-cured patients. But usually, interictal EEG abnormality were more diffusely distributed in non-cured patients.

Complications

In the 45 TLE

Clinical morbidity affected 3 patients (6%): one persistant mild controlateral hemiparesia (2%), one persistant mild controlateral facial paresia (2%), one persistant hemianopia (2%), and one phlebitis (2%).

Memory deficit in the dominant lobe was observed in 7/20 patients (35%) who had a left temporal disconnection: 6/20 (30%) had a verbal memory worsening, 4/20 (20%) had a visual memory worsening, 4/20 (20%) had a working memory worsening. Lateral superior quadrantanopia was observed in 23 patients (51.1%).

In the 17 extra-temporal epilepsies

One patient had a severe contralateral sylvian ischemia due to a spontaneous dissection of the contralateral carotid at the cervical level, which may be related to the operative position. Postoperative MRI as well as Doppler angiography did not show any parenchymal lesion and the outcome at 2 years after surgery did not present any sequelae.

The other postoperative complications were as following: one transient facial paresia (frontal lobe epilepsy), two transient mild hemiparesia, one permanent quadranopia, one permanent hemianopia (temporo occipital epilepsy) and one double vision. One patient had a postoperative distal sciatic palsy due to a misposition during surgery.

Discussion

Disconnections are used for perisylvian hemispherectomies, and hamartomas of the third ventricle, as surgical procedures meant to minimize the duration of the surgery, and to avoid the ablation of the deafferented parenchyma, as the absence of remnant connections between the epileptogenic area with the rest of the brain is theoretically necessary and sufficient to prevent the occurrence of seizures. In these cases, as well as in the present study, this theoretical concept is verified and validates this approach. For example, our results are similar to those obtained in our group in a series of consecutive temporal lobectomy[2]. Moreover, this approach is justified by the low morbidity, and the reduced morphological disturbance of the brain, particularly concerning the brain shifts and subdural collections.

What happens to the epileptic zone? One could have expected that the deafferented lobe could become deprived from inhibitory influences coming from the rest of the brain, therefore leading to aggravated epileptic states, or even to status epilepticus. This has not been observed, and there are no deleterious effects to be feared, related to an exacerbation of the epileptic focus and associated release of metabolic by-products.

On the contrary, total disappearance of epileptic activity in the deafferented parenchyma has not been observed, discarding the hypothesis of an excitatory influence coming from the rest of the brain, which could be responsible for the sustained epileptic activity before surgery.

What is surprisingly not observed is the existence of infraclinical spikes in the deafferented lobe, supporting again the concept of seizure suppression secondary to the isolation of the epileptogenic zone.

Completeness of disconnection and absence of remnant connective pathways are logical conditions to achieve in order to obtain seizure suppression. However, a better knowledge of the precise pathways responsible for the seizure spreading could open the possibilities of partial resection (superior temporal gyrus, for instance) to facilitate disconnection, dependent on individual anatomical variations, particularly about the insula. Indeed, it might be possible, if not certain, that in lobectomies,[2] as well as in total disconnections, interruption of certain pathways might not be always necessary. Functional imaging, particularly MEG, could provide data allowing such an approach.

What is the benefit of disconnection versus lobectomy?

Postoperative MRI show that there is less bleeding in the cavity, partly because this cavity does not exist, or is much smaller. Similarly, during surgery, it is clear that the section of the parenchyma with a spatula induces little bleeding, because after the section, the application of the two walls of the section reapply on each other and provide a haemostatic effect.

Disconnection needs a shorter operating time: there is no dissection of the hippocampus from the brain stem and the vascular contents of the Bichat fissure, as there is no neural connection all along it. The intrahippocampal vascular lamina does not need to be dissected as well.

What are the drawbacks?

The narrowness of the approach requires the usage of only a thin aspirator holding a cotton as a retractor, and a smooth spatula severing the cortex and white matter, sparing the vessels and not even cutting the arachnoid on the skull base, therefore sparing also all the vasculature contained at this level.

Conclusion

Disconnection has the same efficacy compared with resective surgery. The morbidity is similar or reduced as compared with lobectomy, but a larger number of patients is required before stating a definite conclusion. Disconnecting the EZ is sufficient to cure the patient, removal of the EZ is not mandatory, as long as the cause of the epilepsy is not evolutive. This is evident for tumors, but is not demonstrated in dysplasia, as their evolutivity is unknown. Similarly, cavernomas should not be left in place by disconnections as they may evolve, but also they may bleed even if they are not epileptogenic anymore. However, one might consider that the focal removal of a cavernoma associated to a disconnection of a larger parenchymal zone might be an option to consider in some circumstances.

The current work and its results, although preliminary, and together with the experience of other teams,[13] open the possibility for future more minimally invasive disconnective procedures.

123 Corpus callosotomy

G Morrison and M Duchowny

Anatomy and physiology

The corpus callosum is a prominent cerebral midline interhemispheric commissural connection said to have approximately 180 million axons in humans[1] (Figure 123.1). The connections are homotopic and heterotopic[2] and the effects can be excitatory or inhibitory.[3] There is a differential pattern of callosal connection which may be the result of postnatal elimination of transitory callosal axons.[4] The corpus callosum participates in the interhemispheric integration of perception and cognition. The fibers of the corpus callosum principally connect associative regions of the cortex and are distributed in a rostrocaudal fashion.[5] Studies have tried to correlate the size of callosum with function. The splenium has been reported to correlate with intelligence, with a larger splenium being associated with higher intelligence.[6] The posterior third of the callosum is reported to be larger in dyslexic men.[7] This relationship between anatomy and physiology continues to unfold and requires additional study.

Concept and history

The concept of a corpus callosotomy for a patient with medically intractable epilepsy is palliation, not cure, and is based on the diminution of interhemispheric propagation of epileptic activity. This would then prevent/reduce bilateral synchrony of cortical epileptiform activity and thus interrupt secondary seizure generalization. This may also result in a global diminution of synaptic connectivity of the cerebrum. Thus, a corpus callosotomy should be effective in treating patients with seizures that require bilateral cortical activation for their clinical expression.

In 1940, Erickson reported that complete division of the corpus callosum in fourteen monkeys prevented the spread of discharges to the opposite hemisphere.[8] In the same year (and in the same journal), Van Wagenen and Herren reported the first series of callosotomies for seizure control in humans.[9] It is interesting that their rationale for the surgery may have been their observation that patients with tumors of the corpus callosum would have decreasing seizure frequency as the callosum was destroyed by the tumor. Additionally, the seizures seen early in these patients were generalized and, as the tumor grew, the seizures were often unilateral and without loss of consciousness.

Alternatively, it may have been their observation that epileptic patients who sustained a stroke involving the corpus callosum often had improvement in their seizure disorder. Regardless of their thought process, they probably did not know of Erickson's work. Erickson did fairly note previous experiments going back to 1914, including similar work reported by Gozzano in 1936.[8] Numerous investigators followed Erickson's initial observations[10,11] and it was established that the corpus callosum was primarily responsible for ensuring bilateral synchrony of spike and wave discharges, at least in the feline penicillin epilepsy model.[12]

Dandy may have had the first report of a corpus callosotomy but that was for access to pineal region tumors.[13] More then 20 years after Van Wagenen and Herren's report, Bogan reported on 'cerebral commissurotomy'[14,15] but the concept was not well received (utilized infrequently) until Wilson began reporting on callosotomy for seizure control in the late 1970s and early 1980s.[16–19] Wilson's first patient was a 9-year-old boy having 30 generalized seizures a day. Wilson did a complete commissurotomy (entire callosum, hippocampal and anterior commissure, and one fornix) and, remarkably, the boy became seizure free, off medications.[16] Luessenhop performed callosotomies on young children[20] but most early reports dealing with children were patients in the second decade.[21–26]

Indications

There has been a wide disparity of indications for a corpus callosotomy. Very few intractable epilepsy syndromes have not been recommended for callosotomy at one time or another. In fact, this operation has applied to virtually any refractory form of seizures where there is no possibility of a focal resection. Twenty years ago corpus callosotomy was recommended primarily for patients with secondarily generalized seizures or with infantile hemiplegia. In the latter case, it was as an alternative to a hemispherectomy.[27] Some patients with partial seizures (usually with rapid secondary generalization) were also treated with callosotomy as have patients with frontal lobe epilepsy or Rasmussen's syndrome. In all cases, the seizures could not be localized or an eloquent region was involved. Callosotomy has been recommended for patients with Lennox-Gastaut syndrome.[28,29] These seizures may be tonic, atonic, myoclonic, atypical absence, or generalized tonic-clonic in nature but it is the 'drop attack' seizure produced by either atonic or tonic seizures that is the most likely to respond to a callosotomy.[30–33] Callosotomy has even been reported as being beneficial in the treatment of tuberous sclerosis[34] and Sturge-Weber syndrome.[35] More recently, most comprehensive epilepsy centers are recommending callosotomy for patients with tonic, atonic, or 'drop attack seizures'.[31,36–41]

Patient selection

Similar to candidates for other epilepsy surgery procedures, candidates for corpus callosotomy should be experiencing frequent and debilitating epileptic seizures that have been determined to be medically intractable. Their quality of life should be seriously impacted by the seizures, i.e., affected patients would potentially be held back from employment options, operating a motor vehicle, achieving in school or participating in enduring social relationships.

Patients must have undergone extensive pre-surgical evaluation and have well documented seizure manifestations. For patients with multiple seizure types, the most debilitating seizure type should be the primary surgical target. Seizures that produce physical injury or life-threatening status epilepticus provide a strong rationale for intervention. When multiple seizure types exist in the same patient, it is reasonable to expect that secondary seizure types would not necessarily respond to corpus callosotomy as the primary target seizure type.

The principle goal of preoperative studies is to exclude localized seizure foci amenable to excisional procedures. EEG and video-EEG monitoring studies that document ictal capture are mandatory. If seizures are localized at onset, it is then necessary to document that there is subsequent spread and secondary generalization. It is also important to document independent seizure types that arise from both cerebral hemispheres.

There are no specific age-related criteria governing surgical intervention. Patients as young as 4 months[20] and as old as 55 years[26] have undergone the procedure. The majority of patients have been adolescent and young adults. It is advisable to consider corpus callosotomy as soon as the patient demonstrates and extablished seizure type that is not localized and would potentially benefit from callosal sectioning. Treating physicians should provide informative discussion emphasizing that the potential for complete seizure-freedom is limited, and that palliative goals are more realistic.

Seizure types

Seizure type is a decisive variable in the selection of epilepsy patients for corpus callosotomy. A comprehensive review of amenable seizure types has been carried out by Spencer.[42] Most centers perform corpus callosotomy for intractable generalized seizures including tonic, atonic, generalized tonic-clonic and absence seizures.[38] These seizures types would be expected to benefit from a procedure that would decrease bilaterally synchronous EEG abnormalities. As alternative subcortical pathways participate in bilateral EEG synchrony, complete abolition of generalized EEG activity is unlikely, but not required for improved seizure status.

The benefit of corpus callosotomy has repeatedly been shown for patients with disabling drop attacks. Reutens[41] reported a favorable outcome after corpus callosotomy in 64 patients, particularly for drop attacks in the setting of a unilateral focal lesion or true generalized epilepsy. Complete seizure suppression in 9/19 patients with falling attacks and an 80% reduction in 7/19 patients was noted by Rossi.[43] Generalized tonic-clonic seizures were less improved. Higher rates of seizure-freedom were reported by Shimizu[44] who found that 29 of 34 patients with drop attacks were seizurefree after callosotomy and four had only infrequent attacks. Only one patient did not show benefit. They additionally noted concurrent improvement in cognition and speech in 77% of their patients. Follow-up studies revealed that the cohort of children derived greater functional benefit than the adults.[45] Similarly favorable results were reported by Kim.[46]

The variation in outcome as a function of seizure type is notable. The superior outcome of patients experiencing drop attacks suggests that the corpus callosum may be of heightened importance in cases of bilateral synchrony associated with negative motor phenomena. In contrast, positive motor manifestations of generalized epileptic discharges appear less influenced. This would suggest the existence of different mechanisms for generalization for seizures that appear bilaterally sunchronous at seizure onset.[47]

Etiology

Corpus callosotomy has been advocated as treatment for a variety of neurological disorders associated with secondary bilateral synchrony. One of the earliest documented applications of corpus callosotomy was for patients with congenital hemiplegia.[20] Callosotomy was envisioned as a less aggressive procedure than hemispherectomy. Hemispherectomy could then be performed as a back-up procedure should corpus callosotomy prove ineffective.[48] Goodman[27] reported 'excellent' results in four of five patients with congenital hemiplegia and stressed the low incidence of complications in comparison to hemispheric ablation. Should anterior callosotomy prove ineffective, complete callosal sectioning may offer additional relief.

Selected patients with epilepsy due to cortical malformations have been treated with corpus callosotomy. Difficulties associated with localization of seizure origin and the extensive cortical involvement of some malformations has undoubtedly played a crucial role in candidate selection. Modest success after corpus callosotomy has been reported in three patients with subcortical laminar heterotopia.[49] Ambrosetto[50] reported amelioration of drop attacks in a retarded girl with the congenital bilateral perisylvian syndrome, Pallini[51] noted improvement in four patients with bihemispheric cortical dysplasia, and Landy[52] described improved atonic seizure status in a patient with band heterotopia. In contrast, anterior callosotomy offered no benefit to a patient with generalized seizures due to hypothalamic hamartoma.[53]

The experience with corpus callosotomy in young patients with epileptic encephalopathies has been mixed. Improvement in infantile spasms in West syndrome and cessation of drop attacks in patients with previous West syndrome was reported by Pinard.[54] Seizure reduction after callosotomy was reported in an 11-month-old patient with lissencephaly presenting as West Syndrome.[55] Improvement in patients with Lennox-Gastaut syndrome occurs predominantly for drop attacks.[56]

Corpus callosotomy has been advocated in a variety of clinical presentations where localization has been challenging, including frontal lobe seizures,[57] multifocal epilepsy and Rasmussen syndrome.[48] The advent of more sophisticated techniques for localization of seizure origin has largely rendered these indications obsolete.

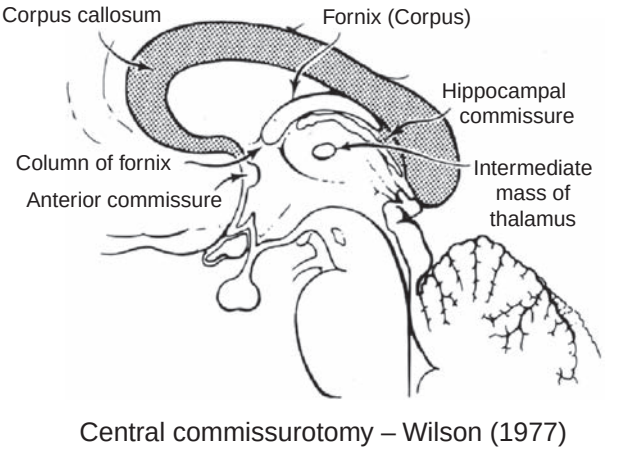

Figure 123.2 Diagram of the anatomy of early commissurotomy.

EEG

The preoperative EEG has been advocated as a tool for selecting candidates for corpus callosotomy. The degree of bilateral synchrony and the morphological similarity of generalized spike-wave discharges between hemispheres have been singled out as potential screening criteria. Matsuzaka[58] reported that a more favorable surgical outcome occurred in patients with the least variation in synchrony for bursts of spike-wave discharges. Prognostically favorable ictal EEG features include generalized slow spike-wave discharges, electrodecremental patterns and low amplitude fast frequencies.[59] It has also been suggested that posterior-dominant epileptiform discharges portend a poorer outcome after anterior callosotomy than anteriorly localized discharges.[60]

Others have been less inclined to attach significance to preoperative EEG patterns. In 36 patients undergoing anterior, posterior or two-stage callosotomy, Quattrini[61] observed a reduction in bilateral synchrony in the EEG but found no correlation with reduction in seizures. Similarly, the degree of lateralization of generalized epileptiform discharges did not correlate with reduction of tonic-atonic seizures as over 80% of patients obtain seizure reduction independent of their EEG patterns.[62] Blockage of bisynchronous discharges does not confer improved seizure status in children with Lennox-Gastaut syndrome.[63] It has also been shown from the postoperative EEG that a reduction in the number of epileptiform discharges or epileptic foci is not necessary for improved seizure status.[64] The persistence of bilaterally synchronous discharges in some post-callosotomy patients suggests that bilateral synchrony is also mediated via subcallosal pathways involving diencephalic or mesencepahlic structures.[65]

Technique

As with most surgical procedures, different techniques have been utilized by different neurological surgeons, usually with similar results. The very early procedures involved transecting the corpus callosum, the hippocampal commissure, the anterior commissure, and one fornix (Figure 123.2). The procedure evolved to a more limited sectioning of the callosum and the hippocampal commissure with rare sectioning of the anterior commissure. Centers also differed on how much of the callosum to transect at the first operation. Some (Minnesota) initially favored a total transection in one operation while most advocated (and still do – e.g., Yale) sectioning the anterior two-thirds to three-quarters during the first operation (Figures 123.3 and 123.4). One center (Dartmouth) staged the procedure with sectioning of the posterior half divided first.[66] Regardless of which part was sectioned initially, the callosotomy was only completed if the results were unsatisfactory after the partial transaction. At the present time, the only patients suitable for a complete transaction in one operation would be the very afunctional, globally developmentally delayed individual where a postoperative disconnection problem would not clinically alter the functional level.

Although most neurological surgeons favor an open approach, callosotomies have been performed with stereotactic radiofrequency[67] and with radiosurgery.[68] Some centers have used intraoperative EEG information to tailor the length of resection[23,69,70] but most groups use it, if at all, for investigative purposes and the authors have abandoned its use.

The two most popular positions are with the head lying on the side (so that gravity will help with the retraction) or brow up with the head elevated (the author's preference). If neuronavigation is to be utilized (which can be very helpful),[71] then 3-pin fixation is mandatory, otherwise it is optional. General anesthesia is similar as for other craniotomies with possible

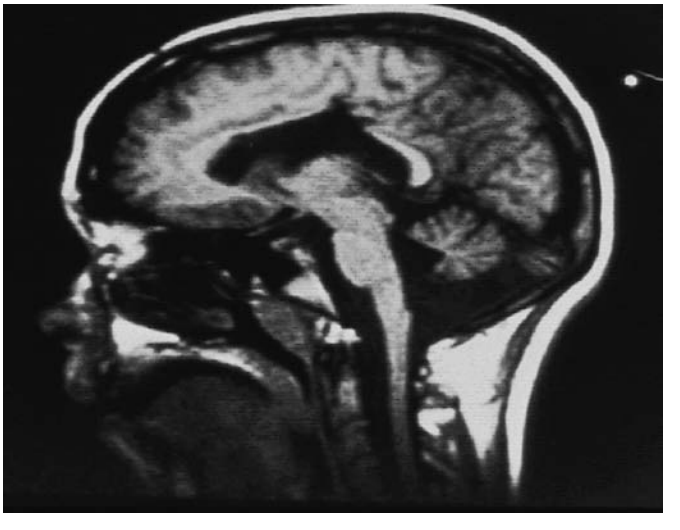

Figure 123.3 MRI of corpus callosum after an anterior two-thirds sectioning.

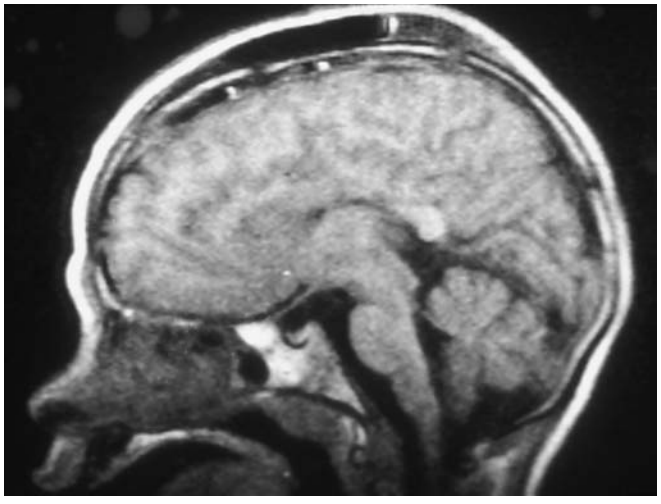

Figure 123.4 MRI of corpus callosum after an anterior three-quarters sectioning.

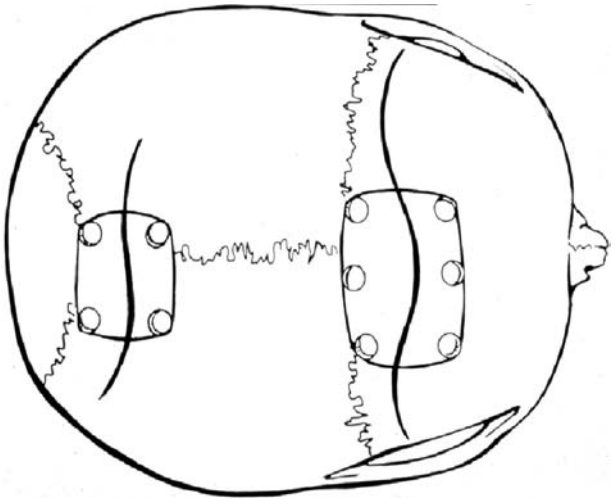

Figure 123.5 Diagram of head with a skin incision and craniotomy flap outlined. A complete callosotomy can be done from the anterior incision and the craniotomy flap may be safely extended slightly behind the coronal suture. The posterior incision is used if a second operation is performed to complete the callosotomy.

precautions for air embolism taken if the head is far above the heart. Dexamethasone and prophylactic antibiotics are used without scientific evidence of their efficacy.

A bi-coronal (or Soutar) incision is preferred (Figure 123.5) with the right sided limb a little longer. A bilateral craniotomy is then done at the level of the coronal suture (Figure 123.5). A callosotomy can be performed through a small craniotomy, but a larger opening gives the surgeon more flexibility in identifying the best corridor down the falx to the callosum. The venous anatomy will dictate the specific corridor as great lengths are taken to avoid sacrificing the bridging veins. Although a right-sided approach is often favored (right-handed surgeons and nondominant hemisphere), the anatomy may change the approach to the left side. This is arguable for left-handed patients but is sometimes dictated by the venous anatomy found at surgery. Theoretically this venous anatomy could be determined preoperatively (MRV) but, as of yet, this does not always show the required detail.

It is important to expose the midline and the sagittal sinus so that it can be retracted (by traction sutures on the dura or with a self-retaining retractor). This is also added by opening the dura based on midline. Mannitol (0.5–1g/kg) is usually given before the interhemispheric dissection is begun.

The dissection is then done with the aid of magnification (the author prefers the operating microscope) with careful separation of the midline structures. This is usually straightforward but can be confusing and there can be vessels not easily identified to one side or the other. If this occurs, it is wise to abandon this dissection and to dissect further anterior or posterior and the true anatomical nature of this vessel will usually become apparent. Although the cingulate gyrus has been confused with the corpus callosum, the adage of 'if it's not white, it's not right' is quite accurate. The white corpus callosum is visually unique. The vessels overlying the callosum are identified, separated, and preserved (Figure 123.6).

Dissection is performed anteriorly and posteriorly before the actual transection to identify and secure the boundaries of sectioning. The anterior boundary is the genu and the posterior boundary is approximately two-thirds of the callosum. This is usually easily identified as the location where the callosum begins to curve or slope inferiorly. Neuronavigational systems are a help as are measurements taken from the preoperative MRI. If a total callosotomy is to be done, the head may be moved to facilitate the posterior dissection.

After the dissection, the transection begins and is carried throughout the course (Figures 123.7 and 123.8) An attempt is made to stay exactly in the midline because, even in absence of a cavum septum, there is usually a small space or midline raphe to guide the surgeon and to facilitate staying out of the ventricular system. Most neurosurgeons use combination of suction and the bipolar forceps, but various microdisectors are helpful and some surgeons have used ultrasonic aspiration and even an endoscope (in cadaveric preparations).[72] An attempt is made to stay out of the ventricle but the author has not seen the difficulties described by others (e.g., hydrocephalus).[16,18] However, some blood in the ventricular system can produce postoperative fever. This may be ameliorated by the use of

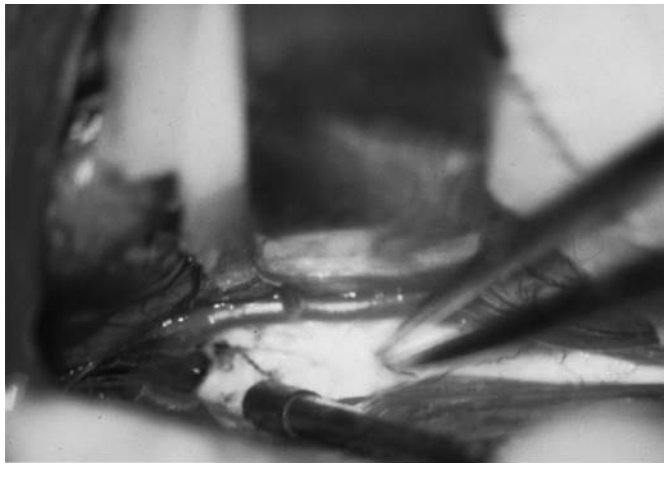

Figure 123.6 Operative photograph of corpus callosum exposed prior to transaction.

Figure 123.7 Operative photograph of transected corpus callosum.

dexamethasone. Some neurosurgeons have left a titanium clip at the posterior limit of the transaction to identify the boundary by neuroimaging and, as an aid for identification if further surgery is performed. This has not been the author's practice. Following the transaction and establishment of hemostasis, a standard closure is performed. In addition to steroids, patients are given a couple of doses of antibiotics and otherwise standard postoperative management.

If a second procedure is indicated, the neurosurgeon could go back through the anterior callosotomy incision, but scarring will make the dissection difficult and most would favor a separate, posterior, incision and craniotomy (Figure 123.5). Posteriorly, the falx goes to the callosum which makes its identification, and that of midline, easier. The same principles as outlined for the anterior procedure are followed and here, instead of identifying the anterior cerebral arteries after sectioning of the genu, the vein of Galen will be visualized as the splenium is transected and appropriate respect is given to it. The underlying arachnoid, beneath which lie the quadrigeminal cistern and the pineal, is preserved.

Results

The first series of Van Wagenen and Herren included 10 patients reported in detail.[9] They operated on an additional 17 patients who were not reported in detail. They reported the conversion of generalized seizures to lateralized seizures with preservation of consciousness. Nine of the originally reported ten showed significant improvement.[9] It is difficult to make generalizations from subsequent reports since candidacy for callosotomy, technique, and the methods of quantifying outcome have been variable. It is difficult to compare the outcome of different published series of callosotomy patients because of variables that include: seizure type, patient's functional ability pre- or postoperatively, extent of pre- or postoperative investigation, and the definition of a 'good', 'satisfactory', or 'excellent' outcome. Indeed the variation is so extreme that some report complete, or almost complete, control of atonic, tonic, or generalized tonic-clonic in the majority of patients after callosotomy,[19,25,73] whereas others report a favorable response in less than 50% of operated patients.[26,32]

Several series have reported a significant reduction in bisynchronous discharges after callosotomy.[17,19,38,74,75] One related the EEG changes to the extent of transection.[65] Seven patients who underwent an anterior callosotomy showed a decrease in the quantity of epileptiform discharges.[76] Postoperatively, the total number of epileptiform burst activities, mean duration, and the total number of spike discharges decreased significantly.[76] There have been reports of increased partial seizure activity after callosotomy in humans[25,77–82] and in subhuman primates.[10,83] This worsening of seizure activity may be secondary to the loss of an inhibitory influence[84,85] and Spencer has described clinical seizures as being more intense.[66,84] Alternatively, postoperative partial seizures may represent a remnant of the patient's preoperative generalized seizures.[73]

Satisfactory outcomes have been reported to be between 50% and 80% where 'satisfactory' means a seizure reduction in frequency and/or severity of 50–80%.[29,66,85] Patients with atonic seizures have fared better than those with tonic seizures.[19,23,33,36,38–40,43,45,80,85–88] However, dichotomy exists. Madsen reported 80% significant improvement for drop attacks of either tonic or myoclonic origin, 69% for atonic drop attacks, 70% of atypical absence seizures, and 55% of generalized tonic-clonic seizures.[37] An early report from Dartmouth found excellent results in four or five patients who had a callosotomy instead of a hemispherectomy for congenital hemiplegia.[27] A report from Taiwan stated an 82% significant improvement (more than 50% reduction in seizure frequency) in patients with generalized tonic-clonic seizures, 73% with atonic seizures, and complete seizure freedom in 19%.[89] However, most reports continue to show better results for atonic seizures than for generalized epilepsy. A Japanese report found that 'total callosotomy is more effective for the treatment of drop attacks than partial callosotomy and that children receive more benefit than adults after callosotomy'.[45] They reported an overal 85% satisfactory outcome (90% or more seizure reduction).

