Dudley S Dinner MD
April 17, 1947 – May 1, 2007

I dedicate this book to Dudley,
my dear friend and colleague, whose contributions to epilepsy surgery
will have a permanent impact on the specialty.

Dudley joined the Cleveland Clinic Epilepsy Center as a fellow in clinical neurophysiology in 1979, shortly after I became the Director of the Center. This marked the beginning of a remarkable thirty years of extremely productive, daily collaboration. Throughout this period, Dudley participated in all major projects of the Center: contributing ideas, assisting in the organization of these projects, and managing their execution. Dudley's absolute loyalty, reliability, intellectual honesty, complete dedication, exemplary modesty, and willingness to sacrifice to achieve our objectives were essential ingredients in the development of the Epilepsy Center at the Cleveland Clinic. Dudley, as an expression of his unselfishness, never demanded recognition for his contributions. Dudley was so often the driving force behind the scenes. I would like to use this opportunity to express my deepest appreciation for Dudley's invaluable contributions, but also – and perhaps most importantly – to thank him for his friendship and unwavering support. I particularly notice his absence in my current efforts to organize an Epilepsy Center at University Hospitals. I realize now how much I relied on Dudley's help in so many of our projects. I greatly miss him as a colleague and as a dear friend.

It is a great honor to dedicate this book to Dudley.

Contents

Preface

It was just 7 years back, in 2001, that Dr. Youseff Comair and I edited the last book dedicated to epilepsy surgery.[1] It is encouraging to note that epilepsy surgery has again made major advances, calling for a complete rewriting of essentially all the chapters of that book. Interestingly, the development of new diagnostic techniques, which certainly permit a more precise and reliable diagnosis of the epileptogenic zone, with very few exceptions, have not replaced some of the more classical diagnostic methods. In this sense, it is notorious that clinical semiology and clinical neurophysiology continue to be irreplaceable diagnostic techniques that provide a wealth of information. Moreover, modern technology, which makes recording, storage, and computer analysis of large amounts of neurophysiological data possible, gives us access to new data, such as the high-frequency oscillations or the EEG DC shifts, which promise to play important roles in the definition of the epileptogenic zone.

This *Textbook of Epilepsy Surgery* includes over 20 chapters dedicated exclusively to the history of epilepsy surgery in different countries. I felt that it was important to collect this information on a timely basis when many of the main players who actually participated in the development of epilepsy surgery, or at least directly witnessed the developments, are still active in the field.

As in our previous book on epilepsy surgery, in this book too we devote significant space to the description of the semiological seizure classification and the detailed clinical description of the epilepsies that are remediable by epilepsy surgery.

In this book, we follow a systematic approach to the diagnostic evaluation of patients who are candidates for epilepsy surgery. We first discuss the general principles of epilepsy surgery, and then divide the presurgical evaluation according to the six zones (symptomatogenic zone, irritative zone, ictal onset zone, the epileptic lesion, the functional deficit zone, and the epileptogenic zone) described in the general principles chapter. These series of chapters conclude with the description of the Epilepsy Surgery Management Meeting, an essential and indispensable part of the surgical evaluation.

The book also incorporates detailed discussions of the cortical mapping techniques and the numerous surgical techniques that can be used to surgically treat epilepsy. This is complemented by surgical outcome, the post-surgical medical management, surgical failures, and neuropathology. Finally, selected case presentations are discussed, and proposals for the establishment of an epilepsy surgery program, classification of surgical outcome, and protocols for storage and processing of brain tissue for molecular studies are presented.

I feel that epilepsy surgery is still an extremely attractive management tool for patients with medically intractable epilepsy. Unfortunately, in spite of dramatic increases in the number and mechanisms of action of modern antiepileptics, close to a third of all epileptics still suffer from uncontrolled seizures. A significant proportion of these patients are excellent surgical candidates. The extreme precision of our current presurgical evaluation methods and the recent advances in neurosurgical techniques make it imperative that all these patients get evaluated at an epilepsy center that offers epilepsy surgery. In a significant proportion of these patients, the epilepsy can be either eliminated (cured) or a significantly better seizure control can be achieved, with relatively low surgical risk. Referrals for epilepsy surgery have been continuously increasing since the pioneering efforts at the end of the 19th century. I hope that this book will contribute to making epilepsy surgery available to an even larger percentage of patients with medically intractable epilepsy.

Acknowledgments

I would like to acknowledge the help of Ms. Connie Scolaro and Ms. Autumn Semsel who, throughout the editorial process, assisted me as executive secretaries, making the editorial process so much easier.

Introduction

Studying the history of epilepsy surgery from stone age cranial surgery to the emergence of brain surgery for epilepsy in the 19th century, is fraught with several difficulties. First, it may be difficult to determine if a defect found in a stone age skull is the result of a trepanation on a living person, and second, even if is clear that a trepanation has been performed, it is difficult, on the basis of archaeological skulls, to be certain why it has been performed.[1] More specifically, any effort to describe the pre-modern history of epilepsy surgery has to acknowledge that epilepsy was not always seen as a medical disorder of the brain as we do today. As elegantly summarized by Temkin,[2] the competing view held over many centuries was that epilepsy is a demonical disorder, and seizures were frequently interpreted as evidence of spiritual possession. Not surprisingly, trepanation for treatment of seizures may have been performed for medical reasons, for example in patients with underlying trauma, as well as for magical-religious, ritual, or spiritual reasons and as a dramatic miracle cure.

Although a general discussion of trepanation is beyond the scope of the chapter, it is well recognized that trepanation is the earliest form of surgery known.[3,4] Trepanation of the human skull is the removal of a piece of calvarium without damage to the underlying blood vessels, meninges and brain.[18] Trepanation of the skull is described in written records as early as 1500 BC. A human skull, recovered from a French archaeological site, carbon dated to 5100 BC, from a patient who survived trepanation (based on evidence of healing around the surgical site and age at death of 50 years) represents the oldest example of a successful neurosurgical procedure.[5] The evidence for trepanation begins in the Neolithic, and extends to the present, and comes from every corner of the world. Trepanation is intended to remove a piece of the skull by scraping, gouging, boring and sawing, sawing alone, and drilling (properly trephination). There are thousands of samples of trepanation from the ancient world, many of them from central and northern Europe, where the operation may perhaps have been most active during the Neolithic, but has been performed continuously ever since to this day.[1] Trepanation was performed in Greece, sometimes with great skill, in Bronze Age Karatas, Asine, Lernas and Mycenae, and in Early Geometric Argos (900–850 BC).[1] It is noteworthy that the different types of trepanation are not evenly distributed geographically, the scraping method was used more often in Europe, while the South Americans favored sawing.[1] Although not proven, trepanation may have been done to relieve pressure on the brain, to elevate depressed skull fractures or to remove bone fragments in the case of penetrating head injury. Since the archaeological record shows that there are signs of healing on many trepanned areas, even on prehistoric skulls, it seems that at least some patients often survived the procedure.[3–5] Many of the examples of trepanation occur on skulls that had suffered injury. It is therefore not unreasonable to consider that among those on whom trepanation was performed were victims of depression fractures who were suffering from post-traumatic seizures or epilepsy.[5] In addition, the apparent indications for trephination also included depressive symptoms, psychosis, and headaches.[4,5] General surgical procedures used in the past for treatment of epilepsy such as bloodletting, vascular litigations, or cauterization of limbs will not be discussed here. The history of modern epilepsy surgery which began in the 19th century has been covered elsewhere.[6,7] In this chapter we briefly summarize the evidence of cranial surgery for epilepsy in Europe from the Neolithic to the end of the 18th century prior to the emergence of modern epilepsy surgery.

New Stone Age trepanations for epilepsy? A controversy between Paul Broca and Victor Horsley

In 1886 large craniotomy defects were discovered in ancient skulls from France, most of which are now estimated to be late new Stone Age (Neolithic), or approximately 5000–5500 years old (Figure 1.1). These findings raised many questions in the minds of those who found them and many more in those who reported on them from then on until today.[8] Although it may be extremely difficult to conclusively identify trepanation in archaeological skull specimens, for our discussion of the history of surgery for epilepsy, we need to consider two questions. First, were the observed defects in archaeological specimens, at least in some cases, the result of trepanations performed on the living (as opposed to blade or axe or other injury, depression fractures, tumors, infections, congenital

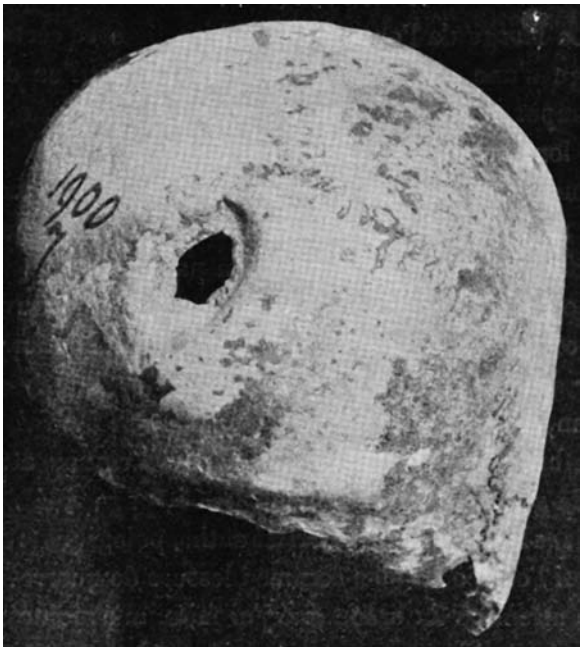

Figure 1.1 A Neolithic skull showing signs of trepanation. The skull was found in a dolmen in France by Pruniéres (with permission, Wellcome Library, London).[38] Broca concluded that this skull was trepanned before and after death.[10]

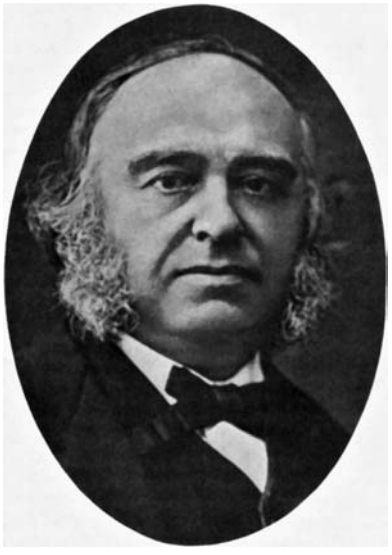

Figure 1.2 Paul Broca (1824–1880).[8]

defects, or post mortem rituals or damage)? And if so, second, was the trepanation done for treating epilepsy or convulsions?

When Prunières, a medical practitioner who had found the skulls in central France, reported his findings in 1874, he initially concluded that the skulls had been opened post mortem to transform them into drinking cups for rituals.[9] On second thought, he suggested that they may have been a therapeutic component to trepanation. Prunières now maintained surgical trepanation could have been performed to treat cranial fractures or depressed bone pieces.[9] He suggested that splinters of bone could cause bizarre behavior, including convulsions and delirium. These signs and symptoms would disappear following removal of the fractured bone. In any case, the problems would have been recognized as arising from the bone itself. Over time, he surmised, the procedure could have been extended to include the insane, the mentally ill, and even patients with convulsions without skull fractures. Now Paul Broca, Professor of External Pathology and of Clinical Surgery at the University of Paris, who later was to become famous for discovery of the motor speech area in the third frontal convolution, entered the debate (Figure 1.2). Broca was very much interested in trepanations since he had the opportunity to examine a trepanation defect in a Peruvian skull a few years earlier.

Although Broca agreed with Prunières that there was a therapeutic goal for doing trepanations, at least in some patients, he strongly disagreed about the specific malady or the theory behind it. Broca pointed out that there was no evidence for associated fractures, and furthermore he did not believe that Neolithic people had any understanding of the physiological functions of the brain nor, for that matter, anything like sophisticated surgery. He concluded: 'I think for my part that they were inspired, not by observation, but by superstition'.[10] Nevertheless, he considered a therapeutic goal for doing trepanation. In his mind, the goal was 'to avoid a danger, which could be more or less imaginary'.[10] How Broca finally ended up with the hypothesis that the goal of trepanation was to prevent infantile convulsions will be discussed in the next paragraph.

Trepanation to prevent infantile convulsions

Broca was convinced that trepanation had been a treatment for epilepsy in the past. In addition, he learned that trepanation was still performed in some parts of the world to exorcise demons thought to cause seizures. He hypothesized that Stone Age humans probably had a similar reasoning much like primitives in modern age. Broca had also read the work of Taxil from Arles who lived early in the 17th century. Taxil surmised that it was not possible to find an epileptic who was not possessed by demons and suggested that making a door in the skull would help the demons (and seizures) to elude.[2] Furthermore, Taxil also believed that an amulet made of skull bone would protect from having seizures. To Broca's delight, Taxil commented that epilepsy was very common in children. Broca himself thought that epilepsy was rare in children below age 10, and anyway, he had doubts that trepanation was able to cure epilepsy.[11] Thus by elimination, Broca was left with infantile convulsions, including febrile seizures, who, he knew, would often get better anyway, with or without trepanation. Broca's theory on Neolithic trepanation in its final form was that the cranial holes allowed the demons causing convulsions in infants to escape. In addition, as suggested by Taxil, Broca proposed that the skulls of those who survived trepanation were thought to have mystical properties and once they died, were cut out for amulets. Durin;g the mid 1880s, Victor Horsley (Figure 1.3) would prefer Prunières concept involving fractures, adding a modern twist of his own, over Broca's demonic hypothesis as we shall now see.

Victor Horsley on Neolithic trepanation for epilepsy

Although Horsley never picked up a shovel to dig for prehistoric skulls, he took an avid interest in Broca's findings. He examined and photographed the Neolithic crania in the Broca Museum in Paris where some of them were stored after Broca's death in 1880. His new variation of Prunières' theory stemmed from his observation that the holes made during the

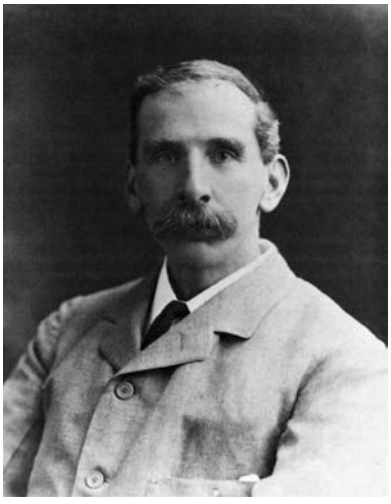

Figure 1.3 Victor Horsley (1857–1916).[40]

Neolithic period were not randomly placed but mostly over the vertex of the head, more or less above the motor cortex as it was then envisioned. In Horsley's mind, that was proof enough that surgical trepanations had been performed for epilepsy. In his own words:

> By means of this composite arrangement it was demonstrated beyond question, that in almost all known instances of this practice the opening of the skull was made over that portion of the surface of the brain which is known to be more especially the seat of representation of movement. This region of the brain, moreover, is the seat of origin of that special form of convulsions which is known as Jacksonian epilepsy, and which so frequently follows injuries to the skull and the brain.[12]

Horsley's enthusiasm for his hypothesis of medical trepanations in the late Stone Age must have received a boost by his recent success at the operating table. He had, at age 29, on 25 May 1886, operated on his first patient with epilepsy in the National Hospital for the Paralyzed and Epileptic. James B., a 20-year old Scotsman who was under the care of Jackson and Ferrier, had sustained a depressed skull fracture 15 years earlier. He then had intermittent Jacksonian seizures starting in his right leg. More recently, episodes of status epilepticus had developed. Horsley's skilful use of the trephane revealed a vascularized scar in the superior frontal sulcus, and removal of the scar and some surrounding cortex led to seizure freedom for one year.[13,14] Coming back from the operating table where he had cured epilepsy, Horsley felt that his experience with modern trepanation and cortical resection for epilepsy strongly supported his theory on the medical usefulness of Neolithic trepanation for epilepsy. He suggested that removing bone fragments and splinters will eliminate or severely diminish epilepsy. In his words: 'Consequently the operation would gain a certain reputation for the cure of convulsions generally, and as such might have been frequently practised among savages ....'[12]

Although being devoid of demonology, Horsley's surgical theory was met with considerable skepticisms from the anthropologists whose territory he had clearly entered. Sir William Osler, one of the most respected physicians of his time, clearly favored Broca's theory. According to Osler:[15] 'the operation was done in infantile convulsions, headache, and various cerebral diseases believed to be due to confined demons, to whom the hole gave a ready method of escape'. But to many people then and now, the weakest part of Broca's theory was that it confined trepanation to infantile children, he could not provide evidence for trepanation of skulls of infants. Also, others pointed out that a number of skulls showed several trepanation defects which seemed difficult to reconcile with a medical procedure.[16] In addition, Horsley's suggestion that the holes were made over the motor cortex was challenged. To others it seemed that the holes were indiscriminately placed over the vault of the skull. With all due respect for Horsley's enthusiasm, the enigma of Neolithic cranial trepanation baffles researchers to the present days.[1] We still have many firm views and few conclusive data on Stone Age surgical trepanation for epilepsy, if any. With that, let us continue our search for further, and perhaps better evidence of trepanation for epilepsy in Europe from ancient times to 1800.

Trepanation for epilepsy from Ancient Greece to the 18th century

The earliest mention of trepanation with a detailed description of different techniques and indications stem from the 5th to 4th century BC and are found in the Hippocratic writings as quoted above. In his aphorisms 'On Injuries of the Head', written in 400 BC he states:

> and if, when an indentation by weapon takes place in a bone, it be attended with fracture and contusion, and even if contusion alone, without fracture, be combined with the indentation, it requires trepanning.

The use of the crown trepan for drilling is mentioned. Two crown trepans have been found in the grave of a Roman army surgeon in Bingen, Germany (Figure 1.4).

Other procedures used for trepanation are scraping, or an incision resulting in a rectangle or round skull defect. The prevalence of trepanation in Europe is difficult to ascertain,

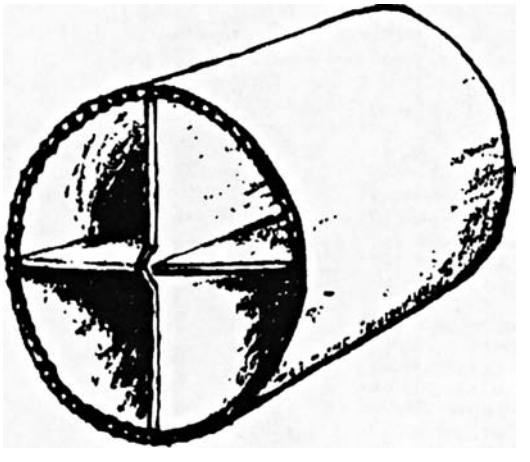

Figure 1.4 Cylindrical crown saw or trepan. This one was found in the grave of Roman military surgeon in Bingen, Germany.[41]

definitions of trepanation vary, and the pre-Roman and Roman custom of cremation may have destroyed evidence. Despite these obstacles, it has been estimated that 630 skulls showing at least one trepanation have been collected in 17 European countries.[17]

In Europe trepanned skulls became rare after the Neolithic era, partly because in the later Bronze Age the dead were mostly cremated. Nevertheless a few examples are available from France, Scandinavia, Germany, Czechoslovakia, Hungary, Rumania, Bulgaria, Russia and other countries.[18] In the European medical tradition, in addition to its use in treating head injury, particularly for depressed fractures and penetrating head wounds, trepanation for epilepsy was practised by ancient Greek and Roman surgeons.[2] According to Temkin,[1] Aretaeus the Cappadocian (ca. 150), one of the most famous Greek clinicians, began the tradition of trepanning as a treatment of epilepsy or convulsions. It lasted, with ups and downs in its acceptance, into the 18th century.[2] According to Caelius Aurelianus, the Methodist Themison employed the trephine as a therapeutic adjunct in cases of epilepsy and paralysis.[19] During the European Renaissance, craniotomies used to be performed for epilepsy, especially of traumatic origin, although the purpose of the operation was still to remove bone fragments or a build-up of fluid, or 'evil' air, – not to remove epileptogenic brain. In the Sloane manuscript, a collection of medical manuscripts at the end of the 12th century, a person with epilepsy ('epilepticus') is undergoing both trepanation and cauterization (Figure 1.5). The legend of the figure is 'epilepticus sic curabitur' (The way to cure an epileptic).

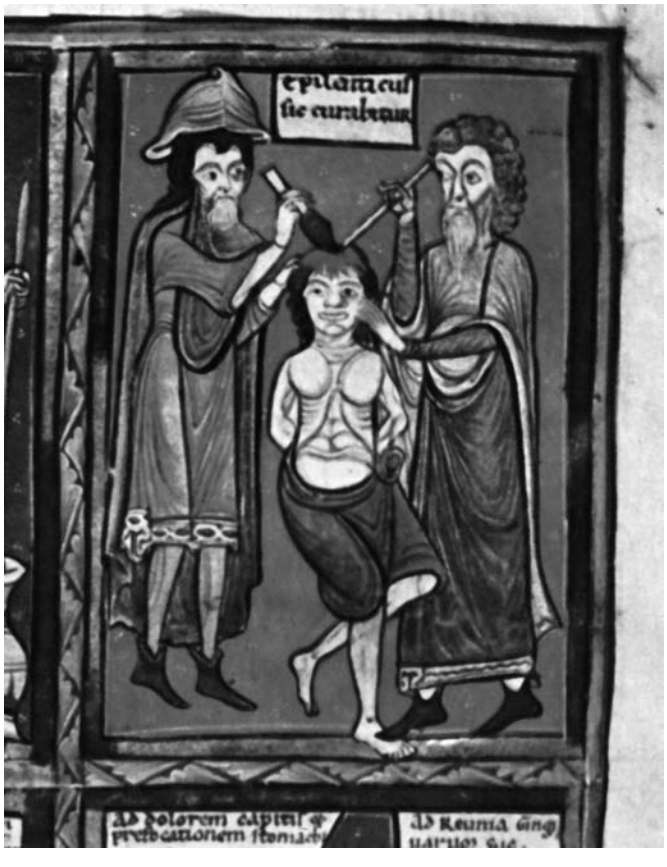

Figure 1.5 The way to cure an epileptic (Epilepticus sic curabitur) is the inscription of this picture showing a person with epilepsy undergoing trepanation and cauterization. The picture is from the Sloane manuscript, a collection of medical manuscripts from the end of the 12th century (with permission, British Library, London).

Cauterization was considered a form of treatment used in the Middle Ages and perhaps before when trepanation had failed to control the seizures.[20] The usual site of application was the back of the head or brow, sometimes the spine, chest or arm. It is unclear if cauterization was usually done before trepanation was considered, or performed in cases refractory to trepanation or together as suggested by Figure 1.5. In a 13th-century surgical text, *Quattor magistri* for example, opening the skulls of epileptic patients was recommended 'that the humours and air my go out and evaporate' (Temkin, p. 235).[2] Although we found no reports if trepanation and cauterization affected seizure control, it is not inconceivable that the drama of the operation may have led to a transient remission of seizures, at least in some patients. It seems that there was seldom a medical reason for the surgery, for example to raise a piece of the skullcap which had entered the inner part of the skull, as a result of an injury, perhaps in war, and which was thought to have caused epileptic seizures in the person. In such a case, the surgeon tried to raise a piece of the bone and thus remove the cause of the epilepsy. However, as will be shown in the next paragraph, medical charlatans, quack-doctors and barber /surgeons took advantage of the concept of medical trepanation for epilepsy, by pretending to remove brain stones 2 × 1′′ by incision of the scalp.