Wilson reported that 16 of 20 patients had a greater than 50% reduction in overall seizure frequency.[17,19] Geoffroy had similar success in six of nine patients,[22] Luessenhop in three of four,[20] Amacher in four of four,[21] Rayport in seven of nine,[90] and Bouvier in six of six.[91]

Engel looked at the outcome of a large number of patients (197) from 16 centers and found that only 5% were completely seizure free, 71% improved, and 24% unimproved.[92] A follow-up survey in 1991 of 563 patients found that 8% reported seizure freedom with 61% improved.[93] Spencer reported a series of 22 patients, five to 39 years of age, in which complete control of seizures was seen in six of seven with tonic seizures, two of two with atonic seizures, 16 of 21 with tonic-clonic seizures, nine of 22 with complex partial seizures, and none with simple partial seizures.[25]

He also reported that complete callosotomy was twice as effective as partial section.[25] Spencer collected data on 330 patients and reported a success rate of 71% for atonic seizures following anterior section and 74% after total section; for tonic-clonic seizures the response was 56% and 75% respectively; for tonic seizures 47% and 75% respectively; and for absence seizures 33% and 64% respectively.[94] Roberts reported that for all seizures taken together, only 29% of patients undergoing anterior transaction achieved success (80% or greater reduction of seizures) but that this increased to 62% success following completion of the callosal section.[95]

Unfortunately, there has been much variability of reported success following callosotomy. Commonly, reports state results of 57% 'complete suppression of the generalized seizures associated with drop attacks' (12 of 21 patients and a 'seizure reduction of more than 75% in 6 of the 21.[46] Gates reported on 24 patients with 'a highly statistically significant reduction of postoperative tonic or atonic seizures'.[73]

One report stated that a very good outcome was present in 92% of patients more than ten years of age[96] and in a pediatric series where callosotomy was the predominant surgical procedure for intractable epilepsy (30% of the cases), a surgical cure for drop attacks was reported to be 91% following a total callosotomy and 67% after partial transection.[97] In the latter series, the most frequent preoperative EEG abnormalities were diffuse bilaterally synchronous epileptic discharges (72%). The neuropsychological consequences of the procedures are not clear, but improvement in quality of life was reported to occur in 77% of patients (97).

A small series of ten patients with bihemispheric malformations wherein a total callosotomy was performed reported cessation of drop attacks in eight (one patient subsequently relapsed).[98] Overall daily functional level was also reported to improve.

Completeness of resection

Although Spencer initially reported that outcome depended on the completeness of the transection,[25] other authors have shown no differences in seizure control between partial or complete sections.[41,23,99] Spencer later reported that a complete transection of the corpus callosum should be reserved for patients who did not respond to an anterior two-thirds section[82] but there is a clear benefit in proceeding to completion in patients with persistent generalized seizures after partial section.[94] An early report of 24 medically refractory seizure patients (a variety of seizure types) revealed a significant reduction in seizure frequency and severity in 75% after anterior two-thirds corpus callosum section.[100] In contrast, nine of 14 patients improved after a complete callosotomy in the treatment of West syndrome, while only two of 13 improved after an anterior callosotomy.[54]

Prognosis

The preoperative EEG has been used to predict outcome. It has been reported that the 'preoperative quantitative EEG analyses enabled ... to predict ... the surgical outcomes in patients undergoing corpus callosotomy'.[58] Another report stated that 'the ictal EEG but not other factors is able to identify a group of patients who have a better than 90% chance for total of nearly total resolution of seizures causing sudden falls'.[59] Better results may be obtained in patients with lateralized EEG abnormalities.[22]

Quality of life issues are more difficult to judge; while some have reported a favorable social outcome,[101,102] others have pointed out that overall clinical improvement or global measures of quality of life do not always correlate with seizure reduction.[103,104] However, eliminating drop attacks associated with craniofacial trauma, by corpus callosum section, is an extremely important goal, even if other seizure types persist.

In an early series, Ferrell did formal neuropsychological testing on eight patients and reported improvement in six.[105] Yang reported that 76% of families surveyed were satisfied with the surgical result and 72% were satisfied with the family's quality of life.[102] Positive behavioral changes, social skills, and attention spans were reported. Gillam noted similar results in that 15 of 17 families reported overall satisfaction with reported improved alertness and responsiveness.[104]

Complications

The usual complications of a craniotomy are seen but, fortunately, infrequently. Bone flap infection may be slightly increased because this is free bone flap and not an osteoplastic flap. Venous damage can result in an infarct as can damage to one of the deep arteries. Blood in the ventricle is to be avoided, but in the author's experience it has not been a problem and the development of hydrocephalus has not been observed. Contralateral weakness (if present) is usually transient and should be discussed pre-operatively. Long term neurological problems are rare but an exacerbation of previous lateralized deficits has been reported.[106]

Of concern are clinical situations particularly unique to a corpus callosotomy. There are possible acute and chronic sequelae of a callosotomy and these neuropsychological/behavioral changes have been well described[107–114] even though initial reports stated that callosotomy produced little alteration in cognition.[110] An acute disconnection syndrome may occur in some patients after an anterior two-thirds transection but almost always following complete transection. Affected patients are lethargic, apathetic, and mute,

a presentation that can be very disturbing to the family. This disconnection syndrome should also be discussed before surgery. Families should be informed that patients virtually always get better but that this recovery can take from days to weeks.

The problem of mutism following a callosotomy has been recognized for twenty three years.[115] Additionally, there may a hemiparesis (leg greater than arm), an apraxia and hemineglect (if testable), bilateral Babinski signs, urinary incontinence, and an increase in focal motor seizures.[29,85]

The chronic disconnection syndrome is often very subtle and identified only by careful neuropsychological testing. It is most often present when the splenium of the corpus callosum has been transected. Deficits in tactile transfer can exist which consist of poor naming of objects held in the nondominant hand and visual transfer problems which consist of poor naming of objects seen in the nondominant hemifield. Thus, it especially involves sensory and/or visual pathways and their connections for speech production. For example, with a posterior callosotomy an object seen only by the left visual field may be recognized but the information can not be transferred from the right hemisphere to the left dominant hemisphere for naming. In practice, this is rarely noticeable clinically because objects are viewed in both visual fields. An 'alien hand syndrome' has been reported wherein there is antagonistic or poorly cooperative behavior between the two hands.[108] This syndrome is usually transient but can, rarely, persist. Although poorer memory and concentration have been reported,[116,117] this may be more of an attentional impairment than actual memory dysfunction[118] or may occur when preoperative extracallosal damage exists, particularly involving the fornix.[119]

Although early reports stated that patients 'do not experience functionally significant intellectual, emotional, or social impairment',[105] deficits are possible in all patients after callosotomy and finding them may be a function of the index of suspicion. Most deficits are topographic in nature, must be carefully searched for, and are rarely clinical significant.[120] In fact, neuropsychological and psychosocial assessments are not significantly altered when compared with preoperative functional levels.[121] 'Deficits due strictly to callosal section can be almost completely predicted by the patient's preoperative behavior, cognitive deficits, and the presence of unilateral lesions resulting in interhemispheric dependence for function'.[66,106] Anterior sections result in disruption of sensory or motor integration functions as would be expected.[120] This is somewhat in disagreement with a report by Tassinari wherein only two of six patients undergoing an anterior callosal section demonstrated an impairment in intermanual transfer of tactile localization.[122] With careful testing it is apparent that effective binocular integration across the midline requires an intact corpus callosum.[123] Patients undergoing a callosotomy for seizure palliation may be different than other partial callosotomy patients, such as those who have a interhemispheric disconnection after traumatic brain injury where the deficits seem mild or transient.[124,125]

Long term problems are related to the amount of sectioning[25] with deficits almost doubled for a complete callosotomy compared to an anterior two-thirds transection.

Spencer reported motor difficulties in 15% vs. 8%, language impairment in 14% vs. 8%, and cognitive/behavioral impairments in 11% vs. 8%. Age may also be a factor, as the plasticity of the young provides for much better response and adaptation to any brain injury, including callosotomy.[66,126]

Some authors have reported that patients with low preoperative IQs are at greater risk of developing neuropsychological deficits following callosotomy,[41,126] but others report no relation between IQ and surgical outcome.[127,128,129] There are reports of improvement of psychomotor function, even after total callosotomy.[45,97,126]

Future

As noted, there are many conflicting reports regarding the indications for corpus callosotomy, the extent of transection, and, most importantly, on outcome. Outcome differs markedly, in part, because of the different interpretation of 'success', the methods and length of follow up and the degree to which neuropsychological, neurophysiological, or neurocognitive deficits were investigated.[130]

While our understanding of the indications and expectations for corpus callosotomy for the treatment of intractable epilepsy continues to evolve, the last decade has seen a sharp decline in the use of corpus callosotomy for intractable epilepsy. This may be partially due to the introduction of new anticonvulsant drugs and partially because of the increased ability to identify an epileptogenic zone with improved anatomic and functional neuroimaging and metabolic studies. However, even in 'nonlesional' cases, more aggressive investigation (e.g., increased use of implanted electrodes with extraoperative monitoring, increased use of ictal SPECT, PET, MEG) has allowed for more focally resective surgery.

New techniques might be of some benefit,[114] but are highly speculative at this time. The role of vagal nerve stimulation has yet to be determined. It can be stated that a microsurgical extraventricular division of the corpus callosum can help a number of patients and that staging the procedure remains a reasonable alternative approach as a complete callosotomy is not required in all patients. Behavioral and neuropsychological sequelae of commissurotomy are well-recognized, but are rarely of long term clinical consequence. In the majority of patients the potential benefits of the procedure outweigh the risks and, finally, callosotomy is currently an underutilized procedure, especially for children with intractable atonic seizures associated with recurring falls and injuries. Corpus callosotomy should remain in the surgical armamentarium of every comprehensive epilepsy program.

124 Radiosurgical treatment of epilepsy

I Yang and NM Barbaro

Introduction

Radiosurgery is the precise application of focused radiation to a targeted volume area within the brain identified on magnetic resonance imaging.[1] Initially conceptualized by Leksell for use in functional neurosurgery, radiosurgical treatment for neurologic disorders has progressively widened its utility and is now also an option for several neoplastic and vascular indications.[2,3] Differing from standard dose-fractionated radiotherapy, radiosurgery allows the neurosurgeon to deliver precise and accurate radiation to a smaller volume without effecting large portions of normal parenchyma allowing for a powerful radiobiologic effect on the chosen targeted volume.[1,4–6]

Patients with epilepsy who are refractory to medical management may be referred for possible surgical management, and approximately half of them are found to be candidates for surgical resection of their seizure focus.[7] Focal partial epilepsies are typically responsive to surgical treatments and are increasingly being treated using 'structural' means.[2,8] The most common type of surgery performed is an anterior temporal lobectomy, resection of a portion of the temporal lobe.[7,8] Microsurgical resection of mesial temporal lobe structures can be performed with low morbidity and even lower mortality.[6] Open procedures have inherent risks including damage to the brain (either directly or indirectly by injury to important blood vessels), bleeding (which can require re-operation), blood loss (which can require transfusion), infection, and general anesthetic risks. In addition, surgical incisions can result in significant postoperative pain. Several clinical studies evaluating the morbidity of temporal lobe microsurgery report that 5–23% of epilepsy patients undergoing open surgery had a symptomatic neurologic deficit post operatively.[9–13] Furthermore, open procedures require several days of care in the hospital including at least one night in an intensive care unit which contribute to the economic costs of resective surgical treatment.[2] There also exists a population of patients with medically intractable epilepsy that is unsuitable for conventional resective surgery.[2] These patients may have their epileptic focus in eloquent regions of the brain which could result in irreversible language, motor, or visual impairment with surgical resection.[2,3]

Radiosurgery is now being evaluated as an alternative treatment to open resective surgery for intractable epilepsy. Specifically, radiosurgery is under study as a treatment of epilepsy associated with vascular malformations, gelastic epilepsy associated with hypothalamic hamartomas, and medial temporal lobe epilepsy associated with mesial temporal sclerosis.[1,3,4,6,14–37]

Preclinical evidence

Animal studies investigating focused radiosurgery in animal models of epilepsy have demonstrated the potential utility of radiosurgical treatment applied to epileptic foci to reduce seizure activity. Early animal experiments in cats indicated the potential of focused radiosurgery in a cat model of epilepsy.[2,14,17] Using doses between 10 and 20 Gy (one gray, Gy, is equivalent to one joule of energy per kilogram of tissue), cats with epileptic foci treated with an implanted cobalt source had reduced seizure activity. Histologic analysis of these animals revealed 'neuronal reafferentation' as the proposed mechanism of seizure amelioration.[14,17]

Recently, Sun *et al.* report that focused radiosurgical treatment successfully reduced seizure activity and raised the seizure threshold in a rat epilepsy model.[3] A linear accelerator was used to perform radiosurgery at doses of 10 or 40 Gy at the 90% isodose line using a 5 mm collimator. The seizure threshold to external electrical stimulation in these rats was significantly increased and the length of after-discharges was significantly decreased in the 40 Gy group. These antiepileptic effects were detectable 1 week after radiosurgery and continued for a three month follow-up period.[3]

Experiments from the University of Virginia were designed to evaluate the effects of radiosurgery on a chronic spontaneous limbic epilepsy model.[38] In this model, hippocampal electrodes were implanted utilizing a single 90-minute period of stimulation to produce a rodent spontaneous limbic epileptic model. Ten weeks later, Gamma Knife(r) radiosurgery with doses of 10 to 40 Gy, using a 4 mm collimator, was applied. While the lowest dose group (10 Gy) showed no decrease in seizures, the 20 Gy group did exhibit a gradual and continuous reduction in seizure occurrences from 2 to 6 months after radiosurgical treatment. Lastly, the 40 Gy group displayed a dramatic reduction in seizures by the second month. Histologic analysis of radiosurgical treated targets revealed no necrosis. Furthermore, penicillin induced epileptic activity was reduced in the brain slices of those rats that were treated with 40 Gy. Synaptically driven neuronal firing was found to be intact in these brain slices, suggesting that neuronal death was not responsible for the identified seizure resistance.[38]

Experiments at the University of Pittsburgh were designed to determine the dose of radiosurgery that was necessary to eliminate seizures in a kainic acid rat epilepsy model.[28] In this study rats underwent stereotactic injection of kainic acid into the right hippocampus to induce seizures. Ten days after the injections, the injection site was treated with Gamma Knife(r) radiosurgery using a 4 mm collimator over a range of 20–100 Gy.

The animals treated with a 20 Gy dose showed a reduction in the number of daily seizures during each week of observation after radiosurgery. Furthermore, three weeks after radiosurgery, all radiation groups – 20 Gy, 40 Gy, 60 Gy and 100 Gy showed a significant reduction in seizure activity confirmed with EEG evaluations. The authors report that histologic evaluation revealed no radiation-induced necrosis in any animals except for the 100 Gy cohort. However as the injection of kainic acid induces a loss of CA3 neurons in all animals, interpretation of histological findings may be difficult. Small areas of kainic acid necrosis were seen in 2/20 control animals and in 14/37 irradiated animals, but only in the 100 Gy radiosurgery treated group did the necrosis noted match the collimator size.[28]

A second study using the same kainic acid rat epilepsy model was undertaken to further evaluate the pathological and behavioral effects of 'subnecrotic' radiosurgery doses.[39] Stereotactic hippocampal kainic acid injections were followed by single isocenter radiosurgery using a 4 mm collimated Gamma Knife(r) with radiosurgery doses of 30 or 60 Gy. A significant reduction in seizures was noted in all animals, and this effect was seen earlier in the 60 Gy cohort than in the 30 Gy group (weeks 5–9 compared to weeks 7–9). Furthermore, rats treated with radiosurgery did not demonstrate a deficit in new memory attainment tasks with water maze testing compared with kainic acid injected animals, but both groups showing impairment compared to controls without kainic injection. Two blinded, experienced observers rated the histological specimens from all animals at 13 weeks following radiosurgery. Changes typical for kainic acid injections were seen in all animals including a loss of pyramidal cells in CA3-4. In 25/46 injected animals unilateral hippocampal atrophy with cell loss extending into CA1 and CA2 was noted. Although histologic assessment is difficult to assess given the use of kainic acid, necrosis matching the target volume of radiosurgery was not observed in any of the animals.[38] The authors again suggest that cessation of seizures following radiosurgery does not require concomitant loss of neurons.[39]

Two recent studies from the radiosurgery group in Prague report on their characterization of a 'subnecrotic' dose using radiosurgery in an animal model.[40,41] The investigators studied doses of 25, 50, 75 or 100 Gy delivered bilaterally to rat hippocampus. Memory function tests, MRI and histological examination were performed at 1, 3, 6 and 12 months following radiosurgery. A time and dose-dependent response was noted in memory function, T2 edema and necrotic histopathology. Animals dosed with 100 Gy died by 6 months following radiation and all had necrotic lesions. All animals treated at 75 Gy displayed memory impairment at 6 and 12 months, edema on MRI, and necrotic lesions, whereas only one of the animals treated with 50 Gy were effected by edema and necrosis. Otherwise, 25 and 50 Gy irradiated animals did not show any functional or structural impairment at up to one year after radiosurgery.[4] This finding of potential subnecrotic radiosurgery dose parameters prompted a second study where a 35 Gy radiosurgery dose was used and the animals were evaluated over 16 months.[40] By 6 months postirradiation, T2 edema was evident on MRI and this edema peaked at 9 months. By 17 months, two of six animals had postnecrotic cavities. The four animals without frankly necrotic cavities had severe atrophy of the corpus callosum, loss of thickness of somatosensory cortex and damage to the striatum oriens hippocampi.[40] These studies clearly indicate that the full radiobiologic and histological effect of radiosurgery may only be manifested after several months following treatment.

These preclinical studies report the amelioration of seizures as well as histologic neuronal changes associated with radiosurgical treatment in different animal epilepsy models. These animal studies suggest that the antiepileptic efficacy of radiosurgery is dose dependant.[6,28,38,39] Most of these studies suggest that a radiosurgery dose of approximately 25 Gy is required to see therapeutic antiepileptic effect, and that the full histological and other toxicity may require several months to fully develop.[2,3,28,38–44]

Clinical evidence

The first radiosurgical application for epilepsy surgery was utilized by Talairach in the 1950s with the implantation of radioactive yttrium in patients with MTLE without a lesion.[2,3,6] Further clinical experiences with Gamma Knife(r) radiosurgery and linear accelerator (LINAC) based radiosurgery for the treatment of arteriovenous malformations and low grade tumors also noted the incidental antiepileptic effects of radiosurgery.[6,18,20,23,25,26,37] Using Gamma Knife(r) and LINAC to treat arteriovenous malformations (AVMs), several groups have reported a supplementary improvement in seizure control.[27,35,42] Although it is not established whether reduction of tumor size or angiographic occlusion of the vascular malformation itself may reduce seizures, these reports of clinical seizure improvement with radiosurgery provided the impetus for investigating radiosurgery as an alternative treatment for medically intractable epilepsy.

Medial temporal lobe epilepsy

Medial temporal lobe epilepsy (MTLE) associated with mesial temporal sclerosis is perhaps the most well defined epilepsy syndrome responsive to surgical intervention. When temporal lobe epilepsy is due to underlying mesial temporal sclerosis (MTS), surgical cure can be expected in between 65 and 90% of patients.[2,7,8,43–49] This form of adult intractable epilepsy is particularly amenable to radiosurgery because 80–90% of these cases show changes on magnetic resonance imaging.[4,46]

Recently, radiosurgery has been explored as an alternative to open resective surgery for MTS associated medial temporal lobe epilepsy. In the first application of Leksell Gamma Knife® for epilepsy, Regis *et al.* utilized radiosurgery in a small number of patients showing amelioration of seizures with minimal morbidity and mortality.[31,34] A prospective, multicenter European study evaluating Gamma Knife(r) surgery for MTS showed comparable efficacy rates (65%) for seizure reduction by conventional surgery or radiosurgery after 2 years of follow up.[6] Using a marginal dose of 24 Gy, Regis *et al.* demonstrate that radiosurgery can be used as an alternative to conventional resective surgery to treat medial temporal lobe epilepsy associated with MTS and improve quality of life with favorable rates of morbidity and mortality (Figure 124.1).[6]

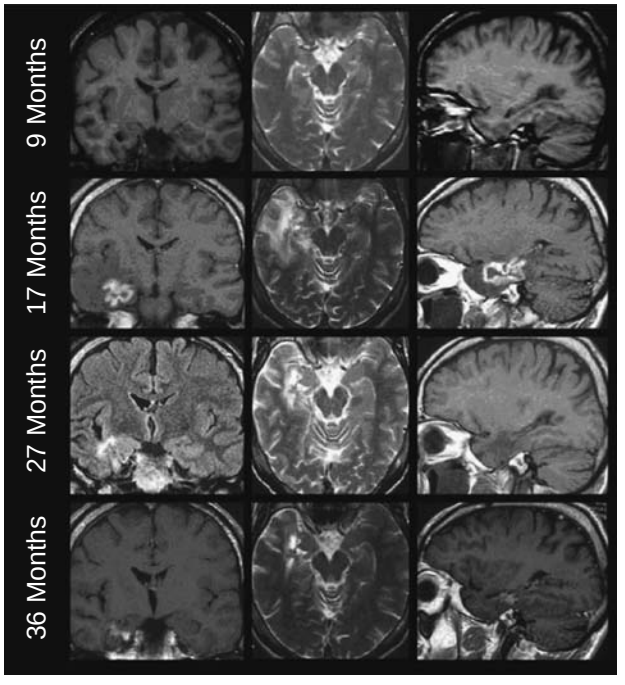

Figure 124.1 Representative radiographic changes on magnetic resonance imaging (MRI) after radiosurgical treatment of mesial temporal lobe epilepsy. Radiographic effects are not observed until after 1 year correlating with delayed clinical manifestation of therapy.[6]

In the US, a multicenter pilot trial is currently being conducted with initial results showing that 85% of patients treated with 24 Gy (to the 50% isodose line) to the medial temporal lobe, including the amygdala, anterior hippocampus and nearby cortex followed for at least 24 months are seizure-free with minimal morbidity (Barbaro *et al.* unpublished). This group is planning a larger, phase 3 trial comparing open surgery with radiosurgery for patients with clinically and radiographically defined MTS.

Although radiosurgery has proven effective and safe in ameliorating MTS associated seizures, the beneficial effects of radiosurgery are not displayed immediately. Most patients achieve seizure reduction at 9–12 months and complete cessation of seizures between 18–24 months after radiosurgical treatment. A transient increase in partial seizures (auras) is noted typically at approximately the same time as complex seizures decrease.[6] Greater than half of treated patients may require corticosteroids to treat the radiation-induced edema associated with the initial radiosurgical effect (10–15 months posttreatment) (6 Barbaro, personal observation).

One of the difficulties in applying radiosurgery broadly as an application for intractable epilepsy is the definition of the radiosurgical target. Because the MTS associated with MTLE is not well defined anatomically, the precise boundaries for radiosurgical treatment are not well known and hence is difficult to standardize amongst different treatment centers. Successful radiosurgical treatment has been shown to be target related. Recently, Regis *et al.* radiosurgically targeted the mesial temporal lobe structures in their series whereas Kawai *et al.* defined their treatment to the amygdala or hippocampus, and each series reported contrasting rates of successful amelioration of medial temporal lobe seizures with radiosurgery.[6,22,31,34] Although target definition may be variable amongst different neurosurgeons, radiosurgery for MTS associated MTLE is an attractive option because of its low morbidity and mortality. Furthermore, conventional open temporal lobectomy can also be pursued if the initial radiosurgical treatment is ineffective and sufficient time has been permitted for the delayed radiosurgical antiepileptic effect after 3 years.[6]

Recent dose studies have also indicated that a lower marginal dose of 20 Gy may be less effective in reducing seizures. Cmelak *et al.* report unsuccessful seizure reduction with radiosurgery using a 15 Gy marginal dose.[50] Kawai *et al.* also report two cases of radiosurgery with unsuccessful anti epileptic effect with a marginal dose of 18 Gy.[22] Finally, Srikijvilaikul *et al.* from the Cleveland Clinic report their series of failed radiosurgical treatment for seizure control with a 20 Gy marginal dose.[5]

The radiobiology of radiosurgery in the setting of MTS associated MTLE is not yet completely understood. While some animal studies have suggested an anti-epileptic effect of radiation with subnecrotic doses,[39] human studies indicate that a certain amount of tissue damage may be required to see a significant amelioration of seizures. The importance of this question is that radiosurgical treatment of eloquent brain regions would be possible if an effective subnecrotic dose could be found.

Histologic evaluation of radiosurgical treatment

Histological examination of radiosurgically treated human mesial temporal tissue for MTLE has been limited, but some histologic analysis of radiosurgically treated tissues involving patients who underwent resection due to lack of seizure control have been reported.[22,50,51] Using a subtherapeutic dose of 15 Gy, Cmelak *et al.* noted no radiation-induced histopathologic changes after radiosurgery.[59] In another two patients treated with 18 Gy, one patient was noted to have a necrotic focus with some prominent vascular changes consisting of vessel-wall thickening, fibrinoid and hyaline degeneration. The other patient treated with this subtherapeutic dose showed no necrosis or vascular changes.[22] Treated with a higher, yet subtherapeutic, dose of 20 Gy, all five patients from the Cleveland Clinic also showed necrosis, perivascular sclerosis, and macrophage infiltration upon resection and histologic evaluation.[51] These observations suggest that in humans, significant histologic changes may only be observed in radiosurgical doses greater than or equal to 20 Gy. These radiobiologic and histological changes may be required for a full antiseizure effect. Thus, a dose that produces some tissue damage without producing an excessive response, likely 24 Gy, is the optimal effective dose in the radiosurgical treatment of MTLE.[6,31,34]

Hypothalamic hamartomas associated gelastic epilepsy

Hypothalamic hamartomas are rare lesions with a prevalence of 1–2 in 100,000 commonly associated with precocious puberty, developmental cognitive delay, and gelastic epilepsy.[29,54] An overwhelming majority of seizures associated with hypothalamic hamartomas are gelastic in nature and are

medically refractory.[29,52,53] These hamartomas are ectopic tissue consisting of glia, neurons and fiber bundles.[24,52,53]

Surgical resection of hypothalamic hamartomas has been reported to improve control of gelastic seizure activity, but due to the technical difficulties of reaching this deep lesion in a critical area, open microsurgical resection is often difficult, incomplete and associated with a high risk of complications such as motor, visual and hypothalamic deficits.[24,52–55]

Unger *et al.* report two patients treated with low-dose radiosurgery for hypothalamic hamartomas with significant seizure improvement after 36 and 54 months.[36] This therapeutic delay is consistent with the radiobiological effects of radiosurgery.

In a recent retrospective multicenter study, Regis *et al.* report ten patients treated with 18 Gy that had improvement in their seizures after radiosurgical treatment of hypothalamic hamartomas.[29] In a larger series, 19 out of 30 patients were shown to have short-term improvements in 6 months of followup, but further follow-up data is still being evaluated in this series.[33] This alternative treatment holds great promise as an effective alternative treatment given the surgical morbidity associated with microsurgical dissection of hypothalamic hamartomas. Further investigations with larger series, longer follow-up in a prospective manner must be conducted to establish the true safety and efficacy of this treatment option.

Cavernous malformation associated epilepsy

The most frequent presentation of cavernous malformations is seizures. These congenital vascular malformations can cause hemorrhage and repetitive neurologic deficit, but more commonly manifest as repetitive seizures.[30,56] The incidence of medically intractable epilepsy associated with cavernous malformations is not yet established.[30]

Radiosurgical treatment for cavernous malformations is controversial because clear evidence for protection from hemorrhage has yet to be established.[21,24,30] Although resective, open microsurgical treatment of cavernous malformations remains the standard efficacious therapy, a recent series by Regis *et al.* suggest a role for radiosurgery in the treatment of seizures associated with cavernous malformations near 'highly functional cortex' that may preclude open resection.[30] Using a mean dose of 19 Gy, 53% of 49 patients with refractory seizures became seizurefree and 20% were significantly improved at 2 years after treatment,[30] demonstrating that epilepsy associated with cavernous malformations near eloquent cortex may be treated with radiosurgery to reduce seizure frequency. Given the low bleeding risk of cavernous malformations in cortical regions and common presentation with seizures,[57] patients seeking an alternative to microsurgical resection with decreased morbidity may opt for radiosurgical treatment of medically intractable seizures associated with these cavernous malformations. In addition to cavernous malformations near eloquent cortex, deep seated cavernous malformations which are not amenable to open procedures may also potentially be amenable to antiepileptic therapy with radiosurgery for medically intractable seizures. Unfortunately these deep seated lesions have a higher risk of clinical bleeding and poor neurologic outcome,[57] and the effect of radiosurgery on this risk is still unclear.[21,24,30] Without clear evidence of the effect of radiosurgery on bleeding risk, microsurgical resection remains the standard therapy for cavernous malformations.