Stone cutting for epilepsy?

Hieronymus Bosch and other early Renaissance artists depicted 'stone operations' in which stones were supposedly surgically removed by quack doctors from the head as a treatment for mental illness including epilepsy. Although we found no reports on postsurgical seizure outcome, it is not inconceivable that the drama of the sham operation on the scalp may have led to a transient remission of seizures, at least in some patients. Probably the most famous depiction of trepanation for mental disease is Hieronymus Bosch's (1460–1516) 'The Cure for Madness or Folly', also known as *The Stone Operation* of around 1485 (Figure 1.6).

After Bosch there were a number of painters, usually Flemish, depicting the removal of stones as a cure for madness and folly. In the 'Stone Cutter' from Jan Sanders of Hemessen (ca. 1500–1555), exhibited in the Prado Museum of Madrid, a barber/surgeon enjoying his work pretends to remove a stone with a razor knife (Figure 1.7). Up to the 18th century 'stone cutters' would roam European countries pretending to be medical healer and making a living with their quackery.

In a miniature of the 'Book of properties' by Bartholomeus from the middle of the 15th century, taken from the section on epilepsy, Saint Lucas is shown to perform an incision of the scalp (Figure 1.8).

These works, shown in Figures 1.6–1.8, have usually been interpreted either as portraying a contemporary practice of medical charlatans or an allegory of human folly, rather than a real event (see Schupbach 1978).[21] However, as trepanation for head injury and mental disease including epilepsy was actually carried out in Europe at this time, another interpretation is that it is likely that Bosch, and the other artists, who produced the various pictures of stone operations, knew of the existence of the actual contemporary medical procedure of trepanation (Gross, 1999).[4] Indeed, the details of their portrayals of 'stone operations' were often very close to the

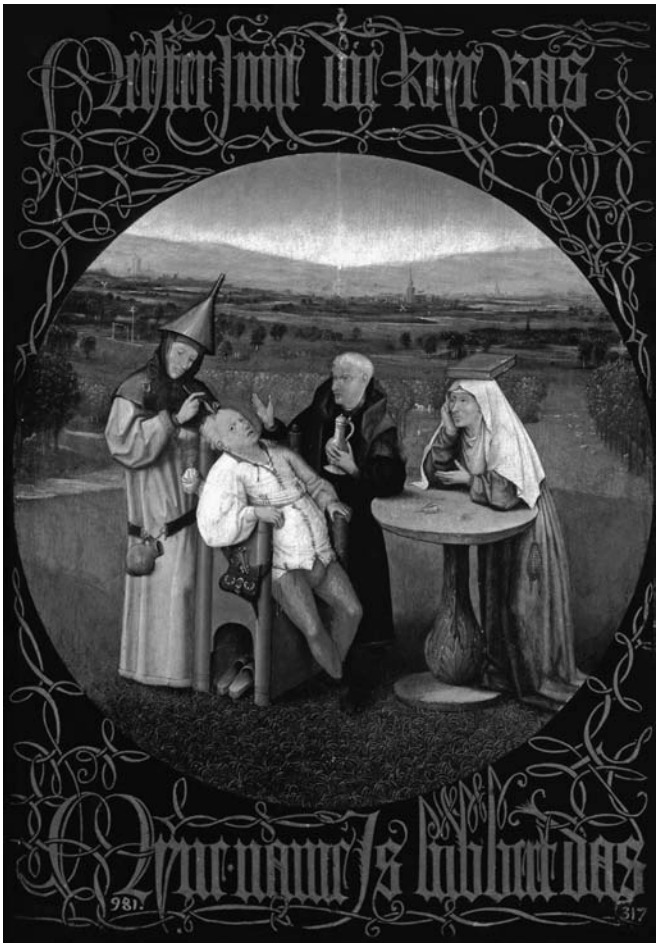

Figure 1.6 'Stone Cutting'. The painting by Hieronymus Bosch from approximately 1845 shows a patient who is undergoing 'stone cutting' by a quack. Stones were thought to be responsible for a number of brain diseases including epilepsy. However, Bosch has exchanged the traditional 'stone' as the object of sham extraction with a tulip. Another tulip is on the table. Two interpretations exist why a tulip has been chosen. One idea is to show that the doctor is a charlatan, as does the funnel hat. The other interpretation is that the flower is a pun on 'tulip head' – meaning mad in the Netherlands. The inscription reads: 'Meester snyt die Keye ras–myne name is Lubbert' (Master cut away the stone–my name is Lubbert Das). Lubbert Das was a comical/foolish character in Dutch literature. Barber/surgeons and quacks earned a lot of money by fraudulent claims that they could cut open the head and extract stones which they had hidden in their palm (with permission, Prado Mùseùm, Madrid).[42]

Figure 1.7 **'**Stone Cutting'. The painting by Jan Sander van Hemessen (around 1500–1555). shows a patient who is undergoing 'stone cutting' by a quack on a fair. The barber/surgeon with knife in hand seems to be pleased about the success of the mock surgery. Behind him one sees a number of stones on a string as a sign of his success as a stone cutter. The stone has already been planted by the quack in the surgical wound and will be removed from the incision any time soon. The next patient to be operated on can be seen on the right. He is desperately wringing his hands and turns his head to the sky, perhaps praying (with permission, Prado Mùseùm, Madrid).[42]

detailed instructional diagrams on trephining in surgical handbooks such as that of Johann Schultes or Joannis sculte-tus' *Armamentarium Chirurgicum of* 1655 as pointed out by Gross (1999).[4]

The first account of epilepsy surgery in the 16th century

The first account of surgery specifically for epilepsy was by Divetus (1527–1586), as described by Meador (1999):[22]

> A bone of the skull of a twelve-year-old youth had been broken and depressed by a fall and had by negligence not been restored. The brain was therefore hindered in its growth, since the injured bone itself could not grow so as to become able to hold a larger brain. Consequently in his eighteenth year the youth suffered from epilepsy because of the oppression of the brain. He was, however, cured by perforation of the depressed bone, for thus the oppression of the brain was removed.

Trepanation for epilepsy in the 17th and 18th centuries: a last resort

In cases with penetrating war injury trepanation was performed by Matthäus Gottfried Purmann (1648–1721), a military surgeon at the time of the Thirty Years' War. He operated on a soldier with an open penetrating frontal lobe injury who suffered from convulsions on the third day. The patient who was unconscious for two days was surgically treated on the third day with a trepanation and extraction of pieces of bone and the projectile (Purmann, 1693).[23] He regained consciousness and survived both the injury and the surgery. Although Purrmann was delighted about the surgical outcome, he cautioned that: 'It is certainly a rare and remarkable example, which occur in hardly one of thousand (cases)' (Purmann 1693).[23] Despite such individual success stories, the benefit of the procedure must have been less impressive for many, considering that by the 17th century trepanation for epilepsy was seen as a last resort. As noted by Riverus in the 'The Practice of Physick' (1655):

> If all means fail the last remedy is to open the fore part of the Skull with a trepan, at distance from the sutures, that the evil air may breath out. By this means any desperate epilepsies have been cured and it may safely done if the Chyrurgeon be skilful (Temkin, 1971, p. 235).[2]

Lorenz Heister (1683–1758), one of the most prominent trauma surgeons of the 18th century, warned however,

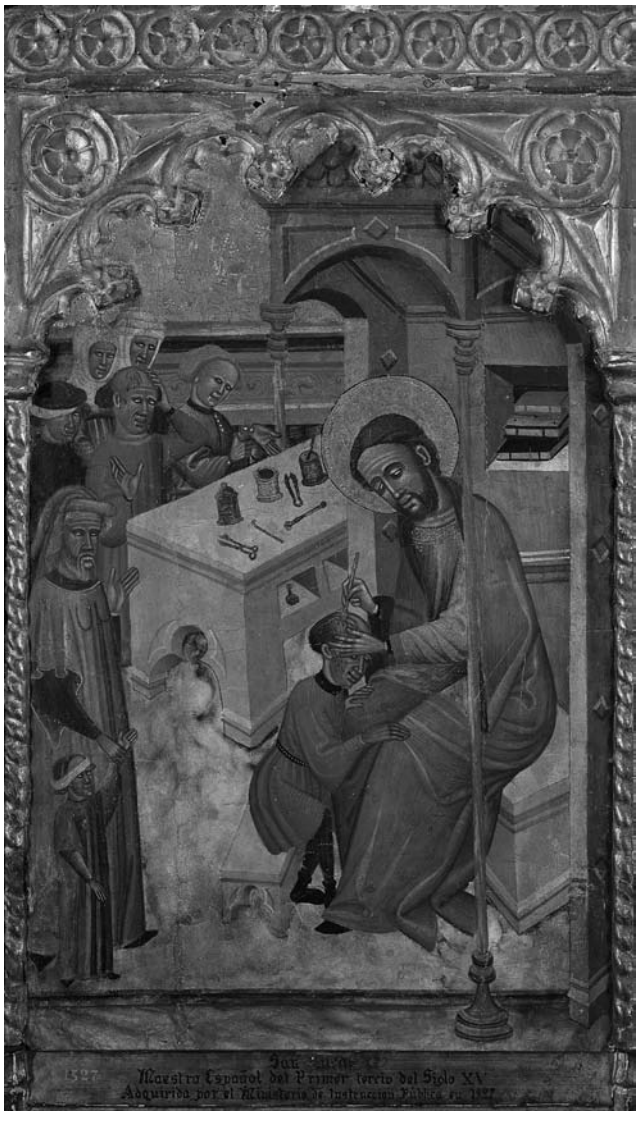

Figure 1.8 Saint Lucas performing an incision of the scalp. A miniature of the 'Book of properties' by Bartholomeus (Bibliotheque Nationale, Paris) from the middle of the 15th century. The adult patient with balding hair has child-like proportions, as has the next patient to be operated on shown on the left. In the background, an adult-sized patient can be seen with bleeding still showing from the earlier incision (with permission, Prado Mùseùm, Madrid).[42]

that trepanation is only clearly justified in fractures or depressions of the skull with clinical symptoms such as convulsions. The French 'Encyclopedie' by Diderot (1763) depicted a trepanation (Figure 1.9). For trepanation, two instruments were commonly used. One was a hand trepan (Figure 1.10a). The other a more sophisticated one for two hand use (Figure 1.10b). Twelve hours after the scalp incision to allow for clotting of blood in the wound, trepanation with the one hand trepan would begin with the so-called male crown with a little longer sharp central point to stabilize the trepan (see Figure 1.10a,b) followed by successive use of the other trepan instruments to be rotated with an hand turn.

By the 18th century, there was agreement that trepanation should never should be performed on epilepsy without trauma.[24]

Figure 1.9 The French 'encyclopedie' depicting a trepanation (Diderot, 1763, cited by Ruisinger, 2003).[24]

From skull surgery (trepanation) to brain surgery

The transition from skull surgery (trepanation) to the beginning of modern brain surgery took place between the mid 18th century up to the middle of the 19th century.[25-27] The 1881 Medical World Congress in London marked the beginning of modern brain surgery.[27] At the Congress established figures of the rapidly changing field of modern medicine – such as David Ferrier, Hughlings Jackson, Jean Marie Charcot, Louis Pasteur, Joseph Lister, Rudolf Virchow – met with the first representatives of the developing field of neurosurgery – William MacEwen from Glasgow, Richman Godlee and Victor Horsley from London, and William W. Keen from the USA. The transition from pre-modern skull surgery to modern brain surgery was prompted by an increasingly critical view of trepanation, by the emerging localization theories of the brain, and last, not least by the introduction of antisepsis and better pain treatment.

Growing concern about the risk of trepanation

The surgeons themselves were becoming increasingly criticial about the merits of trepanation. For example, Benjamin Bell (1749–1806), in his textbook on surgery, denounced extensive use of unproven and unnecessary trepanations.[28] He and others

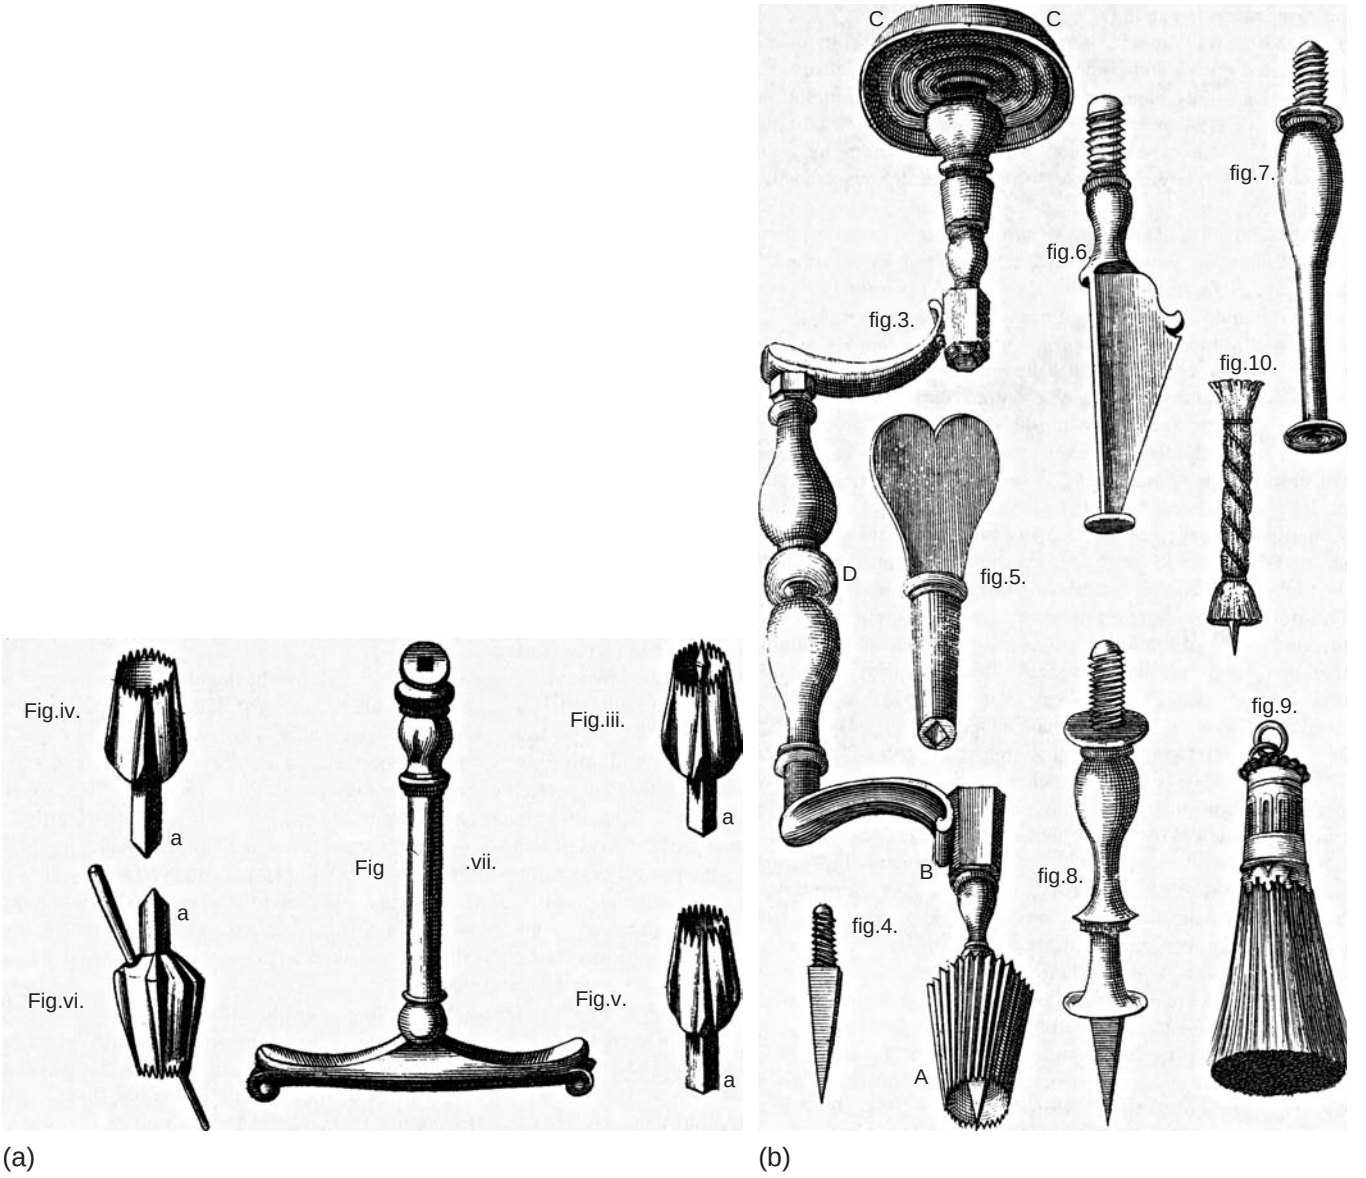

Figure 1.10 For trepanation, two instruments were commonly used. One was a hand trepan (a). The other, a more sophisticated two hand trepan as recommended by Lorenz Heister (b) (from Ruisinger 2003).[24]

pointed out the ill-defined indications for trepanations. Although some experts, for instance, August Gottlieb Richter, Professor of Surgery at the University of Göttingen, Germany since 1766, tried to maintain trepanation by delivering clear clinical indications for the procedure.[29] In his seven-volume handbook from 1780 about surgery ('Wundarzneikunst'), he defined three indications for the surgical intervention in head trauma: the open skull wound, the skull impression fracture, and interestingly, epileptic seizures ('Zufälle'). However, Richter was critical about the prophylactic use of trepanations as performed extensively by Percival Pott (1713–1788) in England. Henri Francois Le Dran from France (1730) noted that not the skull fracture itself but the following brain damage was the cause of drowsiness and loss of consciousness.[29]

Victor Bruns, Professor of Surgery at the University of Tübingen, Germany in 1850, pointed out that besides defined indications of trepanation as in epidural hematoma, subdural hematoma and brain abscess, the interventions in most of the cases were not successful because the intracranial localization of the disturbances was difficult due to limited knowledge of brain function.[30]

The work of Bruns indicated for the first time the transition from skull surgery *per se* to brain surgery. The interest on the functional relevance of the brain stimulated the research in the functional organization of the cortex. The localization theory had both pre-scientific and scientific roots that will be discussed now.

The development of localization theory

For centuries study of the human physiognomy was an accepted wide-spread and social method, method for judging disposition, affection, and character from the features of face and body. Phrenology, as a part of sub-profession physiognomics, tried to explain distinct cognitive and moral abilities of each individual by describing the surface relief of the skull.[31] Franz Joseph Gall (1758–1828) and J.C. Spurzheim were important founders of this theory.[32] Following the

hypothesis that the brain is the organ of the soul they started to project characteristics of the personality directly to distinct regions ('Organgrenzen') of the brain surface. The association between individual functions and distinct brain areas was however generated intuitively and was not scientifically verified. Although phrenology was scientifically untenable, nevertheless it stimulated research of the cortex. Thus phrenology was the first pre-scientific step to associate morphology and function.

Meanwhile Hermann Munk, a physiologist in Berlin, Germany, was the first in the middle of the 19th century who pointed out in his intensive studies of the cortex that the perception of sensoric stimuli is located within the Rolandic cortex.[33] Gustav Fritsch and Eduard Hitzig (1870)[34] from Berlin experimentally verified Munk's findings and extended them to the motor system. A few years later, David Ferrier (1876) delivered the first functional atlas of the cortex. Additionally, he associated the surface of the brain to external points of the skull thus providing important landmarks for surgeons. The motor speech area was described in 1863 by Pierre Paul Broca and the area of sensoric speech by Karl Wernicke (1848–1905). Even as phrenology was discredited, a scientifically verified roadmap of the brain functions was developing step by step. Based on this insight, Jackson initiated the first successful operations in patients with epilepsy by carefully analysing hemimotor seizures.[13,35]

From the morphological point of view,Theodore Meynert (1833–1892) was the first who correlated structurally different cortical areas with their functions. During the following years data were generated in zytoarchitecture (K. Brodmann, W. Campbell), in myeloarchitecture (C.u.O. Vogt), and in angioarchitecture (Pfeifer).

Antisepsis and treatment of pain

In addition to an improved knowledge of brain function and localization of brain function, the introduction of antisepsis and the treatment of pain during an operation was important for the development of brain/epilepsy surgery. Joseph Lister (1867)[36] and Robert Koch (1878)[37] were important pioneers in the introduction of antisepsis. Pain-free operations were performed in Boston by William Morten and John Collins Warren in 1846 for the first time with ether-aerosol and by James Simson in 1847 with chloroform (as) narcotics.

Now the pre-conditions for the development of modern brain / epilepsy surgery were in place.[38]

Conclusions and summary

Pre-modern surgery for epilepsy was undoubtedly performed, at least in some patients. However, surgery was limited to trepanation or cauterization of the bone. Trepanation was done for medical reasons such as to elevate bone fragments after trauma and for mystical reasons such as allow demons or the devil to escape from the ailing brain. However, nobody was thinking about epilepsy as a cortical disorder of the brain before John Hughlings Jackson's did in 1870, let alone that epilepsy could be treated by removing seizure-causing tissue on the surface of the brain by Horsley.[25,26]

2 Epilepsy surgery in Asia before the 19th century

N-S Chu, T Hori, S-K Lee, Y Mayanagi, K Radhakrishnan, and H Shibasaki

For preparing this chapter, data were collected by Dr. N-S. Chu for China and Taiwan, by Dr. K. Radhakrishnan for India, by Drs. Y. Mayanagi and T. Hori for Japan, and by Dr. S-K. Lee for Korea. The collected data were integrated into a chapter by Dr. H. Shibasaki. In spite of extensive literature survey, at least in these countries, clearly documented evidence of epilepsy surgery has not been found until the end of the 19th century.

However, archeological excavation of a multi-trephined skull of a Neolithic woman from the pit-dwellers of Burzahom in the northwestern Himalayan region (Kashmir valley of the present day) suggests that trephination might have been practiced in prehistoric India (4000 to 4300 years ago) for acquired neurological ailments.[1] Multiple skulls from the same era have been found during different excavations, providing evidence that trephination or multiple craniotomy was carried out by the Harappan people of Indus Valley. One particular skull from Burzahom, first discovered in 1968, revealed 11 attempts at trephination, with six neatly completed circular or oval perforations, all in the left parietal bone (Figure 2.1). The left calvarium showed hypertrophy, which could have been related to long-standing atrophy of the underlying brain. It is likely that drills of various sizes were used; however, no instruments for such surgery were found at the site, raising the speculation that an Indus civilization 'surgeon' with personal instruments might have lived then. It was impossible to establish the precise symptoms that might have afflicted the individual, but the Burzahom woman might have been either 'insane, epileptic, or otherwise different'.[1] The carefully performed trephination, suggestive of a multistage procedure on a possibly anomalous skull, argues for a surgical approach for medical reasons on a living person who did not survive the procedure. It is also likely that this might have been part of a ritual in a primitive society that regarded epilepsy or other neurological disease that the Burzahom woman suffered from to be a result of possession by spirits.