Long term radiosurgical complications

Although the long-term complications of radiosurgery are not yet fully characterized, it appears that these risks are minimal. There are reported cases of radiosurgery associated 'radiation-induced' malignancies, but these reported cases are extremely rare.[6,58–61] Much longer periods of follow-up must be investigated to fully appreciate the possible long term complications, as the development of new radiation-induced neoplasms requires decades to develop. A conservative estimate suggests this rate as 3% in 30 years.

The antiepileptic radiosurgery mechanism

Although radiosurgery has been shown to reduce seizures in various forms of medically intractable epilepsies, the mechanism by which this abatement occurs is not clear. It has been suggested that radiation itself has a direct antiseizure effect. This effect has been purported to operate through several mechanisms. As glial cells are more radiosensitive than neurons, Barcia-Salorio proposed low-dose radiosurgery may reduce glial scar formation allowing increased dendritic sprouting, improved cortical reorganization and fewer seizures.[15] Elomaa proposed the antiepileptic effect of radiation is mediated through effects of somatostatin.[62] Although the clinical results of the most recent human studies suggest the therapeutic efficacy of radiosurgery is linked to necrosis of mesial temporal structures, proof for this concept would need to come from direct observation of tissue samples in patients where radiosurgery has controlled seizures. This is unlikely to occur, as only patients with persistent seizures are likely to undergo further open resective surgery.

Surrogate markers of radiation effect such as imaging changes on MRI have thus far shown mixed results. Radiation-induced edema has become evident in most patients 9–15 months following radiosurgery. These changes are usually time-limited, they are often followed by focal atrophic changes. Thus, MRI changes may not be diagnostic of true radiation necrosis. The actual mechanism by which high-dose radiation reduces neuronal hyperexcitability will not likely be found from human studies.

Although preclinical evidence and the results from two early human trials suggested control of seizures might be possible with doses of radiosurgery that were lower than those typically applied to tumors,[16,19] recent case reports also describe the failure of low-dose radiosurgery to control seizures.[22,50,51] While failure of seizure control is easy to identify, it is a much more difficult task to determine that this is due to an insufficient radiosurgery dose. The time dependence of radiosurgical effects is also a confounding factor that has not been fully explored. A consensus among different treating radiosurgical centers for when radiosurgical treatment has

'failed' has not yet been agreed upon.[32] As noted, recent, prospective results suggest that radiosurgery may have results very similar to resection where ~30% of patients will continue to have seizures.[6] The reported failures of low-dose radiosurgery are case reports and as of yet do not demonstrate a failure rate of 30%. Furthermore, radiosurgery patients who did not show adequate seizure reduction commonly had radiation doses of 20 Gy or less, and these patients showed little evidence of radiation-induced necrosis in their pathologic specimens.[22,50,51] Thus, the best evidence to date from human and animal experiments suggests that there is a steep dose-response effect for seizure reduction, that some neuronal damage is required to produce seizure abatement, and that the dose required to eliminate seizures is very close to the absolute tolerability of human brain tissue.

Conclusions

Recent data suggests radiosurgery is indeed effective at reducing epileptiform activity and seizures in several forms of medically intractable epilepsy. In animals, the low doses of radiation required to be therapeutic have not been shown to cause histologic changes, disruption of normal neuronal firing patterns or significant learning deficits. When multiple isocenters are employed, and animals are observed over longer time periods, the patterns of changes seen on MRI closely mimic those observed in human trials and histological analysis indicates that structural lesions are created. Animal studies have not yet proven if the antiepileptic effects of radiosurgery are due to tissue damage sufficient to cause functional ablation and necrosis or if seizure activity has been eliminated in still functional parenchyma. However, the available data suggest that it is necessary to produce changes on MRI consistent with tissue damage in order to eliminate seizures in humans.

Recent prospective trials suggest that radiosurgery may be an effective and safe treatment for medically intractable epilepsy associated with MTS. Prospective trials with larger numbers of patients will be required to establish radiosurgery as a standard therapy for MTLE. Further promise is shown in expanding the utility of radiosurgery for seizure control in medically intractable epilepsy associated with cavernous malformations and hypothalamic hamartomas. Radiosurgery may prove to be especially appealing in treating lesions near eloquent cortex or deep seated lesions when open microsurgical resection may not be feasible without significant morbidity. As the true long-term toxicity of radiosurgery is not known, patients treated with this modality should be carefully followed.

125 Vagal nerve stimulation: experimental data

S Chabardès, I Najm, and HO Lüders

Introduction

Vagus nerve stimulation (VNS) is a worldwide applied technique for the treatment of intractable epilepsy that cannot benefit from resective surgery. Recent clinically-controlled trials have reported a 50% seizure control rate in about 30% of patients'. However, its efficacy seems to vary among teams and the type of patients who can benefit from this technique is so far unknown, despite more than 26,000 people treated worldwide. Moreover, the mechanisms of action are still not fully understood despite increasing interest in this field.

The purpose of this chapter is to give a critical overwiew of the experimental data existing in this field together with our experiments performed on rats at the Cleveland Clinic Foundation.

On the efficacy of VNS against seizures induced in animals

Original reports

At the end of the eighties, several teams reported the effect of repetitive VNS on seizure activities in generalized, or partial, secondary generalized models of epilepsy. It was based on preliminary observation[2,3] which indicated that low-voltage vagus nerve stimulation could significantly reduce spikes from a neocortical focus produced by topical application of strychnine. First, Zabara *et al*. reported[4,5] their experience in a chemically-induced generalized model of epilepsy using intravenous injection of strychnine in 20 dogs. They found that electrical stimulation of unilateral vagus nerve at a frequency that ranged from 30–80 Hz could abort seizures within usually less than 1 sec. This effect could last several minutes (up to 20 min) after the end of stimulation. These original very exciting results should be balanced at several levels: first, the seizure activity was not directly monitored by EEG recording, but only by EMG electrodes implanted bilaterally in both gastrocnemius muscles. Second, the authors monitored the EKG and respiration and used them as markers to asses that electrical current was properly delivered to the VN. They showed that in each case, there was a rapid but consistent bradycardia at the onset of the stimulation period together with hyperventilation. As the EEG was not monitored, one could easely argue that the powerfull cessation of 'EMG seizure' was in fact a nonspecific response to a severe vegetative dysfunction.

In 1990, Lockard *et al*.[6] were the first to report the effect of VNS on a monkey model in a robust, well-designed study. They used four animals, all equipped with an epidural EEG screw and who exhibited chronic, secondary generalized, spontaneous partial motor seizure obtained after subpial injection of alumina gel in the left central cortex. Seizure activity and severity was assessed for several months with chronic video-EEG monitoring. Left VN was stimulated in two animals, and right VN was stimulated in the remaining two. Each constant-current stimulation was delivered at the onset of every spontaneous seizure and lasted for the whole seizure. This stimulation period lasted 2–6 weeks preceded and followed by at least 2 weeks of no stimulation period (baseline). Stimulation parameters were as follows: frequency from 50–250 Hz, pulse width from 0.5–0.6 ms. Two monkeys became nearly seizure free during the stimulation period, while two others were not ameliorated. According to the authors, VNS had no consistent effect on either seizure severity or EEG interictal spikes and concluded that if VNS could influence 'the epileptogenic process', its efficacy was 'still in question'.

At the same time, Woodbury and Woodbury[7] reported the effect of VNS in the Pentylène-tétrazole (PTZ) and the 3-mercaptoproprionate (3-MP) model in rats which creates convulsive status. In an additional experiment they also used maximal electroshock seizure (MES) in wakeful rats. They showed that VNS was effective in preventing seizure, but that VNS could not terminate ongoing seizures in both PTZ and 3-MP models. They found that delay between onset of seizure, onset of stimulation, and seizure duration was significantly positively correlated. In the MES model, the authors found that VNS could not change the total duration of seizure but could prevent the tonic phase when C fibers of VN could be properly stimulated.[8]

The general conclusion of the authors was that VNS was effective in these three models, but the design of the study did not allow random stimulation periods. Moreover, the fact that rats which were not improved (number was not given) were all suspected not to have received the appropriate electrical stimulation properly because of technical problems is questionable as the anatomical study of VN integrity was not described in the paper.

Later, McLachlan[9] reported experimental data on anesthetized rats rendered epileptic by application of local penicillin (PG) in the motor cortex and ip injection of PTZ in an attempt to quantify the effectiveness of VNS on PG-induced

interictal spikes and the tonic-clonic phase of PTZ-induced seizure. The vagus nerve was stimulated using a grass system with biphasic square-wave pulses delivered at the onset of seizures. The stimulator was set at the following parameters: 0.01–1.2 mA, 20 or 50 Hz, 0.5 ms pulse duration, 1–20 s in duration. Mean spike frequency decreased significantly from 42 ± 11 to 28 ± 11 (mean reduction: 33%, $p < 0.001$) and the effect lasted 20 s after stimulation.

Amplitude of residual high voltage spikes was also reduced during and immediately after VNS. This effect appeared to be positively correlated with the current amplitude, while variation of frequency did not change the response. VNS could also decrease the duration of PTZ-induced seizure, and seemed to affect the clonic component of seizure which has been shown to involve the rostral mesencephalon, while tonic phase is more integrated in caudal brainstem structures. This point was not in agreement with the aforementioned study of Woodburry *et al.*[8] which reported that VNS was effective on the tonic phase in the MES model.

As in the study of Zabara *et al.*, VNS had strong effect on the heart with a mean 50% reduction in heart rate and caused immediate respiratory arrest for a maximum of 5 s. Interestingly, tail heating had the same effect on spike reduction compared to VNS, suggesting that stimulation of C-unmyelinated fibers could influence in a non specific manner the interictal spikes, independently from the type of stimulus (electrical or physical) and that the effect was not due to the location of the stimulation. The author concluded that this reduction in interictal spike frequency was real, but was probably due to a nonspecific arousal.

Recent studies

Cleveland clinic experience: VNS and kainic acid limbic seizure model in rats

Our group performed an experimental trial in the kainic acid limbic model of epilepsy in rats treated by VNS stimulation using the same parameters usually used in humans.

Materials and methods

Seven male Wistar rats were used in this study. Cervical surgery using microsurgery tools was performed under general anesthesia (ketamine) in order to implant one single-cuff electrode around the left vagus nerve. These electrodes were specially designed to be implanted in rats (Cyberonics). The diameter of the cuff electrode was 1.0 mm and the two contacts were 1 cm apart. Each electrode was placed around the VN after having isolated the VN itself from the carotid artery to minimize current linkage to surrounding structures (see Figure 125.1). VNS lead was secure with cement at the cranial level and was connected to the cyberonics stimulator during the trial. During the same surgical procedure, four epidural electrodes located bilaterally at the frontal and parietal level were inserted and two electrodes were stereotactically and bilaterally inserted into the posterior hippocampus according to the atlas of Paxinos. One week later, under continuous video-EEG monitoring, kainic acid was injected intraperitoneally in order to get reproducible limbic, secondarily-generalized status. The design of the study is illustrated

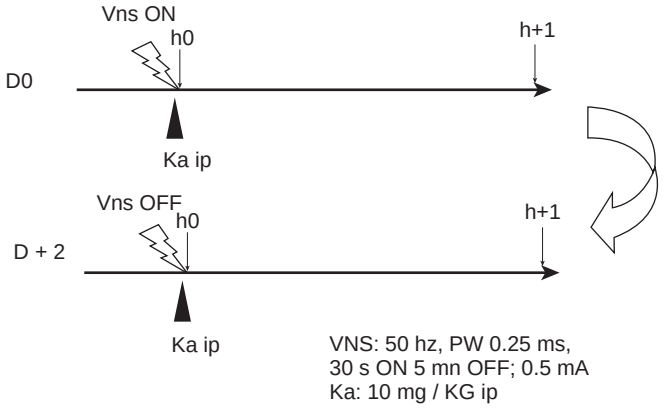

Figure 125.1 Design of the study.

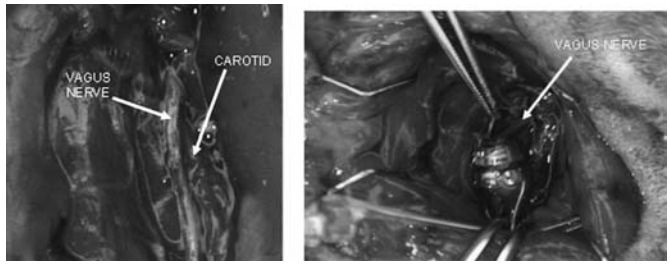

Figure 125.2 Surgical view of a VNS electrode surrounding the left VN in rat.

in Figure 125.2. Briefly, each rat received ip KA and at the same time, VNS was randomly turned on or off for 1 hour. Two days later, the same rat was again rendered epileptic using the same dose of KA and VNS was turned on or off depending on the previous randomisation. Each rat was then sacrificed after the experiment to assess the integrity of VN and the anatomical position of the VNS and hippocampal electrodes. EEG files were stored and reviewed offline. We particularly paid attention to the delay of first limbic and generalized seizures, the mean number and duration of limbic and secondarily generalized seizures. The off-period of each trial constituted the control situation.

Results

Details are presented in Graphs 1–4 and Figure 125.3. No artefact was seen on epidural EEG during the ON period of stimulation. One rat died when the VNS was turned ON. In two rats out of six, there was a trend to delay the first occurrence of hippocampal or generalised seizure, but in one rat. this delay was shorter. In one rat out of six, VNS worsened the accumulated duration of hippocampal or generalized seizure, while in three animals, accumulated duration of generalized seizures tended to be smaller during the VNS period.

In our experimental conditions, when data were pooled, VNS did not change significantly mean delay of first hippocampal and generalized seizure, mean accumulated duration of hippocampal and generalized seizure, nor mean duration and number of individual hippocampal and generalized seizures for 1 hour following KA ip injection. At the individual level, VNS in our experiment had in some case both anticonvulsive or proconvulsive effects.

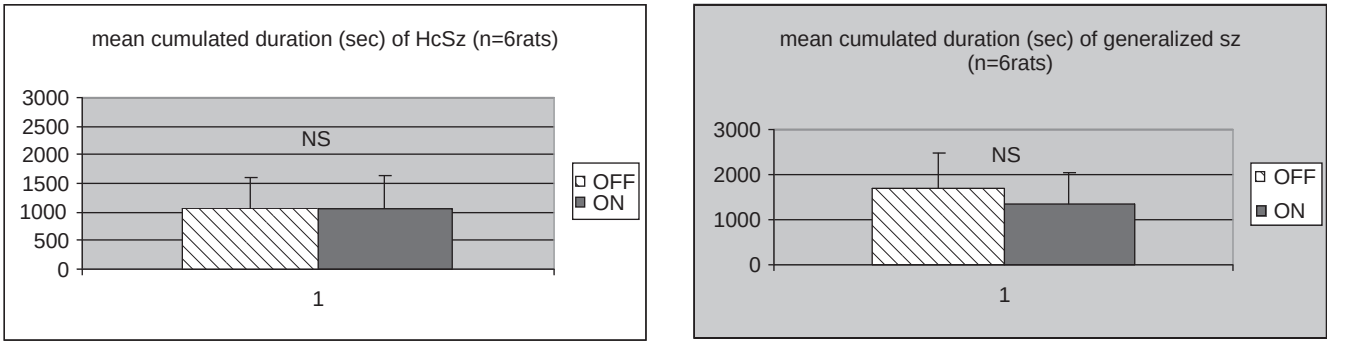
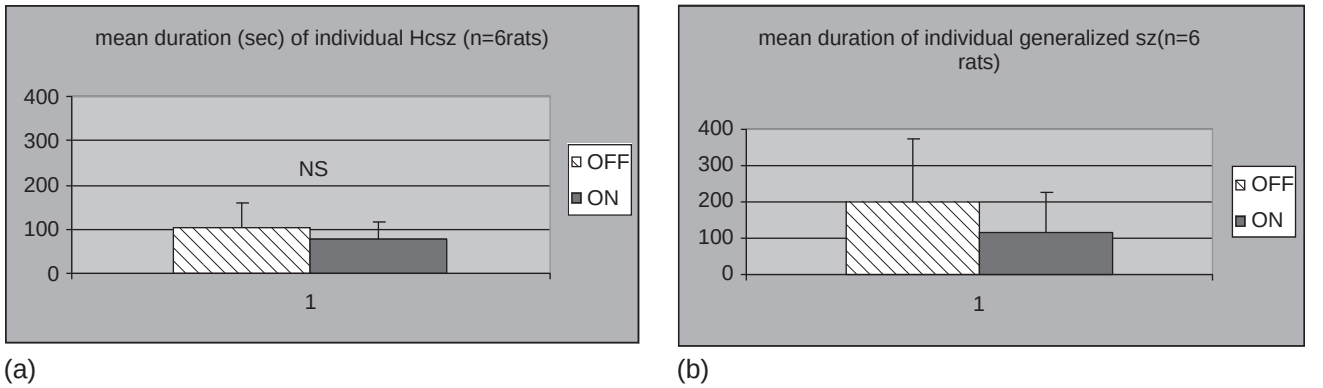
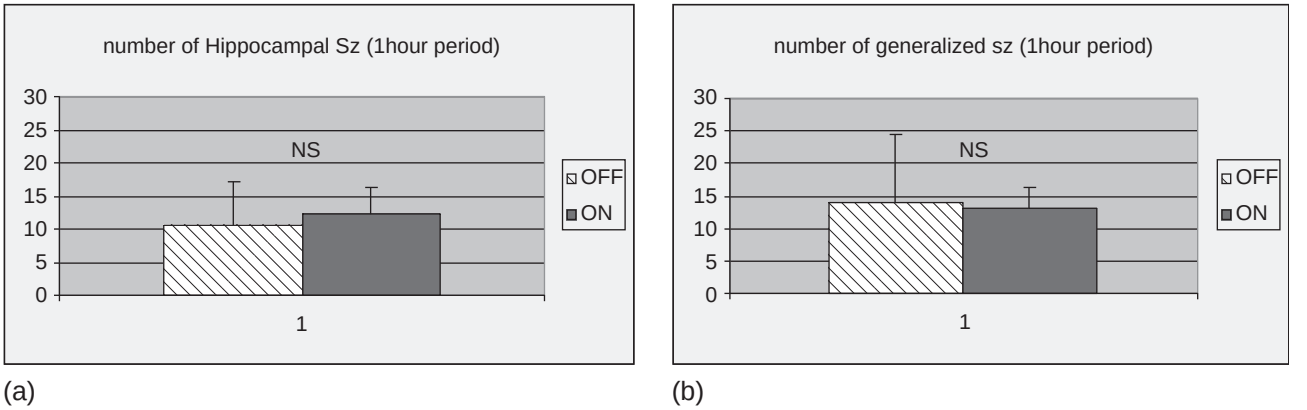


Graph 2 Mean cumulated duration of hippocampal seizure (a) and generalized seizure (b).



Graph 3 Mean duration of individual hippocampal seizure (a) and generalized seizure (b).



Graph 4 Mean number of hippocampal seizure (a) and generalized seizure (b).

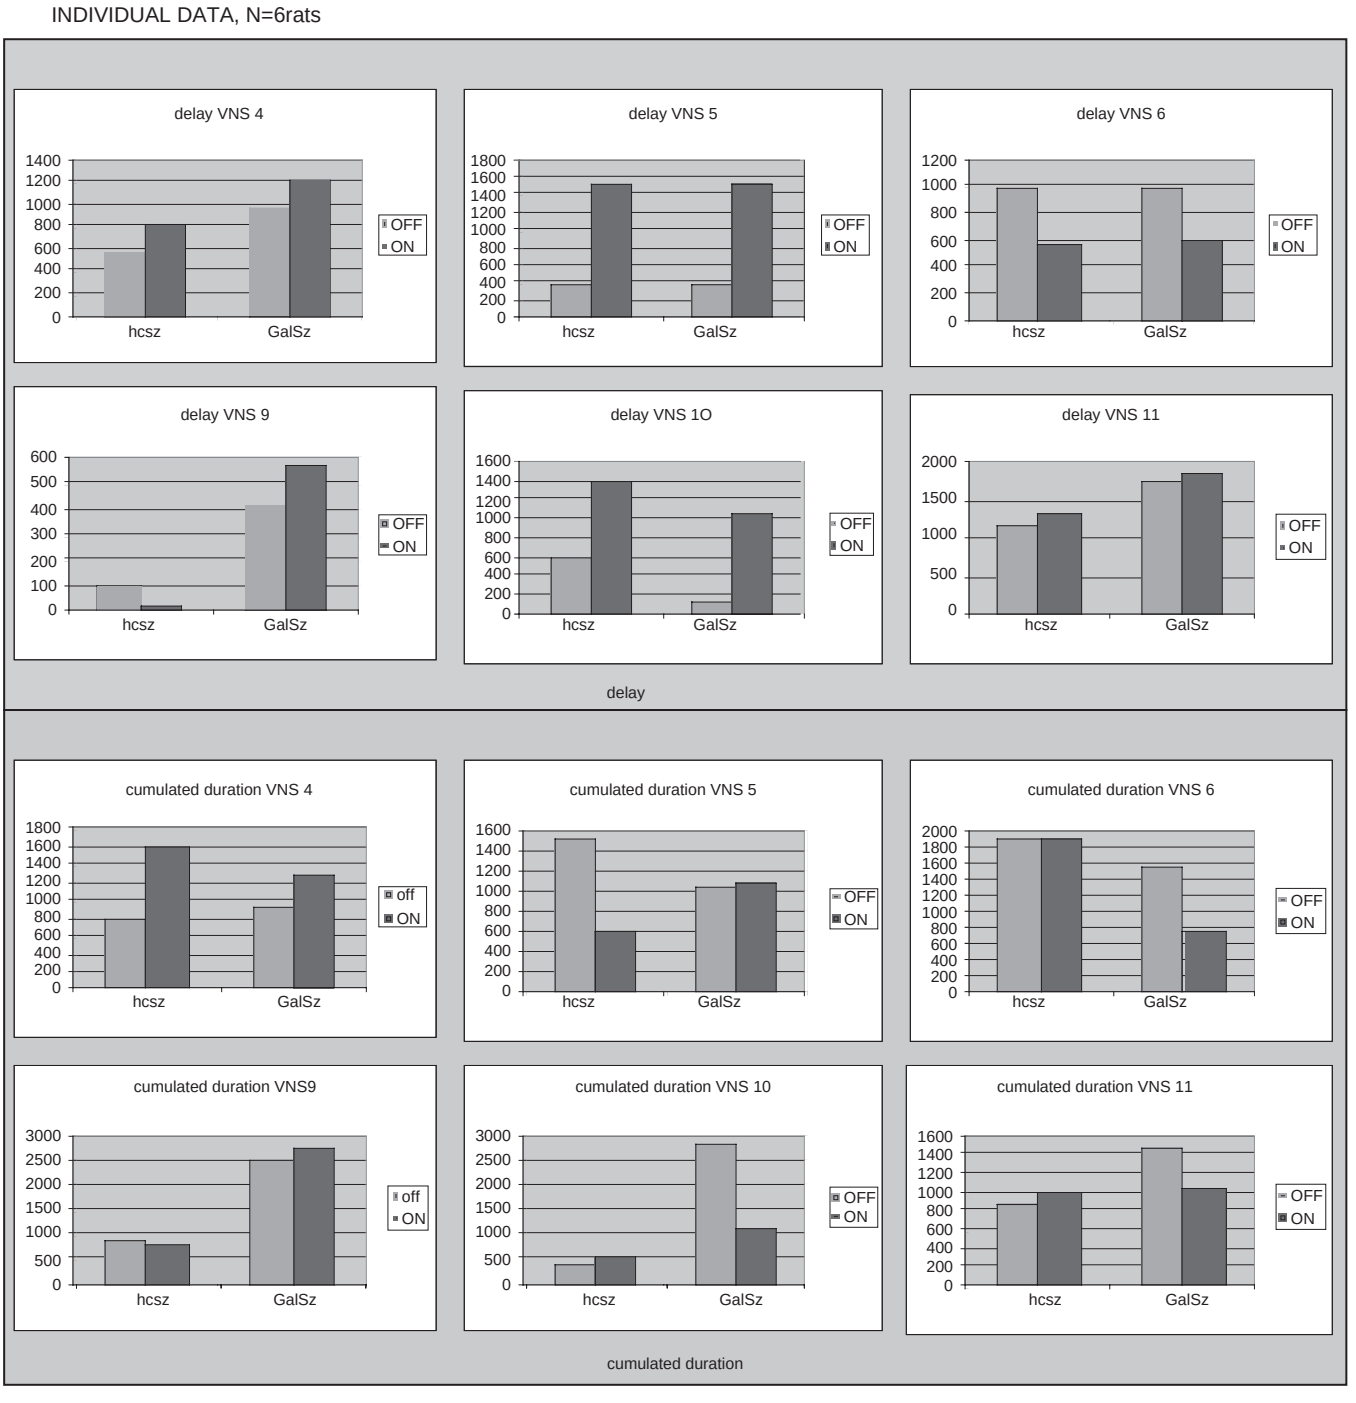


Figure 125.3 Graphs of all the six rats used in the experiment and showing the delay (upper part) and the accumulated duration (lower part) of limbic and secondarily generalized seizures. Note that both anticonvulsive or pro-convulsive effects can be seen.

VNS and amygdala-kindled seizures in rats

The group from Ghent in Belgium[10] have very recently reported the effect of VNS in amygdala-kindled seizures in rats. In a first paradigm, a group of eight rats received left-VNS 2 h prior to daily kindling stimulation. The result of this first experiment showed that VNS could not impact kindling epileptogenesis and had no prophylactic anticonvulsive effect on stage-5 seizures. Moreover, convulsive duration was significantly longer when VNS was applied prior to the kindling phase as compared to control situation. In a second paradigm, left VNS was applied 2 s after induction of the kindling stimulus that was determined to elicit a stage-5 seizures. The results of this experiment were as following: (1) the mean after discharge duration was significantly reduced after a 60 s VNS train compared to the control situation (50% reduction aproximatively). (2) However, only two out of six rats showed a complete suppression of stage-5 seizures. The authors concluded that VNS had both anticonvulsive and proconvulsive effects on amygdala-kindled seizures. This study is in accordance with our experiments described above in limbic seizure induced by ip injection of Kainic Acid.

VNS and absence seizures

The same group have also studied the effect of VNS in genetic absence epilepsy rats from Strasbourg (GAERS).[11,12] Briefly, 39 rats were used for this experiment in which VNS was applied acutely and chronically. In the first paradigm (acute experiment), a randomized cross-over design was used and VNS was applied when a spike and wave (SW) discharge appeared on the EEG and the stimulation was stopped at the end of the SW. The results of this experiment showed that mean duration of SW was significantly longer compared to the control situation and that VNS acutely applied worsened absence seizures. In the second paradigm (chonic stimulation), VNS was applied for 1 week after a first week of baseline. Compared to the control situation, VNS did not modify the number of SW or the mean and accumulated duration of SW. The authors concluded that a longer period of stimulation might be necessary to modify absence seizures in this model. This study does not confirm prior studies that showed that VNS was effective in another model of acute absence seizures induced by ip injection of PTZ.[13] In the PTZ model, Takaya *et al.*,[14] concluded that a preventive effect of VNS was seen in about 1/3 of rats and that this effect was better when the stimulation lasted 60 mn before the beginning of the PTZ injection.

According to the literature, PTZ-induced seizures are sensitive to VNS, whereas VNS appears to be ineffective on genetically determined absence seizures. The anticonvulsivant effect of VNS in this model is not related to the site of stimulation as demonstrated by Fanselow *et al.*,[15] who reported a 78% reduction of seizures in the same model using acute, trigeminal nerve stimulation.

VNS and maximal electroshock model in rats

Krahl *et al.*[16] have recently highlighted that the Locus Coeruleus was involved in the circuitry necessary for the anticonvulsivant effects of VNS. For this experiment, the authors used the maximal electroshock seizure (MES) model in rats and compared the severity of seizures during VNS, with and without chemical lesion of the locus coeruleus. They showed that VNS was effective on the severity of MES and that this effect was inhibited when the Locus Coeruleus was lesioned. In this report, VNS did not modify the number of seizures but their severity was expressed by a reduction of duration of hind limb extension.

Conclusions

VNS has complex effects on seizures and studies on animal models of epilepsy are difficult to analyze. It seems that, as in human studies, partial seizure might be influenced in approximatively 30% of cases, and that in cases of generalized epilepsy, studies can show improvement or at the opposite, no effect and sometime worsening.

Technical issues in animal experiments might explain in some part the difficulty to clearly demonstrate a consistent effect, like the difficulty to conduct chronic, long-lasting stimulation in animals, or the difficulty in stimulating specifically afferent fibres in the VN. Moreover, specific electrodes which allow better contact with fibres of VN should be designed in order to deliver current with much better efficacy. Animal experiments cannot so far answer the following question: does efficacy improve after chronic stimulation as compared to human pathology? Could the fibrosis surrounding the fibers of VN not explain in some part the heterogeneity of effects seen in animal experiments and in humans? Are we sure that the ratio of ON stimulation period compared to the OFF period is sufficient and can be applied in animal models?

We still believe that, as in other DBS techniques which are currently challenged, well-conducted animal experiments are mandatory to study the circuitry involved during VNS and that modulation of this circuitry either by lesion or activation could give to the scientific community strong experimental data supporting the antiepileptic effect of this therapy.

126 Vagal nerve stimulation:surgical technique and complications

WE Bingaman

Introduction

Vagal nerve stimulation (VNS) is FDA approved for the treatment of medically intractable partial onset epilepsy in patients over 12 years old. Efficacy and safety issues have been addressed in several large clinical trials and will not be addressed here.[1–4] The current device is manufactured by Cyberonics (Houston, TX) and includes a pair of helical electrodes (2 mm or 3 mm diameter), a battery-powered generator (models 100, 101, and 102), a tunneling tool, software and programming tools, and supplies for the patient (Figure 126.1). The aim of this chapter is to review surgical technique and perioperative management.

Background and patient selection

Indications for VNS include patients with medically intractable partial epilepsy without resective surgical options or those where surgery is contraindicated for medical reasons. Contraindications to implantation include patients with history of previous left neck surgery or prior cervical vagotomy. Relative contraindications may include pregnancy, asthma, chronic pulmonary disease, active peptic ulcer disease, and insulin dependent diabetes mellitus. Additionally, implantation in patients requiring periodic magnetic resonance imaging (MRI) should be avoided because of safety concerns in the higher Tesla magnetic fields now commonly employed. Common adverse effects include coughing, hoarseness, dyspnea, and headache. These effects are seen during stimulation and tend to habituate with time. Serious adverse effects have been reported and include vocal cord paralysis, infection, Horner's syndrome, lower facial muscle paresis, and cardiac arrest. Sudden unexplained death has also occurred, but not at a rate different than the epileptic population.[5] Mechanical complications can occur such as lead fracture or failure and generator malfunction.

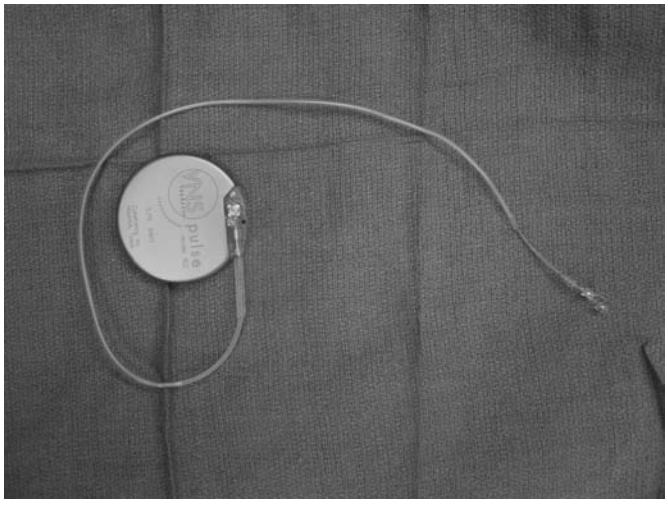

Figure 126.1 VNS Model 102 generator and electrodes. (Cyberonics, Inc. Houston, Texas).

Patients with epilepsy uncontrolled by anticonvulsant medications may be candidates for VNS. The definition of medically intractable generally includes a description of an adequate drug trial without unacceptable side effects. The exact definition of an adequate drug trial is not clear. Because the efficacy of VNS is similar to a new medication trial, it is the author's opinion that VNS candidates should exhaust medication options prior to consideration for VNS therapy.

Patients should also undergo a routine pre-surgical evaluation to exclude resective surgical options. This may include inpatient video-EEG monitoring and magnetic resonance imaging of the brain. Other studies might include positron emission tomography (PET) and ictal cerebral blood flow studies (SPECT). The patients are then presented at a multidisciplinary epilepsy conference and management options are discussed including VNS implantation. The patient is then instructed to keep a seizure diary for three months prior to implantation. Prior to surgery, the patient and family are counseled on post-operative expectations and side effects of stimulation. They are given a videotape of patient information published by Cyberonics.

Although not FDA approved for treatment in the pediatric population, there is growing evidence that VNS is safe and similarly effective in this population.[6–8]

Pre-operative discussion

The patient and family should be educated about the nature of the device being implanted. This includes a discussion of the expectations of the patient and the reality that they will likely not be seizure free. They should be counseled that the device will need a battery change in the future. They should be informed about the avoidance of MRI scanning while the VNS

electrode is in place around the vagus nerve. In addition, the use of diathermy is forbidden. Routine side effects are discussed (mainly hoarseness during VNS 'on times'). Complications such as the risk of infection and the risk of injury to the carotid artery, jugular vein, or vagus nerve should also be mentioned. The patient is also supplied with magnets from Cyberonics which enable the user to turn on or off stimulation. The use of these magnets is straight forward and should be explained to the patient and family members.

Finally, the patient should be counseled about the risks of revision surgery should the lead need to be removed or replaced. This includes an increased risk for vagus nerve injury from surgical trauma that is difficult to quantify as large numbers of revision surgeries have not yet been performed at many centers. At our institution, removal with or without replacement of the electrode has been done in ten cases with one case of transient hoarseness felt secondary to surgical manipulation.

Anatomy and surgical technique

The vagus nerve is a mixed cranial nerve containing approximately 80% sensory fibers. Efferent fibers innervate the larynx and provide parasympathetic control to the heart, lungs, and abdominal viscera. The right vagus nerve innervates the sinoatrial node of the heart while the left innervates the atrioventricular node. In the dog model, stimulation of the right vagus nerve caused more cardiac slowing then the left.[9] For this reason, the left human vagus nerve is implanted. Adverse cardiac complications have not been commonly seen, perhaps because stimulation of the nerve can be done on a segment away from the origin of the cardiac branches. The nerve is suited for implantation in the cervical region where it courses between the cervical carotid artery and the jugular vein. A segment of nerve approximately 3 cm in length is easily dissected in this region. It is our practice to begin with a segment low in the cervical region as patients may need another VNS electrode implanted on a different part of the nerve in the future.

The procedure itself is straightforward and is performed by any surgeon familiar with neck anatomy. Neurosurgeons are ideally suited because of the familiarity with epilepsy and their active roles in comprehensive epilepsy centers.

On the day of surgery, the electrode and generator are inspected and tested prior to the procedure. A spare generator and electrode should be available in case the primary device fails. Once verified that the equipment is functioning, preoperative antibiotics are given and the patient undergoes a general anesthetic.

A primary surgeon and assistant participate. The patient is positioned supine on the table with the anesthesia team at the head. The primary surgeon stands at the left side of the neck, his assistant opposite him. The patient's head is positioned on a donut and slightly extended and turned to the right. The surgeon may use a roll under the scapula to help extend the neck. After preoperative antibiotics are given, the neck and chest is prepped with betadine scrub and paint solutions. The electrodes are implanted in the left neck by either a 'carotid' incision or a transverse 'collar' incision. A 3–4 cm incision should be centered at mid-neck level (cricothyroid interval) and on the anterior border of the sternocleidomastoid muscle (Figure 126.2). The skin is incised with a #10 scalpel and the skin edges widely undermined with Metzenbaum scissors. The platysma muscle is divided in the direction of its fibers and the deep cervical fascia is opened to identify the sternocleidomastoid muscle. This muscle is mobilized and retracted laterally to expose the neurovascular bundle. This bundle is then incised to expose the carotid artery and jugular vein. The vein is retracted laterally and the main trunk of the vagus nerve is usually found deep between the artery and vein. Approximately 3–4 cm of nerve should be mobilized from surrounding loose connective tissue. Stay sutures in the carotid sheath can be utilized to deliver the nerve towards the surgeon. Mobilization and handling of the nerve should be done with fine forceps. Care must be taken to avoid injuring the main trunk or one of the branches.

Once the nerve dissection has been completed, the left chest incision is marked along the anterior axillary line and opened with a #10 scalpel. A subcutaneous pocket over the pectoralis fascia is created with sharp and blunt dissection. The pocket must be large enough to accommodate the generator while avoiding strain on the incision line.

The electrode array is removed from the sterile package and brought onto the surgical field. Skin edges should be isolated with sterile gauze and the electrode tunneling device passed from the neck incision to the chest incision in a plane just above the sternocleidomastoid muscle, being careful to pass superficial to the clavicle. Once the tunneler is passed, the metal rod is removed leaving the plastic sheath in place. The electrode cables are then inserted into the plastic sheath and the sheath pulled through to the chest. The ends of the cable are wrapped in a sterile towel until connected to the generator (Figure 126.3).

The electrodes are implanted on the vagus nerve by gently winding the electrode spirals around the nerve. The electrode array consists of three spiral coils. The first is not an electrode but a tethering coil, which is placed around the distal (caudal) portion of the nerve. The next is the cathode electrode and the most distal is the anode electrode, which ends up being placed on the most cranial portion of the nerve (Figure 126.4).

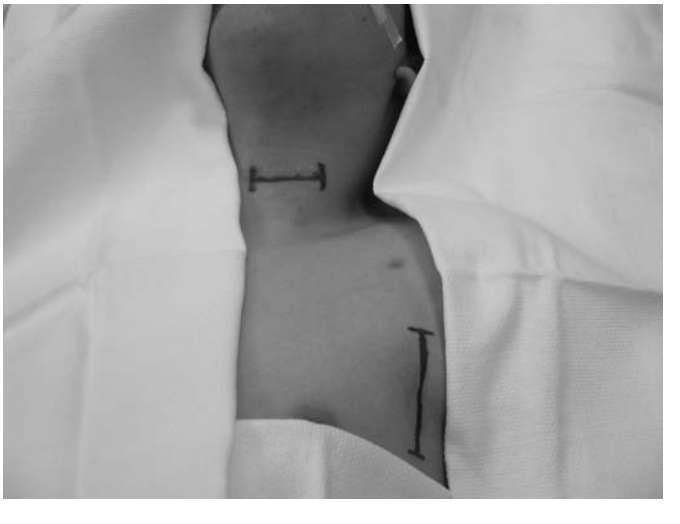

Figure 126.2 Location of incisions: left neck and left axilla.

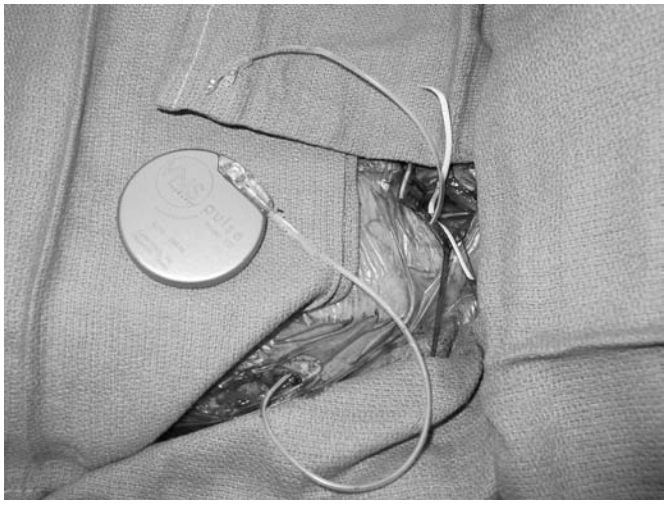

Figure 126.3 VNS electrode tunneled from neck to chest.

The actual electrode coils should be handled with care to prevent electrode breakage. Each coil has a small string attached, which is useful for deploying it around the nerve. The deployment of the electrode coils should be done with the primary surgeon and assistant surgeon working together to pass the electrode spirals around the nerve without placing undue tension on the electrodes or the nerve. Fine jeweler's forceps work well during this stage of the procedure. Once coiled properly around the nerve, a strain relief loop should be created above the carotid sheath with excess electrode cable. The loop is tied down with silicone ties provided in the electrode kit. These ties should be sutured to the cervical fascia deep to the platysma muscle. Avoid tying to muscle as the electrode may shift position when the patient moves their neck. Care should be taken to avoid inadvertently displacing the electrode from the vagus nerve during intraoperative manipulation and wound closure.

The pin is then connected to the generator at the chest incision, making sure to slide the connector all the way in and then tightening it with the wrench provided. This wrench will give way when the appropriate torque is reached. For older model electrodes with two pins, the cable marked with a white stripe is the positive electrode and should be placed into the model 102R generator in the positive receptacle. The other cable is the negative electrode and goes into the negative receptacle. Care must be taken to ensure the electrode pins are placed completely into the generator in the appropriate receptacle and tightened securely.

Figure 126.4 Electrode array deployed around nerve.

The neurologist or intraoperative neurophysiologist may assist you at this stage. The computer and hand-held wand are powered up. Make sure the batteries in the hand-held wand are new. Place the hand-held wand in a sterile drape and place it over the generator in the surgical field. During this programming, lead impedance and all connections are tested to verify integrity of the system. A 1-minute lead test is then performed with a stimulus delivered at 20 Hz frequency, output current of 1 mA, and a pulse width of 500 microseconds. During this test, the patient's vital signs and EKG are monitored for bradycardia. Some centers will then turn on the system at the lowest setting, while others prefer to wait 1–2 weeks before initiating stimulation therapy.

Once the system is tested, the generator is internalized and sewn to the pectoralis fascia with a permanent suture (prevents generator migration). Both incisions are then irrigated with antibiotic solution and closed anatomically with self-absorbing skin sutures. The patient is then discharged to home after a short period of observation in the recovery room. Prior to discharge, the patient should be assessed for vocal cord function.

Post-operative management and complications

Patients should be counseled to observe the wound for signs of infection. The sutures are self-absorbing and need not be removed. Return to normal preoperative activities is allowed after 48 hours. Patients should be warned that this therapy will not result in cessation of seizures and they should continue to practice seizure precautions and continue their prescribed anticonvulsant therapy. A return to care in two weeks with the treating neurologist is indicated to begin or increase VNS stimulation.

In 1994, Ben-Menachem *et al*. reported the most common side effects of VNS as hoarseness and throat pain.[10] Other reported adverse effects include dyspnea, coughing, and paresthesias. Importantly, the study concluded that VNS does not carry the CNS side effects associated with oral anticonvulsant therapy. The effects on vocal cord function have been reported in the otolaryngology literature with most studies reporting some effect on vocal cord function both related to implantation and ongoing chronic stimulation.[11,12] Additionally, rare cardiac complications have been reported.[13–15] In a 2004 report, Ali *et al*. described three patients who experienced asystole with complete heart block during intraoperative lead testing at a current of 1 mA.[13] The cardiac rhythm strips from these patients demonstrated a complete atrioventricular nodal block. In all patients this was transient and resolved with cessation of stimulation. One patient then went on to successful VNS implantation. Similarly, asystole and bradycardia were reported in 1999 by Asconape *et al*.[14] These cases also occurred during lead testing under anesthesia with no permanent sequelae. As Heck *et al* point out, 'occurrence of bradycardia is extremely rare when FDA-approved VNS parameters are used' (output currents in the range of 0.25–3.5 mA).[15]

The most common complication is wound infection. This occurs at the rate of 3–8%.[16–19] When identified early, antibiotic therapy should be initiated with the hopes of preventing device removal. Often however, both the generator and electrode need to be removed until the infection is cleared. Once cleared, the device can be re-implanted, typically 3–6 months later.

Rarely, injury to the vagus nerve may occur during implantation and will result in permanent voice change. Finally, mechanical device complications such as generator failure or lead breakage occasionally occur.

Revision surgery is necessary at generator battery end-of-life and usually involves opening the chest incision with replacement of the generator. Prior to revision surgery, consideration should be given as to which model VNS generator and electrode the patient has implanted, as the older electrode design (two pin) is not compatible with the latest generator (model 102, single pin). In the event of lead failure requiring lead revision, a second generator may need to be implanted. In this case, the hospital will lose the cost of the opened but not implanted generator. This scenario has been seen in the case of the patient with a model 100 or 101 generator and two-pin electrode who comes in the hospital for a battery change. Typically, a model 102R (two-pin compatible generator) would be connected to the existing electrode and the lead test carried out. If the lead impedance is a problem, then the electrode will need to be revised and perhaps the single-pin electrode implanted, which is not compatible with the 102R generator. Once a generator has been opened it is no longer a reusable item. Therefore, the surgeon needs to verify and check all components prior to opening the sterile packaging. We have found it useful to first check the existing electrode's impedance by disconnecting the existing generator and electrode and then reconnecting it tightly and running a lead test prior to opening any new VNS components (assuming some battery life is left in the existing generator). If the lead is a problem, the single-pin electrode would be implanted along with the 102 generator. If the lead is ok, the 102R generator would be implanted with the existing two-pin lead. Also, the surgeon should personally interrogate the patients implanted device to confirm battery life and lead impedance prior to the planned procedure. If any question exists as to which device is implanted or lead integrity then an X-ray of the device should be done prior to the revision surgery. In any case, informed consent should be obtained to include lead revision if necessary.

Occasionally the electrode lead will need to be replaced or removed due to breakage, high lead impedance, infection, necessity for MRI scanning, or patient desire. This can be undertaken, but entails risk to the vagus nerve. A recent series of seven patients underwent microsurgical removal without apparent injury; however the small number of patients makes it unclear exactly what the risk is.[20] As previously mentioned, the author has one case out of ten of transient vocal cord paralysis with electrode removal. Certainly, meticulous dissection of the electrode coils around the nerve is required, usually with loupe or microscopic magnification. Patients should be counseled on the risk of vagus nerve injury.

Summary

Vagal nerve stimulation therapy offers hope for highly select patients not responding to other more traditional epilepsy treatments. Despite initial high expectations, VNS therapy leads to a significant clinical response in only the minority of patients. Realistic outcomes and the necessity of avoiding MRI scanning once implanted should be carefully discussed with each patient prior to the operative procedure. Long term effects of VNS therapy remain unknown.

127 Vagus nerve stimulation: human studies

T Loddenkemper and AV Alexopoulos

Introduction

History

Early reports of vagus nerve stimulation in patients with seizures date back to the early 1880s, when the New York neurologist James Leonard Corning (1855–1923) experimented with carotid artery compression and transcutaneous vagal nerve stimulation.[1] These methods were reinvestigated after further development of the EEG in the late 1930s, when first studies of VNS on EEG fast activity in cats were observed.[2] Suppression of interictal spiking in cats in a strychnine epilepsy model was first observed by Zanchetti in 1952,[3] and later confirmed in the same model by Stoica and Tudor.[4] Additional evidence of EEG desynchronization by VNS in cats was collected in the 1960s.[5] Evoked cortical potentials from VNS were first described in 1951 [6] and further characterized in rabbits, monkeys and cats in the 1970s.[7–9]

The effect of vagus nerve stimulation on epileptiform activity in humans was reexamined by Jacob Zabara.[10] Based on the theory that vagal nerve stimulation suppresses vomiting and gastro-intestinal motility,[11] Zabara hypothesized that VNS could have a similar effect on seizures and tremors. Zabara investigated seizures induced by pentylenetetrazol in dogs. Left vagal nerve stimulation was found to decrease seizure activity despite ongoing pentylenetetrazol infusion.[10] Several other investigators were able to reproduce these findings in other animal models, such as maximal electroshock and pentylenetetrazol-induced seizure models in rodents, and the alumina-gel model in primates.[12–14]

The first human patient, implanted in 1988 by Penry, became seizure free.[15] Further patients were implanted by Uthman *et al.*[16] The first randomized active control study was performed in 1992 and followed by five more studies that led to the FDA approval of the device on July 16th 1997 (Figure 127.1).

Anatomy and physiology of vagus nerve stimulation in humans

Anatomy of the vagus nerve

The vagus nerve consists of 80% afferent fibers, from the visceral organs – such as heart, lungs and gastrointestinal tract – from gustatory sensors in the mouth, and from a small skin area adjacent to the ear. Afferent fibers connect in the brainstem, in particular in the nucleus tractus solitarius and then project to higher centers, such as the thalamus, hypothalamus, amygdala, and insular cortex. Efferent fibers innervate the heart, lungs, and gastrointestinal organs, and also provide some motor innervation to voluntary muscles of the larynx and pharynx.

Efferents of the vagus nerve

Efferents include autonomic fibers to the visceral organs including heart, lungs, gastrointestinal tract and kidneys.[17] These efferent fibers originate from the medullary dorsal motor nucleus and the ambiguous nucleus and synapse with neurons of parasympathetic ganglia located in the periphery near the innervated structures. Interestingly, there is specialization of the left and right vagus nerve with respect to innervation of the heart. The right vagus nerve subserves the cardiac atria, whereas the left vagus is more closely related to the cardiac ventricles.[18] Consequently, the left vagus nerve is selected for stimulation in order to theoretically decrease the risk of cardiac side effects such as stimulation-induced dysrhythmias.

Additionally, efferent motor fibers originate from alpha-motor neurons in the nucleus ambiguous and supply the vocal cords as well as other laryngeal and pharyngeal muscles. These fibers are implicated in the generation of current dependent stimulation-induced side effects, such as hoarseness, vocalization and vocal stridor.

Afferents and projections of the vagus nerve

Afferents of the vagal nerve include information on visceral sensation from the larynx, pharynx, and visceral organs, somatic sensation from an area around the ear and taste from the lower pharynx. Cell bodies of these afferent neurons are mostly located in the superior and inferior vagal ganglia near the jugular foramen. Fibers connect in the dorsal medulla and synapse in the nucleus of the tractus solitarius (NTS), the nucleus of the spinal tract of the trigeminal nerve, the medial reticular formation, the area postrema, the dorsal motor nucleus of the vagal nerve and the nucleus ambiguus.[19–25]

The NTS is a bilateral tube-like structure within the rostral pons and the dorsal medulla oblongata. Each nucleus receives afferents from both the right and left vagus nerves. In addition to vagus afferents the NTS receives and processes multiple other projections originating from the spinal cord, other cranial nerves (V, VII, and IX), and brainstem structures, including the rostral ventrolateral medulla, the dorsal tegmental nucleus of the midbrain, the parabrachial nucleus, and others. These afferents are processed in order to compute the various visceral and motor efferents. The NTS in turn projects to the parabrachial nucleus,

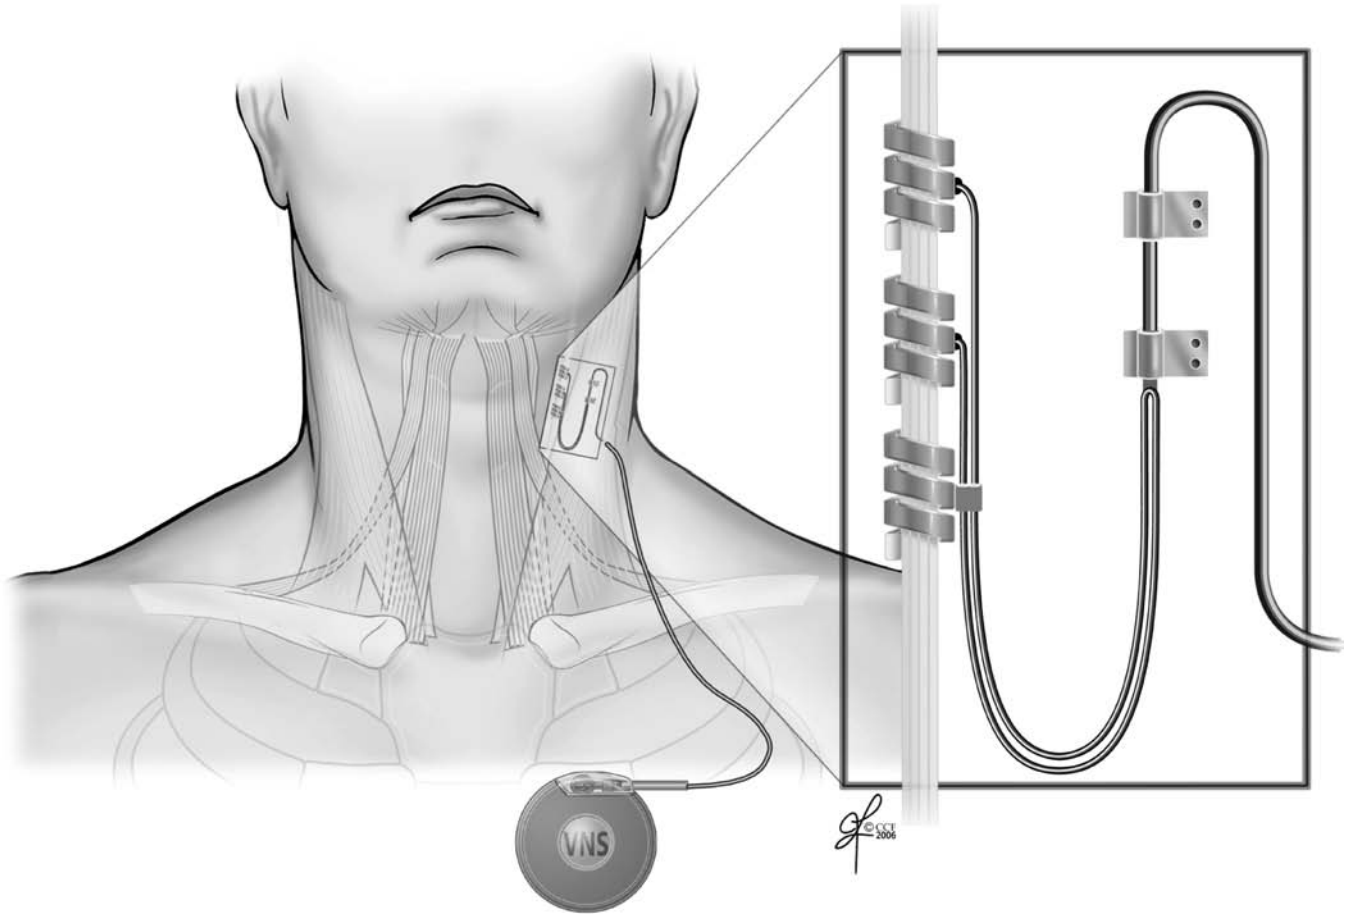

Figure 127.1 This schematic illustration demonstrates the left sided vagal nerve stimulator electrode placement and fixation.

the Kölliker-Fuse nucleus, the locus coeruleus, the raphe magnus nucleus, the inferior and medial cerebellar regions – including the vermis and cerebellar hemispheres – the periaquaeductal gray and other nuclei in the pons.[20,24,26–28] These connections allow influence on respiratory patterns and pain processing. Additionally, connections with the locus coeruleous allow either inhibitory (via the nucleus prepositus hypoglossi) or excitatory (via the nucleus paragigantocellularis) modulation of the noradrenergic system;[22,29] and connections to the raphe nuclei subserve the modulation of the serotonergic system of the brain. It has been speculated that this access to the adrenergic and serotonergic systems underlies the seizure modulating effects of VNS.[30] Afferents via the parabrachial nucleus connect to the thalamus, hypothalamus, amygdala, insula and other parts of the cortex, mediating gustatory and autonomic information.

The medial reticular formation of the medulla projects to the reticular and intralaminar nuclei of the thalamus along with other projections to the striatum and cerebral cortex.

Projections from the spinal trigeminal nucleus ascend unilaterally to somatosensory thalamic neurons, and then to the inferior postcentral gyrus and parietal lobe mediating pharyngeal and laryngeal sensation.

The area postrema is characterized by a high density of neuropeptide receptors and a capillary network with few tight junctions that facilitate neuropeptide diffusion. Afferent information to the area postrema is transmitted via blood neuropeptides. The area postrema also receives direct afferents from the vagus nerve, which project to the parabrachial nucleus and the NTS. This area is involved in controlling reflex function, such as the vomiting as well as the cardiovascular and respiratory reflexes.