About 2000 years ago in India, medicine practice was based on Āyurveda (knowledge and practice of wholesome healthy living), and *shalya chikitsa* (surgical treatment) was one of its major branches.[2] The sage Sushruta was a master surgeon of his time, and his surgical techniques have been documented in the treatise of *Sushruta Samhita* (Sushruta's surgical treatise). Although well versed in many aspects of surgery, no specific references to epilepsy surgery have been made in the treatise. In Ayurveda, epilepsy was referred to as *Apasmara*; the prefix *apa* meaning negation or loss and *smara* meaning consciousness or memory.[3] At that time, aura was already recognized, and epilepsy was classified into four types according to clinical manifestations.[3] Since then, a modern era of neurosurgery in India was not to commence for several millennia, until the arrival of the British. The first medical schools were established by the British in India in the 19th century (Calcutta in 1835, Madras in 1836, and Bombay in 1845).[4] The first department of neurosurgery was founded in 1949 at the Christian Medical College of Vellore, in southern India.[4] The first modern epilepsy surgery in India was performed in 1951 by Jacob Chandy of the Christian Medical College, Vellore.[5]

In China, skulls with holes that had evidence of healing were also found in prehistoric men on recent archeological excavations (personal communication with Professor Wu Xun of Beijing). Shortly after, Hippocrates wrote a monograph on the Sacred Diseases in around 435 BC and opposed the supernatural force as the cause of epilepsy.[6] The first description of a clinical picture of epilepsy in Asia appeared in the *Yellow Emperor's Nei Ching* (The Canon of Internal Medicine) in China which was compiled between 300–100 BC and is considered the earliest work of classic Chinese medicine.[7] It was in the section of *Dian Kuang* that the falling sickness was mentioned. Dian Kuang referred to madness or psychosis; *Kuang* to mania; but *Dian* either to falling or insanity. The ambiguity of *Dian* led to confusion between epilepsy and insanity in Chinese medical literature.[8,9]

In the Siu dynasty (589–618 AD) in China, the term *Xian* was introduced and referred to convulsion or seizure.[10,11] In the authoritative book *Principles and Practice of Medicine* by Wang Keng-tang (1549–1613), *Dian, Kuang,* and *Xian* were put together as the title for a chapter.[12] Chinese medicine was based on the concept of Ying (negative) and Yang (positive), the theory of Five Elements (wood, fire, earth, metal, water), and the idea of a correspondence between microcosm (body) and macrocosm (nature). Thus, the falling sickness was considered a disease of excessive negative force, wind, excessive heat, excessive fullness, or emotional shock. Classification of seizures in China was first attempted by Chao Yuan-feng (610 AD) who proposed three classifications; based on age of onset, *Xian* for seizures occurring before the age of 10 years and *Dian* for those occurring after 10; based on symptoms and causes, *Yang* (positive) epilepsy, *Ying* (negative) epilepsy, wind epilepsy, wet epilepsy, and labor epilepsy; based on causes, wind epilepsy, frightened epilepsy, and eating epilepsy.[10] Another classification by Sun

Figure 2.1 Photograph of the Burzahom skull showing trephination (white arrow) and attempted trephination (black arrow) on the left parietal bone. This trephination is estimated to have been done 4000 to 4300 years ago in the northwestern Himalayan region. (Cited from Sankhyan AR, Weber GHJ, Int J Osteoarcheol 2001[1] with permission).

Szu-mo, a contemporary of Chao, was based on the similarity of epileptic cry to animal cry; goat epilepsy, horse epilepsy, pig epilepsy, dog epilepsy, cow epilepsy, and chicken epilepsy.[11] He also classified epilepsy according to the organ involved; heart epilepsy, liver epilepsy, spleen epilepsy, lung epilepsy, and kidney epilepsy.[11] Many etiologies were proposed and usually based on *Ying–Yang* (negative–positive) imbalance, dysfunction of organs, climatic influence (particularly wind and heat), and disturbance of qi, phlegm, and blood. According to *Nei Ching*, infantile seizure was caused by emotional shock of the mother when she was pregnant,[7] and it was called 'fetal disease'. For later authors, the main cause of pediatric epilepsy was prenatal maldevelopment or postnatal malnutrition.[11] It is interesting to note that only the brain was left out. In the early 19th century, Wang Ching-jen proposed that epilepsy was due to insufficiency of vital energy and blood stagnation of 'brain marrow'.[13] Although he advocated brain as the seat of mind, he still considered the brain as bone marrow inside the skull.

In Chinese medicine, herbal drug has been the main method of treating epilepsy. Prior to the 19th century, there were over 100 prescriptions claimed to be effective for treating epilepsy. Particularly interesting were drugs of animal origin. Scorpion, centipede, earthworm, and stiff silkworm (*Bombyx batryticatus*) were often used to combat epilepsies from wind, phlegm, frightfulness, or stagnation.[14] Certain epilepsies were treated by inducing sweating, vomiting, and diarrhea. Non-medical treatments that may be considered as equivalent to minor surgery have included acupuncture, catgut implantation, and blood letting. Acupuncture was advocated to treat falling sickness in *Yellow Emperor's Nei Ching*.[7] The meridians that connect with the head or the 'brain marrow' were chosen. Acupuncture points on and around the head were also favored.[15] In *Mai Xien* (catgut implantation), a piece of goat (sheep) intestine was buried into the acupuncture points. The layman term for epilepsy was 'goat falling madness' either because epileptic cry was thought to resemble goat's cry,[8] or epileptic convulsions resembled goat's bucking-like movements. Another belief was that the onset of epilepsy was linked to the consumption of goat (sheep) meat while the mother was pregnant.[16] Blood letting by acupuncture needle at acupuncture points was also attempted to release evil phlegm, excessive heat, or other unfavorable conditions.[15] Epilepsy surgery was performed first by Omura[17] in Taiwan in 1942 during the Japanese colonial period and by Duan *et al.*[18] in 1955 in China.

In Japan, epilepsy was described as early as 984 in the first textbook of medicine 'Ishinpou' compiled by Yasuyori Tanba. This compilation was so extensive as to cite more than 200 Chinese and Korean medical books including Yellow Emperor's Nei Ching.[7,19] Since then, symptoms and signs of epileptic seizures have been discussed in details, though without mention of the relationship between epilepsy and brain.[20] The term 'Ten-Kan', meaning epilepsy, is composed of two Chinese characters; 'Ten' (the same word pronounced Dian in Chinese) meaning adult epilepsy and 'Kan' (the same word pronounced Kuang in Chinese) meaning childhood epilepsy. Today 'Ten-kan' is an official medical term for epilepsy in Japan. An impressive drawing of generalized epileptic seizure, compiled in a medical book 'Ihon Yamai no Soushi' (Illustrations of Diseases – a variant version) in the 12th century, surprisingly shows precise observation by the painter to express dreadful aspects of a generalized convulsion[21] (Figure 2.2). In the 16th century, the Portuguese came to Japan and introduced European medicine, later followed by the Dutch. Starting in 1639, Japan had been closed from the western world for 230 years due to the national isolation policy of the Tokugawa Shogunate, during which time only the Dutch traders were allowed to come to Dejima, a small island of Nagasaki. Through this narrow canal, Japanese scientists sought information about the progress in the world outside. For example, in 1699 Yeikyu Narabayashi translated the Dutch version of Ambroise Pare's textbook of surgery into Japanese. This book was published in 1706 as 'Geka Soden' and widely distributed.[22] Genpaku Sugita had a very rare occasion to watch dissection of a cadaver in 1771. Impressed by the exactness of the drawings of a book, Tafel Anatomia (a Dutch version of J. A. Kulmus' Anatomische Tabellen in 1647) that he had bought before, he in collaboration with Ryotaku

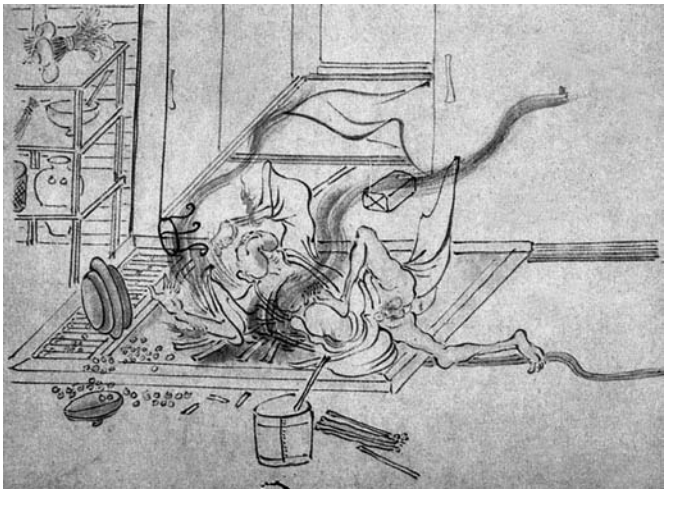

Figure 2.2 Drawing of generalized epileptic seizure from the medical book 'Ihon Yamai no Soushi' (Illustrations of Diseases – a variant version) compiled in the 12th century in Japan (from collections of National Kyoto Museum).[21]

Maeno translated this book into Japanese in 1774; 'Kaitai Shinsho' (New Text of Anatomy).[23] At the dawn of the 19th century, Seishuu Hanaoka accomplished total resection of breast cancer under general anesthesia for the first time in the world. However, nothing about surgical treatment of epilepsy was documented in Japan until the end of the 19th century.[24]

Epilepsy surgery in Japan developed in parallel with general neurosurgery. Susumu Sato made a trephination for a depressed fracture and drainage of a brain abscess during the Meiji civil war in 1877. This operation is admitted as the first craniotomy in Japan.[25,26] According to the monograph by Keiji Sano,[27] Hayari Miyake in 1893 precisely described an operation for an open depressed fracture performed by Julius Scriba, Professor of Surgery at Tokyo University. In his paper, Miyake also referred to Jacksonian seizure and cerebral functional localization.[27] Later, Miyake became Professor of Surgery at Kyusyu University and in 1905 removed a brain tumor successfully for the first time in Japan. Hayazo Ito was the first surgeon in Japan who took interest in epilepsy surgery[28,29] (Figure 2.3). During three years' stay in Bern, he learned cranial decompression for epilepsy from Theodore Kocher, and performed experimental studies on the treatment of epilepsy based on Dr. Kocher's idea that epilepsy occurs due to abnormal excitation of motor cortex following abrupt increase in intracranial pressure.[29] After returning home as Professor of Surgery at Kyoto University, he reported his own experience on 39 cases at the first meeting of the Japan Medical Association in 1902.[30] Chugei Yamagata of Sendai, impressed by Ito, also reported six cases of cranial decompression in the same year.[31] Ito kept his interest in epilepsy surgery throughout his professional career and later applied a more essential procedure to the treatment of epilepsy, such as the repair of depressed fracture or cortical resection by Horsley. Until his retirement in 1924, he operated upon 182 cases of epilepsy.[32] Further development of epilepsy surgery in Japan has been summarized by Seino and Mihara in the previous edition of this book.[33]

Figure 2.3 Profile of Dr. Hayazo Ito (1864–1929) who was the first surgeon in Japan who took interest in epilepsy surgery.

3 Epilepsy surgery in Latin America before the 19th century

MG Campos

Introduction

Even though epilepsy and its treatment are as ancient as mankind, its historical background within the pre-Columbian South American peoples is hardly known since the Incas and their predecessors did not have a writing system. However, they had significant graphic representations in ceramics, such as the so-called *huacos*. These figures represent different diseases and medical procedures.

Such knowledge can be tracked back through the Paleopathology, a science devoted to study the diseases that are likely to be demonstrated in ancient human or animal remains. Therefore, little was known about epilepsy prior to the advent of written documents since the materials used by Paleopathology consist basically of bone remains from caves, deposits, or from a necropolis. The main pathologies that can be diagnosed are traumatic injuries (fractures) (Figure 3.1), infections (osteomyelitis, syphilis, tuberculosis, etc.), metabolic diseases (raquitism, scurvy), degenerative diseases (arthrosis, spondylosis, etc.), bone tumors, or meningeomas and dental conditions.[1,2]

Trepanations in pre-Columbian America

The word 'trepanation' means removal of a fragment of skull bone by means of an instrument called a trepan, which comes from the Greek word *tripanon* (puncher).[3] In the pre-Columbian America, trepanations were carried out only occasionally in North America, Central America (Mayas), and Mexico, where the Zapotec and then the Mixteca cultures established themselves in the huge city of Monte Alban, Oaxaca. They probably carried out trepanation just as a ritual, since the skulls found belong to young people of both genders.[4,5]

Nevertheless, trepanations became more frequently performed on the coast of the South America Pacific Ocean, within the arid climate zones that today belong to Peru and North of Chile (the Paraca, Nazca, and Mochica cultures) as well as in the central Andean highlands (Altiplano) of Peru and Bolivia (Huari or Wari, Tiahuanaco, or Tiwanaku, Chimu, and Inca cultures).[6] The dry climate of the Peruvian coast has allowed an excellent conservation of more than 15,000 mummies from the pre-Columbian period; most of them are stored in the National Museum of Anthropology and Archaeology in Lima, Peru.[7] The age of these mummies can date back to 2500 years and 5% of them show evidence of *in vivo* trepanation. Seventy percent of the skulls from the pre-Columbian Peru belong to men.

The Spanish chronicles of the conquest make no reference of trepanations, thus it is suspected that these practices were either abandoned or secretly practiced during this period. Furthermore, little or no attention was paid to the 'surgical instruments' that decorated the museums. In fact, most of the conquerors were not erudite men and just a few of the participants of the expeditions wrote the chronicles. Felipe Guaman Poma de Ayala[8] was an exception; he illustrated his observations in hundreds of drawings. That was the way we probably got the first description of epilepsy in the pre-Columbian Peru. It referred to Mrs. Chimbo Mama Cava, spouse of Capac Yupanqui, one of the last Inca emperors, who ruled until he died in 1525[9] (Figure 3.2). Other references of epilepsies in the Inca period come from Garcilazo de la Vega's writings in *Real Comments on the Incas*, which describe probable focal epilepsy events.

There was no specific term for 'epilepsy' in *Quechua* (a language used by the Inca people), which defines it as a special neurological condition. However, many Quechua expressions might have been used to refer to epilepsy, e.g. *Sonko-Nanay*. This is based on the fact that *Sonko* has different meanings: heart, mind, and in some cases, brain; i.e. the essential component of the human being, while the word *Nanay* means pain or illness.[9] Therefore, *Sonko Nanay* may have been used to refer to epilepsy cases, mental diseases, syncope, etc.

It has also been posed that the Quechua word *ayahuayra* may have been used to refer to epilepsy. This word derives from the expression *aya*, which means death, and *huayra*, wind or air. Consequently, the Quechua cultures may have associated epilepsy to death.[10]

The word *Perlesía* was used by the Spanish conquerors to denominate a series of 'neurological syndromes' such as stroke, hemiplegia, and possibly epilepsy or 'non-neurological diseases', e.g. heart diseases or syncope.

The first trepanned 'Incaic' skull was described by Samuel G. Morton in his book *Crania Americana* in 1839, though it was interpreted as a war injury. In the year 1865, Efraín G. Squier, explorer and USA Business Attaché in Peru, published his book 'Incidents from a trip to Peru, country of the Incas' and presented part of a trepanned skull in the Academy of Medicine in New York (Figure 3.3).[11] Squier showed this trepanned skull to Paul Broca (1824–1880), who had previously described the language localization and the hemispheric dominance. In addition to having been one of the

Figure 3.1 (a) Skull with a depressed frontal fracture (bone depression). (b) Skull with exophytic meningioma. National Museum of Anthropology and Archaeology, Lima, Peru.

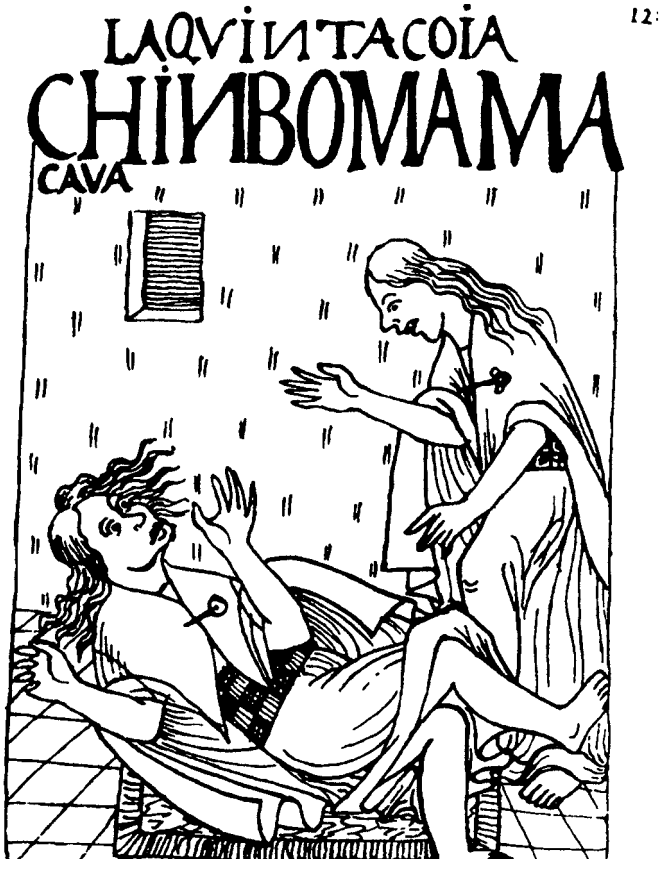

Figure 3.2 Drawing from Guaman Poma de Ayala, who describes: 'The lady was very beautiful, peaceful and modest. After her marriage she got epilepsy, which made her suffer three times a day. She cried and screamed, attacked others, and pulled her hair. She was left very ugly'.

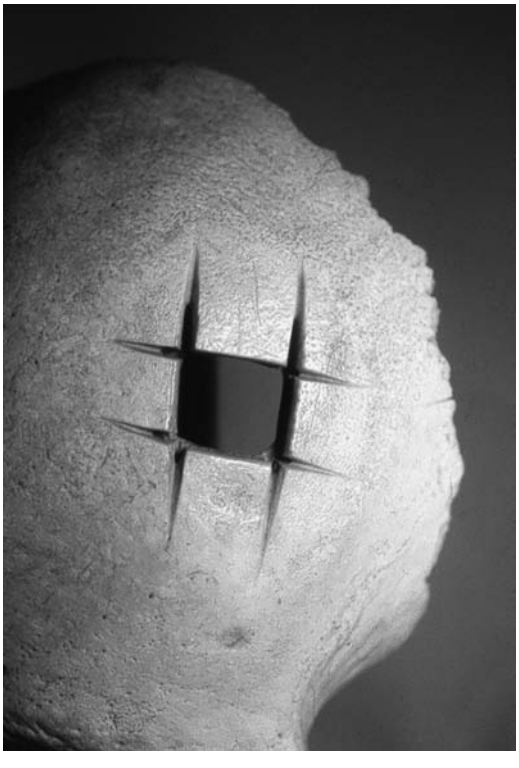

Figure 3.3 Skull from the Inca cemetery of the Yucay Valley, showing a left frontal quadrilateral trepanation and slight healing signs. It was obtained by EG Squier in the house of a lady from Cuzco. The skull is dated between 1400 and 1530. At present, it is found in the Natural History Museum of New York.

founders of the Anthropologic Society of Paris, Broca suggested that the Inca skull belonged to a person that had survived for 1 or 2 weeks.[12] This discovery preceded many trepanned skulls that were subsequently found in Europe (France, Germany, England, Check Republic, etc.). These skulls were also studied by Paul Broca, who was the first medical doctor in modern age to propose trepanation as a possible surgery for epilepsy (this had been previously mentioned by Hippocrates). It was also proposed later on by Victor Horsley (1857–1916) upon examining Broca's collection of trepanned skulls.[13]

Figure 3.4 Operated fronto-temporal fracture, with no patient survival (no healing signs), which could belong to a soldier hurt during the battle.

Historical background

There is a mistaken tendency to refer to 'Inca trepanations', since the Inca Empire was rather new at that time. It is estimated that it was founded by *Manco Capac* by year 1200 AD, following unification of all the peoples of the region under only one Emperor. In other words, when the Spanish arrived, the Inca Empire was only 300 years old. In fact, most of the trepanations were carried out by pre-Incaic peoples (Paracas, Nazca, Mochica, Ica, Huari, Tiahuanaco, and Chimú cultures), who practiced them much more frequently and long before the Incas.[6] The oldest skulls come from the Paraca culture (1000–200 BC) located in the South-Central Coast of Peru, and also from the Tiahuanaco culture, around the Titicaca lake, which is today Bolivia, where they found trepanned and deformed skulls dating back to 1500 BC.

The Incas used to name their empire as *Tahuantinsuyu* or 'the land of the four corners'. In 1492, when Christopher Columbus (*Cristóbal Colon*) discovered America, the Inca Empire was already the largest in the world. This included the current countries of Peru, Ecuador, Bolivia, and some parts of Chile, Colombia, and Argentina. Unfortunately, the Inca empire fell in less than 100 years, soon after the arrival of the Spanish Francisco Pizarro, in Tumbes, together with 179 conquerors in 1532.[7]

Purposes of trepanations

Craniotomies seem to be a common cultural practice among many societies, independent of the period (since the Neolithic, 10,000 years to date) or geographical location (Europe, Latin America, Oceania, Northern Africa, etc.).[13–19] However, in no other place but the South American Pacific lands were such a significant number of procedures performed, with an estimated survival rate in 50–70% of 'patients'.[7]

The probable motivations of the pre-Incaic peoples to practice trepanation could have been as follows.