The dorsal motor nucleus of the vagus and the nucleus ambiguous give rise only to efferent motor fibers targeting the larynx and visceral organs.

Cerebral projections of the vagus nerve encompass connections with the thalamus and hypothalamus (via the nucleus of the tractus solitarius, the parabrachial nucleus, the reticular formation and the spinal trigeminal nucleus), the amygdala, and various cortical areas including the insular and the prefrontal cortex (Figure 127.2).

Mechanism of action: human studies

Ictal and interictal EEG

Desynchronization of the EEG has been described as a potential mechanism in animal studies including cats,[5] rats,[12,13] dogs,[10] and monkeys.[14] However, the desynchronizing effects of VNS observed in animals could not be reproduced in human studies.[25,31,32] Hammond was not able to demonstrate suppression of interical epileptiform activity in humans.[33] Ictal EEG was modified in two patients out of five. No change in background activity was observed in this and in another study.[34]

More recent studies, however, suggest an effect of VNS on interictal EEG. Koo *et al.* followed 21 patients between 4 and 31 years at 3, 6, and 12 months after VNS implantation. Five patients with frequent interictal discharges at baseline showed

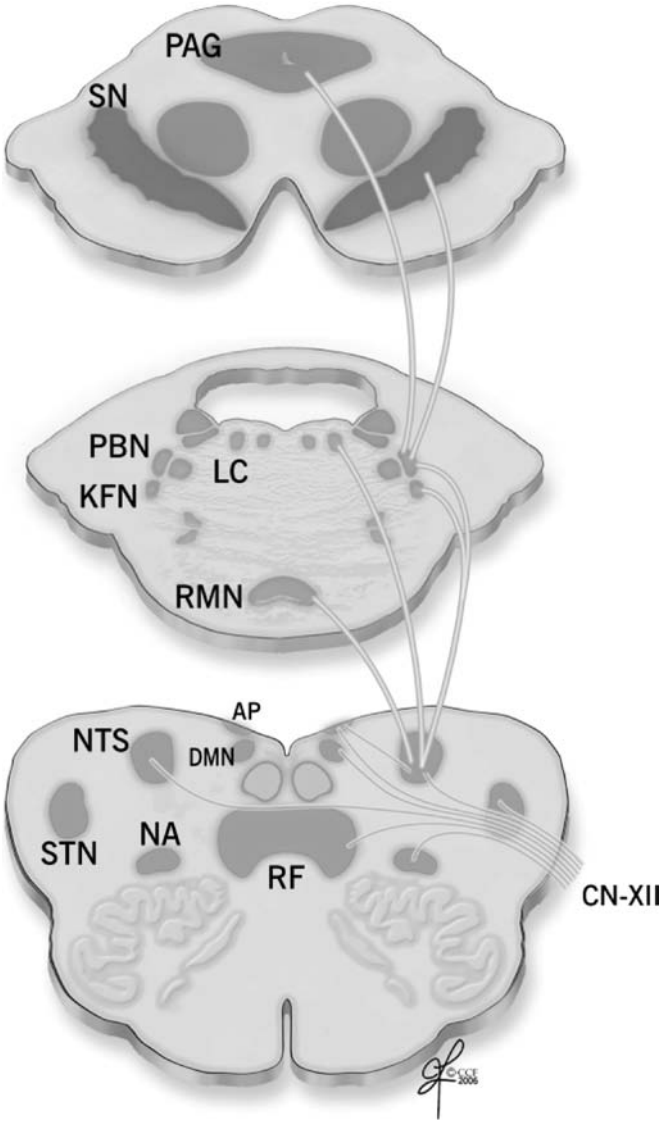

Figure 127.2 (a and b) This schema illustrates left vagus nerve afferents synapsing at several sites in the dorsal medulla, followed by projections from the pons via ascending vago-solitario-parabrachial pathways. Abbreviations: NTS – Nucleus tractus solitarius; PBN – parabrachial nucleus; PAG – periaquaeductal gray; CNA – central nucleus of the amygdale; PVN – periventricular nucleus of the hypothalamus; VPM – ventral posteromedial nucleus of the thalamus; STN – spinal trigeminal nucleus; VPL – ventral postero-lateral nucleus of the thalamus; PCG – post central gyrus; IPL – inferior parietal lobule; KFN – Kölliker-Fuse nucleus; LC – locus coeruleus; RMN – raphe magnus nucleus; PBN – parabrachial nucleus; AP – area postream; RF – reticular formation; DMN – dorsal motor nucleus of the vagus; NA – nucleus ambiguous.

synchronization of epileptiform activity, progressive increase in duration of spike-free intervals, and progressive decrease in duration and frequency of spike and wave activity with time. Patients with less frequent interictal epileptiform discharges also had a progressive decrease in the number of spikes on EEG with time, but did not show obvious synchronization or clustering of spikes. This alternating synchronization followed by more prominent desynchronization of EEG was felt to represent a potential mechanism for the action of VNS.[35]

Kuba *et al.* also reported reduction in the number of interictal epileptiform discharges (IEDs) during the period of stimulation and the interstimulation period – as compared to baseline – in fifteen patients with focal epilepsy. Interestingly, the reduction of IEDs was greater in patients, who responded to VNS (as defined by >50% reduction of all seizures).[36] These findings were reproduced by Hallbook *et al.* in children, where VNS was found to reduce IEDs, especially during REM, delta sleep, and EEG seizures. Again, there was evidence for a correlation between reduction of IEDs and effect on seizures.[37]

Evoked potentials

Animal studies showed that VNS could elicit evoked potentials in the cortex,[6,8,19,38] thalamus,[6,19,38] hypothalamus,[7] and cerebellum.[9] The effect of chronic VNS on brainstem auditory evoked potentials and somatosensory evoked potentials in humans was investigated by Naritoku *et al.* This study demonstrated interval increase between cervicomedullary and thalamocortical somatosensory evoked potentials in three VNS patients (as compared to baseline and to normal subjects). The authors suggested that vagus nerve stimulation alters neuronal networks outside of the brain stem vagus system, and highlighted the potential use of somatosensory evoked responses in titrating VNS therapy. However, it is difficult to draw meaningful conclusions from these series given the small number of VNS responders.[39]

Cerebral evoked responses following direct electrical stimulation of the vagus and esophagus were compared in eight epileptic subjects and with those recorded after esophageal stimulation in 12 healthy nonepileptic controls. Direct vagal stimulation was performed using a left cervical vagal pacemaker, which is used in the treatment of epilepsy. Esophageal stimulation was obtained with the use of an esophageal assembly incorporating two electrodes positioned 5 and 20 cm orad to the lower esophageal sphincter.

Another study compared evoked responses after direct electrical stimulation of the vagus nerve with a left vagal pacemaker and of the esophagus with two electrodes placed with a manometric assembly on the esophageal mucosa in eight patients with epilepsy undergoing esophageal stimulation and in 12 healthy nonepileptic controls.[40] Similar to the study by Naritoku *et al.* conduction velocity of the afferent response was found to be slower (7.5 m/s) in epilepsy patients as compared to healthy controls (10 m/s).[40] In contrast, a third study, which investigated the effect of VNS on visual, auditory brainstem, and long latency cognitive evoked potentials, did not detect any significant changes.[41]

Neurotransmitters

Hammond *et al.* reported increases in the metabolites of dopamine and serotonin – homovanillic acid and 5-hydroxyindoleacetic acid – in three out of six patients.[42] In addition a decrease in aspartate was seen in five of the six patients. Changes were associated with a decrease in seizure frequency.[42] Another study analyzed CSF neurotransmitters in sixteen patients before and 3 months after VNS. Decreases in the excitatory amino acid, aspartate, and increases in its inhibitory counterpart GABA were reported. Additionally, correlations between seizure reduction and increases in asparagine, phenylalanine, phosphoethanolamine, alanine and tryptophan concentrations were observed.[43]

Cerebral blood flow measurement by PET

Garnett *et al.* were the first to investigate the effect of VNS on cerebral blood flow by means of $H_2{}^{15}O$ PET in five patients

with epilepsy. Increased blood flow was demonstrated in the left anterior thalamus and the cingulate gyrus. These results may have been confounded by the fact that two out of the five patients had seizures during the PET scan.[44] As part of the manufacturer (Cyberonics) funded E04 trial, Ko *et al.* investigated three patients with $H_2{}^{15}O$ PET blood flow functional imaging. Left sided VNS resulted in activation of the right thalamus, right posterior temporal cortex, left putamen, and left inferior cerebellum.[45]

Henry *et al.* measured VNS-induced cerebral blood flow (CBF) effects after immediate and prolonged VNS in ten patients by performing $H_2{}^{15}O$ PET scans within one day after the onset of stimulation and by repeating the study after a period of 3 months.[32,46] Most subcortical sites activated during immediate stimulation were also activated after 3 months. During both times, VNS-induced CBF increases were found in similar locations in the bilateral thalami, hypothalami, inferior cerebellar hemispheres, and right postcentral gyrus. Cortical modification of CBF was less prominent after three months (including decreased CBF in bilateral hippocampal, amygdalar, and cingulate areas and increased bilateral insular CBF).[32] Interestingly seizures were found to be better controlled, when cortical blood flow decreased as a result of VNS.[32] These authors postulated a relationship between seizure reduction and decreases in cortical CBF.[32]

SPECT and perfusion

Ring *et al.* used (99m)Tc-HMPAO single photon emission tomography (SPECT) to investigate the effects of VNS on regional cerebral activity in seven patients, who had been receiving vagal nerve stimulation for a period of at least 6 months. VNS was found to be associated with decreased activity in left and right medial thalamus.[47] Vonck *et al.* investigated 12 patients by means of a 99mTc SPECT with a single-day split-dose protocol before and immediately after initial stimulation and noted a decrease in left thalamic CBF after the onset of stimulation. There was no evidence to suggest a correlation between hypoperfusion and seizure reduction.[48,49] Another study by the same group in a larger population of 23 patients showed evidence of deactivation in the left thalamus, right parahippocampal gyrus, and right hippocampus during initial stimulation with VNS.[50] In this latter study, a correlation between, initial stimulation changes in the right amygdala and therapeutic response was reported.[50] Another group confirmed the presence of decreased perfusion in the contralateral thalamus and cingulate and also reported additional areas of deactivation involving the ipsilateral brain stem, cingulate, amygdala and hippocampus.[51]

Functional MRI studies

Functional MRI studies during VNS in five patients demonstrated the most robust activation in both thalami (left greater right) and in the insular cortices bilaterally.[52] Additional activations of the ipsilateral basal ganglia, the postcentral gyri, the right posterior superior temporal gyrus, and the inferomedial occipital gyri were noted.[52] Liu *et al.* investigated five patients with complex partial seizures using blood oxygenation level dependent functional magnetic resonance imaging (BOLD fMRI). Activation of the frontal and occipital lobes was seen in all patients. However, thalamic activation was only observed in the two patients with reduced seizure frequency.[53]

Stimulation paradigms

VNS parameters that can be manipulated include current intensity in milliamperes, frequency, pulse width, duration of stimulation and pattern of stimulation (stimulation paradigm). Therapeutic stimulation parameters for the E03 and E05 trials consisted of output current 0.5–3.5 mA, frequency 20–50 Hz, pulse width 500 μs, and stimulation on-time of 30–90 seconds followed by off-time of 5 minutes. The active 'control' group underwent 'low-dose' stimulation with output current 3.5 mA, frequency of 1–2 Hz, pulse width of 130 μs and stimulation on-time of 30 seconds with off-times ranging from 90–180 minutes.

Frequency

FDA recommended stimulation frequencies between 20 and 30 Hz. Lower frequency stimulation at 5 Hz is associated with reduced brain stimulation, as evidenced by fMRI studies comparing 5 Hz and 20 Hz stimulation protocols.[54] Furthermore, low frequency stimulation may facilitate stimulation of slow conducting C-fibers and lead to increased side effects.[55,56] Stimulation frequencies of 50 Hz and higher may result in irreversible vagal nerve fiber damage.[55]

Intensity

Currently available stimulation intensities range from 0.25 mA to 3.5 mA.[57] Currents between 0.8 mA and 2 mA are usually considered effective.[56] Stimulation can be increased incrementally by 0.25 mA – usually every 1–2 weeks – up to 2 mA. Stimulation (with a fixed pulse width) first produces depolarization of the large myelinated fibers with subsequent involvement of smaller myelinated and lastly unmyelinated fibers as intensity increases. Threshold for stimulation of fast, myelinated A fibers is 0.02–0.2 mA, for B fibers 0.04–0.6 mA and for unmyelinated C-fibers 2 mA and above.[58] The initial hypothesis that therapeutic VNS effects are related to depolarization of unmyelinated C-fibers has been disproved by Krahl *et al.*[59] Selective destruction of C fibers with capsaicin did not influence the antiepileptic effect of VNS in a pentylenetetrazol seizure model in rats.[59] Stimulation-induced side effects may increase with rising current delivery (either increased intensity or widened pulse width).

Pulse width

Available pulse widths include 130 μs, 250 μs and 500 μs. Usual settings include 500 and 250 μs. Increase of the pulse width leads to increased delivery of current, although this increase is not linear.[56] Comparison of different pulse widths (130 μs, 250 μs, or 500 μs) in fMRI studies showed that fMRI activations were greater with pulse widths of 250 and 500 μs – compared with the shorter pulse width of 130 μs – but not significantly different from each other; fMRI deactivation was greater for pulse widths of 130 μs and 250 μs as compared to the longer pulse width of 500 μs.[60]

Stimulation interval

Standard stimulation intervals consist of a 30 second on and a 5 minute off period. It is recommended that duty cycles do not exceed 50% of the complete stimulation paradigm in order to prevent nerve injury.[55,61] Some patients may experience better seizure control with faster cycles. DeGeorgio retrospectively

analyzed the effects of device parameter changes on seizure frequency in 154 subjects, who completed the long-term XE5 study. Comparisons were performed for the three most common off time periods of 3, 1.8, and 1.1 min. A change in off time to 1.1 min resulted in significant improvements in efficacy in a subgroup of VNS-resistant patients. A median seizure reduction from 21% before the change in off time, to 39% after the decrease in off time was observed in this subgroup of patients, who were initially felt to be VNS resistant.[62] However, other investigators have not observed improved seizure control with shortened off periods.[63]

Stimulation paradigms

These include open loop and closed loop stimulation. Open loop stimulation follows a certain stimulation pattern without consideration of seizures. Closed loop stimulation attempts to respond to the first warning symptoms of a seizure. In the preapproval studies (E03, E04, and E05) the device was programmed to deliver current to the treated group every 5 minutes for 30 seconds, regardless of seizure activity (open loop stimulation). Additionally, patients with a history of auras were encouraged to place a magnet over the VNS, when sensing that seizures were about to occur (closed loop).

Adjustment of parameters

After VNS implantation many centers do not start stimulation in the immediate post-operative period and for up to 5–14 days post-op. Other centers (including ours) prefer to program the device in the operating room. Initial settings usually include patterns of 30 second stimulation (on-time) every five minutes (off-time). Output current is usually increased in 0.25 mA steps.

Adjustment of stimulation parameters may be indicated in patients under the age of 12 years. Koo *et al.* performed intraoperative investigations during implantation of VNS in 21 patients aged 4–31 years and recordings made from the rostral end of the vagus nerve. These authors demonstrated that threshold current is higher in young children as compared to adults indicating that a higher current or larger pulse width is required in children in order to achieve equivalent effects.[64]

Efficacy of VNS

Randomized, double blind studies: E03 and E05

Two randomized placebo-controlled trials examined VNS prior to FDA approval, the E03 and the E05 trial. The first multicenter, double blind, randomized controlled trial, the E03 trial, included 114 patients over the age of 12 years with predominantly partial seizures and compared baseline seizure rates to those observed after stimulation in a 'high' and 'low' stimulation group.[31,65–67] The second multicenter, double-blind, randomized controlled study (E05) included 199 patients with complex partial seizures, who were followed for a period of 3 months. Again, patients were split into two groups with 'high' and 'low' stimulation: 28% of patients in the high stimulation group experienced seizure reduction as compared to 15% in the low stimulation group.[68]

Inclusion criteria

Patients were included in the two randomized, controlled, preapproval trials if they were between 12 and 60 years old, if they had at least six seizures per month and if they were being treated with zero to three AEDs. In the E05 study, patients were also required to have complex-partial seizures.

Stimulation paradigms

As mentioned above, both of these trials compared two different VNS stimulation paradigms, 'high' versus 'low' stimulation for the treatment of partial seizures. In the E03 trial settings in the high stimulation group included an output current of 0.5–3 mA, a frequency of 20–50 Hz (control=1–2 Hz), pulse width of 500 microseconds (control=130 microseconds), on time of 30–90 seconds (control=30 seconds), and off periods of 5 minutes (control=90 minutes). In the E05 trial, settings in the high stimulation group consisted of an output current of up to 3.5 mA, a frequency of 30 Hz (control=1 Hz), pulse width of 500 microseconds (control=130 microseconds), on time of 30 seconds and off periods of 5 minutes (controls=180 minutes).

Design and timeline

Baseline monitoring of seizure frequency was performed over a 12–16 week interval. During this baseline, preimplantation interval, seizure frequency was recorded and AED changes were only allowed in cases of toxicity or low levels. Eligible patients, who fulfilled all baseline criteria, were subsequently implanted. Randomization to either 'high' or 'low' frequency stimulation was completed 2 weeks after implantation. During the following 2 weeks after initiation of VNS treatment, therapeutic stimulator settings were increased as high as tolerated. On the other hand, the low-stimulation group received stimulation intensities that were increased to the level of perceptible stimulation. Treatment results and seizure frequency was monitored during the following twelve weeks.

Results

In E03, 125 patients were initially enrolled and 114 of those were implanted. Fifty-four patients were randomized to the high stimulation group, whereas 60 patients underwent low stimulation. In E05, 199 out of 254 initially enrolled patients fulfilled the eligibility criteria and proceeded to implantation. In the E05 trial, 95 patients were randomized to the high-stimulation group and 103 to the low-stimulation group; in addition one patient was excluded due to device infection.

The primary outcome parameter was change in seizure frequency during treatment as compared to baseline. Seizure frequency reduction in the E03 trial was 24.5% in the high stimulation group versus 6.1% in the low stimulation group ($p<0.01$). Seizure frequency reduction in the E05 trial was 28% in the high stimulation group as compared to 15% in the low stimulation group ($p<0.05$).

Secondary outcome parameters in the E03 trial were also in favor of the high stimulation group. 31% had >50% seizure reduction in the high stimulation group as compared to 13% in the low stimulation group ($p<0.05$). In the E05 trial, 11% experienced greater than 75% seizure reduction in the high stimulation group as compared to only 2% in the low stimulation group ($p<0.01$).

The E03 and E05 trials are the only studies included in a Cochrane library review and metaanalysis.[69] The overall odds ratio for 50% responders across both studies was estimated to be 1.93, by pooling the data from both the E03 and E05 studies. These results suggest that VNS may be effective as

additional treatment for patients with medically intractable partial seizures, who are older than 12 years of age at the time of implantation.

Problems with the E03 and E05 trials

A randomized trial with vagus nerve stimulation poses more problems than a pharmacological trial. In a pharmacological trial, patients can be treated with a placebo pill. In a VNS trial, randomization mandates implantation of the stimulator in both study groups. The active control group was also exposed to stimulation, delivered for a much shorter period of time and using lower frequency and pulse width. (high stimulation group 500 microseconds pulse width, 30 Hz, 30 s on, 5 min off; up to 3.5 mA versus low stimulation group 130 microseconds pulse width, 1 Hz, 30 s on, 90 or 180 min off, up to 3.5 mA). The fact that participants or physicians may have been able to detect current delivery in the treatment or placebo arm due to possible stimulation-related side effects constitutes a potential limitation of this study design. Further, unblinding or change in outcome may have resulted from lack of perceived VNS output after handheld magnet activation in the control group. Both trials were funded by the manufacturer and were limited to a relatively short period of observation post-VNS implantation. There are no randomized controlled data related to long-term VNS use. Other limitations include the lack of comparison to available pharmacological treatments. It is important to remember that the results of the E03 and E05 studies pertain to a certain patient population and that it is not possible to extrapolate these results to other groups such as patients with generalized epilepsy or children under the age of 12 years.

Non-double blind and long-term studies

The first patient received a vagus nerve stimulator in November 1988. Between November 1988 and September 1989 eleven patients were implanted. The first uncontrolled study with preliminary results on the use of VNS in humans was published in 1990.[15] Four out of the eleven patients with medically intractable epilepsy became seizure free in this first reported case series.[15] Additional early studies and uncontrolled observations documented seizure reductions by up to 50% in 30% of patients.[70–74] A first single blind pilot study by Uthman *et al.* [16,75] demonstrated a mean seizure frequency reduction of 46.6% after 14–35 months of VNS.

The first randomized active control study (E03) was completed in 1992 and the second one (E05) in 1996. Subsequent open label, non-blinded, longer term studies indicate that VNS treatment efficacy seems to further improve during the unblinded periods of follow up (after completion of the initial blinded treatment interval). Completion of the blinded 14-week long E03 period was followed by an open, non-blinded long term evaluation.[66] George *et al.*[66] reported long term follow up for 16 to 18 months after completion of the blinded E03 trial. All patients were treated with open label high frequency VNS. Twenty-six of the 31 patients initially randomized to high frequency VNS had a 52.0% seizure frequency reduction and 24 of the 36 patients initially randomized to low frequency stimulation experienced a 38.1% reduction of seizure frequency.[66] Salinsky *et al.* found similar results in 100 patients followed for a year after completion of the E03 trial.[76] In this series, response to VNS during the first three months predicted longterm outcome.[76]

Patients with six or more complex partial or generalized tonic-clonic seizures, who had been enrolled in the pivotal E05 study, were prospectively evaluated for a period of 12 months during the XE5 trial (long-term prospective efficacy and safety study = XE5).[62,71,77] In the E05 trial seizure frequency reduction of 28% was seen at three months. The vast majority of patients (195 out of a total of 199 patients) selected to continue treatment after this initial period. In the subsequent months 21 patients dropped out due to decreased efficacy and two patients died of unrelated conditions. After 12 months of follow up, 35% of remaining patients had a >50% reduction in seizures, and 20% had a >75% reduction in seizures.[77] After 15 months of follow up mean and median seizure frequency reduction was 37% and 45%, respectively.[71] An additional analysis of stimulation parameter changes suggested that the increased efficacy was not primarily related to changes in stimulation parameters.[62]

Morris *et al.* followed a total of 440 patients up to 3 years and found 50% seizure reduction in 36.8% of patients after 1 year, in 43.2% after 2 years, and in 42.7% after 3 years. Median seizure

Table 127.1 Adverse events of VNS in the E03 and E05 study

Adverse event	E03 *n*=114	E05 trial n=198 Number of patients (%)	Sum *n*=312
Voice alteration/hoarseness	28 (24.6%)	94 (47.4%)	122 (39.1%)
Increased coughing	9 (7.9%)	87 (43.9%)	96 (30.8%)
Pharyngitis (E03: throat pain)	13 (11.4%)	59 (29.8%)	72 (23.1%)
Pain (E03: muscle pain)	4 (3.5%)	58 (29.3%)	62 (19.9%)
Headache	6 (5.3%)	47 (23.7%)	53 (17%)
Paresthesias	5 (4.4%)	43 (21.7%)	48 (15.4%)
Dyspnea	4 (3.5%)	35 (17.7%)	39 (12.5%)
Nausea	NR	35 (17.7%)	N/A
Vomiting	NR	31 (15.6%)	N/A
Dyspepsia	NR	30 (15.1%)	N/A
Fever	NR	30 (15.1%)	N/A
Injury	NR	25 (12.6%)	N/A
Infection	NR	23 (11.6%)	N/A

*Only side effects in greater than 5% (E03) and greater than 10% (E05) were reported.

reductions were 35% after the first year, 44.3% after the second year, and 44.1% after the third year. Interestingly, about 25% of patients chose to discontinue VNS treatement.[78]

Similar sustained improvement have been observed up to 4[79] or 5 years.[80,81] Ben Menachem *et al.* followed 64 patients for up to 5 years. The average follow up in this series was 20 months. Twenty nine out of 64 patients had greater than 50% seizure reduction at their last follow-up.[80]

Five to 7 year follow up was available on 26 patients in the series reported by Spanaki *et al.* [82] Charts were reviewed after 1 year and after 5–7 years. Seizure frequency was decreased by 28% at 12 months and by 72% on final follow up.[82] Table 127.2 summarizes the findings of these long term follow up studies.

Currently, all long term studies are uncontrolled and data is usually collected during an open-label phase of the trial. In addition, medications and VNS parameters are allowed to vary and are commonly adjusted during the period of observation. Selection bias is a consistent limitation in these long-term studies, as patients with poor response to stimulation tend to exit early (accounting for a significant percentage of drop outs), leaving only patients with relatively good response to stimulation during longer follow up periods.

Vagus nerve stimulation in selected patient populations

Children

No randomized trials for pediatric patients are available. The E05 trial included 60 patients under the age of 18 years. Compared to baseline this group exhibited a 23% seizure reduction at 3 months and over 40% seizure reduction after a period of 6 months.[68] Nonrandomized pediatric case series were reviewed by Crumrine in 2000, who reported greater than 50% seizure reduction in 19 to 53% of pediatric patients followed for 3–24 months.[83]

VNS has been investigated in pediatric patients with epileptic encephalopathies,[84,85] Lennox-Gastaut syndrome,[86–88] tuberous sclerosis,[89] hypothalamic harmatomas [90] and Landau-Kleffner syndrome.[91]

VNS led to 17% median decrease in seizure frequency after 1 year in a study of 17 patients with epileptic encephalopathies.[85] In patients with Lennox-Gastaut syndrome, median seizure frequency reduction ranging from 52–58% has been reported after 6 months of VNS.[86,88] After 24 months, Aldenkamp *et al.* noted only a 20% average seizure frequency reduction in 19 children with Lennox-Gastaut syndrome.[87] Treatment effect was most prominent in the group with the highest mental age at baseline.[87]

Ten pediatric patients with tuberous sclerosis were reviewed in an open-label, retrospective study. Nine patients had at least 50% reduction in seizure frequency, and five achieved seizure frequency decreases that exceeded 90%. Comparison with medically treated tuberous sclerosis patients revealed improved seizure control with VNS. However, when the VNS-treated group was compared to patients with tuberous sclerosis undergoing epilepsy surgery better outcomes were observed in the surgically-treated group.[89]

In small series of patients with Landau-Kleffner syndrome and with hypothalamic harmatomas, half of the patients in each of the two series showed improvement in seizure frequency as compared to baseline. [90,91] Finally, a single case of interruption of status epilepticus has been reported after initiation of VNS in a 13-year-old.[92]

Elderly

Sirven *et al.* investigated vagus nerve stimulation for refractory epilepsy in 45 adults 50 years of age and older.[93]After 3 months, 12 out of 31 patients had greater than 50% decrease in seizure frequency, whereas after 1 year, 21 out of 31 patients had 50% or greater decrease in seizure frequency.[93] Additionally, patients experienced a significant improvement in quality of life (QOL) scores. These results suggest that VNS merits consideration as a treatment option in older individuals with epilepsy.

Safety and tolerability: complications and adverse effects

Infection

Infections due to the surgical intervention occur in 3 to 6% of patients and are usually controlled with oral antibiotics.[77,80,94] Fluid collection around the generator with or without infection can be managed conservatively with aspiration and antibiotics.[95] Irrigation with antibiotic solutions may be an alternative to explantation.[96] In the E05 trial, 1.5% of patients required device explantation due to infection.[68] The risk of infection may be higher in younger children and patients with developmental delay, because frequent drooling and inadvertent electrode and wound manipulation may predispose to infection.[97,98]

Hardware defects including breaks in the equipment at the electrode-wire junction were common surgical complications in early trials.[16,99] A recent study reported hardware failure in 2.7% of 74 patients with a minimum follow up of 1 year.[94]

Lower facial weakness was observed in a total of three patients enrolled in the E03 and E05 studies.[100] This was most likely related to high surgical incisions during early implantations; the risk of such adverse effect can now be neglected.[100]

Vocal cord paralysis and dysfunction can occur as a result of the surgery itself and/or as a result of the stimulation. Most frequent side effects include vocal cord dysfunction and hoarseness during stimulation.[31,68,99] Occasional cases of ipsilateral vocal-cord paralysis have also been described.[99] Delayed vocal cord paralysis may be related to post-operative nerve edema, which is a potentially preventable complication.[99] Post-operative vocal cord paralysis is frequently only temporary and patients may recover as swelling improves.[101] Laryngeal electromyography of the cricothyroid and thyroarytenoid muscles indicates that degeneration of the recurrent laryngeal nerve occurs in approximately 60% of patients after prolonged repetitive stimulation.[102] Self-inflicted vocal cord paralysis can also occur, when patients manipulate the leads under the skin.[103]

Other common side effects

In addition to hoarseness, patients enrolled in the E05 study complained of cough, throat pain and pharyngitis, muscle pain and pain at the insertion site, headache, paresthesias, and dyspnea.[31,68] Other less common symptoms reported in the same trial included nausea and vomiting, dyspepsia, fever, and infection (see Table 127.1). [68]

Table 127.2 Long-term follow up after VNS

Author	Year	n	Patient population (seizure types, epilepsy, or syndrome)	Design	Follow-up (maximum)	Outcome parameter	Completion rate/Drop-outs
George *et al.*[66]	1994	114 (67)	Complex partial seizures (EO3)	Prospective; open-label; not controlled	16-18 months	Seizure reduction by 50% in 50% of patients	67 out of 114 continued study; complete data on 50/67 (74.6%)
Salinsky *et al.*[76]	1996	114	Complex partial seizures (EO3)	Prospective; open-label; not controlled	1 year	Median seizure frequency reduction by 32%	14/114 (lack of efficacy)
Clarke *et al.*[130]	1997	10	Complex partial seizures	Prospective; open-label; not controlled	50 months	10 fold increase in the mean number of 14-day seizure–free periods	8/10 (80%); unchanged AEDs
Amar *et al.*[71]	1999	199	Partial seizures with alteration of consciousness; >12 y/o (XE5 trial)	Prospective; open-label; not controlled	15 months	Median seizure frequency reduction was 45%	164/199 (82.4%)
Vonck *et al.*[79]	1999	25	Complex partial seizures 17–44 y/o	Prospective	Average 29 months (up to 40 months)	Mean complex partial seizure frequency reduction 42.8%	15/25 (60%)
Morris *et al.*[78]	1999	454	Partial and generalized seizures (EO1–EO5 trials)	Prospective, open-label; not controlled	3 years	Seizure reduction by 50% in 43%; median seizure frequency reduction 44%	440 entered long-term trial; 93/454 at 3 years (20.5%)
Ben-Menachem *et al.*[80]	1999	64	47 focal epilepsy; 9 idiopathic generalized epilepsy; 8 LGS	Prospective, open-label; not controlled	Average 20 months (up to 5 years)	Seizure reduction by 50% in 45%	57/64 (89%)
DeGiorgio *et al.*[77]	2000	195	Partial seizures with alteration of consciousness; >12 y/o (EO5/XE5)	Prospective; open label; not controlled	1 year	Median seizure reduction 45%; seizure reduction by 50% in 34%	164/195 (84%)
Aldenkamp *et al.*[87]	2002	19	Children with LGS (6–20 y/o)	Prospective; open-label; not controlled	2 years	Mean seizure reduction was 20.6%	17/19 (89%)
Kawai *et al.*[131]	2002	13	Partial seizures; age 19–47 y/o	Prospective; open-label; not controlled	4 years (median 56 months)	Mean seizure frequency reduction 63%	13/15 (86.6%)
Tanganelli *et al.*[132]	2002	51	Focal or generalized seizures; age 7–49 y/o	Prospective; open-label; not controlled	6 months	Seizure frequency reduction by 50% in 46.8%	47/51 (92.1%)
Chavel *et al.*[133]	2003	30	Partial onset seizures; >12 y/o	Prospective; open-label; not controlled	2 years	Seizure reduction by 50% in 61%	23/30(76.6%)

Uthman *et al.*[134]	2004	48	Head trauma (10); encephalitis (4); febrile convulsions (1); unknown (33); 13–58 y/o at implant	Prospective; open-label; not controlled	12 years	Mean seizure frequency reduction by 52%	25/48 (52%)
Spanaki *et al.*[82]	2004	26	Partial epilepsy (24); 'atypical absence' epilepsy (1); generalized epilepsy (1)	Retrospective, chart review	5–7 years	Median seizure frequency reduction by 72%	26/28 records; Preselection; included only patients with follow-up
Huf *et al.*[135]	2005	40	Low IQ patients (<70);	Prospective; open label; not controlled	2 years	Seizure reduction by 50% in 27.5%	40/40 (100%)
Majoie *et al.*[81]	2005	19	Lennox-Gastaut Syndrome; 5–18 y/o	prospective	2 years	Seizure frequency reduction of 20.6%; seizure reduction greater 50% in 21%	19/19 (100%)
Halböök *et al.*[37]	2005	15	MCD (5); encephalitis (1); HIE (5); unknown (4); age 4–17 y/o	prospective	9 months	Mean interictal spike frequency reduction by 18%	15/15 (100%)
Rycklicki *et al.*[112]	2006	36	Children 18 mos to 18 y/o; 9 LGS; 27 focal epilepsy;	Prospective; open-label; not controlled	Mean follow up 30 months;	Seizure reduction by 50% in 71%	NR
Alexopoulos *et al.*[98]	2006	49	Tuberous sclerosis (3); MCD (6); encephalitis (2); mitochondrial disease (2); hypothalamic hamartoma (1); head trauma (1); generalized (4); unknown (34); 1–16 y/o	Prospective;	Median follow up 2 years	63% at 1 year; 83% at 2 years; 74% at 3 years	39/49 at 1 year (79.6%) 23/49 at 2 years (46.9%) 16/49 at 3 years (32.6%)

Less common stimulation-related side effects besides cough and hoarseness include outbursts of laughter, shoulder abduction, urinary retention, dysphagia, and torticollis.[94] A correlation between the intensity of the current and the degree of hoarseness has been described.[104]

Privitera *et al.* attempted to divide VNS side effects and complications to two groups: those attributed to implantation per se and those that were related to the stimulation. The authors reported that cough (OR 2.9), paresthesias (OR 6.3) and possibly pain (OR 2.2; nonsignificant trend) were associated with implantation of the device, whereas dyspnea was associated with stimulation (OR 2.65). Hoarseness was related to implantation, but additional hoarseness could be a product of stimulation (OR 14.5).[69]

Cognitive and psychiatric side effects

Side effects on mood and cognition as a result of VNS warrant further investigation. VNS usually leads to improvement of behavioral problems and has mood stabilizing effects.[85,86,105,106] Nevertheless, acute psychosis and depression have been described in relationship to VNS.[85,107,108] Effects on memory are variable. While some authors report improvement in word-recognition memory,[109] others have found decline in figural memory during VNS.[110] Additionally, central pain suppression has been reported with VNS. [111]

Respiratory changes and aspiration.

Dyspnea appears to be another stimulation-related side effect.[56] As demonstrated by laryngoscopy, dyspnea occurs due to adduction of the left vocal cord, which results from intensity dependent stimulation of the recurrent laryngeal nerve.[104]

Snoring, sleep apnea and gasping has been reported during sleep.[112–114] Due to its effect on breathing patterns, some authors consider obstructive sleep apnea syndrome as a relative contraindication to VNS. [115]In addition, an increase in respiratory rate has been documented during wakefulness.[116]

Rarely, aspiration during VNS has been observed in children with severe preexisting mental and motor disabilities.[117] Smyth reported that one of his patients died of aspiration pneumonia 30 days after VNS implantation.[94] Schallert *et al.* performed swallow studies in 8 children with VNS, which did not show any evidence of aspiration. Only one patient had laryngeal penetration of barium caused by VNS, but no aspiration was seen.[118] Increased drooling as a side effect of VNS has been reported in patients with Lennox-Gastaut syndrome.[86]

Cardiac asystole is a rare complication during testing of the vagus nerve stimulator at the time of implantation. Five patients have been reported up to date.[119,120] This complication seems to be exclusively limited to the intraoperative setting with an estimated frequency of one in 875 (0.1%). [121] Suspected causes include malfunction of the device, errors during surgery such as polarity reversion of the electrodes or atypical electrode placement, or possible indirect stimulation of cardiac afferents.[121] No major autonomic effects on heart rate variability have been described with chronic VNS.[122]

Death

Annegers *et al.* followed a cohort of 1819 patients for 3176.3 person-years from the time of VNS implantation. Twenty-five deaths were assessed for possible Sudden Unexpected Death in Epilepsy (SUDEP). Mortality and SUDEP rates were found to be equal to those seen in patients with severe pharmacoresistant epilepsy. Interestingly, the rate of SUDEP was 5.5 per 1000 during the first 2 years, but dropped to 1.7 per 1000 thereafter.[123]

VNS and pregnancy

Eight pregnancies during VNS have been reported by Ben-Menachem. Two patients had elective abortions, one experienced a spontaneous abortion and five pregnancies led to healthy, full term babies, including one twin delivery.[124]

Outlook

Advantages

VNS is an important addition to the currently available antiepileptic armamentarium. Its use in patients with pharmacoresistant seizures and may help decrease the number of antiepileptic medications and side effects associated with polypharmacy. Existent level one evidence supports the use of VNS in patients with focal seizures[69] and level two evidence is being collected in other patient populations.[121] About one third of patients experience seizure reduction of at least 50%[57] and similar results have been observed in adults and children, with additional improvement after longer stimulation duration.[98] The observation of positive VNS effects on mood, alertness and quality of life has ignited interest and ongoing study of VNS in other clinical areas such as depression and mood disorders,[125,126] anxiety,[58] migraines,[58] obesity,[127] and possibly conditions with memory difficulties and impaired alertness.[128]

Limitations

In most cases, however, VNS treatment provides a palliative and curative option for patients with seizures refractory to medications and ineligible for resective epilepsy surgery. Indications and criteria for VNS use have not been carefully defined nor have ideal stimulation parameters been clarified. No information on patients with less refractory epilepsy is available.[121] Additionally, there are no studies providing head to head comparisons with established antiepileptic drugs.

Furthermore, no randomized double-blind data exist for children younger than 12 years, for the elderly or for individuals with generalized epilepsies. Our current inability to predict responders prior to VNS leads to costly, unnecessary implantations. Observable benefit may be quite delayed in some cases.

All randomized preapproval studies have been funded by the industry. Furthermore, both the E03 and E05 trials are limited by the fact that randomization in stimulator trials is never completely blinded.[69] Patients and physicians may have been able to decipher stimulator settings and group allocation on the basis of the presence or absence of side effects related to the stimulation. Additionally, long-term follow up data are only available during periods of unblinded observation. Published long-term studies tend to be biased by drop-outs – patients who frequently discontinue VNS due to decreased efficacy leaving only the responders in the study.

Implantation of the metal stimulator limits future MRI scanning due to possible diathermy effects and manipulation

of stimulator settings by the magnetic field. Furthermore, the cost of the device and surgical intervention and the need for future battery replacements should be factored when making the decision for or against VNS.

Future perspective

Ideally future trials should address the variable stimulation paradigms and predictors for response to stimulation, should be independently funded, employ improved trial designs and target a broader patient population.

Improved trial designs

A randomized controlled trial including a sham or low-frequency stimulation that closer approximates side-effects of high frequency stimulation is needed. Prolonged periods of blinded randomized investigation and head-to-head comparisons with established antiepileptic drugs would be highly desirable.

Variation in stimulation paradigms and devices

Is it possible to define specific open or closed loop stimulation paradigms with stimulation frequencies and patterns tailored to certain types of seizures or patient populations? Such an approach may also lead to improvements in terms of side effect profile, battery life and MRI–compatibility of electrodes and stimulator.

Ability to predict outcome prior to implantation

Methods/studies that would lead to improved selection of favorable VNS candidates are eagerly awaited.

Expansion to different patient populations

Future trials should include a broader group of individuals with epilepsy such as patients with generalized epilepsy, patients with less advanced or less refractory epilepsies, elderly and children under the age of 12 years.

Financial issues

Independence from industrial funding. All major studies have been funded by industry that may have an interest in merchandising their product. Cost including the device, surgical intervention and maintenance is also a concern, although VNS treatment may lead to reduced costs over a longer period of time.[129]

VNS is the first FDA approved neurostimulation technique in epilepsy. Since its approval multiple other stimulation sites in the central and peripheral nervous system and techniques have been investigated for the treatment of epilepsy. Although VNS is not the ultimate treatment for seizures, it has opened the door for a burgeoning field of research in epilepsy and neurostimulation. VNS serves as a nonpharmacological, adjunctive and well-tolerated treatment alternative in selected patients with medically refractory epilepsy.

128 Experimental evidence for the involvement of the basal ganglia in the control of epilepsy

C Deransart and A Depaulis

Introduction

Investigation of the basal ganglia (BG) circuits, shunt-connected to circuits for initiation and propagation of seizures, is essential in order to understand the chronic nature of the epilepsy, the episodic nature of the seizures and the phenomena underlying transition between interictal and ictal states. Over the past decades, the role of the BG system among the circuits involved in the genesis of different types of seizures has been mainly addressed in animal models. The development of rodent models with recurrent spontaneous seizures has greatly contributed to this investigation. Several data from different laboratories working with various models have led to the suggestion of a particular role for the BG circuits in epilepsy. In the present review, we will first briefly summarize the general functional anatomy of the BG before considering the possibility that BG circuits can generate or participate in the initiation and/or propagation of seizures, based on experimental data. In the second part of this chapter, data suggesting the involvement of the BG in the control of seizures will be discussed.

Functional anatomy of the basal ganglia circuits

The BG are connected to the cerebral cortex through several multisynaptic loop circuits. The cerebral cortex provides the main source of glutamatergic projections to the striatum and the subthalamic nucleus (STN), the two major input structures of the BG. As a consequence, the striatum processes information from all areas of the cerebral cortex, the midline and intralaminar thalamic nuclei, the amygdala, and the hippocampus. The inputs to the STN arise from a more restricted part of the cortex involving the motor, premotor, and prefrontal areas and from the parafascicular thalamic nucleus.

In turn, the two output stations of the BG, the substantia nigra pars reticulata (SNR) and the entopeduncular nucleus (the rodent equivalent of the internal segment of the globus pallidus), innervate a diversity of thalamic and brain stem nuclei through which they can influence cortical electrogenesis. In rodents, the projections to the thalamus mainly extends throughout the entirety of the ventral medial nucleus, but also the lateral and ventral parts of the medial dorsal nucleus, the intralaminar nuclei parafascicular, central medial, paracentral and restricted parts of the ventral anterior/ventral lateral complex and the lateral dorsal nucleus.[1–5] Through these thalamic nuclei, the BG influence the frontal cortex including the prelimbic and orbital prefrontal areas, the anterior cingulate and the sensory-motor areas. In addition, the BG also innervate by nigral GABAergic projections the intermediate and deep layers of the superior colliculus and the pedunculo-pontine nucleus from which arise major projections to the ventral medial and intralaminar thalamic nuclei.[6–9] Via the ascending projections of these brain stem structures, the BG can influence widespread areas of the cerebral cortex. Altogether, these anatomical data show that the BG are tightly connected to regions of the cortex playing a leading role in the generation of seizures and are in a privileged position to control the propagation of the paroxysmal discharges through multisynaptic loop circuits.

Based on anatomical and electrophysiological observations, a conceptual model of BG circuits and their relationships with the cerebral cortex has been proposed.[10,11] In this model, cortical information is transmitted from via three main pathways: (i) a direct striato-nigral pathway, (ii) a direct subthalamo-nigral pathway (also defined as the 'hyperdirect' pathway due to its fast conduction velocity), and (iii) an indirect striato-pallido-subthalamo-nigral pathway. Because the striatal projection neurons are GABAergic whereas STN neurons are glutamatergic, the trans-striatal and trans-subthalamic pathways exert opposite effects, respectively inhibitory and excitatory, on the output neurons like the GABAergic nigral projections. In accordance with this model, electrical stimulation of the cerebral cortex induces in these neurons a sequence of synaptic events consisting of an inhibition preceded or not by an early excitation and followed or not by a late excitatory event. The inhibitory event results from the activation of the direct striato-nigral neurons; the early excitation results from the activation of the hyperdirect subthalamo-nigral pathway and the late excitation of the indirect pathway.[12–14] In this indirect pathway, the inhibition of the GABAergic pallido-subthalamic neurons by the cortically-evoked striatal activation leads to a disinhibition of the STN cells. Because the BG output neurons are GABAergic and tonically active, their inhibition by the direct striatal pathway leads to a *disinhibition* of the BG targets in the thalamus and the brain stem.[15] Conversely, the trans-STN circuits (hyperdirect and indirect) reinforce the inhibitory influence that BG exerts on their targets.

Experimental evidence supporting the role of the basal ganglia in the control of seizure

The basal ganglia as a generator of seizures?

Although the BG circuits are known to generate spontaneous oscillatory activities in several physiological as well as pathophysiological conditions,[16–19] the possibility that they initiate or promote epileptic seizures appears quite unlikely. Indeed, oscillatory activities observed in BG circuits have very low frequencies and when recorded during seizures they appear to result from propagation processes. Furthermore, electrical or chemical stimulations of the BG structures rarely initiate seizures and their lesions never abolish the occurrence of seizures (for review see Deransart and Depaulis, 2002).[20] On the contrary, changes in neuronal activity revealed by EEG, glucose metabolism or expression of immediate early genes studies suggest that the BG circuits may rather 'detect' the beginning, localization and/or intensity of a seizure. It is thus conceivable that changes of activity of these circuits may have some consequences on the development of the on-going seizure.

Several lines of evidence have accumulated over the past 30 years to support the existence of a system involving the SNR and the BG which may control the propagation and/or the generation of different kinds of seizures in animals (reviewed in Depaulis *et al*. 1994).[21] Evidence has been mainly collected from pharmacological or electrical modulation of the BG circuits and more recently from electrophysiological recording of neuronal activity during spontaneous seizures as well as measures of long term modifications of the functioning of these circuits.

Effects of manipulations of the substantia nigra pars reticulata

In 1980, Gale and Iadarola were the first to correlate an increase of GABA in the SNR (induced by the systemic injection of an inhibitor of GABA-transaminase) with antiepileptic effects.[22] Later, they showed that the potentiation of the GABAergic neurotransmission within the SNR, by bilateral microinjections of GABAmimetic drugs, suppressed convulsions in various models of generalized seizures in the rat.[23] It was later shown that such local pharmacological manipulations also suppressed the EEG expression of seizures in a model of generalized nonconvulsive epilepsy.[24] Inhibition of the SNR could also be obtained by blockade of the glutamatergic input, which mainly arises from the STN. In particular, injection of different NMDA antagonists into the SNR suppressed absence-seizures in GAERS, whereas non-NMDA antagonists were without effects.[25] Since then, several studies have confirmed that pharmacological inhibition of the SNR suppresses different forms of convulsive and non-convulsive generalized seizures.[21] Recently, it was shown that 130 Hz stimulation applied to the SNR, also suppressed convulsions induced by fluorothyl inhalation.[26,27] The critical nigral projection involved in seizure suppression remains to be determined. However, disinhibition of neurons of the superior colliculus, one of the main targets of the SNR, appears to play a significant role in the mediation of these antiepileptic effects in some forms of seizures.[28,29] Within this structure, specific populations of neurons appear to be involved in the control of different forms of seizure.[30–32] This is in agreement with the fact that inhibition of nigral neurons was shown to be without effect on tonic seizures involving brainstem structures, as seen in audiogenic-sensitive rats suggesting that such manipulations are more efficient on seizures involving forebrain circuits.[33] Furthermore, a differential involvement of anterior *versus* posterior populations of the SNR was also suggested in adult male rats.[34] The circuits involved in the antiepileptic effects resulting from the inhibition of the SNR may thus differ according to the type of seizure under control, and remain to be characterized.

Involvement of the direct striatonigral pathway

The possibility that the direct GABAergic striato-nigral pathway could modulate seizures through inhibition of the SNR was first suggested by experiments showing that intranigral injection of GABAA agonists have antiepileptic effects in most models of seizure in the rat (see Depaulis *et al*., 1994[21] for review). Indeed, activation of cells in the striatum, either by glutamate or D1 agonists, increases the release of GABA in the SNR as measured by microdialysis,[35] and decreases SNR activity.[36,37] Several studies have shown that injection of either NMDA agonist[38,39] or a GABA antagonist[40,41] in the striatum can block convulsive seizures. The anticonvulsant effect was detectable throughout the entire extent of the striatum. However, the predominant suppression was elicited from sites located in the ventral and posterior part of the striatum. In addition, this suppression of seizures could be reversed by the subsequent injection of a GABA antagonist into the SNR.[41] We have confirmed and extended these findings in the genetic model of absence-epilepsy in the rat where activation of striatal neurons by NMDA or by a D1 receptor agonist, significantly suppressed spike-and-wave discharges.[42] These antiepileptic effects were obtained with doses that do not produce behavioral effects, and were mainly observed when injection sites were located in the core of the nucleus accumbens. Conversely, blockade of the D1 receptors in the nucleus accumbens or of the GABAA receptors in the SNR *increased* the occurrence of absence-seizures in GAERS, confirming the critical role of this ventral direct striato-nigral projection in the control of this form of seizure.[42] However, intrastriatal injection of a D1 agonist failed to suppress clonic seizures in the pilocarpine model,[43] suggesting that different circuits are involved depending on the type of seizures.

Involvement of the hyperdirect subthalamo-nigral pathway

The glutamatergic input from the STN appears to be critical in the maintenance of the SNR neuronal activity. Bilateral injections of a GABA agonist into the STN, or high-frequency stimulation of this structure, decrease the activity of nigral neurons.[44,45] We were the first to show that both ways of reducing the excitatory influence of the STN can also suppress epileptic seizures.[25,46] In both cases, the suppression of absence seizures in GAERS by STN inhibition was dissociated from behavioral side-effects such as dystonia or stereotypies. The antiepileptic effects of pharmacological STN inhibition were

also confirmed in generalized convulsive seizures induced by fluorothyl inhalation,[47] amygdala kindling,[48] intravenous bicuculline or by its focal application into the anterior piriform cortex.[49] More recently, 130 Hz stimulation of the STN was reported to protect against seizures induced by systemic injection of kainite,[50] injection of kainate into the amygdala[51,52] or fluorothyl inhalation.[53] It is also in agreement with previous findings showing that intranigral injection of NMDA antagonists have antiepileptic effects in several models (see above or Depaulis *et al*, 1994).[21]

The pallidum and the trans-subthalamic pathway

The involvement of the GABAergic input from the pallidum to the STN has been investigated only in a few models of convulsive epilepsy, supporting that pallidal structures could be involved in the seizure spread mechanism that occurs during secondary generalization.[54–57] In GAERS, disinhibition of the globus pallidus or the ventral pallidum by injection of a GABAA antagonist, suppresses absence seizures at doses without behavioral effects. This antiepileptic effect was correlated with a decrease in glutamate levels in the SNR as measured by microdialysis, suggesting that this effect is mediated, at least in part, through a reduction in activity of the STN.[58] Antiepileptic effects were more pronounced when the injection sites were located in the ventral part of the pallidum. Conversely, an *increase* in the occurrence of absence-seizures was observed following inhibition of the ventral pallidum,[58] The preferential involvement of the ventral aspects of the pallidum is in agreement with the stronger suppressive effects observed following pharmacological manipulations in the ventral striatum and was confirmed in amygdala kindling. In this model, disinhibition of the ventral pallidum by a GABAA antagonist reduced both the behavioral expression of seizures and the duration of the afterdischarge. Conversely, inhibition or disinhibition of the globus pallidus (i.e., dorsal part), failed to have any effect (personal observations). Further data obtained in other models of seizures are necessary to confirm the involvement of the ventral pallidum in the control of seizures.

Involvement of the indirect striato-pallido-subthalamo-nigral pathway

The involvement of the dorsal and/or ventral pallidum in the control circuit of seizures is somewhat in agreement with data obtained following intrastriatal injection of dopaminergic agonists of the D2 receptors. Several data have suggested that these receptors are preferentially located on neurons projecting to the globus pallidus.[59,60] Although such a segregation has been revised[61,62] activation of striatal D2 receptors results in neuronal inhibition and, among other things, leads to disinhibition of pallidal neurons.[63–65] Injections of D2 agonists into the dorsal striatum was shown to block seizures in different models of convulsions, whereas injections of D2 antagonists in the same region have proconvulsant effects.[43,66–69] Injections of D2 agonists at lower doses also significantly suppressed absence seizures in GAERS, whereas aggravation was obtained with antagonists (see Figure 128.1). In this model, antiepileptic effects were more selective when injections were located in the nucleus accumbens.[42] Furthermore, an additive suppression of absence-seizures was obtained when combined injections of low doses of a D1 and a D2 agonist were performed in the core of the nucleus accumbens.[42] This is in agreement with the potentiation of antiepileptic effects observed after combined injection of a GABAA agonist and an NMDA antagonist into the SNR, at doses shown to have no effect by themselves.[42] These data suggest that the trans-striatal and trans-subthalamic pathways could cooperate in the suppression of absence seizures, and that striatal dopaminergic transmission plays a key role in the modulation by the BG of this form of epilepsy (see below).

Electrophysiological evidence for an endogenous control system by the basal ganglia circuits

The pharmacological data reported either in the model of absence seizures or in other models of generalized epilepsy have raised the possibility that some BG circuits may act as an endogenous control system able to interrupt epileptic seizures and/or to modulate their occurrence,[21,70] According to such

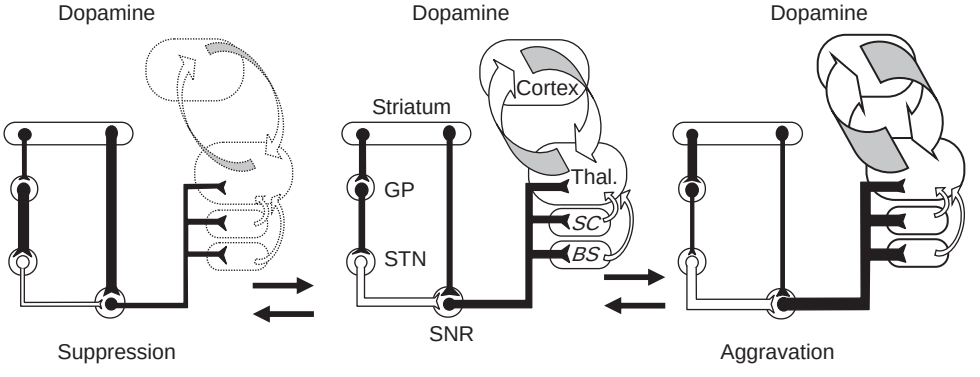

Figure 128.1 Effects of pharmacological manipulations of the basal ganglia structure. Schematic representations of the connectivity within the basal ganglia system thought to be involved in the control of absence-seizures in GAERS. Thickness of neuronal outputs is proportional to the activity of the projection, as modified following intracerebral pharmacological manipulations. An increased activity in the striatal dopaminergic tone has antiepileptic effects (left panel) whereas a decreased activity in the dopaminergic tone has proepileptic effects (right panel). For instance, dopamine at the striatal level is thought to simultaneously potentiate the inhibitory influence of the trans-striatal direct pathway and decrease the excitatory influence of the trans-striatal indirect pathway through D1 and D2 dopaminergic receptors, respectively. BS: brain stem; GP: globus pallidus; SC: superior colliculus; SNR: substantia nigra pars reticulata; STN: subthalamic nucleus; Thal: thalamus.

a hypothesis, changes of neuronal activity associated with the occurrence and/or interruption of seizures should be detected in some circuits of the BG. There is good evidence from electrophysiological recordings in both human patients and animal models, that changes in basal activity is observed in the BG concomitantly with an epileptic discharge.[71–77] In animal models, data were mainly collected during pharmacologically- or electrically-induced seizures, and the 'endogenous' nature of the observed changes of activity was thus difficult to determine. To investigate the possible relationships between unit activities in the BG and the cortical EEG during ictal and interictal periods, the genetic model of absence seizures was preferred for its spontaneous occurrence of frequent seizures and for the lack of motor components that could interfer with the recording procedure.[78,79] Single-unit recordings in GAERS maintained under neuroleptanalgesia indicated that SNR and STN neurons increase their firing rate, concomitantly with the occurrence of spike-and-wave discharges at the cortical level, whereas dopaminergic neurons of SNC tend to decrease their activity. Conversely, at the end of the seizure, SNR and STN neurons decrease their firing rate, whereas dopaminergic neurons of the SNC display a transient overactivity.[80] Because fentanyl and haloperidol used for neurolept-analgesia are known to interfere with neurotransmissions involved in the BG, we developed multi-unit recordings with a chronically-implanted movable tetrode in the freely-moving GAERS. Combined with off-line sorting of the tetrode data, this approach allowed to record single-unit activities in the SNR and showed no particular organization of the discharge mode during interictal periods, as compared to recordings performed in nonepileptic rats in previous studies.[81] However, when a spike-and-wave discharge occurred on the cortical EEG, the frequency of discharge of the SNR neurons increased and action potentials became organized in bursts (see Figure 128.2). These bursts always followed the spike component of each spike-and-wave element by a few milliseconds. In addition, a few seconds before the end of the EEG discharge, a decrease in SNR neuronal activity was often observed. These results, obtained in the freely-behaving animal, clearly showed that the spontaneous occurrence of epileptic discharges modifies the activity of SNR neurons.[78] The delay observed between the occurrence of the cortical EEG spikes and the burst of action potentials suggests that the SNR is involved in the propagation rather than the generation of the seizure. In addition, the decrease of unit activity observed before the end of the seizure, suggests that inhibition of SNR neurons could participate in the blockade of an ongoing seizure. The nature and the temporal pattern of these changes are in agreement with what could be predicted from the pharmacological data, and suggest that these events could contribute to the antiepileptic effects resulting from a physiological triggering of the control system.