Treatment of cranial trauma

This is based on the fact that these were warrior peoples who used stone mallets; therefore, they were exposed to trauma and cranial fractures, including bone depression. Moreover, the fractures could have been associated to intracranial haematomas. There are multiple trepanned skulls associated to fractures supporting this hypothesis (Figure 3.4); many of them show injuries in the temporal or left fronto-parietal area, which indicates that the attacker was right-handed. Also, trepanned skulls have been found in the altiplanic Inca's military zones, the valley of Urubamba, near Cuzco (capital of the Inca Empire). It has been suggested that from 30% to 50% of the trepanations in the altiplan were due to battle injuries.[11,20]

Religious procedures

Many of the trepanned skulls show deformations provoked by pads and boards that were tied to the head since childhood (Figure 3.5). Some of these deformed skulls also show some trepanations. Even today there are some seaside tribes that carry out ritual trepanations in the occipital region, which is also seen in the pre-Columbian adult skulls of the Huara culture.[2,21]

Epilepsy surgery

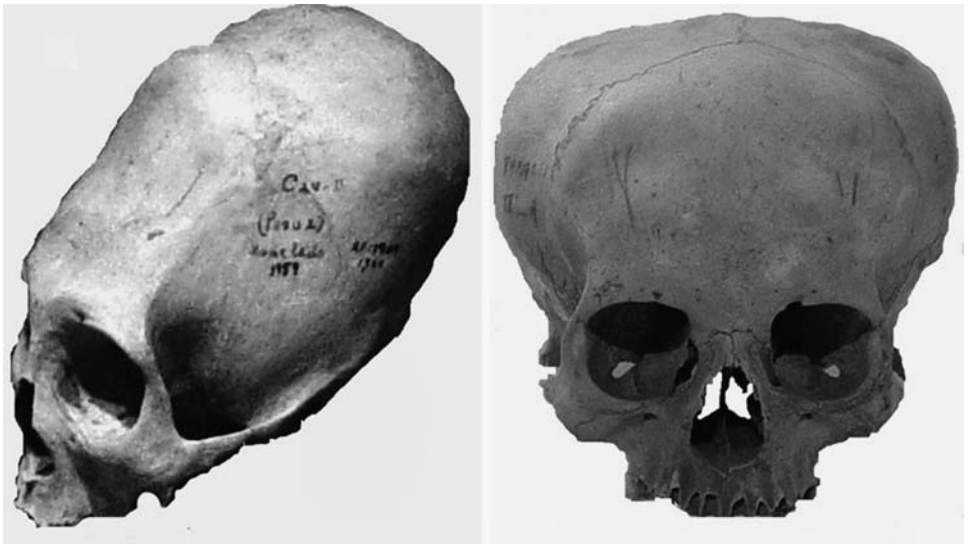
It has been proposed that trepanation may have been performed to remove the cause of the disease. This is based on the fact that most of the trepanned skulls have neither fractures, nor deformations; however, many of them show more than one trepanation, performed at different times. This is known because there are different healing levels in the various trepanations of the same skull (Figure 3.6). Therefore, these were individuals with chronic conditions (epilepsy, headache, etc.) or people predestined to multiple trepanations, due to unknown reasons.[19,20] Such hypothesis is contrary to the finding that trepanations in children were very few.

It is also worth noting that the Incas, unlike the Mayas, did not attribute the cause of epilepsy to 'a possession by the devil'.[22]

Pre-Incaic peoples as neurosurgeons

Surgery rooms

Craniotomies were practiced throughout the Inca Empire, except in the Amazonian area, corresponding mostly to the actual Peru, part of Bolivia, and North of Chile, though there were also necropolis that were real trepanation centers. The existence of neurosurgical centers or training schools in



(a) (b)

Figure 3.5 (a) Deformed skull in the shape of a tower. (b) Skull with bilobulated deformation.

Paracas and Cuzco has even been suggested, where possible ruins of hospitals have been found.[23]

The 'neurosurgeon'

Probably, there were two types of 'surgeons': the ones who had been trained, called *Hampicamayac* (Figure 3.7) and the others called *Soncoyoc* (Chamanes), who had neither knowledge nor technical skills.[6,11] The expression *Sirkak* is also known to refer to the surgeon or 'sangrador' (blood-letter). Most of the trepanned skulls show a 'surgery' performed with anatomical knowledge, e.g., outside the path of the venous sinuses. Besides, more than a half of the skulls found show signs of survival, either with healing evidence or osteomyelitis. The risks of infection were evidently present and multiple skulls with different degrees of osteomyelitis were found (Figure 3.8).

Sedation

Sedation may have been applied to conscious patients, using fermented 'mandioca' or alcoholic beverage. It is also believed that they used Coca (*Erytroxylon coca*) in powder and chewable coca leaves. This plant has anesthetic properties and it is native to the Andes.[24] Thus, it helped to relieve the pain produced by the scalp incision, which was the only painful part of this surgery.

Surgical instruments

Both stone cutting instruments, like volcanic crystal (pedernal) and a volcanic rock called obsidian, as well as a knife-shaped piece of metal (copper or bronze) known as the classical 'Tumi' (Figure 3.9), which is a knife in the shape of a half circle, were used. The knife occasionally had a human or animal figure engraved in its handle. There were also pincers that may have been used to remove bone fragments or for depilation purposes (see Figure 3.13).[4,11,25,26]

Haemostasis

The bleeding may have been controlled with the use of extracts from the roots of *ratania* and the liana *pumacbuca*, both of which are rich in tannic acid and well known by the pre-Columbian peoples.[7,24]

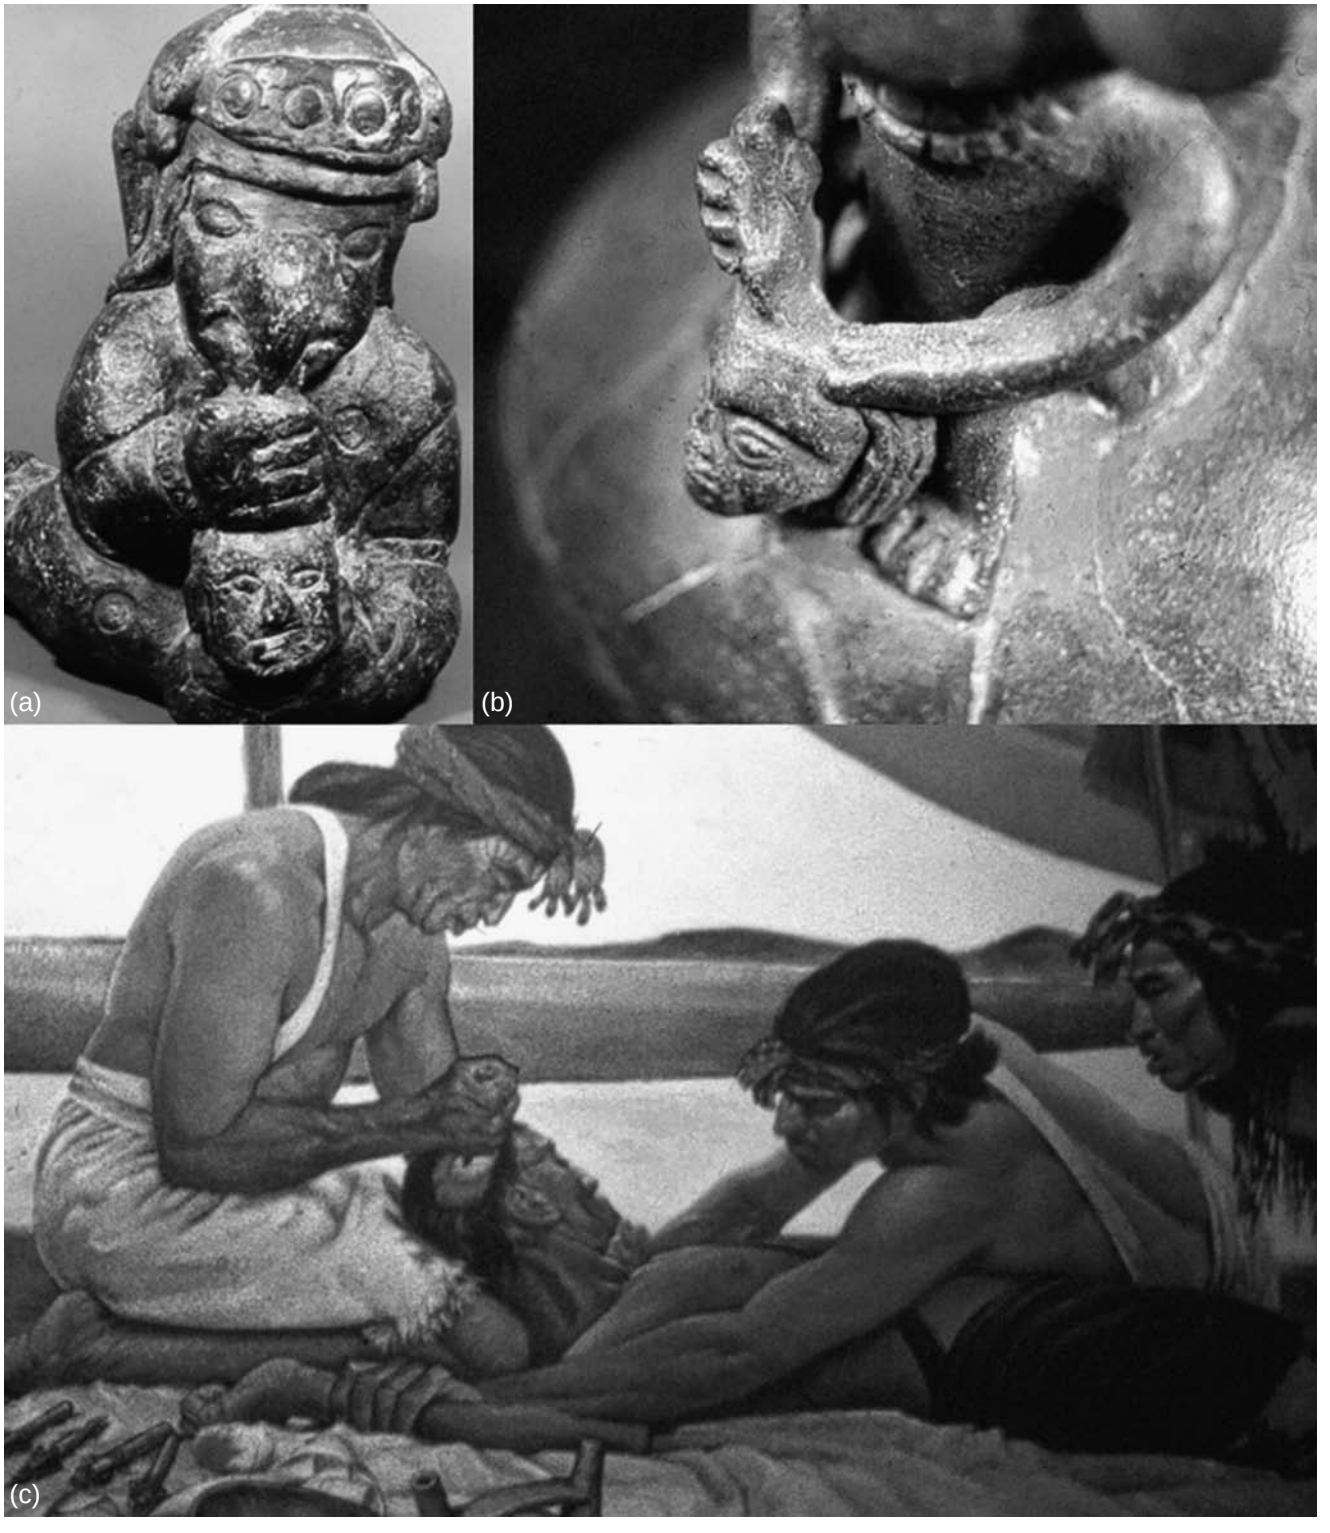

Figure 3.7 (a) Ceramics representing skull surgery performed by a man with a bird-mask. (b) This ceramics was found in the 'Casma' cemetery, on the Peruvian coast, near the Callejón de Huaylas. This *huaco* was made public in 1916 by Dr. Carlos Morales-Macedo. It shows a 'surgeon' working on a skull with a Tumi. (c) Artistic representation of an Incaic trepanation; the surgical instruments are underlined in the inferior left angle, together with the sedating beverage.

The surgical technique

Skulls with no significant signs of healing and cases that failed to survive the surgical procedure have allowed us to gain a wider knowledge of the techniques employed. There were basically three (Figure 3.10). The first corresponded to craniotomies with straight cuts limiting quadrilateral, polygonal, or circular edges in these procedures. They possibly used hard obsidian knives with strongly polished edges. The second type referred to scrapings, probably by means of an abrasive stone tool, which was rubbed over the surface of the skull until the internal skull board was pierced and it reached the meninges. Subsequently, the opening was widened to keep on fracturing the weakened borders of the bone. This technique was used by the Paraca culture, but these skulls usually did not show signs

(a) (b) (c)

Figure 3.8 (a) Bone regeneration, which would probably cause spontaneous healing or by means of healing herbs. (b) Extensive osteomyelitis with bone porosity. (c) Wide bone healing which might have taken many years of regeneration and survival. It is worth noting that these are probably accompanied by a significant suppuration of the wound after surgery or due to meningitis.

(a)

(b)

Figure 3.9 (a) Volcanic stone (Obsidian) with a pointed shape, used for trepanations, which was either mounted or not in a wooden handle. (b) Half-moon shaped knives called Tumi. It was originally an axe, which was used for multiple cutting activities. Therefore, this was not a specific surgical instrument and it was possibly used to open the skin of the patient, not the bone, unless it was a Tumi of the chisel type.

Figure 3.10 (a) Lineal trepanation; evidences of a cutting tool are seen in the borders, (b) Craniotomy with cutting tool of the punch type, which leaves marks on the borders. (c) Skull close-up, showing the external board, the spongy one, and the internal board. The diploe porosities indicate that there was no survival. (d) Trepanation by knife rotation over the skull.

of survival. The third technique corresponded to multiple drill holes bordering the bone area to be removed. Punchers with polygonal profiles were rotated and spinned until the skull was perforated.[6,7,11,27]

Suture

Metal needles and pieces of cotton thread have been found in burials, which suggest the method used to suture the skin. Another hypothesis is that they tied up the hair to the edges of the wound and then joined the borders.[24]

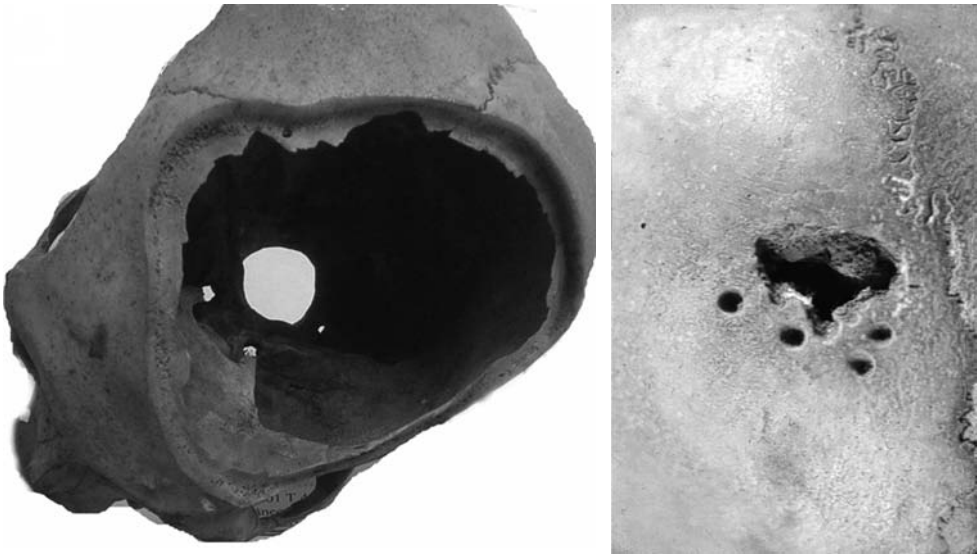
Surgery time

It is estimated that it took an expert neurosurgeon between 30 to 60 minutes to carry out a trepanation. The latter has been demonstrated on two occasions in Peru. The first case was in Cuzco in 1944, where two neurosurgeons operated with original pre-Incaic instruments on a 22-year old young man with cranial trauma after a tree fell down on his head. The instruments used were obtained from the Archaeological Museum of this city. They used a Tumi to make the incision in the skin and the separation of the periostium; and then they were able to open the bone with a sterilized obsidian chisel and were able to carry out a 6×3 cm. trepanation. They sutured the edges of the wound with a *champi* needle. The surgery procedure lasted one hour but the patient died 7 days later because of pneumonia. We must remember that antibiotics were not yet available.[28]

The second case was in 1953, where two Peruvian neurosurgeons (Graña and Rocca)[29] first carried out experimental surgery on a cadaver. They obtained Tumi and obsidian knives from the National Museum of Anthropology and Archaeology in Lima. They then practiced an *in vivo* surgery on a patient with cranial trauma, hemiplegia, and aphasia. The patient was intubated and sedated and then the sterilized pre-Inca instruments were used to perform an oval craniotomy with exposure of the meninges and drainage of a haematoma.

Complications

The first complication was death, which occurred in less than 50% of 'patients' (Figure 3.11). However, bone infections (osteomyelitis) were very frequent, presenting either as little porosities around the trepanation, or as severe infections



(a) (b)

Figure 3.11 (a) Extensive craniotomy, with no survival signs. (b) Some trepanations consisted of just some small holes, but they also show osteomyelitis at the borders.

including signs of regeneration. In such cases the original type of trepanation cannot be recognized, but they are indicative of survival for many years. We can even find mummies showing replacement of the normal skin by a fibrous tissue, which becomes adhered to the meninges. Some individuals died during surgery and then were mummified; this has allowed us to learn about the way the 'neurosurgeon' opened the skin of the skull with cross-like (cruciform) incisions.[11]

Figure 3.12 Skull with two trepanations, the one at the back shows a cranioplasty with a golden slice. The 'patient' does not present signs of survival. This skull repair method may have been applied to people belonging to aristocracy (Lima, Peru).

Cranioplasties

It was has been proposed that the treatment of bone that failed to heal may have been done with organic elements, such as mate or coca leaves or pumpkin skin, though it is biologically impossible. Likewise, small gold slices used to repair such bone defects have been found (Figure 3.12). They are believed to have been used in patients who were members of the nobility; however, these skulls do not present survival signs, which suggest a failed attempt to close the bone defect.[30]

Variant of a trepanation

A variant of a classical trepanation corresponds to a pseudo-trepanation (scraping or small trepanation) carried out over the inions of the occipital region, in the masto-occipital suture, over the so-called 'wormian bones' (Figure 3.13), which are small intercalated bones. Fifty-two percent of these skulls with wormian bones also show intentional deformations,[21] as compared to 33% of the skulls with no deformations. Some authors believe that these were not real trepanations but bone necrosis due to pressure.

Figure 3.13 Trepanation with a punch in Wormian occipital bones (Lima, Peru).

4a The history of epilepsy surgery in the United Kingdom

CE Polkey

Introduction

A historical survey of epilepsy surgery in any particular geographical location must be subject to two influences. The first is the need to recognize that only major players can be identified and considered to have an influence on the course and development of the topic. The second is that the course of epilepsy surgery has to be viewed in relation to developments in other geographical areas and also the ebbing and flowing of the subspeciality within the main body of neurosurgery. This review has been assembled on the premise that a number of periods can be identified. In some circumstances the pre-eminence of one group or individual may have been the major inspiration for a particular phase or development. It is convenient therefore to consider the following sequential periods:

1. The early years:	1890–1930
2. The doldrums	1930–1950
3. The perception of pathology	1950–1970
4. The influence of direct brain imaging	1970–2005
5. The present	2005

These divisions are of course artificial and merge into one another. The first two periods between 1890 and 1930 are no longer within the experience of any living individual and the material for these sections has been obtained from literature review and 'folklore'.

The early years

Trephining or trepanation was a well accepted method of operating on the head at the time when this review starts. There are some 56 papers in the literature from British authors describing the use of this procedure in epilepsy. The earliest, from Newcastle in 1877, describes a case of an acute seizure following a frontal wound. The patient was operated seven days after the injury and subdural pus was found. The patient unfortunately died seven days later and at autopsy there was extensive subdural pus.[1] Thereafter there are a number of accounts, some of which describe treatment in acute cases but others at some interval after injury, for example Bennett and Gould describe a patient operated six years after injury for focal seizures. The dura was opened but nothing abnormal was found. The fits are said to have been relieved for five months.[2] In the early part of this period the basis of surgery was based on the idea that thickening or distortion of the skull could, of itself, cause epilepsy and if this distortion or thickening were relieved the epilepsy would be cured. A clear distinction is made in the literature between 'Jacksonian' epilepsy and other kinds of epilepsy. It was recognized, especially with increasing knowledge of cerebral localization, that 'Jacksonian' epilepsy was connected with local brain injury and this was usually due to head injury. The procedure was still regarded seriously and much debated. The notion that such operations were undertaken lightly or thoughtlessly is not borne out by the literature. It must also be remembered that the medical treatment of epilepsy at that time was inefficient and as individual patients developed epilepsy the frequency and severity of the seizures would increase to a level seldom seen nowadays, causing the patient and their advisers to seek desperate remedies. In addition, as the 19th century drew to a close, the introduction of anesthesia and antisepsis made the procedure safer and to some extent more effective by allowing the surgeon time to work. Walsham describes a case operated at St Bartholomew's Hospital where trepanation was performed twice on a patient with post-traumatic epilepsy four years after a fall from scaffolding. These operations reduced the frequency of the patient's seizures although the dura does not appear to have been opened. He then reviews 82 cases of post-traumatic epilepsy described in the literature. Mortality was 20.2% but he also notes that at that time mortality from trephining in general was between 10.6% and 14.5% and infers that the increased mortality is due to late deaths not related to the surgery. His conclusion, which may be that of an enthusiast, is as follows.

> Where there is a clear history of injury, a well-marked cicatrix or sinus leading to dead bone and the epilepsy has as clearly followed the injury, there can, I think, be no doubt of the propriety of trephining, and there are few surgeons, I should imagine, who under such circumstances, would hesitate to do so.