The involvement of the BG is further supported by recent in vivo intracellular recordings showing that spike-and-wave discharges are associated with a transient interruption of striatal output neurons firing and a synchronized rhythmic bursting in STN neurons.[82,83] These distinct changes in activity during absence-seizures in the striatonigral and subthalamonigral pathways are likely to produce an imbalance between excitation and inhibition within the SNR and lead in turn to synchronized burst firing of SNR neurons in phase with the spike-and-wave complexes in the EEG, thus providing an endogenous mechanism controlling positively the maintenance and the duration of the seizure. Hence, the rebound of excitation observed at the end of a spike-and-wave discharge in most of striatal output neurons[82] and consistent with the decrease of SNR activity[78] might have a negative modulatory effect on spike-and-waves and thus contribute to the interruption of an ongoing absence-seizure.[83]

Role of the dopaminergic transmission

Both pharmacological and electrophysiological approaches have revealed a critical role of the striatal dopaminergic neurotransmission in the control of seizures. It suggests that this part of the BG circuit is involved by seizure propagation and/or triggering of the control circuits. Indeed dopamimetic

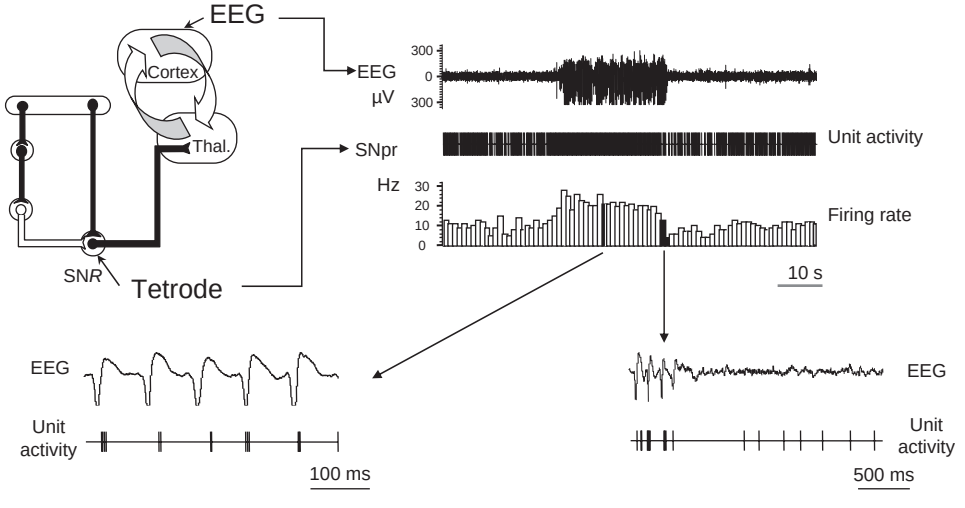

Figure 128.2 Changes in extracellular unit recordings in the SNR in a freely behaving GAERS. Cortical EEG and unit activity obtained from a freely behaving rat equiped with a movable tetrode chronically implanted within the substantia nigra pars reticulata. The lower panels display an enlargement of spike-and-wave complexes with simultaneous bursts of action potentials (left panel) and changes occuring at the end of an absence-seizure (right panel).

drugs have been reported in both human and in animals to have antiepileptic effects (for review, see Starr, 1996).[84] For example, a suppression of absence-seizures in GAERS was reported following systemic injection of dopamimetics, whereas aggravation was observed after injection of dopamine antagonists.[85] The critical influence of dopamine in the control of absence-seizures was also confirmed by experiments showing that local 6-OHDA lesion of dopaminergic neurons within the ventral mesencephalon (pars compacta of the SN and ventral tegmental area) temporarily aggravates absence seizures in GAERS (personal observations). In addition, the recurrent involvement of this neurotransmission by the repetition of seizures may result in long term modifications as evidenced in both rats and humans.[75,86,87] In fully amygdala-kindled rats, a decreased presynaptic dopamine turnover has been demonstrated in the ipsilateral nucleus accumbens, by microdialysis,[88] as well as an increase in D2 receptor binding and mRNA expression.[87,90] These changes may represent a compensatory process for the seizure threshold-lowering effects of the kindling process.[84] However, the motor patterns of the convulsive seizures (i.e., clonic or tonic movements), as well as the secondary behavioral effects e.g., stress, anxiety[91–93] learning impairment[92,94] observed in kindling are likely to also interfere with the dopaminergic neurotransmission.

Investigation of the expression of different dopaminergic transcripts in the striatum of GAERS revealed an increased level of D3 mRNA expression in neurons of the core of the nucleus accumbens in adult GAERS as compared to nonepileptic control rats, whereas no differences were observed in the shell or in other regions (dorsal striatum, olfactory tubercles, islands of Calleja). This was specific to D3 receptors since no change in the expression of mRNAs coding for other neuronal dopaminergic markers (tyrosine hydroxylase, membraneous and vesicular dopamine transporters) or D1, D2, and D5 receptors were observed. Interestingly, D3 transcripts were not increased in 21-days juvenile GAERS[95] where no absence seizures had yet occurred.[96] Our data thus suggest that this transcriptional change is likely to represent either a part of the epileptogenesis process or an adaptive response to repeated seizures. Its localization in the core of the nucleus accumbens is in line with the dopamine-sensitive antiepileptic sites in the ventral striatum and further supports the involvement of ventral structures of the BG system in the control of absence seizures.[42] Although the functional consequences of an up-regulation of D3 receptors on neurons of the n. accumbens are still unknown, it is likely to be related to the overactivity of the dopaminergic neurons observed at the end of the absence seizure (see above).

Altogether, our results and data from the literature, support the hypothesis that epileptogenesis and/or recurrence of generalized seizures induce persistent, transcriptional changes of striatal dopaminergic neurotransmission. Whether these changes represent an alteration of the controling capacities of the BG, as suggested by some clinical data,[75] or an adaptive attempt to reinforce control of seizures, remains to be examined.

Conclusion and perspectives

Although it is clear that the BG circuit cannot generate seizures and are unlikely to be involved in their initiation, numerous experimental data presented in this review have revealed that changes in the activity of the BG system influence the occurrence and/or cessation of epileptic seizures. In addition, the dynamic of changes observed in BG neuronal activity during seizures suggest that these structures stand at a nodal point not only to detect but also to interfere with an on-going seizure. Electrophysiological approaches allowing a more acute space- and time-resolution in order to simultaneously follow changes in seizure activity and changes in the activity of the BG are expected to provide further evidence for this hypothesis. In particular, it will be necessary to further investigate how this remote control system is triggered endogeneously and to determine how changes in SNR activity affect the thalamo-cortical circuit.

The collection of pharmacological and electrophysiological data in animal models of epilepsy has led to the emergence of the BG as a possible control circuit of the seizures. These experimental data have already led to initial clinical trials using high-frequency stimulation of the STN in epileptic patients.[52,97–99] These preliminary data, as well as clinical observations involving BG activity in epileptic patients[75,77,86] encourage further research in chronic models of epilepsy, to better determine the exact output circuits involved in seizure interruption, the mechanisms triggering SNR inhibition and whether the same circuits are involved in the control of different types of seizures.[100] This will allow identification of the optimal target structures and the forms of epilepsy likely to benefit from this new therapeutic approach.

129 Repetitive transcranial magnetic stimulation

F Tergau and BJ Steinhoff

Introduction

Transcranial magnetic stimulation (TMS) was introduced in 1980[1] as a technique for noninvasive stimulation of the brain and other parts of the central nervous system[2] and has been quickly developed as a standard procedure in clinical neurophysiology to investigate conduction properties of the pyramidal tract.[3,4] When technical limitations had been overcome it soon became clear that repetitive application of magnetic pulses to the brain was capable of modulating the excitability of cortical neurons.[5,6] Moreover, it was very soon discovered that repetitive transcranial magnetic stimulation (rTMS) could be used to induce plastic changes of cortical excitability that last beyond the period of stimulation itself. Since it had been described that rTMS may improve patients with major depression,[7] this technique is continuously in discussion as a therapeutic tool in various neurologic and psychiatric disorders.[8,9] In particular, for epilepsy rTMS seems to have the potential of evolving as a promising therapeutic alternative since there is still a substantial proportion of patients in whom – despite numerous newly-developed drugs and improved surgical techniques – seizures are not sufficiently controlled. Even more so since rTMS is a noninvasive, nondestructive technique that could fulfil substantial prerequisites for a treatment strategy in drug-resistant epilepsy syndromes with epilepogenic focus in eloquent cortical areas that can not be treated by resective surgery.

Obviously, the concept of stimulating the brain to treat epilepsy is not new. Early in the 20th century attempts were started to develop different techniques of electrical stimulation in different parts of the brain to reduce epileptic activity and to treat epilepsy. The most promising electrical stimulation procedures for epilepsy treatment are discussed in detail in an earlier chapter of this book section.

Technical considerations

Magnetic stimulation differs from electrical stimulation in several aspects: First, all electrical stimulation techniques used in epileptology so far are invasive and need surgical procedures to place the stimulation electrodes either on the brain surface or into deep brain structures. With TMS a coil with windings of a strong copper wire held against the surface of the head induces a magnetic field of up to 2 Tesla by short but strong currents of about 4000 amps delivered from high-voltage capacitors. The magnetic field penetrates the skull without diminution and, by rapid change of field strength, induces an electric current in any conductive tissue, thus also in the brain. The electrical current when flowing through the brain leads to activation of neuronal axons and induces action potentials that run along physiological pathways and connections within the brain. At that site the rTMS effects share some common aspects with electric stimulation but the stimulation effect should largely depend on the direction of the stimulating current. While with electrical stimulation the current runs from anode to cathode and current density depends on the electrode size, with magnetic stimulation the induced current runs parallel to the wire of the coil that produces the magnetic field and the current density depends on the coil shape and the distance from the coil.[10]

It should be noted that there are magnetic stimulation types other than rTMS that are also mentioned in the literature but which are not discussed here. While in rTMS studies pulsatile stimulation of high intensities are used (200 μs, 1–2 Tesla, 20–50 Hz repetition rate), for example the workgroup of Dobson[11,12] investigated the effect of constant DC magnetic fields with intensities of about 1–2 milliTesla (10^3-fold less than rTMS) on spike frequency in epilepsy patients. The electromagnetic field of power line (1–2 microTesla, 10^6-fold less than rTMS, 50–60 Hz) was investigated in many studies and also in animal models of epilepsy.[13,14] Finally, effects of a so-called magnetic field therapy were described in epilepsy[15,16,17,18] using continuous or sine-wave fields mostly with intensities in the picoTesla range (10^{12}-fold less than rTMS).)

Parameters of stimulation

As indicated above, there are some crucial factors that influence the effect of TMS and rTMS. The impact of these factors has been largely studied at the motor cortex where the effects can easily be evaluated by measuring the size of the motor-evoked potentials induced in a target muscle of which the area of cortical representation is stimulated.[9,19] It may be assumed that most of the experience from the motor cortex may hold true for other cortical areas although this has not been shown so far. The main parameters of TMS will be introduced as follows:

Coil shape

The shape of the copper wires formed into a coil has great impact on the intensity, orientation, and depth of penetration of the magnetic field. Two major types of coils are used: the circular or round coil has a circular winding of about up to

9 cm diameter. The induced magnetic field and additionally the induced current in the brain is circular, as well, which means that the magnetic field covers a great target area with similar intensity although orientation of the current is different at any point. In contrast, the so-called figure-of-eight coil consists of two adjoining circular windings of about 7 cm (and more) in diameter. With the current running in opposite directions in the two ends of the figure-of-eight, superimposition of the magnetic fields produces a focal magnetic field beneath the joint with an approximately linear orientation and, compared to the round coil, with increased penetration depth.[20,21] For the brain it seems most likely that with these coil types TMS only reaches the cortical surface of the brain, intensity strongly attenuates with depth and may not activate neurons more than 5–6 cm below surface of the scalp.[22] Field strength and penetration depth increase with stimulation intensity and with coil size but focality weakens and vice versa: the smaller the coils and the lower the stimulus intensity, the more focally it stimulates but also the more its field strength decreases.[23]

More recently, other, more complex types of coils have been designed with the advantage of improving penetration depth. The most promising is the so-called H-coil[24] which has been designed with the aim of reaching areas 3–4 cm deeper than the figure-of-eightcoil and is probably capable of activating the mesial temporal lobe, though this has not been investigated yet.

Stimulation site and coil orientation

As indicated above, the coil shape is important for the direction and orientation of the induced current. To stimulate a certain brain region it seems important where and how focal the stimulation takes place and what the orientation of the induced current is. For the motor cortex a strong dependency on coil orientation has been described.[25,26]

Pulse shape

For a long period of TMS research little attention was paid to the shape of the magnetic pulse. Mainly for technical reasons, manufacturers designed TMS devices with widely different pulse shapes: monophasic as well as biphasic pulses were used, some with asymmetrical polarity and time course. However in recent years it was shown that for single pulses as well as for rTMS, the pulse shape has great impact on the effect of brain stimulation.[27–29]

Intensity

Since the magnetic field is not homogenous, it is impossible to provide exact information about the intensity of stimulation in a specific part of the stimulated brain area.[22] Researchers have therefore opted for taking the percentage of maximal stimulator output as a measure of the stimulation intensity. For better adaptation to individual subjects and patients, intensity was adjusted according to an individual's motor threshold; this is a biological parameter and is defined by the minimal stimulus intensity needed to elicit a motor evoked potential in a target muscle when stimulating the motor cortex.

Stimulus frequency

The rate at which rTMS pulses are applied is vital for the type of induced after-effects, since rTMS can be used to induce both elevation and reduction of cortical excitability. Whether the excitability of the stimulated cortical network is up- or down-regulated and therefore is facilitated or inhibited seems to mainly depend on the stimulation frequency.[19,30] From studies on rTMS applied to the human primary motor cortex, evidence exists that rTMS frequencies of 5 Hz and above lead to an increased excitability,[5,31] while frequencies of 1 Hz or less result in reduced motor cortical excitability.[32,33]

Number of stimuli and number of repetitions

From the motor cortex, evidence exists that the after-effects of rTMS depend on the number of repetitive stimuli.[9] In treatment studies, trains consisting of 500–2000 stimuli were used on a arbitrary basis. So far, there is no evidence for a rational prediction of the number of stimuli needed to induce long-term effects and there is also no evidence regarding whether a correlation exists between the number of stimuli and the strength or duration of the after-effects.

However, there is strong evidence that daily repetition of the rTMS train leads to a magnification or consolidation of the after-effects.[34]

Physiological basis of rTMS

From a historical point of view the antiepileptic effect of TMS and rTMS was discovered somewhat by chance as described later in this chapter. When rTMS effects were first studied in humans and even when pilot studies on epilepsy treatment with rTMS in patients had started, there was still no clear idea of the physiological mechanisms behind the long-term effects and the processes that would render repetitive stimulation beneficial in epilepsy. For a better understanding it may therefore be useful to outline the main ideas regarding the physiological mechanisms thought to be involved in the rTMS effects. Although only little is proven, it seems nevertheless reasonable to build on established hypotheses regarding the physiological basis of electrical brain stimulation that were derived from the observation that long-term modulation of synaptic strength can be induced by high-frequency repetitive electrical stimulation.[35] Some time passed after the discovery of the so-called *long-term potentiation* (LTP) before a contrary phenomenon, *long-term depression* (LTD) was demonstrated, at first in the cerebellum[36] and later in hippocampal slices.[37] Furthermore, it was shown that LTP and LTD could be induced in the same neuronal structures, depending on the stimulation frequency: while high-frequency stimulation induces LTP, LTD was obtained by low-frequency stimulation[38] – but this strong dichotomy may not always hold true since the order of different stimulation types has great impact.[39] When similar phenomena were induced in neocortical neurons they were considered to be LTP-like and LTD-like phenomena, and it could be shown that these mechanisms largely share similar mechanisms.[40–42]

In several studies mainly on hippocampal tissue, mechanisms of LTP and LTD were found to contribute to

epileptogenesis[43,44] and it could be shown that low-frequency electrical stimulation is capable of reducing spontaneous as well as induced epileptogenic activity in hippocampal tissue.[45] The interaction of electrical stimulation and epileptogenesis has been largely investigated and, moreover, important animal models of epilepsy are based on kindling and other effects of electrical stimulation that enhance or induce epileptogenicity.[46,47–49] In contrast to the large body of literature on epilepsy and electrical stimulation in animals, there are far fewer studies on magnetic stimulation in animals or in tissue slices. This is probably due to technical problems with the coil dimensions needed to stimulate sufficiently (see above). Coils may be too large or brain and slices too small for stimulation focal enough to investigate particular aspects of the rTMS effects. This may be the reason why rTMS in humans was not preceded by animal studies but vice versa.

Animal studies of rTMS

When it became clearer that low-frequency rTMS, like low-frequency electrical stimulation, may have antiepileptic effects, the effect of rTMS was also studied in different animal studies. Seizure induction by intraperitoneal injection of pentylenetetrazole, a GABA antagonist, as a model for generalized seizures in the rat was investigated by Akamatsu *et al.*[50] They found that 1000 pulses at 0.5 Hz led to a prolonged latency for seizure development. Moreover, rTMS effectively prevented the development of status epilepticus of pentylenetetrazol-induced convulsions. Already investigating the effects of high-frequency rTMS some years earlier, Jennum and colleagues[51] showed that a series of 1 or 5 seconds of 50 Hz rTMS did not alter seizure induction after pentylenetetrazole injection, but that repreated rTMS over 30 days reduced the time for inducing seizures after pentylenetetrazole injection. This is well in accordance with the frequency-dependency of proepileptic and antiepileptic effects of repetitive stimulation, although in this study seizures were not directly induced neither under acute rTMS nor after repeated application.

Nevertheless in another animal model, the amygdala kindling model for mesial temporal epilepsies, the results were the opposite. A single rTMS train of 20 Hz for 3 sec resulted in elevation of after-discharge threshold[52] 2 weeks after rTMS but did not affect the kindling process itself. The interpretation of these findings is not clear. So far, complementary studies of low-frequency rTMS on the amygdala kindling model has not been performed; also a proepileptic effect of any kind of high frequency rTMS in amygdala kindling model has not been shown directly. Nevertheless, there is evidence for an antiepileptic effect of low-frequency rTMS shown indirectly in an animal model of epilepsy: using a rat flurothyl kindling seizure model, intraventricular injection of cerebrospinal fluid (CSF) of humans after 1 Hz rTMS and after 10 Hz rTMS led to a decreased kindling rate with CSF after low-frequency stimulation and tended towards a higher kindling rate, which supported the hypothesis that CSF after rTMS has antiepileptic or proepileptic properties, depending on the stimulation frequency.[53]

Nevertheless, the biological basis for the long-lasting effects of rTMS is not well understood and further studies are still needed.[54,55]

Safety aspects of TMS and rTMS

Even before repetitive application techniques of TMS were introduced, it was debated whether TMS applied as single pulses or as a series of a few pulses could produce side-effects and, in particular, provoke seizures. In order to deal with this apprehension appropriately, we studied the literature extensively.

Provided the exclusion criteria are followed (cardiac pacemakers, intracranial electronic devices, intracranial metal objects), single pulse TMS is regarded as safe in normal subjects, even in epilepsy patients.[56] Nevertheless, in a few cases epileptic seizures were observed in patients with neurological disorders,[57–59] though it was unclear whether TMS was directly responsible for them.

Single TMS also seems to be safe for patients with single seizures or epilepsy. Liepert and colleagues[60] did not observe any seizures when investigating motor pathways with TMS in 21 patients who had previously had a single seizure. In a study of 53 epilepsy patients in which motor-evoked potentials were investigated with TMS, only two patients developed complex-partial seizures of their typical semiology.[61] In another study using TMS for monitoring the conduction properties of central motor pathways in 58 epilepsy patients, seizures were not induced and the epilepsy was made worse.[62] When trying to activate the epileptic focus in 48 epilepsy patients, only six patients developed seizures, although 22 patients did develop seizures after-discharges following activation of the epileptic focus.[63] In another study of 140 epilepsy patients, only six ictal events occurred immediately or shortly after TMS.[64] Nevertheless, during verbal working memory testing, 20 patients with intractable epilepsies experienced three auras and two seizures.[65] Only one study published so far has described reproducible induction of focal seizures by TMS in one patient suffering from a focal epilepsy originating from a documented epileptic focus in the left supplementary motor cortex.[66] The semiology of seizures triggered by TMS was identical to the spontaneous ones. From a meta-analysis, overall risk of induction of seizures in epilepsy patients by single or double pulse TMS studies seems to be no higher that 3.6%.[67]

Repetitive TMS

When rTMS is used with high frequencies, epileptiform activity and seizures are more likely. Even in normal subjects, a spread of excitation was observed under high intensities of high-frequency rTMS and a seizure occurred in one subject.[68,69] In a depressed patient under rTMS antidepressant treatment, a complex-partial seizure presumably of the frontal lobe was induced.[70] When stimulating the assumed epileptic focus, Hufnagel *et al.*[71] were able to induce after-discharges in 12 of 13 epileptic patients and a complex-partial seizure in one patient, but failed when stimulating other brain areas. Trying to replicate these findings under identical conditions, Schuler *et al.*[72] only found activation of the epileptic focus in three out of ten patients while hyperventilation was more often provoked (six patients). Dhuna *et al.*[73] were unable to induce any seizure when performing rTMS on the hemisphere containing the presumed epileptic focus in intractable epilepsy patients for presurgical evaluation, but induced a seizure in one patient

after applying maximal intensity rTMS on the other hemisphere. Another group[74] was not able to induce any seizure in epilepsy patients with 30 Hz and 50 Hz rTMS, but observed reduction in spike frequency over 10 minutes after rTMS. In a more recent study on 21 epilepsy patients for presurgical evaluation, rTMS of the assumed epileptic focus was not sufficient to induce any seizure.[75] Thus, it was concluded that TMS and rTMS do not seem to be helpful in lateralization during presurgical evaluation in intractable epilepsies.[75,76]

The question of safety with rTMS was addressed in several other studies[68,77–79] and recommendations from the *International Workshop on the Safety of Repetitive Transcranial Magnetic Stimulation*, June 5–7, 1997, Bethesda, USA, are available.[80] From all studies known so far it can be concluded that the risk of inducing seizures increases commensurate with the intensity and frequency of an individual's seizures? Additionally, the intertrain interval of several rTMS trains is an important safety criteria.[77] A seizure has never been seen with rTMS at intensities below 100% resting motor threshold or at frequencies below 1 Hz. In patients with severe epilepsy, seizures may occur under low-frequency rTMS although the causative role is unlikely. Moreover, the opposite effect is assumed (see below).

Several other studies were also unable to detect side effects from TMS and rTMS. No cognitive impairment was found after TMS in normal subjects nor in patients.[81–85] Only little is known on possible morphological changes in human brain tissue after rTMS, but no lesions were found in human hippocampal tissue of two patients who received 2000 pulses of 25 Hz rTMS trains before undergoing epilepsy surgery.[86] Although it was described that electrodes may heat under rTMS and may cause tissue damage,[87] such a case has so far never been reported.

In summary, rTMS when applied according to the safety criteria appears to be relatively safe in patients with epilepsy, since conclusive evidence of TMS being a trigger of ictal events has only been found in a very few cases (see above). However, not all possible side effects have yet been thoroughly addressed and long-term side-effects are still possible.[88] High-frequency rTMS studies in epilepsy are only justified for diagnostic reasons, and the patient must be informed of the potential risk of seizure induction.

Antiepileptic effects of rTMS in humans

As indicated above, the antiepileptic effect of TMS was discovered unintentionally when attempts were made to elicit epileptic activity. When Hufnagel and Elger[63] tried to activate the epileptic focus in 48 patients with intractable epilepsies by using single-pulse TMS, they found enhancement but also suppression of epileptiform potentials in seven patients with continuously spiking epileptic foci. Additionally, they described temporary interruption of epileptiform paroxysms for 1–3 sec. in nine cases, and found persistent suppression of spontaneous spikes in one patient. These results were early evidence that TMS pulses may inhibit epileptiform activity. When applying single TMS pulses repetitively every 3 to every 10 seconds (0.3–0.1 Hz) – before the term repetitive stimulation was coined and before repetitive stimulators were built – Steinhoff and colleagues noticed a decrease in spike frequency for at least 5 min after stimulation, most prominently bilaterally when TMS was applied contralateral to the epileptic focus in seven patients with medically intractable complex-partial seizures of mesiobasal limbic onset.[89] These results may represent evidence that TMS influences cortical network excitability across the hemisphere.

In 1997, preliminary data on three patients with cortical action myoclonus were presented showing that 1 Hz rTMS over 30 min was able to reduce action myoclonus. Although applied over several days, the effect always decayed two hours after rTMS.[90]

Based on these experiences, several studies with different designs were performed to evaluate the antiepileptic efficacy of rTMS in patients. These studies are described in a short summary below, and the table gives an additional overview.

Open, uncontrolled studies

Based on the evidence of antiepileptic effects of low-frequency rTMS, an open study on nine patients with intractable temporal and extratemporal focal epilepsy was performed in order to investigate long-term therapeutic effects.[91] Seizure frequency during four weeks before and then after rTMS treatment was compared. During five consecutive days, 1000 pulses (100% motor threshold intensity, 0.33 Hz) from a repetitive magnetic stimulator were applied by an unfocal round coil (9 cm diameter) placed over the vertex. All patients tolerated rTMS treatment well and worsening of epilepsy did not occur. Eight of nine patients reported a reduction in seizure frequency or reduced severity of seizures. In all nine patients, average seizure frequency (seizures per week) was significantly reduced by approximately 39%. Two patients did not show any seizure reduction; the other patients showed decreases of less than 20% ($n=1$), 20–50% ($n=3$) and more than 50% ($n=3$). The effect decayed over 4–8 weeks.

In another open study of eight patients with drug-resistant epilepsies due to malformation of cortical development, focal rTMS with 600 pulses of 0.5 Hz led to a reduction of epileptiform activity by 46.4% and 42.1% at 15 and 30 days, respectively, after the single rTMS session. This electroencephalographic effect was accompanied by reduction in seizure frequency by 57.3% and 51.2%, respectively.[92]

Seizure reduction by 19.1% over 2 weeks after rTMS was found in seven patients with different types of extratemporal epilepsies when treated with rTMS (90% motor threshold stimulus intensity), 0.9 Hz over 15 min twice a day over 5 days, described by another group.[93] When analysed separately, they found a 35.9% reduction of complex partial seizures compared to a 7.4% reduction of simple partial seizures. Moreover, patients with smaller differences in resting motor threshold and active motor threshold showed higher reductions of complex partial seizures. However, all effects were not significant.

Most recently, the effect of hemispheric cerebellar rTMS was investigated in an open study of 6 patients with single and multiple epileptic foci.[94] During a 4-week period of 5 Hz rTMS with 100 stimuli per day and 95% motor threshold stimulus intensity, five of six patients showed a reduction in

seizure frequency by 34.8%–100%; the seizure rate returned to pre-rTMS level directly after the treatment period.

Case report studies

These positive group effects were supported by a few case reports. In a patient with focal dysplasia, biweekly treatment with one hundred stimuli at 0.5 Hz and 95% motor threshold intensity using an unfocal coil placed over the area of dysplasia reduced seizure frequency by 70% over a 4-week period of treatment.[95] With a similar protocol (0.5 Hz rTMS biweekly over 4 weeks, focal stimulation but 90% motor threshold stimulus intensity) another group found a reduction in seizure frequency of up to 42% in two patients with single focus while there was no benefit in patients with multiple foci.[96] Myoclonus-related epileptic activity could be shown to be reduced when treated with 15 min 1 Hz focal rTMS in a patient with cortical dysplasia in the primary motor cortex and continuous positive myoclus of the contralateral forehand.[97] In another patient with epilepsia partialis continua due to a cortical dysplasia in the motor cortex, rTMS (0.5 Hz, 90% motor threshold intensity, 100 pulses) nearly abolished seizure activity for a period of almost 2 months and the effect was reproduced.[98] In contrast, high-frequency rTMS with 20 Hz (50% stimulator output stimulus intensity) in two patients with epilepsia partialis continua interrupted epileptic activity for up to 24 h after rTMS and, moreover, was accompanied by a decrease in perfusion measured by SPECT.[99]

Placebo-controlled studies

Nonblinded, uncontrolled therapeutic trials and single case studies in epilepsy should be interpreted with caution since placebo effects may play a substantial role. In a trial studying 24 patients with focal epilepsy, randomized to either active or sham stimulation with 15 min 1 Hz-rTMS twice a day at 120% motor threshold stimulus intensity applied focally over the epileptic focus, the group by Theodore and colleagues[100] found a mean seizure reduction of 16% for actively treated patients and of 1% for sham-stimulated patients over a post-stimulation period of 2 weeks and a reduction of 4.5% and –0.4% over 8 weeks, respectively. The difference did not reach significance.

From a second placebo-controlled trial only an interim analysis has been published so far.[101] They carried out a placebo-controlled, cross-over design 1.0 Hz and 0.33 Hz rTMS treatment with 1000 pulses per day (100% motor threshold stimulus intensity) over 5 consecutive days with an unfocal stimulation coil placed over the vertex. For the placebo condition, stimulation with 0.66 Hz was applied using a specially designed coil with a reduced output that was ineffective in reaching the cortex. For the 17 patients who completed the study in this analysis, there was no significant difference between the 1.0 Hz, the 0.33 Hz and the placebo stimulation types. Only for the week in which stimulation was performed was there a significant reduction by approximately 40% of seizure frequency when compared to baseline – and a 2-week post-stimulation period still shows significant reduction in seizure frequency when referred to baseline. When compared to placebo, the 0.33 Hz condition fell slightly short of significance. However, the preliminary analysis of the full data set on the 23 patients who completed the full study (Tergau *et al.*, in preparation) does not show any significant effect at all for either condition, not even for the week during which stimulation was performed.

Another study [112] on 43 patients with a similar design using 0.3 Hz stimulation verum and placebo did not show any significant effects although there was a slight reduction in seizure frequency (15%) in verum group versus 9% reduction in the placebo group; additionally frequency of epileptiform EEG discharges neither showed any significant effects, only 12 patients of 38 patients showed spike reduction by >50%. With a stimulation protocol slightly changed (1 Hz) 5×1200 pulses, Fregni and colleagues (2006) reported significant reduction in seizure frequency when stimulated focally the focal lesion. EEG pattern were also reduced.

There is another study in which four subgroups were compared without a placebo condition: patients with focal epilepsies and patients with non-focal epilepsy were treated with focal stimulation and unfocal stimulation, respectively, both subgroups were subdivided in two groups with long stimulation procedure (total pulses 3000) and short stimulation (1500 pulses). There was a non-significant reduction in seizure frequency by 13.9% with a non-significant differences between long and short stimulation (−23 vs. −3%). But there was no difference at all between focal and non-focal stimulation types.

rTMS for treatment of epilepsy – where are we now?

So far, only some 80 patients with epilepsy have been included in studies using rTMS as a treatment strategy. This is far below the critical number of patients needed for drawing substantial conclusions on the antiepileptic efficacy of rTMS. Most of the uncontrolled studies indicate a positive effect showing reduction in seizure frequency either during or for a short time after rTMS of up to several weeks. Mainly low-frequency rTMS with 0.3–1.0 Hz was used, mostly with stimulus intensity just below motor threshold; the number of stimuli and the period over which treatment was performed showed large variation. However, the two controlled trials existing so far failed to confirm these positive results or showed only mild and short-lived effects. In the following, with the hope of learning from disappointments in the past, we discuss some aspects that might be important for optimization of rTMS trials in the future.

Why did controlled studies fail to show a therapeutic effect of rTMS in epilepsy patients?

The antiepileptic effect of rTMS does not exist?

The worst and simplest possible explanation for the failures of rTMS studies would be that the assumption of an antiepileptic effect from rTMS is wrong. Although a large number of animal studies and slice studies showed that repetitive electrical stimulation is capable of modulating neuronal activity and

that a special type of repetitive stimulation can reduce epileptic activity, this need not hold true for magnetic stimulation ... and need not hold true in humans. Moreover, LTP and LTD are physiological phenomena demonstrated in small and circumscribed neuronal network areas, but they might only play a minor role in epileptogenesis and 'antiepileptogenesis'. These phenomena may in humans be counterbalanced in the intact, albeit epileptic, brain if induced by rTMS at all. However, although a number of scenarios could be drawn to explain a nonexistent antiepileptic effect of rTMS, there is a large body of evidence that the effect actually exists. For the future, more studies are needed to find and explain the exact physiological mechanisms of the missing links between animal and human studies.

The stimulation type was not optimal

Two basically different rTMS techniques have been used in the studies described above. On the one hand, focal stimulation can be used to affect the epileptic focus, while on the other, unfocal stimulation may be chosen to reduce the cortical excitability of the neuronal network involved in the propagation of seizure activity. Taking into consideration the technical aspects discussed at the beginning of the chapter for both paradigms, we must conclude that there is no definitive answer so far to what direction and what orientation is needed to obtain optimal effects. From the majority of the treatment studies mentioned above, focal stimulation appears more advantageous, even in view of the two unsuccessful controlled studies by Theodore *et al*. and Tergau *et al*.[100,102] A positive effect could have been missed due to incorrect orientation and/or incorrect direction of the focal stimulation.

Another aspect may support the advantage of focal stimulation. It is known that focal stimulation at threshold intensities only activates a small area of cortex lying some 3 cm beneath the skull. It may be assumed that a mesial epileptic focus cannot be achieved effectively. This could be an explanation for the lack of better results in the study by Theodore *et al*., in which 10 of the 24 patients had a temporo-mesial epileptic focus. A subgroup analysis showed that neocortical epilepsies responded much better (24±22% seizure reduction) than mesial epilepsies (–11±28%). This difference, however, was not significant, probably due to the small sample size. Support for the hypothesis of superiority of focal stimulation is presented by the two placebo-controlled studies where focal stimulation showed seizure reduction[110] while unfocal did not (Cantello *et al*.). Nevertheless a direct comparison of those two stimulation types failed to show significant effects.[111]

But also the unfocal stimulation concept may have some support. Brain imaging as well as neurophysiological studies showed that brain areas remote from the TMS stimulation site can be modified.[103–106] However, it must be admitted that induced remote effects could lead to more contrary effects than intended, since inhibition of inhibitory neurons in the vicinity of the epileptic focus could boost epileptic activity regardless of focal or unfocal stimulation. Such a proepileptogenic effect has not been obtained so far but it may be discussed whether under certain circumstances there is a counterbalance of antagonistic effects. Specific study protocols need to be performed on suitable epilepsy syndromes to investigate further the influence of stimulation type.

The stimulation parameters were not optimal

In most of the studies, low-frequency stimulation between 1.0 and 0.3 Hz has been used with trains of up to 1000 stimuli per session and with several sessions over days and even weeks. While selection of the frequency is based on observation of rTMS effects on motor cortex excitability, the number and intensity of stimuli was chosen arbitrarily. No systematic studies have been performed to compare stimulation protocols that differ in these parameters. Regarding the repetition of sessions, there is evidence that a consolidation and/or magnification of long-term effects might occur when trains are repeated the next day, but further studies are needed to evaluate protocols with daily, biweekly stimulation or any other repetition rate. Optimal protocols might be different for different individuals.

Moreover, it is fairly unknown whether the separation between the two obviously contradictory modifications of cortical excitability, facilitation and inhibition, is fixed at a certain stimulation frequency. Indeed, a couple of studies demonstrated a possibly large inter-individual variability with regard to susceptibility to inhibitory and excitatory rTMS.[107] In addition, it is not clear whether the results with the motor cortex can be seen as generally valid for all brain regions. Nevertheless, it is well accepted in general that activation is more likely induced when higher frequencies are used and inhibition is yielded by low frequencies. This seems to be confirmed by a PET study, showing that high-frequency led to an increase of regional cerebral blood flow (rCBF) in the stimulated brain areas, whereas under low-frequency the rCBF decreased.[108,109]

The patient selection was not optimal

The epilepsy syndrome and related factors such as focus localisation, pathology, medication, duration of disease, and seizure types may be of importance for the success of rTMS treatment. Studies so far indicate that patients with focal epilepsies due to cortical dysplasias represent and optimal patient population for rTMS. This could be explained by technical characteristics (see above) but it could also be a matter of the type of cortical lesion. To investigate this further, different types of epilepsies with circumscribed cortical pathology should be compared using identical stimulation protocols.

Furthermore, the patients treated so far have been mostly drug-resistant, which means that they are a negative selection of subjects who had failed any other treatment strategy. To discover the true potential of rTMS, patients who are not drug resistant should also be studied.

Finally, the number of patients was much too small to demonstrate significant effects.

The expected effects could have been overestimated

The impression derived from initial studies is that rTMS induces long-term effects outlasting the stimulation by days and weeks. There is, however, no evidence that any other intervention – not pharmacological treatment nor stimulation procedure – can induce therapeutic after-effects of such duration. So, why should rTMS be an exception? Moreover, physiological studies on the motor cortex showed after-effects of much shorter duration. For most of the other types of brain stimulation, even for the vagus nerve stimulator (see Chapter 127),

Table 129.1 Survey on rTMS studies in epilepsy patients

Authors	Num.of pat.	Stimulation site	Coil	Pulse	Intensity (% of motor threshold)	Frequency (Hz)	Duration	Number of pulses per session	Number of sessions	Treatment period	Total num. of stimuli	Effect
Open trials												
Tergau *et al.*[91]	9	Over vertex	9 cm-round	Monophasic	100%	0.33	25 min	1000	5	5 days	5000	38.6% reduction in seizure frequency, four week post rTMS, significant
Fregni *et al.*[92]	8	Over dysplasia	Figure-of-eight	?	100%	0.5	20 min	600	1	1 day	600	46.4% and 42.1% significant reduction in epileptic discharges at 15 and 30 days post rTMS57.3% and 52.1% significant reduction in seizure frequency at 15 and 30 days post rTMS
Kinoshita *et al.*[93]	7	Over focus	9cm-round	?	90%	0.9 Hz	15 min	810	10	5 days	8100	Overall seizure reduction by 19.1% over two weeks post rTMS, with 35.9% reduction of complex-partial seizures and 7.4 reduction of simple-partial seizures. No significant effect
Brighina *et al.*[94]	6	Over cerebellar hemisphere	Figure-of-eight	Monophasic	90%	5 Hz	2 x 10 sec	100	20	Four weeks	2000	54.1% seizure reduction over four weeks during rTMS but no effect after rTMS
Case reports												
Menkes *et al.*[95]	1	Over dysplasia	9 cm-round	Monophasic	95%	0.5	3.33 min	100	8	Four weeks	800	70% reduction in seizure frequency; 77% reduction of spikes

Daniele *et al.*[96]	4	Over dysplasia	Figure-of-eight	Monophasic	90%	0.5	3.33 min	100	8	Four weeks	800	Reduction by 31–42% in two patients with single focal dysplasia during as well as after rTMSNo seizure reduction in two patients with multiple foci
Rossi *et al.*[97]	1	Over perirolandic area	Figure-of-eight	Biphasic	90%	1.0	15 min	900	1	Once	900	Number of myoclonic jerks was was reduced to 33%, jerk-related spikes were reduced in amplitude; number of jerk-related spikes did not change
Graff-Guerrero *et al.*[99]	2	Over epileptogenic region	Figure-of-eight	Monophasic	128%	20	15 x 2 sec	600	1	Once	600	Reduction of hyperperfusion in of epileptogenic focus in the two patients with epilepsia partialis continua; In one patient seizure stopped for 24 h, one patient showed only minimal improvement
Misawa *et al.*[98]	1	Over dysplasia	Figure-of-eight?		90%	0.5	3.33 min	100	1	Once	100	Epilepsia partialis continua in hand and arm was abolished over 2 months after single rTMS trial. Results were reproduced in the same patient
Controlled trials												
Theodore *et al.*[100]	24	Over focus sham	Figure-of-eight?	?	120%	1.0	15 min	900	14	1 week	12600	Over 2 weeks post rTMS: 16% (active), 1% (placebo) seizure reduction; not significant Over 8 weeks post rTMS: 4.5% (active), –0.4% (placebo) seizure reduction; not significant

Table 129.1 Survey on rTMS studies in epilepsy patients—cont'd

Authors	Num.of pat.	Stimulation site	Coil	Pulse	Intensity (% of motor threshold)	Frequency (Hz)	Duration	Number of pulses per session	Number of sessions	Treatment period	Total num. of stimuli	Effect
Tergau *et al.*[102]	17	Over vertex	9 cm-round	monophasic	100%	0.33 1.0 0.66 sham	50 min 16.6 min 25 min	1000	5	5 days	5000 5000 5000	Approx. 40% seizure reduction during stimulation for 0.33Hz condition, no seizure reduction for any other type or time period; no significant difference to placebo
Fregni *et al*. 2006	21	Over lesion (cortical malfor-mation)	Figure-of-eight	?	100%	1 Hz	20 min	1200	5	5 days	6000	Significant reduction of seizure frequency over two months and significant reduction of epileptiform EEG discharges over 2 weeks
Joo *et al*. 2007	35	Fokal over lesion	Figure-of-eight	? ? ?	100% 100% 100%	0.5 Hz 0.5 Hz 0.5 Hz	5 min 10 min 5 min	300 600 300	5 5 5	5 5 5	1500 3000 1500	Non-significant reduction in seizure frequency compared to baseline (–13.9%); long stimulation showed unsignificantly more reduction(–23%) compared to short (-3%); focal was not different from unfocal Significant reduction in spike frequency
		Unfocal	Round	?	100%	0.5 Hz	10 min	600	5	5	3000	
Cantello *et al*. 2007	43	Vertex	Round	Bipghasic	100%	0.3 Hz	55.5 min	1000	5	5	5000	Non-significant reduction –15%) in verum group (placebo –9%); non-significant reduction in spike frequency (–50% in 12/38 patients)

a higher repetition rate is described as effective. Long-term studies are needed in which rTMS treatment is performed over weeks and months, like other treatment strategies.

Conclusion

Repetitive TMS is a promising tool to modulate cortical excitability. Under certain circumstances rTMS seems to have antiepileptic properties strong enough to reduce epileptic activity in humans. rTMS at present is certainly not a procedure that could replace pharmacological or surgical treatment if applicable. Nevertheless, rTMS is safe, is a noninvasive technique and can be administered easily. Thus rTMS in the future may broaden the spectrum of therapeutic alternatives in epilepsy treatment. To achieve this goal, optimized protocols need to be developed, patient selection has to be improved and therapeutic effects should be confirmed in large controlled trials.

SECTION 17

Surgical outcome

130 Mesial temporal lobectomy: post-surgical seizure frequency

L Jehi

Introduction

Temporal lobe epilepsy (TLE) is the most common type of partial epilepsy in adults.[1] Seizures arise from the mesial temporal structures (amygdale, hippocampus, and perhaps parahippocampal gyrus) in >90% of patients with TLE.[2] Hippocampal sclerosis (HS) represents the pathological substrate in 44–65% of mesial TLE,[3–6] with mesial TLE related to HS (MTLE-HS) recently proposed as an isolated syndromic diagnostic entity.[7] Surgical removal of the mesial structures, either in isolation via a selective amygdalohippocampectomy (SAH) or in addition to varying segments of the temporal neocortex via an anterior temporal lobectomy (ATL), was shown to be of invaluable benefit for the large patient population with pharmacoresistant TLE.[8–10] Seizure freedom after ATL correlates with reduced mortality[9,11–17] and a better quality of life, as reflected by improved psychosocial measures and employment rates.[12,18–20] Mere reduction in seizure frequency is not enough to improve most of those measures.[12] It is therefore essential to optimize our understanding of the various factors impacting postoperative seizure freedom.

Since Bengzon published the first article on outcome in 1968,[21] thousands of studies have addressed the degree and stability of postsurgical seizure freedom while attempting to identify useful prognostic factors. This chapter will review the available outcome measures, discuss the pitfalls of outcome studies, provide an overview of the published success rates, suggest proposed prognostic factors, and finally elaborate on special issues pertaining to postoperative seizure freedom.

Available outcome measures

Definitions of 'seizure-free' vary. Two major classification systems are currently available to assess postoperative seizure freedom.

Traditionally, most studies have used Engel's classification (Table 130.1), reporting favorable seizure outcomes as being either 'excellent' reflecting freedom from disabling seizures (Engel Class I), or 'good' with the additional inclusion of patients having rare seizures (Class I and II). Disadvantages of this system include the following: (a) certain outcome criteria, such as 'worthwhile improvement', are very ambiguous, leading to variation in interpretation among different centers; (b) comparison to AED drug trials is virtually impossible as those typically use '≥50% seizure reduction' as their outcome measure; (c) the 'seizure free' category (Class I) is not restricted to patients who are truly completely seizure free after surgery (Class IA); it also includes those with persistent auras, simple partial seizures, and generalized convulsions upon AED withdrawal (Classes IB–D). Since studies do not usually report outcome using Engel's classification subcategories, the independent evaluation of truly seizure free patients is not always possible.

To address the above issues, the International League Against Epilepsy (ILAE) recently issued a commission report proposing a new outcome classification scheme (Table 130.2). Completely seizure-free patients are classified separately; seizures are quantitated in each category and compared to a well-defined baseline frequency, and results can be easily compared to AED drug trials. To date, only one study[23] compared both systems in its outcome assessment, and found similar results at the last available follow-up.

Some centers reported their outcomes using internally validated scoring systems.[23–25] Others chose a pre-specified period of seizure freedom – usually 12–24 months – as reflecting a favorable outcome.[26–29]

This wide variation in outcome measures is only one of many pitfalls complicating the interpretation and comparison of the results among different outcome studies.

Pitfalls of outcome studies

First, the evaluated patient cohorts are heterogeneous with differing demographic characteristics, epilepsy duration, and pathological substrates. Some studies included patients with temporal and others with extratemporal epilepsy in the same outcome analysis.[30–33] This is problematic as certain prognostic variables may have completely different implications in different populations: febrile seizures for example may represent a good prognostic indicator for TLE patients[34–38] while conferring a grim outcome after surgery in frontal lobe epilepsy.[39] Outcome evaluations in 'non-pure' cohorts may then produce misleading conclusions.

Second, few studies were done in the era of high resolution MRI, and even less accounted for evolving pathological classifications of entities like hippocampal sclerosis and cortical dysplasia. Many 'non-lesional' patients from earlier cohorts may actually have subtle MRI lesions on current imaging.

Third, significant issues exist in the statistical methods used. We know now that cross-sectional studies[40–43] depict outcome at a snapshot in time, usually at 12 or 24 postoperative months, missing late recurrences and not adjusting for the

Table 130.1 Engel's classification of postoperative outcome

Class I: Free of disabling seizures[a]
- A: Completely seizure free since surgery
- B: Nondisabling simple partial seizures only since surgery
- C: Some disabling seizures after surgery, but free of disabling seizures for at least 2 years
- D: Generalized convulsions with AED discontinuation only

Class II: Rare disabling seizures ('almost seizure free')
- A: Initially free of disabling seizures but has rare seizures now
- B: Rare disabling seizures since surgery
- C: More than rare disabling seizures since surgery, but rare seizures for the last 2 years
- D: Nocturnal seizures only

Class III: Worthwhile improvement[b]
- A: Worthwhile seizure reduction
- B: Prolonged seizure-free intervals amounting to greater than half the followed-up period, but not <2 years

Class *IV: No worthwhile improvement*
- A: Significant seizure reduction
- B: No appreciable change
- C: Seizures worse

[a] Excludes early postoperative seizures (first few weeks).
[b] Determination of 'worthwhile improvement' will require quantitative analysis of additional data such as percentage seizure reduction, cognitive function, and quality of life.

variation in the rate of recurrence over time. Univariate methods of analysis, in contrast to multivariable regression methods, do not account for the interaction among the various potential prognostic factors.[31] Studies using multivariable regression methods[30,33,43–46] do not typically account for variation of the rate of recurrence with time, nor in the duration of follow-up among patients: the significance of the prognostic factors thus evaluated only applies to seizure freedom at one point in time, the study's particular follow-up time. This may explain why studies evaluating outcome at 1 versus 5 years after surgery may have identified completely different predictors of seizure freedom. Only a handful of studies[45,47–51] used longitudinal methods of analysis better suited to analyze recurrence at various follow-up intervals.

Fourth, few prospective studies were performed.[12,52–54] Current data is largely derived from retrospective studies where multiple sources of bias compromise the validity of definitive conclusions.[55]

Rates and stability of seizure remission

Table 130.3 summarizes the results of most major TLE surgery outcome studies. Criteria for selecting those studies were publication after 1991, a minimum of 25 patients evaluated, cohorts of either exclusively or predominantly mesial temporal

Table 130.2 Proposal for a new classification of outcome with respect to epileptic seizures

Outcome classification	Definition
1	Completely seizure free;[a] no auras
2	Only auras;[b] no other seizures
3	One to three seizure days per year; ± auras
4	Four seizure days[c] per year to 50% reduction of baseline seizure days;[d] ± auras
5	Less than 50% reduction of baseline seizure days to 100% increase of baseline seizure days; ± auras
6	More than 100% increase of baseline seizure days; ± auras

[a] 'Neighborhood seizures' in the first postoperative month are not counted.
[b] Auras are only counted if they are short in duration, and similar or identical to the preoperative ones.
[c] A 'seizure day' is a 24-h period with one or more seizures. This may include an episode of status epilepticus.
[d] 'Baseline seizure days' are calculated by determining the seizure-day frequency during the 12 months before surgery, with correction for the effects of AED reduction during diagnostic evaluation.

Liu *et al.*[173]	1987–1990	1.1 (0.2–3)	35	ATL	'Seizure free'				28.5%*
Chung *et al.*[139]	1980–1986	n/a (2–n/a)	59	ATL	Seizure free ± auras during the second postoperative year				62%

[a] Assessed at 63 months.
[b] Familial MTLE.
[c] Bold prospective studies.
[d] Italic: all TLE (not distinguishing MTLE from neocortical).
[e*] Those were SF since discharge. An additional 34.2% became SF 'after early attacks'... so maybe included patients with immediate postop sz.
[f**] Included in cohort published in 2005.
[g†] includes extratemporal (temporal only 140).
[h††] includes Kilpatrick 1999.

lobe epilepsy (MTLE) cases, and clear outcome measures and description of the statistical design. When cohorts from the same center were evaluated twice, we only show the most recent evaluation.

In general, outcomes are favorable. One randomized controlled trial[9] showed that only two patients need to be treated surgically for one patient to become free of disabling seizures. This is superior to most interventions in neurology. Several meta-analyses using retrospective studies,[31,32,55,56] and few prospective studies[12,52–54] showed comparable results with about two-thirds of the patients becoming seizurefree postoperatively, compared to 5–8% with medical therapy. Similar outcomes were shown in cohorts of pure HS.[18,27,28,40–42,44,54,57] Favorable outcomes of more than 50% are still seen more than 10 years after ATL reflecting a sustained benefit.[13–15,45,47,51,57,58]

Outcomes are usually stable. If a patient is seizure free at 1 year postoperatively, the likelihood of remaining seizure free is 87–90% at 2 years, 74–82% at 5 years, and 67–71% at 10 years.[13–15,43,45,47,59–61] If a patient was seizure free for 2 years postoperatively, chances of seizure freedom increase up to 95% at 5 years, 82% at 10 years, and 68% at 15 years.[14,23,45,60,62,63] So, seizure-freedom for 2 years might be a better predictor of long-term outcome, although both the 1-year and the 2-year states correlate fairly well with future outcome.

Timing of seizure recurrence: early versus late relapse

Most recurrences happen early during the postoperative course with more than half of first recurrences occurring within 6 months,[12,45,64] 62–86% within the first year,[15,45,51,58,65] and up to >95% within 2–5 postoperative years.[12,15,45,51,65]

An initial phase of steep seizure recurrence is followed by a relapse rate of 2–5% per year for 5 years with subsequent more stable seizure freedom.[14,45,47–51] Recent data suggest that prognostic factors affecting those two phases of recurrence are distinct,[27,47,51,66] possibly reflecting different mechanisms for early versus late relapses.

Multiple factors have been implicated in early recurrences, mostly attributed to incomplete resection of the epileptogenic zone. However, the factor most consistently associated with late relapses (beyond 2–5 years) is lack of abnormal pathology,[47,51] suggesting possibly an underlying diffuse functional abnormality at the molecular or cellular level.[51] An underlying 'age-dependent etiology' of surgical failures was proposed in a recent prospective multicenter study where delay to remission predicted later relapse in medial TLE patients.[52] Long epilepsy duration,[27] increasing age at surgery,[52,61] preoperative bilateral interictal spiking(<80% from one side) with early ictal contralateral propagation (>5 sec) and postoperative ipsilateral spiking[66] were also implicated. Many of the above risk factors are actually seen with long-standing HS. Knowing that HS is likely a progressive disease as suggested by animal studies,[67] increase in the incidence of bilateral spiking with time,[68] the progression to temporal lobe atrophy in chronic epilepsy,[69] and the proven bilaterality in most cases on MRI[70] and pathology[3,4] might make this entity an ideal 'age-dependent etiology' where both genetic[41,71,72] and environmental factors lead to surgical refractoriness after years leading to medical refractoriness.[27]

'Running-down' phenomenon

The counterpart of late seizure relapses also exists. The 'running-down' phenomenon, defined as the late remission of postsurgical seizures,[73] occurs in 3.2–20% of TLE surgery cases.[22,23,44,66,73,74] The frequency of seizures during the running-down interval may be up to several per month,[35] but a seizure-free state is usually achieved within two years.[35,60,62] The most accepted explanation for this phenomenon is a dekindling effect, an opposite process to secondary epileptogenesis, where the induced synaptic dysfunction gradually declines in the surrounding epileptogenic cortex after pacemaker resection, and eventually 'runs itself down'.[35,73,74] Patients in this group are more likely to have a history of febrile seizures,[35] normal neurological examination,[35] unilateral interictal EEG preoperatively,[23,35] etiologies other than head trauma or encephalitis,[35] and a smaller and more anterior epileptiform preresection EcoG,[35] i.e., findings consistent with a more localized anterior epileptogenic focus when compared to those who continue with refractory seizures. Furthermore, this phenomenon occurs more in SAH patients compared to ATL (12% vs 20%)[35,73,75] with seizure freedom being achieved earlier in ATL compared to SAH (2 yrs vs 2.6 yrs). This supports the notion that patients patients who experience the 'running-down phenomenon' have foci of 'intermediate epileptogenicity' between restricted epileptogenic zones in those who immediately go into remission, and larger, often more posterior epileptogenic zones of refractory cases who never remit.[35]

Possible predictors of recurrence

Clinical variables

Age at onset of epilepsy

Patients with an earlier age at onset of epilepsy (usually <5 years)[57,58] or at the initial, often febrile, precipitating insult[76,77] were up to three times[58] more likely to have a favorable postoperative outcome. Some investigators proposed that this variable actually predicts HS which is the actual good prognostic indicator.[28,42] This theory is supported by the observation that those patients were more likely to have features typical of HS such as unilateral hippocampal atrophy on MRI,[76] focal ictal EEG[58] and predominantly partial seizures,[58] and by the fact that age at onset per se was of no prognostic value in studies evaluating pure cohorts of HS[28,40,42] or controlling for pathology.[14,51,52] One study, however, showed that the age of occurrence of remote CNS infection was predictive of outcome regardless of the finding of MTS on MRI suggesting an independent correlation between the age of infection and the resultant cerebral injury.[77]

Duration of epilepsy

Many studies found no correlation of epilepsy duration with outcome.[12–15,28,35,42,43,45,46,51,52,57,58,78,79] A long history of seizures correlated with worse outcome in multiple studies on univariate analysis.[12,23,49,80–83] In some of those same cohorts,