However he goes on to say that if there is a history of head injury and some indication of localized trauma, even if only a persistent tender spot then trephining is justified. He supports this argument partly by stating that it is not a dangerous operation especially if 'the membranes are not wounded'.[3] One of the intriguing puzzles of this period, recognized by practitioners at the time, is how epilepsy could be cured without operating on or exposing the cerebral cortex. However the case reports in the late 1890s almost universally describe opening

of the dura with pathological lesions in many cases. After that a number of successful cases were described. On some occasions more than one trephining was performed. There is a particularly interesting case described by Bidwell and Sherrington in 1893. After head injury a patient developed focal motor seizures involving the foot and ankle. Two trephines with brain resection were carried out. At the first operation discolored brain possibly an old hemorrhage, was removed without improvement. At the second operation Sherrington stimulated the brain and part of the leg area was removed. There was an improvement in the fits affecting the leg but the focal motor seizures affecting the arm were unaffected, however, the patient's daily seizures were abolished.[4] Ransom also described stimulation of the cortex under similar circumstances in 1892.[5] Taylor, discussing the question of operation in the treatment of epilepsy observes that 'Again a history of epileptic fits extending over twenty five years or more is anything but an invitation to operation.' [6] The attitude of physicians towards the operative treatment of epilepsy is revealed in Osler's textbook of medicine published in 1892.[7]

> In Jacksonian epilepsy the propriety of surgical interference is universally granted. It is questionable, however, whether in the epilepsy following hemiplegia, considering the anatomical condition, it is likely to be of benefit. In idiopathic epilepsy, when the fit starts in a certain region – the thumb, for instance – and the signal symptom is invariable, the center controlling this part may be removed. This procedure has been practised by Macewen, Horsley, Keen and others, but time alone can determine its value. The traumatic epilepsy, in which the fit follows the fracture, is much more hopeful. The operation, *per se*, appears in some cases to have a curative effect. Thus of 50 cases for trephining in epilepsy, in which nothing abnormal was found to account for the symptoms, 25 were reported as cured and 18 as improved. The operations have not always been on the skull, and White has collected an interesting series in which various surgical procedures have been resorted to, often with curative effect, such as ligation of the carotid artery, castration, tracheotomy, excision of the superior cervical ganglia, incision of the scalp, circumcision etc. [8]

However, two surgeons who stand out in this era as founders of British neurosurgery, William Macewen and Sir Victor Horsley, adapted their surgery to the evolving knowledge of cerebral function and localization (Figures 4a.1 and 4a.2). Although contemporaneous, they were two very different men. Macewen, relatively isolated in Glasgow, was more of a pragmatic surgeon with no background of experimental work or apparent association with a group of like-minded individuals in the field which would now be described as neurosciences. Indeed, in his Presidential Address to the BMA, meeting in Glasgow in 1922, he plays tribute to the work of Ferrier, Horsley and Beevor in investigating cerebral function in animals and to Horsley Godlee and Balance in applying this knowledge to their operating practice.[9] When he was a student in Glasgow in 1873 he describes seeing a patient who had sustained a fracture of the right parietal bone and thereafter suffered from spasms of the left arm. Operation showed a spicule of bone which had penetrated the dura and lodged in the middle part of the ascending

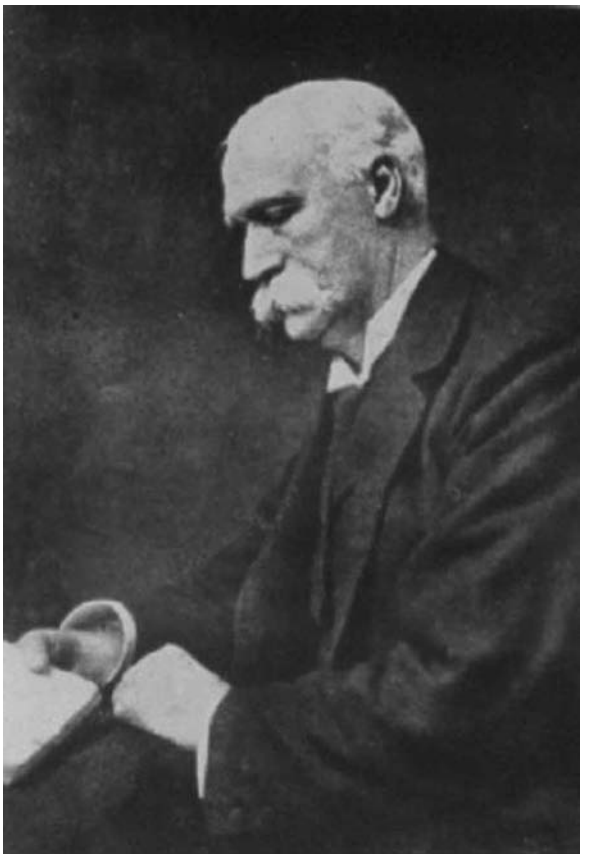

Figure 4a.1 Sir William Macewen (source unknown).

frontal convolution. It was removed, the spasms ceased and the weakness recovered over a few weeks, so he was clearly familiar with the possibility of relieving focal epilepsy by surgery. Horsley, who held appointments enabling him to undertake experimental work as well as clinical work, had also laid down principles for the safe practice of neurosurgery which he set out in his paper of 1886. It is in this paper that he also describes the three cases of chronic epilepsy treated by cortical resection and observes that in one case he and Dr. Beevor were able to stimulate the brain and produce movements.[10] It is not known whether there were any further operations. In 1906 Horsley notes that in 1890 and 1983 he had tried, without success, to persuade physicians to limit the period of medical treatment before referring the patient for surgery.[11]

In the early years of the 20th century skull X-rays began to be used to assist diagnosis. In the first case, described by Palmer in 1910, the patient was subjected to a second operation for focal sensory seizures in which an X-ray showed a dark shadow but exploration by Mr Balance was negative.[12] However, in two further cases where the patients had suffered from epilepsy for over 20 years an X-ray showed a middle fossa mass. Resection of the mass in both cases resulted in cure of the epilepsy.[13,14] By 1924 the position was still ambiguous. At a meeting of the BMA section of neurology Dr. Collier noted that he had never seen a case of traumatic epilepsy benefited by operation. Dr Worster-Drought disagreed, quoting two cases, which had benefited.[15] In a paper on epilepsy in 1926, Symonds, one of the influential neurologists of that time, does not mention surgical treatment directly but hints at it.[16] Davidoff, describing a visit to Prof. Foerster's clinic in Breslau notes that patients with Jacksonian epilepsy are investigated very carefully, including

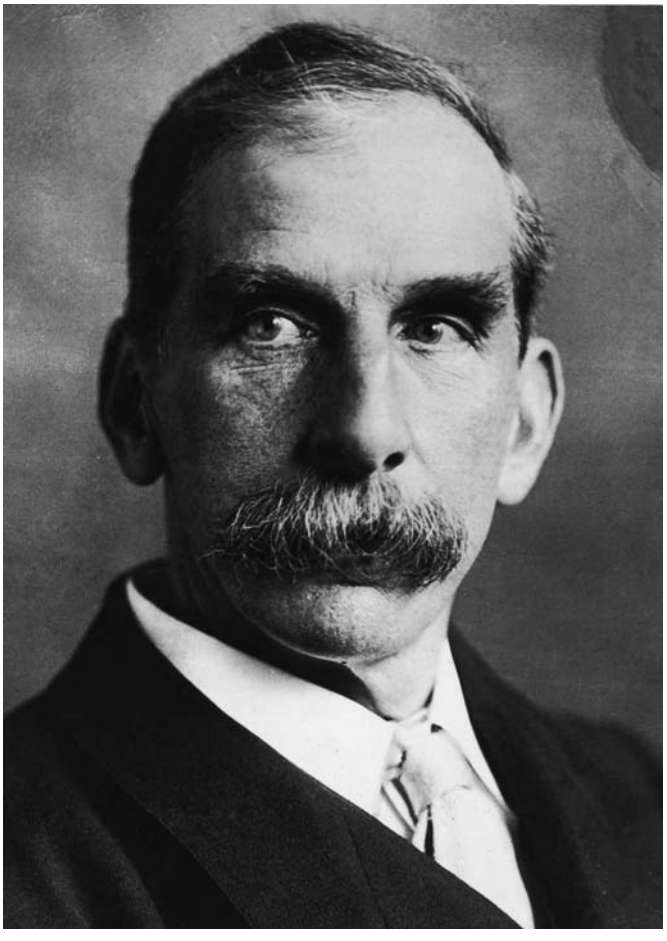

Figure 4a.2 Sir Victor Horsley in 1910 (by permission of the Getty Archive).

the latest imaging technique of air encephalography.[17] In a seminal paper, published in Brain in 1930, and therefore presumably read by appropriate specialists in the UK, Foerster and Penfield describe their experimental and clinical work on traumatic epilepsy.[18] At this stage the advice in Osler's textbook regarding surgical treatment of epilepsy, had been modified, but not changed.[19] The attitude of the British neurosurgical community is represented by two surgeons, Jefferson and Young. At the seventh Congress of La Internationale Societe de Chirugie both were asked to comment on a paper on Jacksonian epilepsy presented by Leriche. Jeffferson noted that Jacksonian epilepsy is rare in civilian practice, stated that he believed that epilepsy has a natural tendency to remit and called attention to the placebo effect of treatment. His own practice, he said, is conservative.[20]

The doldrums

With these uninspiring facts we enter the period of virtual inactivity for 20 years which included World War II. Towards the end of this period, and before the emergence of Murray Falconer and his group at the Maudsley Hospital, there is evidence of activity by two groups although the publications are small. Cairns described three cases of hemispherectomy in 1951, the emphasis being on the intellectual and behavioral benefits. All three became seizure free. Cairns also carried out some neurophysiological investigations co-operating with Adrian and Matthews in 1934 to enable them to record from the exposed occipital cortex before and after the removal of a glioma. (Figure 4a.3.).[21] He is also recorded as using intralesional electrodes to investigate a patient in 1944.[22] Mr. Wylie McKissock, working at the National Hospital, Queen Square, had carried out a substantial number of hemispherectomies following the description of this procedure by Krynauw.[23] In 1956 the British Medical Journal carried an editorial pointing out the benefits of hemispherectomy. The long-term results of McKissock's series were described in 1970.[24] McKissock also carried out other procedures since a patient who underwent a right temporal lobectomy by him in 1944 is described by Ettlinger *et al.*[25] The other active surgeon at this time, again with relatively few publications, was Northfield who was at the Royal London Hospital.

The perception of pathology

The next period between 1950 and 1970 is dominated by the group working at the Maudsley Hospital and closely identified with Murray Falconer. It must be made clear at the outset that although Murray Falconer ran what would in modern terms be recognized as an epilepsy surgery program it was operated at the time as part of a general neurosurgical service. Another player of note during this period was Mr. D.W. Northfield, who worked at what was then the London Hospital, now the Royal London Hospital. Their productivity, in terms of patients operated and academic publications was vastly different and Murray Falconer had the help of a team of fellow professionals, which does not seem to be the case with Mr. Northfield. There is an interesting discussion, recorded in the Proceedings of the Royal Society of Medicine in 1958 between Mr. Northfield and the Maudsley team, which will be referred to later. There were other surgeons doing some surgery, Eric Turner in Birmingham was using a form of temporal lobotomy in the treatment of temporal lobe epilepsy. He was as interested in the effects of his surgery on behavior as epilepsy.[26]

Murray Falconer was a New Zealander who had come to Europe and America in the late 1930s to further his neurosurgical education. He had remained in the UK during the Second World War working in the military services and he had met a number of neurologists and neurosurgeons who would become prominent in their field after the war. In 1942 or 1943 he returned to New Zealand to take up an appointment in the

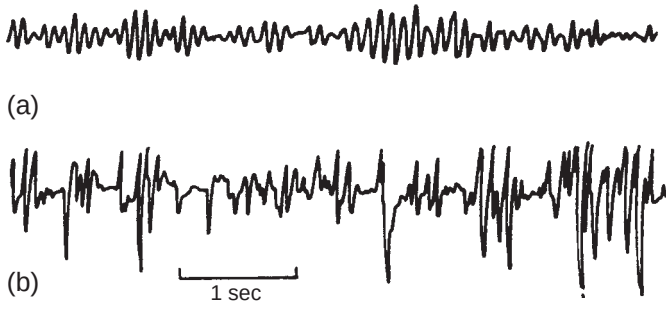

Figure 4a.3 Probably the earliest published electrocorticogram in the English literature. Recorded from a patient operated upon by H. Cairns. From Ref. 21 by kind permission of the Editors of *Brain*.

University of Otago with the express purpose of setting up a neurosurgical service. In the late 1940s Sir Charles Symonds wished to set up a neurosurgical unit in Guys Hospital and there were good reasons for associating this with the Maudsley Hospital. Murray Falconer was invited to become the director of this new unit which initially was located in Guys Hospital and then moved to purpose built accommodation in what had previously been the private patients building of the Maudsley Hospital in 1951 (Figures 4a.4 and 4a.5) From this base, where he continued to work until his retirement in 1975, about 300 patients were operated on in 25 years and a large number of publications were made. An unpublished analysis of his work during this period shows that the majority of the operations, more than 75%, were anterior temporal lobectomies, with the next commonest operation being anatomical hemispherectomy. All this was done with mainly interictal non-invasive EEG, although acute sphenoidal recording was used and in all cases, except hemispherectomy, acute electrocorticography was carried out. For brain imaging plain X-rays, carotid and vertebral angiography and air encephalography were used. Neuropsychological testing including carotid amytal tests was also available. In 25 years between 1950 and 1975 Murray Falconer published 93 papers 61% of which were concerned with epilepsy and its surgical treatment. During this time only seven papers on epilepsy surgery were read at the Society of British Neurological Surgeons, five of which were from Murray Falconer's unit. At various times during this period he had as co-authors or advisors a number of colleagues including: neuropathologists, Meyer, Corsellis, and Cavanagh; clinical neurophysiologists and epileptologists, Hill, Driver, and Engel; psychologists Ettlinger and Blakemore; and psychiatrists Pond, Hill, and Taylor.

Figure 4a.4 Mr. Murray Falconer operating in the late 1960s. (private source).

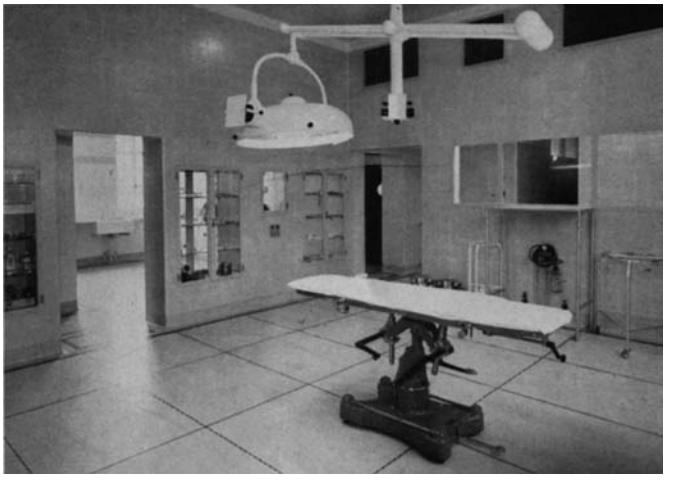

Figure 4a.5 The operating theater at the Neurosurgical Unit at the Maudsley Hospital as shown in the brochure produced at its opening in 1951.

Murray Falconer's other advantage was his proclivity for travel, and his ability to form and maintain a wide network of friends in neurosurgery and epileptology, especially in the USA and Canada. Many of these welcomed him in their departments and also visited the unit at the Maudsley Hospital as witnessed by the signatures in the theater's visitor's book. As a result of this he kept abreast of thinking in epileptology and epilepsy surgery and was able to evaluate developments. At an early stage in performing these operations he realized that if the role of pathology in epilepsy surgery was to be properly evaluated it was necessary to obtain appropriate tissue samples. As a result of this he modified the technique of temporal lobe resection so as to include the mesial structures, the hippocampus, and amygdala, within the specimen delivered to the pathology laboratory. Encouraged by Corsellis's work on mesial temporal sclerosis,[27] and confident that the specimens would be appropriately examined, he began to use him, ably assisted by Clive Bruton, at Runwell Hospital in Essex to do the neuropathology. They began to observe that the lesion of mesial temporal sclerosis was found in about half of the specimens submitted for examination and that this was often, but not invariably, connected with certain events in the patients previous history, notably atypical, prolonged febrile convulsions. He also had close informal links with the Park Hospital at Oxford where Ounsted had carried out his work on the origins and developmental consequences of temporal lobe epilepsy in children. When, at a later date together with David Taylor, they also described the lesion of focal cortical dysplasia, the group began to focus on the events in childhood which might determine subsequent chronic drug-resistant epilepsy. There had also been significant publications, involving David Taylor over many years, of the intellectual, developmental, and psychiatric consequences of epilepsy. Latterly David Taylor was appointed to the Park Hospital in Oxford. Therefore, towards the end of his career, Murray Falconer began to ponder the possibility that surgical treatment of epilepsy in childhood would result in less education and social damage.

In 1968 Northfield, the only other significant operator in the field, described the use of subdural and depth electrodes in the investigation of epilepsy at the London Hospital since 1952.[28] His final series of temporal lobe operations seems to have numbered 58, as quoted in his book, *The Surgery of the Central Nervous System*.[29] In 1958, in the Proceedings of the Royal Society of Medicine, there is an account of papers read at the meeting of the Section of Neurology. The first, by Mr Northfield, explores the notion of the epileptic focus and recounts the difficulties in obtaining appropriate neurophysiological data. There is an account of the 30 cases operated at the Royal London Hospital with results with regard to seizure control and quality of life. There is no account of the pathology from the specimens except to say that tumors have been excluded.[30] The next paper, given by the psychiatrist Denis Hill, describes the selection procedures applied to patients with epilepsy presenting at his psychiatric clinic at the Maudsley Hospital and the results from those who were treated by temporal lobectomy by Murray Falconer. The pathology in the specimens is described and its influence on the outcome is also recounted.[31] In the third paper Murray Falconer describes his experience of 50 patients with adequate follow-up of two to seven years. The rationale and advantages of the *en bloc* removal are explained and the results of pathological examination of the specimens are detailed.[32] Thus at the beginning of the 1970s the major center for epilepsy surgery in the UK was the Maudsley Hospital with the majority of the investigations and all of the surgery being carried out within the neurosurgical unit. The unit, with three consultants, also served as a general training unit in neurosurgery but it is remarkable that few of the trainees, who inevitably worked in their senior placements with Murray Falconer, subsequently set up epilepsy surgery program. In fact only two surgeons successfully continued to practise epilepsy surgery after Murray Falconer's retirement in 1975. Charles Polkey continued the program at the Maudsley Hospital and Chris Adams set up a service at Oxford initially working with the patients from the Park Hospital who had previously been referred to Murray Falconer at the Maudsley.

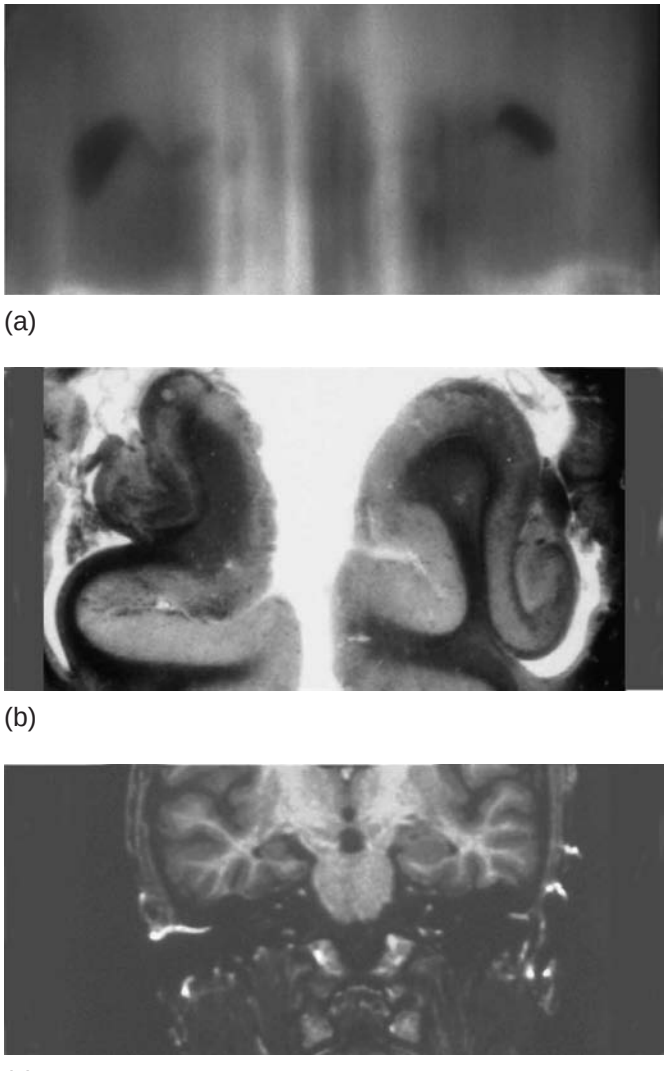

Figure 4a.6 Comparison between the radiological and pathological appearances of MTS. (a) Air encephalogram from 1978 showing dilated temporal horn. (b) Brain cut from Murray Falconer's slide collection comparing sclerosed and normal hippocampus supplied to him by Prof. N. Corsellis in the 1950s. (c) MRI scan showing the same pathology.

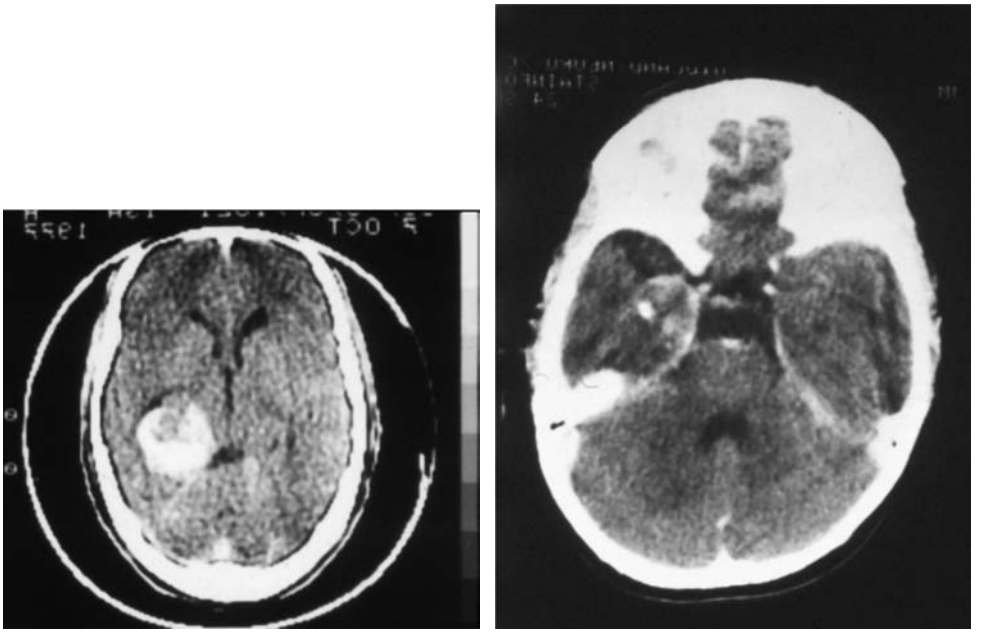
The influence of direct brain imaging

In the mid-1970s, because of the difficulty of structural diagnosis using indirect brain imaging, by which is meant air studies and cerebral angiography, and reliance upon neurophysiological studies of varying complexity, it seemed that epilepsy surgery would remain restricted to a few specialized units. However the invention first of CT scanning, and subsequently of MRI, both incidentally British inventions, changed the situation beyond recognition. (Figures 4a.6 and 4a.7) It had long been recognized, both in the UK and America, that due to processes such as secondary epileptogenesis, solitary lesions could give rise to bilateral EEG changes as reported by Falconer and Cavanagh.[33] This methodology enabled the diagnosis of structural lesions causing long-standing epilepsy to be made in any reasonably equipped neuroscience center. The hit rate was approximately 70% of patients having a structural lesion with CT and 95% with MRI, not all being operable. The second consequence was that patients and their relatives were now aware that in many cases epilepsy was secondary to a structural lesion and were asking about the possibilities of surgical treatment which was itself now regarded as safer than previously. Finally there was a greater awareness in general of epilepsy which must be credited to some degree to the influence of Dr. E.H. Reynolds and his pupils many of whom worked with him on his research projects at the Maudsley Hospital in the early 1970s. They subsequently completed their training and became consultant neurologists, working, as is the custom in the UK, as general neurologists with a special interest in epilepsy. This group would include Prof. David Chadwick in Liverpool, Prof. Simon Shorvon at the National Hospital and Dr. Robert Elwes at the Maudsley Hospital. By their influence they set up units which inevitably spawned surgical teams as part of their research and treatment options. Compared with the 1950s it was now clear the epilepsy surgery needed to be organized into multidisciplinary groups which are now known as epilepsy surgery programs. A number of disciplines were essential to these groups and included neuroradiologists, neuropathologists, neurophysiologists and neuropsychologists. There was



(a) (b)

Figure 4a.7 Two early CT scans taken in 1977 showing: (a) a posterior temporal tumor; (b) a temporal tumor. The technical limitations of the early scans can be seen.

little difficulty in recruiting neuroradiologists since most of the programs were attached to neurosciences centers and the same could be said of neuropathologists, although both of these disciplines were to some extent in short supply for other reasons. However, good neurophysiologists were more difficult to find and interest in these programs. In the case of the Denmark Hill site they were fortunate in attracting Prof. Colin Binnie to return to the UK and he soon established intracranial recording and videotelemetry on that site. When he moved to Queen Square the late David Marsden recognized epilepsy as a growing area of research interest and arranged for Dr. David Fish to spend a year at the Montreal Neurological Institute to study the neurophysiology of epilepsy. Dr. Fish then returned to the National Hospital where he organized telemetry services necessary to run an epilepsy surgery program. This program initially referred patients to the Maudsley Hospital for surgery and received some informal advice on aspects of electrocorticography. However the intention was clearly to develop an independent service and in early 1991 Mr. William Harkness was given a joint appointment between Queen Square and the adjacent Hospital for Sick Children (GOS) again to have a special interest in epilepsy surgery. At the time of taking up this appointment he spent six months as a fellow in UCLA. The development of pediatric epilepsy services followed a similar route. Murray Falconer had formed a link with an 'epileptic colony' for children, St Piers, at Lingfield in Sussex. This link with the Maudsley program continued for many years after his retirement. Referrals from GOS began to come to the Maudsley program after Murray's retirement. Again however it was clear that the Hospital for Sick children would want to set up an independent program. In 1989, Prof. Brian Neville was appointed Professor of Pediatric Neurology there and with Dr. Helen Cross a large program of assessment of children was established. Interestingly, David Taylor, who originally worked with Murray Falconer, joined this team producing the concept of a 'contract' for surgical treatment between the surgical team and the patient and their parents.[34] The link from Lingfield to the Maudsley was then broken with the establishment of the National Center for Young People with Epilepsy (NCYPE), which effectively linked it with GOS. This paralleled the adult situation where the 'epileptic colony' at Chalfont in Buckinghamshire, north of London had been used by the National Hospital as an assessment and long-term treatment center. In addition a charity was set up, the National Society for Epilepsy (NSE), which very successfully gathered funds which were used to buy diagnostic and research equipment. By this means the nucleus of what has become, quite rightly, a large and influential group, expert in the imaging of epilepsy, has emerged. The other problem was the development of neuropsychological services. The neuropsychological service at the Maudsley was continued by Dr. Graham Powell and is now organized by Prof. Robin Morris. Good services with research interests were established by Dr. Pamela Thompson at the National, Prof. Varga-Khardem at GOS, Dr. Susan Oxbury at Oxford, and Dr. Gus Baker in Liverpool.

As well as the London units major working units in epilepsy surgery are now active in Birmingham, Cardiff, Liverpool, Newcastle, and Oxford. In Oxford the supervising neurologist was Dr. John Oxbury, in Liverpool Prof. David Chadwick organized a service with Paul Eldridge as the surgeon. In Birmingham the service was organized by Dr. Tim Betts and the surgery is performed by Mr. Richard Walshe, appointed in 1991, and trained in Seattle by Prof. George Ojemann. In Cardiff Mr. R. Weeks had performed some epilepsy surgery for many years and the service was taken over by Mr. Richard Hatfield who received his general neurosurgical training in Cambridge but after appointment in Cardiff was seconded to the Maudsley for training. In Newcastle the surgery is performed by Mr. David Jenkins. There have been attempts to set up a service in Scotland currently supervised

by Dr. Rod Duncan and some surgery also in Edinburgh. There is an epilepsy surgery service in Eire, set up by Hugh Staunton and currently run by Prof. Jack Phillips, but this is dealt with in a separate chapter. The group at Queen Square asserts, probably correctly, that they now have the largest epilepsy surgery program in the UK and this is almost certainly true if they are considered together with GOS.

Technical advances in the last decade have also to be considered. The most important is probably the refinement in MRI, especially the development of the FLAIR sequence and of fMRI; the latter, especially when co-registered with the structural MRI, is useful in terms of speech determination and primary motor mapping. Such facilities are available both as a clinical and research resource in the larger centers.

The introduction in the operating theater, towards the end of the 1990s, of frameless stereotaxy, which is a general neurosurgical tool, enables the surgeon to reach the resection target or place intracranial electrodes accurately. Neuromodulation as a means of controlling epilepsy has been seen mainly in terms of vagus nerve stimulation. The first system was inserted at the Maudsley Hospital in 1995 and they are now used to varying degrees across the UK. Their deployment depends to some extent on the attitude of financial providers.

There have been a number of other influences on the development of epilepsy surgery during this 25-year period. Presentations about epilepsy surgery at the meetings of the Society of British Neurological Surgeons have increased and diversified but attempts to set up a special interest group have net with no success. In the last five years a British functional neurosurgery group has been set up, mainly concerned with the stereotactic treatment of movement disorder, but including epilepsy surgery. At the first Palm Desert symposium in 1986 there were only seven contributors from the UK, by the second Palm desert symposium in 1992 there were nine. With the setting up of epilepsy programs at the National Hospital and GOS the influence of North American views increased and for some 10 to 15 years there was an increased attendance and contribution from the UK at meetings of the American Epilepsy Society (AES). The main reason for this was because this was the only annual meeting available which had a high standard of basic research and clinical research content. Until recently the influence of our continental neighbors was minimal, there were a number of reasons for this. Epilepsy surgery had been a minority interest on the continent and had mainly developed under the influence of the French School of Talairach and Bancaud. There was both a language barrier, and probably more important, a conceptual barrier with their emphasis on neurophysiological findings especially SEEG, and stereotactic methodology being at odds with the British ideas regarding pathology and epilepsy. Until the late 1990s the training body responsible for neurosurgery in the UK did not think that trainees needed to learn stereotactic methodology. However, as direct imaging became more important the two viewpoints have merged, mainly due to the influence of the late Claudio Munari. There is now a well-organized European meeting on epilepsy every year, whose standard in recent years has approached that of the AES.

The development of pediatric neurosurgery has also influenced epilepsy surgery in the UK. Over the last decade or so pediatric surgery has become more regulated so that consultants must now have at least one year as a pediatric fellow in a recognized department before practising independently. In addition departments which practice this speciality must have a minimal number of pediatric procedures per year and appropriate personnel and facilities for dealing with this age group. These are sensible and much needed changes, but in effect make it difficult to practice pediatric epilepsy surgery outside of a department of pediatric neurosurgery.

The various reorganizations of the NHS in the UK have also played their part. This should be seen against the following background. The Department of Health has taken the view that certain specialized services could be set up in a few centers because they were sufficiently arcane for it to be unreasonable for a local hospital to provide that service. They have always insisted that epilepsy was a common disease whose diagnosis and treatment had to remain at a local level. When hospitals were organized into trusts it was realized that not all trusts could supply all services and therefore a mechanism, extracontractual referrals, was devised whereby a trust providing specialist treatment could reclaim the money from the referring trust, usually the patient's geographical hospital. The income from this kind of activity allowed a sort of expansion of the service which was as it were, self-sustaining. However, another reform handed financial control to local primary care trusts whose function was to contract with local services to treat any particular diagnostic group at the lowest possible cost. This made it more difficult to refer patients away from the local services for two reasons. The first was that understanding of the diagnostic and treatment options involved in epilepsy surgery were less at that level so more time and effort was involved in obtaining finance to treat the patient, and the second was that local services were pressed to treat these patients with the available facilities. This led to attempts at epilepsy surgery being made and then not sustained.

In 1991 the British branch of the International League Against Epilepsy (ILAE) commissioned a report, prepared after a workshop attended by the interested parties, into the surgical treatment of epilepsy.[35] There were 25 attendees of whom four were invited foreign speakers. The remaining 21 participants included only four neurosurgeons and the whole group represented only nine centers. Only four centers performed any particular operation more than five times and the number of operations performed in that year were 10, 13, 18 and 51. A similar exercise was repeated in 2003 and reported by Lhatoo *et al.*[36] The results of the two exercises are summarized in Table 4a.1.

These figures indicate that there has been an increase in the number of surgeons performing these operations over a decade or so although according to the authors this level of work just keeps pace with the new cases leaving a considerable backlog.

Summary

The progress of epilepsy surgery in the UK has been reviewed from its early beginning in 1870 to the most recent developments in the first decades of the 21st century. As might be expected progress has been determined in large part by changes in other fields. The general improvements in surgical and neurosurgical technique have fuelled advances and this was particularly evident towards the end of the 19th century. Improvements in safety made surgery feasible and the weakness of drug treatment made it necessary. The stasis and lack of interest in the early decades of the 20th century are hard to

Table 4a.1 Comparison of the results of two surveys of epilepsy surgery practice in the UK conducted in 1991 and 2003[35,36]

	1991	2003
Number of surgeons responding	58 (50.4%)	110 (76%)
Number of surgeons performing epilepsy surgery	23 (22%)	32 (22%)
Number of operations per year	150	422
Commonest operations		
Temporal lobe resection	Yes	318 (76%)
Extratemporal lesional resections	Not known	58 (14%)
Vagus nerve stimulators	Not applicable	156

explain, especially as considerable progress was being made elsewhere, for example in Europe and North America. Whereas the concepts which led to advances in the latter part of the 19th century were common to America, Europe, and the UK by the middle of the 20th century there was a clear divergence of philosophy between the functional and neurophysiological emphasis in Europe and America on the one hand and the pathological emphasis in the UK, although the practitioners in all three areas shared common interests in seizure semiology and cerebral localization. The explosion of direct brain imaging, especially MRI, directed attention momentarily towards the structural lesions although by the end of the 1990s groups in the UK, as elsewhere, were beginning to address the problem of MRI negative, focal epilepsy. Neuromodulation, almost exclusively in the form of vagus nerve stimulation, appeared in the mid-1990s and so far has been restricted to centers with epilepsy surgery programs. The peculiarly British methodology of disorganized organization has resulted in centers with varying strengths and workloads which are treating a significant number of patients but still with a probable reservoir of untreated patients.

4b Epilepsy surgery in Ireland

P Widdess-Walsh, N Delanty, and JP Phillips

Introduction

The Republic of Ireland has a population of almost four million people, of whom up to 40,000 have epilepsy. Given that approximately 30% of patients will be refractory to medication, and half of these may be surgical candidates, there may be three to four thousand patients who might benefit from epilepsy surgery in Ireland.

Ireland's health system is based on a socialized medicine model, with public hospitals operated by the Irish Department of Health and Children. The total number of public neurology consultant physicians in Ireland is sixteen, one per 244,000 of the population, of whom three have a special interest in epilepsy. Politicized control of resources and manpower has made the development of the Irish Epilepsy Surgery Program challenging. The Irish history of epilepsy surgery demonstrates the achievement of a world-class surgical epilepsy program despite limited resources.

Irish neurosurgery: early origins

One of the earliest accounts of a 'surgical' treatment for epilepsy in Ireland, came from Dr. M. Tuohy of Dublin in 1810:[1]

> Where in consequence of the long continuance of the complaint, and of the violence and frequency of the convulsions, we have reason to fear effusion on the brain might ensue, it will be proper to shave the whole of the head, to cover it with a large blister, which must be left on perhaps for sixteen hours, certainly until a vesication takes place, and to keep up a discharge from it with savin ointment or vesicating ointment until all danger disappears

The origins of *modern* surgery in Ireland ran parallel with the UK, with Mr. John MacDonnell performing the first operation under anesthesia in Ireland at the Richmond Surgical Hospital on New Year's day 1847, 11 days after Lord Lister first used operative ether in London. Neurosurgery was pioneered in Ireland by Professor Adams McConnell in the Richmond Surgical Hospital from 1911. McConnell achieved considerable international reputation in vascular and traumatic neurosurgery, and was one of only a handful of neurosurgeons operating in the UK and Ireland at that time. No accounts exist of primary surgical resections for epilepsy during that time, despite documents showing correspondence between Professor McConnell and Olfrid Föerster on a number of other matters.[2–4]

The Richmond surgical hospital

The Richmond surgical hospital (Figure 4b.1) is intimately connected with Irish Neurosurgery and Epilepsy. The hospital was opened with 129 beds in a former nunnery on 4 June 1811, and was named after the Duke of Richmond, viceroy to Ireland (1807–1813) during the English occupation. The hospital served to provide surgical care to the House of Industry, a workhouse established by the government of the time for the 'relief and employment of unfortunates, deserted infants and children'. The hospital counted as honorary staff, physicians, and surgeons such as Robert Adams, Richard Carmichael, John Cheyne, and Sir Dominic Corrigan.[5] Neurosurgery in Ireland, and eventually epilepsy surgery evolved here until the closure of the hospital and transfer of neurological and neurosurgical services to Beaumont Hospital, Dublin, in 1987.[6,7]

Dublin neurology in the first half of the century

Frank Purser was the first neurologist at the Richmond, until the appointment of Harry Lee Parker in 1934. Harry Lee Parker was a senior staff physician at the Richmond Hospital and Professor of Neurology at Trinity College Dublin between 1934 and 1946, whereupon he returned to the Mayo Clinic to become chair of the Department of Neurology. While in the United States in the early 1930s he published a large series of intracerebral tumor related seizures. He documented cases where the surgical removal of tumors had a beneficial effect on the epilepsy. In one case description, a patient with complex partial and nocturnal convulsive seizures had a 9 cm meningioma removed from the left falx cerebri. There were no postoperative seizures. However, the patient died 11 days after the operation from septic meningitis.[8]

In later publications based on his time in Dublin, he reported a good surgical outcome of a patient with complex partial seizures and a right temporal lobe glioma: 'whatever convulsive attacks he had after surgery can be controlled by drugs'. Prior to the surgery he commented:

> should the tumor be intracerebral, this patient should have a resection of part or all of his right temporal lobe, with the tumor cleanly removed in the center. It is some consolation that the right temporal lobe is the one involved: the left is not so amenable to surgery because of the speechlessness which operation would be certain to cause in a right-handed man.

Figure 4b.1 The Richmond surgical hospital, Dublin, in 1811.

In another 56 year old patient with visual auras, convulsive seizures, and a left temporal 'abnormal focus' on EEG, he states 'direct surgical exploration of the brain in a patient of this age would be unwise, since even if a tumor is present, it is on the dominant side, and removal would be likely followed by hemiplegia and aphasia'.

Based on his work in Dublin, Dr. Parker made many insightful comments on surgical epilepsy, including the existence of drug resistance in epilepsy, Ammon's horn sclerosis, and non-lesional epilepsy; 'some patients under medication do well, but so often the drug used loses its power and attacks start up again', and 'psychomotor seizures ... produce an EEG that is different from that obtained in other forms of epilepsy, and the other safe drugs (*referring to phenobarbital and hydantoins*) do not control these fits'. He recognized at the time the importance of the Spielmeyer's pathological description of Ammon's horn sclerosis; 'pathologists are coming back to that in finding scars in that region'. He realized that many cases of 'idiopathic epilepsy' would become clear in time: 'with modern method of air encephalograms, arteriograms, and electro-encephalography, more and more of the so-called primary and idiopathic epilepsies are being explained and treated scientifically', and 'even after all causes apparently have been excluded, we grudgingly assume that this exclusion is only temporary, and that the final cause is unknown because of a lack of evidence to date'.[9]

The origin of the epilepsy surgery program

After Harry Lee Parker's departure, Neurological services were provided by Brendan McEntee, a self-professed general physician with an interest in neurology (E. Martin, personal communication). The Department of Neurosurgery was pre-eminent in this era, at least until the appointment of Hugh Staunton (Figure 4b.2), the driving force behind Irish epilepsy surgery, as consultant neurologist to the Richmond Hospital in 1971.

The building stones that were in place at the time were Mr. Patrick (Paddy) Carey, consultant neurosurgeon and the EEG services provided by Dr. John (Joe) Kirker. Paddy Carey was appointed in 1957, and performed the first temporal lobectomy in Ireland in 1975. Mr. Carey trained at the Karolinska Institute in Stockholm under Lars Leksell and in Zurich under M. Gazi Yasargil. One temporal lobectomy was performed by Mr. Carey's colleague, Mr. John Lanigan. Mr. Carey retired in 1987, and epilepsy surgeries were continued by Professor Jack Phillips until his retirement in 2006, and currently performed by Mr. Donncha O'Brien.

Figure 4b.2 Dr. Hugh Staunton (1937–).

Dr. Clem Dempsey introduced the first EEG machine to Ireland in the early 1950s (a four-channel Marconi machine), although shortly thereafter diverted to practise family medicine. Dr. John Kirker graduated from Trinity College Dublin, and was a medical student on Harry Lee Parkers rounds. After training with Lennox in Boston, he returned in 1953 to develop Irish electroencephalography.

Hugh Staunton's clinical training was at the National Hospital for Neurology and Neurosurgery at Queen Square, London, and he performed research at the Max Planck Institute for Brain Research, Frankfurt on Main, Germany, based on recruiting responses during direct electrical stimulation of the feline cerebral cortex. Following the reported successes of Bailey and Penfield in performing temporal lobectomy for TLE, the need for temporal lobe epilepsy surgery in Ireland was clearly apparent.[10,11] The first patient was a publican's son from County Louth, who is still working and driving a car today. Initial procedures were based on the Murray Falconer technique,[12] using suction to take 5–7 cm (5 cm in the case of the dominant hemisphere) of the anterior temporal lobe and mesial structures.[13]

Early protocols

The pre-surgical evaluation of the time was based on clinical semiology, interictal EEG, and a bilateral Wada test. Methohexitol-induced epileptiform activity on the interictal sphenoidal EEG, under the supervision of anesthesiology, was used as a supplement to the EEG evaluation, with good success.[14] Wada testing was performed initially by Dr. Staunton personally before the development of neuropsychology services at the hospital in the mid-1980s, as the importance of

pre- and post-operative neuropsychological testing was increasingly recognized. Top psychology graduates from University College Dublin trained and work as clinical epilepsy neuropsychologists. Among them, Teresa Burke and Deirdre McMackin received additional specialist training from Brenda Milner and Laughlin B. Taylor, at the Montreal Neurological Institute (MNI). After further post-doctoral training with Marilyn Jones-Gotman at the MNI in the early 1990s, Deirdre McMackin, went on to develop a comprehensive and mature Neuropsychology Department at Beaumont Hospital, which is now headed by Niall Pender. Computed tomography was not introduced until 1978, and Ireland's first video-EEG telemetry unit opened in 1988. Results demonstrate that despite limited resources of the day, a conservative surgical approach could provide an effective surgical relief of intractable epilepsy.[15] By 1988 over 70 cases had been performed with minimal morbidity, reported at 4%, and no mortality. One early case was associated with a postoperative hemiparesis, presumed to be due to a middle cerebral artery perforator injury before such complications were fully recognized. Postoperative psychiatric outcome was disappointing in some cases; over the course of the epilepsy surgery program 3-4 patients committed suicide in the months after surgery (H. Staunton, personal communication). If epilepsy surgery was performed before the age of 20 years, psychosocial and vocational outcomes were improved.[15] Follow-up was remarkable, and essentially 100%, as Ireland is a uniquely homogenous population served by one epilepsy surgery center.

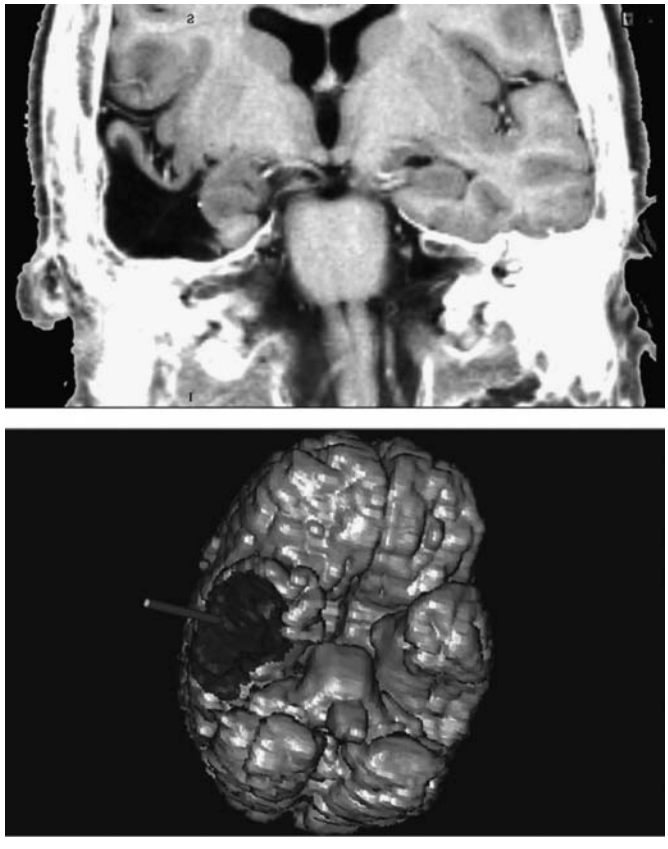

Figure 4b.3 Postoperative coronal T1-weighted MRI with 3D reconstruction demonstrates the extent of resection following a right temporal neocorticectomy.

Neocorticectomy for temporal lobe epilepsy

No formal neuropathologist was employed during the early days of the program, (being between the appointments of Dr. Paddy Bofin and Dr. Michael Farrell), the interim pathologist noted that there was no hippocampal tissue in the pathological sections. Hence, it was presumed that the operation was a temporal neocorticectomy without removal of the mesial structures. The patients undergoing neocorticectomy seemed to do well in terms of seizure freedom and memory outcomes so the procedure was continued in a more formal manner, under the pathophysiological assumption that disconnection of the neocortex from the mesial structures would limit the spread of clinical seizures, remove any cortical generators of epileptiform activity, and leave any hippocampal discharges confined to the hippocampus. Also, given the risk of memory impairment with removal of mesial structures and given the limited resources for pre-surgical localization,[16,17] a conservative approach such as neocorticectomy was favored from the late 1970s to approximately 1992, when the surgical outcomes for standard anterior temporal lobectomies[18] or selective amygdalohippocampectomies[19] were more established, and better services for pre-operative work-up were available. The surgical technique for neocorticectomy was described as (Figure 4b.3):[20]

> the area of resection extends posteriorly to a distance of 4.5–6 cm from the anterior temporal tip. The area of resection takes in the lower half of the superior temporal gyrus along with the middle and lower temporal gyri. The resection extends vertically down to the temporal horn, which is opened. The resection is continued, angulated anteroinferiorly, resulting in an *en bloc* removal. The amygdala and anterior hippocampus are exposed but not resected.

The outcomes for the neocorticectomy group have been published in detail,[15] and have been compared favorably as a group with selective hippocampectomies from Zurich, and anterior temporal lobectomies from Montreal.[21] Perhaps surprisingly, the memory deficits (at least on a range of non-spatial tasks) were similar in each group, which was seen as support for the temporal lobe disconnection theory. In another analysis of the Dublin group, only mild material specific memory deficits were seen after neocorticectomy, supporting the view at the time that neocorticectomy was safer in terms of postoperative memory dysfunction.[22–24] Later results questioned that assumption, at least to some extent, as postoperative MRI analysis of Dublin cases evaluated in the Jones–Gotman study showed that of 24 patients nominally undergoing neocorticecomy, there was some encroachment on mesial structures in 18 cases.

The most common procedure performed since the early 1990s has been a selective hippocampectomy preserving the amygdala and temporal neocortex, with outcomes similar to other series in the Western world (J. Phillips, personal communication).

Building on the foundation

The Richmond Institute of Neurology and Neurosurgery and its fund-raising partner, the Irish Brain Research Foundation (IBRF) were formed by Hugh Staunton, James Toland, and Jack Phillips in 1984 with the objectives of the promotion of postgraduate teaching and research in the neurological sciences, and continues today in the form of the Irish Institute of Clinical Neuroscience.

Funding for a formal epilepsy surgery program was obtained in 1987, after the publication of a report initiated by Dr. Staunton on the potential role of epilepsy surgery in Ireland. The positions of neuropsychologist, physicist, computer programmer, epilepsy nurse, psychiatrist and a research fellow were funded by private or charitable funds via the IBRF/Brain Research for a period of five years. The IBRF and the Department of Health entered into negotiations and the Department for Epilepsy Surgery was established in Beaumont Hospital in 1994. The Irish Department of Health took over the above salaries, and awarded a further grant of $209,000 per year, which was used for capital expenses.

A multidisciplinary approach was emphasized once the program had been established. Dr. Michael Farrell received epilepsy neuropathology training at UCLA with Dr. Harry Vinters. Epilepsy psychiatric evaluations were performed by Professor David Taylor, on a monthly consulting basis from the UK. The video-EEG telemetry unit operated from 1988, with a dedicated telemetry nurse and EEG technicians. Further training and mentorship was obtained by both Hugh Staunton and Jack Phillips. Hugh Staunton met with Peter Crandall at UCLA, and Theodore Rasmussen, Andre Olivier, and Frederick Andermann at Montreal. Jack Phillips undertook a traveling fellowship in 1994 to Montreal (Dr. Andre Olivier), Cleveland (Dr. Yousef Comair), and Seattle (Dr. George Ojeman and Dr. Alan Wyler).

Research

A multifaceted clinical and basic science program played an important role in the development of the Epilepsy Surgery Department, and was critical for maintaining its academic and scientific integrity. Early research focused on *neuropsychology* and *outcomes after epilepsy surgery.*[15,24,25] Eleanor Maguire and Teresa Burke described a novel method of evaluating topographical disorientation by using first-person video of a route in the Irish town of Blackrock and demonstrated abnormalities in both right and left temporal lobectomy patients (excisions typically involved encroachment on mesial structures), despite in some cases, normal standard neuropsychological testing.[26,27] After completing her PhD studies, Dr. Maguire went on to develop this work at The Wellcome Departments of Cognitive Neurology and Imaging Neuroscience, Queen Square, London, where she continues to employ ecologically valid or 'real life' paradigms to explore the role of left and right hippocampi in navigation and episodic memory.

The addition of a physicist, Mary Fitzsimons, facilitated research in neuroimaging, and continues in collaboration with Dr. Colin Doherty'.[27–29] *Basic science* research has contributed understanding to the pathology and biometabolism of temporal lobe epilepsy; Jack Phillips and his research colleagues in the Department of Neurosurgery have successfully performed intra operative microdialysis on patients undergoing temporal lobectomy. Elevated extra cellular levels of glutamate, aspartate, and gamma and aminoliulyric acid were detected in the spontaneously epileptiform hippocampus during the operative procedures.[30–32] An extensive *pregnancy* registry has been established. Genetic and surgical specimen sample banks for substantial numbers of patients will provide fruitful data for current projects including the promising field of *pharmacogenomics.*[33,34] The epilepsy pharmacogenomics project now has over one thousand samples collected.

Other surgeries

Vagus nerve stimulators have been placed in almost 90 patients. Corpus callosotomies for intractable generalized seizures have been performed since the early 1980s. In a series of twenty patients, 80% had a beneficial effect from callosotomy.[36] Subdural contact strips on the inferior and lateral surface of the temporal, or on the mesial and lateral frontal surface have been inserted through burr holes for intracranial EEG recordings. Intra-operative electrocorticography and microdialysis recordings have contributed to the clinical and research programs.[31] Functional hemispherectomies have been performed in three patients. Hemispheric devascularization by embolization of the anterior and middle cerebral arteries was performed in two children with a major reduction of seizure frequency in one patient, the other patient eventually requiring a functional hemispherectomy.[37]

Conclusion

The program initially played to its relative strengths: interictal EEG, neuropsychology, clinical assessment, and highly skilled individuals who sought out the best training and experience available, which, in a setting of lack of funding and resources, was still able to produce a successful surgical program, with one of the highest surgical volumes in the UK and Ireland, and with outcomes similar to other major groups.[21] In the current era, the Irish Epilepsy Surgery Program has embraced and incorporated advances in the field, including MRI technology, ictal SPECT, and pharmacogenomics.

Acknowledgments

We acknowledge the assistance of Dr. Hugh Staunton, Dr. Edward Martin, Dr. Teresa Burke, Dr. Christopher Mascott, and Dr. John Kirker in the preparation of this manuscript.

5 Epilepsy surgery in Germany

A Ebner, H Stefan, B Pohlmann-Eden, and PA Winkler

Introduction

The challenge of writing a historical overview of epilepsy surgery in Germany is honorable but also difficult because of the tremendous and radical political changes caused by the takeover of the fascist regime and World War II. Therefore we subdivide the history of epilepsy surgery in Germany into the period between the first attempts in epilepsy surgery and the year 1933, which meant a radical incision sending epilepsy surgery from a promising start in Berlin and Breslau into a state of hibernation, that lasted for almost thirty years. Awaking from this hibernation was slow, first diffident attempts in epilepsy research were made in the 1960s, but it took another fifty years for a serious and wide application of epilepsy surgery.

Nowadays, epilepsy surgery plays an important role in the armamentarium of modern medicine to treat devastating disease. Despite the economic restrictions medicine today is subject to, epilepsy surgery is still developing and promotable. This is due to the fact that the economic effects of epilepsy apply the lesser, the earlier epilepsy is under control. Still the fastest and least expensive way to control medically intractable epilepsy in many cases is epilepsy surgery, causing the steadily growing establishment of centers all across Germany, providing presurgical evaluation and surgical procedures for epilepsy patients within a fairly acceptable (and continuously improving) time-span for the individual patient.

History of epilepsy surgery in Germany before 1933

Over the centuries well-meaning approaches entering the cranial vault and a variety of other surgical procedures were carried out in an effort to treat epileptic seizures. In the modern history of epilepsy surgery good examples of complementary relationships between medical experimentation and praxis were stated, as enlisted hereby in chronological order.

For instance Wilhelm Griesinger[1] (Figure 5.1) carefully noted ictal symptoms and correlated them with the anatomic location of cerebral lesions identified post mortem. He was active in Tübingen and Zürich (Burghoelzli). On 1 May, 1866 he opened and headed the first autonomous Department of Neurology at the University of Berlin-Charité; in 1868/1869 he proposed the terms 'psychomotor' and 'epileptoid status'. Griesinger therefore provided a first basis for using the clinical features of an epileptic seizure to predict the precise localization of the pathologic substrate.

Gustav Theodor Fritsch and Eduard Hitzig[2] in 1870 published the results of their eminently important work even by today's standard by mapping the canine motor cortex using faradic stimulation – the same method we use nowadays to determine the function of the cortical areas and to narrow down on the epileptic focus.

Another success in 'narrowing down' on epileptogenic structures was proved by Karl Wilhelm Sommer[3] at the Wehlau-Institute in Eastern Prussia with his description of changes on the ammon's horn in the later called Sommer's Sector in 1880. Sommer noted that the CA1-Segment (Cornu Ammonis field 1) appears susceptible to anoxia particularly in epilepsy and ischemia.

Emil Bratz,[4] psychiatrist and director of the asylum Dalldorf, underlined Sommer's term ammon's horn sclerosis and forged in 1907 the term 'Affektepilepsie', affective epilepsy for eventual convulsions, triggered by fever convulsions and abuse of alcohol.

Otto Binswanger[5] was Director of the Department of Neurology and Psychiatry at the University of Jena and chairman of Hans Berger, the inventor of the EEG. He created the term 'surgical enthusiasm' and referred to the recent advances in localization. His own contributions were critical and he stressed the importance of follow-up investigations exceeding six months. Furthermore he pointed out the possible role of secondary scars. He suggested restricting the indication of surgery to patients of reflex epilepsy and of traumatic Jacksonian seizures. Considering the social consequences he concluded that surgical interventions were only justified if the disease was socially disabling, and tended to produce *status epilepticus*. The mortality of these procedures at that time was rather high (5–7%).

A.S.F. Grünbaum, a german physiologist, emigrated to Liverpool. Together with C.S. Sherrington they did a mapping of a chimpanzee's cortex and drew the first accurate cortical map, thus doing the spadework for the later published cortical mapping on human brains by Krause (see below).

Due to the efforts by colleagues to avoid formation of scars resulting from operations Trendelenburg discussed instead of resection the alternative of 'undercutting' the focus, which was applied by Kirschner in the hope of reducing the risk of secondary epileptogenesis from surgical scar. According to Krause the contemporary authors overestimated this risk, an appreciation we today know to be wrong.

Fedor Krause[6–8] (Figure 5.2) dedicated much of his life's work to epilepsy surgery. He seems to have been the first who stimulated the human motor cortex (Figure 5.3). He reported the earliest stimulation in his book '*Chirurgie des Gehirns und Rückenmarks nach eigenen Erfahrungen*', published by Urban and Schwarzenberg in 1911.[6] The patient was a 15-year-old girl with

Figure 5.1 Wilhelm Griesinger 1817–1868, with permission from C.H. Beck-Verlag-München.[109]

Figure 5.2 Fedor Krause 1857–1937.

Jacksonian seizures and Jacksonian status starting at the age of three years and caused by a postencephalitic cyst following meningitis at the age of two years. After the removal of the postencephalitic cyst the patient was followed for 17 years, she became seizure-free and improved considerably in her cognitive performance. Krause preferred the technique of monopolar faradic stimulation and described it meticulously. He felt that monopolar faradic stimulation was less irritating of severe seizures than galvanic stimulation that was preferred by Foerster.[9]

He restricted his resections to the motor-strip, of which he could present a detailed functional map based on electrical stimulation (Figure 5.4).

He reported more restricted resections to avoid loss of motor functions, whereas Foerster according to Krause advocated at the same time more extensive resections to achieve more and better control over epileptic seizures. In 1932 Krause, together with his co-worker Schum published a 900-page book on epilepsy.[8] This work was part of a series of surgical monographs concerned with surgical procedures. Interestingly, interventions like lumbar puncture, pneumoencephalography, transcallosal puncture ('Balkenstich'), sympathectomy, ligation or carotid artery, digital massage, alcohol injection into the focus, application of local anesthetics, adrenotomy, transplantations of endocrinous tissue, and peripheral operations in reflex epilepsy are discussed. Apart from a few specially defined situations these are all dismissed by the authors. Krause and Schum were also very skeptical about procedures that aim at reduction of intracranial pressure in cases of 'genuine' epilepsy. They point out, that this procedure mentioned above is based on unsubstantiated theories. Krause and Schum leave no doubt that the only worthwhile epilepsy surgery is the excision of the 'primary convulsing center' ('primäres krampfendes Zentrum'). The success of surgery in their opinion did not depend on a short history of seizures. They did not want to restrict surgical therapy but considered it in all patients with a definite focus of the seizures, even if no visible pathology was found.

Krause had a lifelong interest in the surgical treatment of intractable focal or Jacksonian epilepsy, accumulating an outstanding experience over 400 cases by the end of his career. Contemporaries described him as a modest and likeable human being. After his retirement he lived in Rome, where he spent his last years and devoted himself to a consuming interest in music.

In his work from 1926, Otfried Foerster (Figure 5.4) from Breslau reported an unknown number of operations in the precentral area and 54 other cortical areas.[10] Foerster became more involved with the surgical procedures of other areas, because there were smaller risks of functional deficits, which allowed more effective surgical interventions. His writings show a more detailed interest in the semiology of seizures and its localizing significance. To understand the entire message of these writings we have to remember that they are based exclusively on anatomical landmarks, detailed analysis of clinical phenomena, and the results of cortical electric stimulation at a time when EEG and electrocorticography (ECOG) were not yet available.[11]

In 1930, an article by Foerster and Penfield discussed the role of scar traction in epilepsy surgery.[12–14] In this article surgical interventions at many sites of the cerebral surface were reported, and case No. 5 described in this article comes close

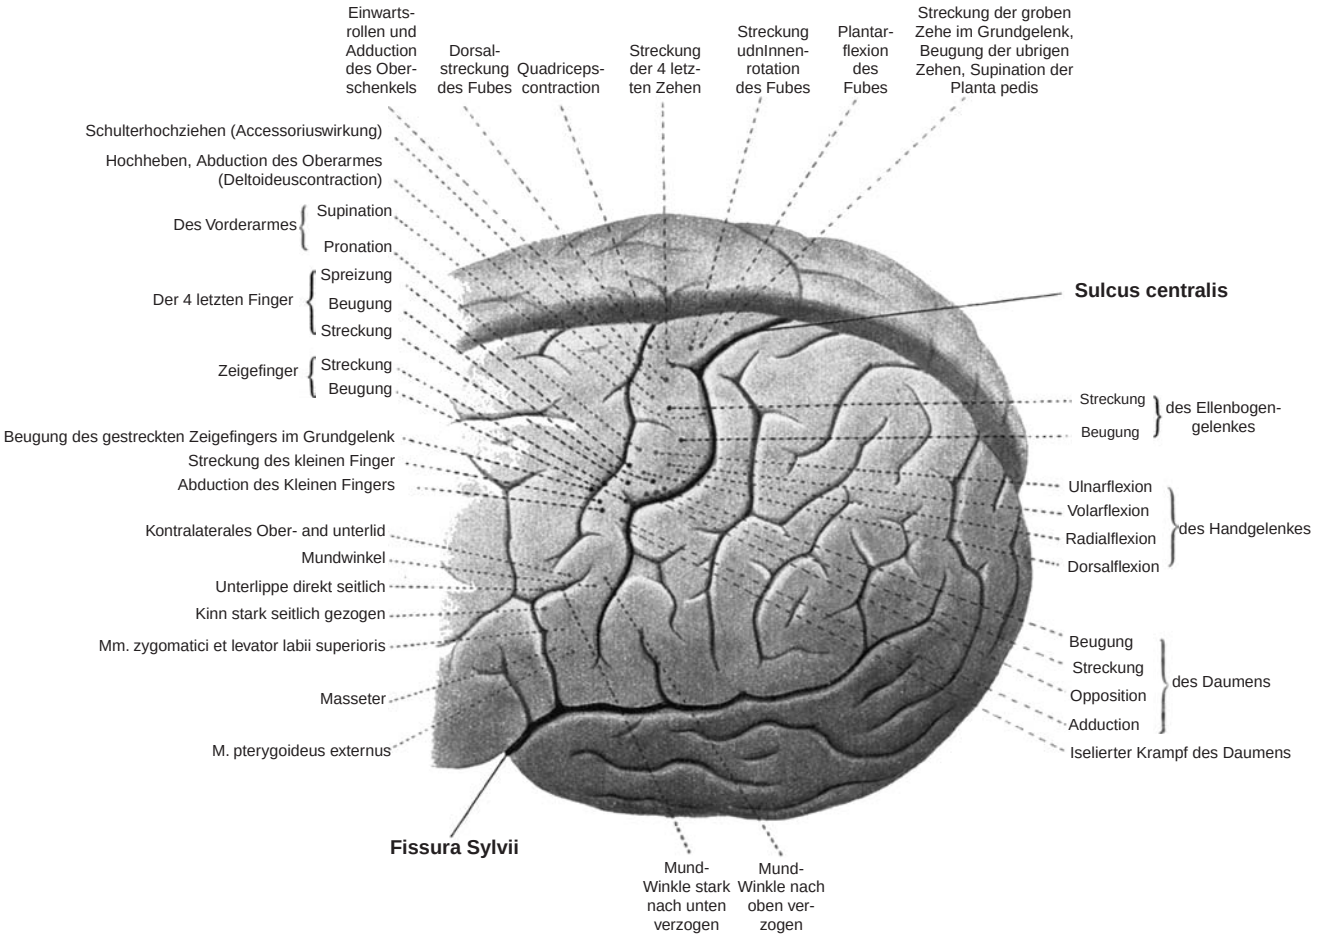

Figure 5.3 Krause's meticulous functional map of the motor cortex based on stimulation results from 142 operations.

to what today is considered a partial hemispherectomy. The article concludes with an account of Foerster's, Krause's, and Penfield's experiences with cortical stimulation in relation to Oskar Vogt's brain map. They concluded that the results of both approaches were convergent.

In the meantime Hans (Johannes) Berger in Jena followed Binswanger as Director of the Department of Neurology and Psychiatry at the University of Jena. In a 1929 publication he claims 6 July 1927 as the 'Day of the Invention' of the EEG, which he called 'Electroencephalogramm'.[15] Bergers publication referred only to the human cortex, the principle of the EEG had already been described in 1877 by the Liverpool physiologist Richard Caton in animal experiments. These results were known to Berger, as well as those published by the Polish physiologists N. Cybulsky and his pupil A. Beck and his Russian colleague V.V. Práwdicz-Neminski, who in 1925 published his 'Elektrocerebrogramm', as he called the photographic documentation of the electric activity of the brain. Ironically, Berger's findings, which are today's diagnostic basis of epileptic disorders, were for a long time not taken seriously especially in Germany. Berger was tolerated generally by his colleagues and especially by the acting chairman of the Department of Physiology of his own medical faculty. Contrary to his reception at home, in the UK and USA his invention was enthusiastically taken up and enhanced.

In recognition of his invention he was nominated for the Nobel Prize, but the Nazi regime pressurized him to renounce the acceptance of this honor. Furthermore it was suggested he retire early from his position as chairman by officials. Disappointed by the political developments in Germany he committed suicide on 1 June 1941.[16]

History of epilepsy surgery in Germany from 1933 to the 1980s

Cecile and Oskar Vogt were dismissed from office by the Nazi government in 1935 because of his protection of Jewish coworkers. Nevertheless by 1937 they had continued with their work in a privately funded institute in Neustadt, in the Black Forest on the identification of the precentral gyrus as the motor cortex brain stimulation in animals,[17] which they had begun on roughly two decades before. The Vogts' and Brodmann's monumental work on brain cytoarchitectonics, supplemented with electrical stimulation of the exposed cerebral cortex, demonstrated correlations between evoked functional responses and the topography of brain regions endowed with distinct cytoarchitectonic structure (topistic units). This opened the field of functional brain mapping, a subject hotly pursued at the present time.[18]

Walther Spielmeyer described ammon's horn-sclerosis as a consequence and not a possible cause of seizures.[19] He was Director of the Institute of Neuropathology, sponsored by the Rockefeller Foundation and named after the german emperor 'Kaiser-Wilhelm-Institut' in Munich, which was the preceding

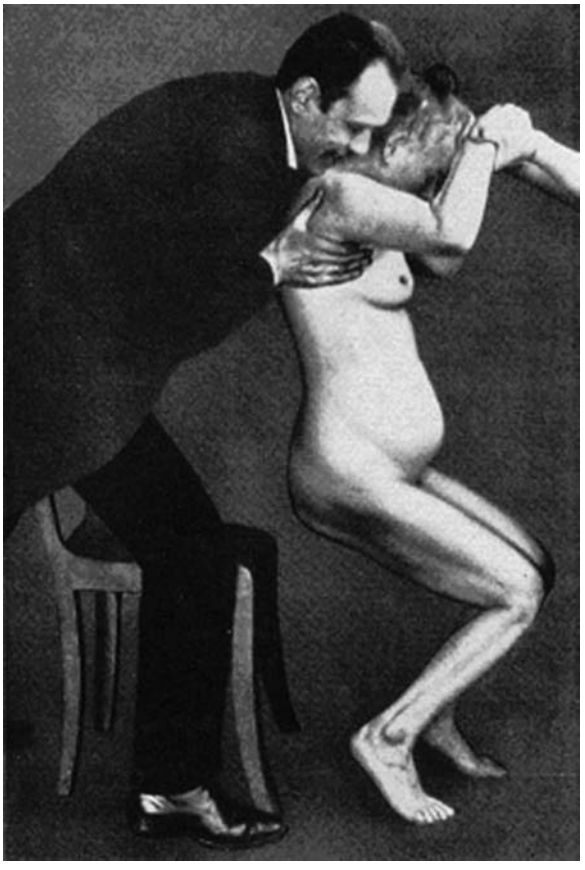

Figure 5.4 The young Ottfried Foerster (1873–1941) assisting a patient.

institute to today's Max Plank Research Institutes. Despite his exposed position he practiced an open resistance against the fascist regime by, for instance, helping many that were prosecuted by the regime, thus endangering his own life.

Stauder was probably the first author after Jackson to write, in 1935, a landmark paper on epilepsy and the temporal lobe.[20] He departed from the observation that convulsive seizures were particularly frequent in diseases of the temporal lobe, especially tumors. By that time, epigastric sensations, dreamy states, and other temporal auras had come, by a still unexplained process, to be considered as a diagnosis for genuine or hereditary epilepsy. Stauder was aware of the likeness of the symptoms of temporal lobe seizures and those of genuine epilepsy, but did not arrive at a critique of the latter concept of temporal lobe epilepsy. These new concepts were developed only under the influence of electroencephalography.

In the surgical field stereotactic procedures were developed initially for the treatment of movement disorders and were later applied to epilepsies with the aim of destroying an epileptogenic focus or to interrupt pathways of epileptic discharge.

Based upon the assumption that the fornix is the major efferent structure of the hippocampus, which regularly discharged on temporal lobe epilepsy, surgeons advocated its section for the relief of psychomotor epilepsy. In 1957 Hassler and Riechert placed lesions in the fornix at the posterior margin of anterior commissure.[21] Umbach reported on 29 patients with partial seizures in whom the fornix was destroyed unilaterally alone, or with lesions in the intralaminar nuclei amygdala, or laminar medialis. Another six patients had bilateral fornix lesions placed six to eight months apart without producing neurological or memory disturbances. Both partial and generalized seizures were eliminated in some patients.[22–24] In a later report of 50 cases, Bouchard[25] and Umbach noted a diminution of *grand mal* seizures by 65% and of lesser seizures by 62%.

Schaltenbrand *et al.*[26] reported on fornicotomies in five patients with psychomotor seizures indicating improvement in four cases. The addition of a lesion of the anterior commissure did not improve the results.

Mundinger[27] also performed stereotactic functional neurosurgery on patients with predominantly temporal epilepsy. He published his results of 45 patients with long term follow-up (up to 24 years) and found an improvement in more than two-thirds of the cases. The advances in the fascinating field of stereotactic neurosurgery were watched with great hope by all neurologists, neurosurgeons, and other specialists interested in the various aspects of causation, symptomatology, diagnosis, and treatment of epilepsy, but their hopes were only partly fulfilled. Other strategies had still to be found.

Despite the dedicated efforts of a few, epilepsy surgery did not exceed a mere beginning due to the break, the Third Reich and World War II had caused for this special field of neurosurgery. Efforts and results began to grow in Germany rather from the 1980s on. Also, it is remarkable that none of the Nuremberg accused physicians was explicitly an epileptologist or epilepsy surgeon.

Epilepsy surgery in recent years

The modern era of epilepsy surgery in Germany started in the mid-eighties. Several programs were initiated with the financial support of the states of Bavaria (Erlangen) and especially North-Rhine-Westphalia (Bonn, Bielefeld/Bethel). Since the development of epilepsy surgery was interrupted in Germany by the Nazi regime and World War II, knowledge of preoperative evaluation and epilepsy surgery had to be acquired from programs active outside Germany such as Switzerland, France, and North America. The numbers of epilepsy surgery programs as well as the numbers of epilepsy surgeries grew constantly over the following years. A survey done in 2004 revealed that 14 programs had been established accounting for ca. 500 cases of surgery a year. Two-thirds of those surgical cases were performed at the top five institutions. The exact numbers are shown in Figure 5.5.

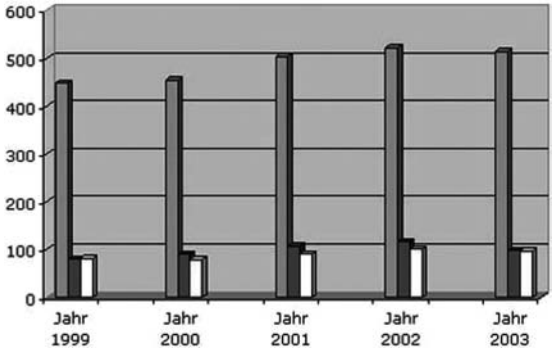

Figure 5.5 Number of epilepsy surgeries per year in Germany from 1999 to 2003. Light gray columns: all surgeries; dark gray: proportion of patients under 16 years; white: number of implanted vagal nerve stimulators.

The German epilepsy surgery program was supported by the German Ministry of Health. The financial support led to the build up of centers for epilepsy surgery and a working committee for preoperative diagnostics and epilepsy surgery including reports of a state of the art and minimal consensus for presurgical evaluation and indications for epilepsy surgery.[28]

In 1992 the Working Committee of Presurgical Epilepsy Evaluation and Surgical Epilepsy Therapy (Arbeitsgemeinschaft für prächirurgische Epilepsiediagnostik und operative Epilepsietherapie e.V.) was founded with the aim of promoting this form of epilepsy therapy in Germany. Scientific symposia and teaching courses are held on a yearly basis covering all aspects of diagnostic and therapeutic issues of this special field of epilepsy therapy.

Guidelines for manpower requirements and apparative equipment were established and published as well as guidelines for the education of all professional specialities working together in the multidisciplinary team.[29,30] The organ of notification of the working committee is the 'Zeitschrift für Epileptologie' (*Journal of Epileptology*), the official organ of the German chapter of the league against epilepsy.

In 2005 a catalogue of criteria which have to be fulfilled in order to get approval as an epilepsy surgery center was published.[31]

A further goal includes establishing and maintaining supportive relationships to other scientific societies on a national and international basis. Financial support of research projects and grants for educational purposes can also be provided. At present there are 170 people of various professions who are active members of this Working Committee. Altogether, the Working Committee can be regarded as a success having contributed to the rapid growth of epilepsy surgery programs of high standards in Germany.

Epilepsy register

A Neuropathological Reference Center for Epilepsy Surgery was established at the Department of Neuropathology, University of Erlangen-Nuremberg (http://www.epilepsie-register.de). Since May 2003, German epilepsy centers from Erlangen, Bielefeld-Bethel, Bonn, Freiburg, Berlin, Vogtareuth, Greifswald, Munich, Marburg, Augsburg, Hamburg, Göttingen, and Münster participated and contributed surgical specimens and/or diagnostic reports for a second opinion as well as collection of surgical specimens. A total of 2673 diagnoses have been reviewed so far. Major entities comprise hippocampal sclerosis ($n = 981$, including 135 cases presenting with dual pathologies), epilepsy-associated tumours ($n = 804$), cortical dysplasias ($n = 344$), vascular lesions ($n = 160$), ischemic lesions ($n = 130$), encephalitis ($n = 44$), traumatic injuries ($n = 10$), and 200 cases without significant neuropathological alterations (including reactive astrogliosis as a solitary finding). The purpose of this interdisciplinary project is to:

(1) standardize neuropathological classification systems of epilepsy-associated lesions;
(2) to establish a comprehensive tissue bank assisting and fostering scientific collaborations across Germany;
(3) to provide a review of surgical specimens (second opinion); and
(4) to support clinical therapy and outcome studies.

Annual meetings were organized to discuss specific topics, i.e., correlation between neuroradiological and neuropathological findings, and to microscopically review interesting cases.

Scientific research in German epilepsy surgery programs

Epilepsy surgery is performed in three different kinds of institutions. Several subdivisions of university departments of neurology subsequently developed highly sophisticated epilepsy programs including presurgical evaluation and epilepsy surgery listed in alphabetical order: Erlangen, Freiburg, Greifswald, Marburg and Munich. There is only one German university department with a specification to epileptology (Bonn) including basic neuroscience. Three additional non-university centers (all of them tertiary referral hospitals) such as Bethel, Kehl-Kork and Vogtareuth (only children) can be considered as comprehensive epilepsy programs in which epilepsy surgery is an integral part of a multidisciplinary approach aiming at a holistic medicine (intensive social counselling, long-term antiepileptic treatment, specialization in learning disabilities and handicapped people, rehabilitation units, education programs, and more). Most centers decided at an early time-point of their epilepsy surgery program to parallel this by more or less intensive and systematic research activities in order to guarantee a high clinical standard and to help establish an evidence-based new form of effective epilepsy therapy. The latter one was also crucial in the beginning of epilepsy surgery programs in Germany to convince health insurance companies to pay for this kind of 'new' treatment. According to the specific profile, logistics and resources of the individual center (some of them linked to basic neuroscience, eg., Berlin, Bonn, and Freiburg), different areas of research interests, and projects developed over time, are summarized in Table 5.1 (only when main focus of research and repeatedly published).

Specific research activities of the individual centers (alphabetical order)

Berlin

- Postoperative outcome in relation to neuropathological findings, psychiatric comorbidity and neuropsychological variables.
- Investigation of epileptogenic tissue in regard of glial function, neurotransmitters (GABA, glutamate), multiple drug transporter expression.[56,77,78,84]

Bielefeld-Bethel

- Extensive analysis of seizure semiology: role of lateralizing semiology for seizure outcome after epilepsy surgery,[32] hyperorality in seizures,[38] orgasmic auras,[37,55] 'alien limb phenomena'.[32] Seizure semiology in children.[5,34,35]
- Cortical dysplasia and pediatric epilepsy surgery.[54,76]

Table 5.1 Research activities of German epilepsy centers with main references relating to these fields

Research field	German epilepsy center	References (selection)
Seizure semiology	BI, KK, MR, M	32–40
Cognition/neuropsychology	BI, BN, E, F	41–46
Language	BI, BN, E, F, MR	47–51
Psychiatric comorbidity	BI, G	52,53
Clinical outcome	BI, BN, G, E	54,55
EEG as predictor for outcome	BI	43,56,57
Seizure prediction	BN, E, F, KK, MR	58,59
MRI – morphology (HS, FCD)	BI, E, F, M, V	49,55,60–62
Functional MRI	BI, BN, F, MR, E	50,51,63
Multimodal imaging-MEG-SPECT	E, M	20,47,64–67
Brain/neurostimulation	BI, BN, KK, MR	68,69
Radiotherapy	F, KK, E	70,71
Neuropathology	BI, BN, E, F,V	72–76
In-vitro- slice	B, BN, F	56,77–80
Molecular genetics	BN, F	81,82
Pharmacoresistance	B, BI, F, G, E	83–85

Abbreviations for epilepsy centers: Berlin (B), Bethel-Bielefeld (BI), Bonn (BN), Erlangen (E), Freiburg (F), Greifswald (G), Kehl-Kork (KK), Marburg (MR), Munich (M), Vogatreuth (V).

- Predictors for seizure outcome with special focus on pre- and postoperative EEG findings (spike-pattern distribution uni- vs. bilateral, -propagation[57]), clinical and MRI-Data.[48,57,86]
- Preoperative psychiatric comorbidity as predictor for postoperative incidence of psychosis.[52]
- Cognitive development of children after epilepsy surgery.[43]
- Brain plasticity and reorganisation with special focus on memory and language transfer using neuropsychological assessment and functional MRI.[44,48,51]
- Perioperative microdialysis of epileptogenic brain tissue as a model to understand pharmakoresistance.[72,83]

Bonn

- Neurophysiology of hippocampal slices of resected human epileptogenic tissue and in animal experiments.[72]
- Hippocampal slices in animal models.[80]
- Neurogenetics and channelopathies.[82]
- Psychophysiology of the mesial temporal lobe as accessed by subdural or hippocampal electrodes.[45]
- Seizure prediction by application of linear and non-linear algorithms to invasive and non-invasive EEG-data.[59]
- Neuropsychology of the epilepsies including studies on the long-term outcome of epilepsy surgeries.[42]
- Functional neuroimaging in patients and healthy subjects.[63]
- Development of modified functional hemispherectomy-technique.[87–89]

Erlangen

- Improvement of non-invasive presurgical evaluation by means of multimodal coregistrations of imaging and electrophysiology: multichannel MEG/EEG recordings in addition to high resolution MRI to define the correlation between structural findings, focal epileptic and functional important regions.[47,64,90]
- Non-invasive registration to preserve brain function by means of neuronavigation and intraoperative MRI and EcoG.[60,91]
- Seizure semiology in presurgical evaluation emotional-affective and autonomic ictal signs.[92,93]
- Pharmacoresistance and multiple drug transporter.[94]
- Radiotherapy.[95,96]
- Postoperative clinical outcome analysis after tailored resection and with regard to etiology.[97–99]

Freiburg (partly in co-operation with Epilepsy Center Kehl-Kork)

- Improving the sensitivity of structural imaging for the detection of subtle malformations of cortical developments using high-field MR scanning[61] and new postprocessing algorithms such as voxel-based morphometry.[63]
- Development of functional MR imaging algorithms for localization of language and memory functions.[50]
- Radiosurgical therapy including stereotactic interstitial radiosurgery and LINAC-radiosurgery in patients with hypothalamic hamartomas.[70,71]
- Epilepsies due to cortical dysplasia: mechanisms and treatment options.[73]
- Development and analysis of seizure prediction algorithms[41] and analysis of network oscillations as electrophysiological correlates of memory processes.[58,100]
- *In-vitro* studies of neuroprotection with special regard to the role of endocannaboids in both animal experiments and human epileptogenic and non-epileptogenic brain tissue.[79]
- Morphological and molecular mechanisms of ammonìs horn sclerosis.[81,101]

- Clinical, radilogical and histopathological correlation of temporal lobe epilepsies.[102,103]

Greifswald

- The role of ictal and interictal SPECT-imaging in the presurgical evaluation oftemporal lobe epilepsy.[104]
- Neuropsychological findings in temporal lobe epilepsy.[53]
- Multidrug transporters in dysembryoplastic tumors as cause for pharmakoresistance.[85]

Kehl-Kork (partly in co-operation with University of Freiburg)

- Correlation of neuropathology and electrocinical findings in cortical dysplasia.[75]
- Hemispheric dominance for language by means of functional MRI.[50]
- R-TMS – a predictor for successful vagal nerve stimulation.
- Predictive variables in presurgical evaluation.[105]
- Brain stimulation and seizure inhibition after automatic seizure detection (closed loop-system).
- Neuropsychology of temporal lobe epilepsies.[46]

Marburg

- Cortex physiology studied by TMS and direct stimulation of and recording from subdural electrodes.[68,69]
- Automated seizure detection and brain stimulation (co-operation Kehl-Kork).
- Language lateralization by means of transcranial Doppler-sonography and WADA testing.[49]
- High-resolution structural imaging by means of 3T and DTI-MR imaging for subtle focal brain abnormalities.[106]

Munich

- Extensive analysis of seizure semiology[36] including movements during epileptic seizures.[39,40]
- Localization of the epileptogenic zone in adults by SPECT and 3D image registration of [C-11]-flumazenil-PET and MRI.[65,107]
- Usefulness of 3-D reconstructed images of the human cerebral cortex for localization of subdural electrodes in epilepsy surgery.[66]
- Neurosurgical microanatomy-laboratory-investigations of deep seated brain areas and their significance for epilepsy surgery.[108]
- MR measurement of regional relative cerebral blood volume in epilepsy.[67]
- Reduction of benzodiazepine receptor binding is related to the seizure onset zone in extratemporal focal cortical dysplasia.[12]

Vogtareuth (children only)

- Cortical dysplasia classification and pediatric epilepsy surgery.[74]

Research networks

Several interdisciplinary research networks have been developed over time in Germany in order to: (1) create linkage to basic neuroscience programs such as, for example, molecular genetics, (2) to develop a neuropathology databasis, or (3) to increase statistical power of variables involved. All the above-mentioned epilepsy centers are part of national and international widespread research networks.

6 Epilepsy surgery in France

P Kahane, A Arzimanoglou, A-L Benabid, and P Chauvel

The pioneer period (1950–1960)

Epilepsy surgery in France was probably born at the beginning of the 1950s, when H. Hécaen, who was already well known for his work on neuropsychology, went for 1 year (1952) to the Montreal Neurological Institute (MNI) to study post-surgical patients with W. Penfield. Although it was not the purpose of his visit, Hécaen was impressed by the results of surgery in terms of seizure relief, and he came back in Paris full of enthusiasm for such a treatment. He therefore encouraged G. Mazars to develop at Sainte-Anne Hospital an epilepsy surgery program based on the MNI method. Mazars was a neurosurgeon who was already interested in epilepsy surgery. He had started with J. Guillaume to operate epileptic patients using peroperative electrocorticography[1,2] and they published their first results in the early 1950s.[3–5] Interestingly, they were probably among the first to describe insular epileptic seizures, and the surgical technique for operating on them.[6,7] Also, Mazars contributed in the following years to the development of original therapeutic approaches such as refrigeration and freezing of the epileptic focus for seizure alleviation.[8]

During the same early period, J. Talairach, the founder of modern stereotactic surgery, was also working in the Neurosurgery Department of Sainte-Anne Hospital, under the supervision of his mentor, M. David. Since 1946, he had been developing stereotactic approaches to functional neurosurgery for chronic pain, movement disorders, pituitary diseases, and unoperable tumors. His interest was especially focused on the stereotactic definition of deep brain structures[9] and he built up a coordinate system based on the anterior commissure-posterior commissure axis, which allowed him to 'normalize' anatomical data from different brains. This led to the publication, in 1957, of his first stereotactic atlas on deep brain nuclei.[10] His second stereotactic atlas, devoted to telencephalic structures, would be published 10 years later while he was already working with J. Bancaud.[11]

J. Bancaud, a neurologist and electroencephalographer, was a student of H. Fishgold, a radiologist who was working at La Salpétrière Hospital in Paris. At the beginning of the 1950s, Fishgold's group joined David's group in Sainte-Anne Hospital, and this undoubtedly represented a turning point for both Talairach and Bancaud's careers. They were then evolving at the same institution, where epilepsy surgery had began, and they benefited from the high scientific experience of P. and M.D. Dell in neurophysiology, and of H. Hécaen and J. de Ajurriaguera in neuropsychology. Bancaud, largely influenced by Hécaen as well as by Penfield's work, understood very early the importance of clinical symptomatology for cerebral localization purposes, either in the presence of lesions or for the assesment of epileptic seizures. This appears in his medical thesis on the relationships between neuropsychological deficits and EEG alterations in patients with cerebral tumors. Bancaud was convinced by the fundamental interest of epilepsy surgery, but considered that current methods of investigation were not well adaptated for the precise localization of the brain regions involved in seizure generation. Since the seizure was the symptom to be cured, it was the cortical region generating epileptic seizures that had to be electrophysiologically defined, in correlation with its anatomical correspondence. In other words, the idea was to accurately record the electrical activity of different brain structures during the course of a seizure, rather than to use findings from the study of interictal spikes.

Bancaud saw the potential of Talairach's method to localize the sources of EEG discharges in three-dimensional space, and he began working with him to develop applications of stereotactic functional exploration for presurgical evaluation of medically intractable epilepsies. An operating room dedicated to stereotactic neurosurgery opened at Sainte-Anne Hospital in 1959, and the project to record epileptic seizures by means of stereotactically implanted intracerebral electrodes became a reality.[12–17] The term stereoelectroencephalography (SEEG) was coined in 1962 to account for this new method,[18] a method which, for many reasons, was revolutionary in the field of epilepsy surgery:

1. SEEG recordings allowed to study the spatiotemporal dynamics of seizure discharges with respect to their clinical features, and with a high degree of anatomical precision;
2. the technique of SEEG offered the possibility to dissociate the presurgical investigation phase from the surgical therapeutic act: SEEG recordings and electrical stimulations were carried out in the operative room under 'acute' conditions; after removal of the intracerebral electrodes, resection surgery was planned, and performed in a second step;
3. SEEG directly derived from a new conceptual approach for studying partial epileptic seizures, which was based on the assumption that the chronological occurrence of ictal clinical signs reflects the spatio-temporal organization of the epileptic discharge within the brain (Figure 6.1).

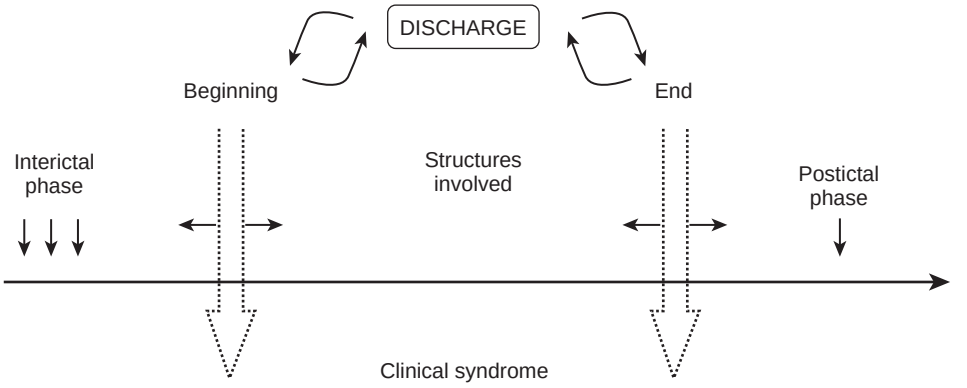

Figure 6.1 The model of a partial seizure, as proposed by Bancaud and Talairach (modified).[19]

This approach, popularized in France under the term of 'anatomo-electro-clinical correlations', has remained the principal guide of the whole presurgical process that Talairach and Bancaud would use all their career, and that they would transmit to their pupils.

The development of SEEG (1960–1970)

The development of SEEG ushered in a new area that coincided with a complete reorganization of the Sainte-Anne Department of Neurosurgery. In 1960, David and Fishgold moved to La Pitié-Salpétrière Hospital (Paris), and Talairach became the head of a new Department of Functional Neurosurgery. In 1964, A. Bonis, a neurologist and student of R. Garcin, joined the Sainte-Anne team and became the 'right arm' of Jean Bancaud. The same year, Talairach's team was completed by G. Szikla, an emigrant from Hungary who devoted his career to anatomy and stereotaxy, and played a major role in the development of stereotactic angiography. More particularly, carefully looking at the close relationships of cortical vessels to the convolutions and sulci, Szikla showed that a meticulous analysis of vascular trajectories allowed to extract gyral form and dimension,[20] and provided constant landmarks for interpretation of anatomical variablity.[21] Thus, stereotactic angiography was not only a routine procedure for safe implantation of intracerebral electrodes, but also a valuable tool for deducing the actual location of electrode contacts, particularly before the availability of modern imaging methods.

With time, the novel SEEG technique of Bancaud and Talairach became a comprehensive methodology, the aim of which was to study, in each individual case, the origin and spread of ictal discharges in order to precisely define the cortical area to be surgically removed (see Kahane and Francione, this book, Chapter 73). The selection of the structures to be explored was based on a very careful analysis of all the data – notably clinical – collected during the non-invasive presurgical investigations. Such an analysis led to one or several hypotheses concerning the site(s) of seizure onset and the pathways of preferential ictal spread.[22] Electrodes were then placed accordingly, in a way that enabled interpolation of intracerebral EEG activity within the interelectrode space. Proceeding this way, Bancaud and Talairach could precisely study how symptoms accumulated as the epileptic discharge propagated into different cortical structures and, in turn, could confirm or infirm their initial hypotheses (Figure 6.2).

The high spatial and temporal resolution coupled with a high power of localization that the SEEG procedures offered, rapidly provided a large amount of data that had immediate repercussions on the practice of epilepsy surgery. In particular, Bancaud and Talairach described the role of the amygdala and hippocampus in the clinical symptomatology of temporal lobe seizures,[23,24] as well as the role of (mesial) frontal anterior and intermediate areas in the occurrence of clinical manifestations usually attributed to generalized seizures and thought to be of centrencephalic origin.[25–28] Their dynamic view of focal epilepsies culminated in a key book published in 1965, *La Stéréoelectroencéphalographie dans l'Epilepsie*.[29] In this book, using detailed observations and discussions, they re-defined topographic diagnosis based on seizure patterns (under this term, Bancaud and Talairach considered that ictal clinical symptomatology must be viewed as a whole, and they regarded the order and sequence of semiological elements as crucial). Also, benefiting from Talairach's experience in the field of stereotaxic neurosurgery using radioisotopes, they translated such a therapeutic possibility in a few patients in whom seizure origin was relatively limited in space.[30]

During this same period, Talairach and Bancaud also developed SEEG criteria for detecting non-expansive brain lesions that could not be shown by the neuroradiological techniques available at the time. In this context, they used the term of 'lesional zone', which referred to the area occupied by electrical silence or various types of slow-wave activity, and which presumed a macroscopic alteration of neural tissue. The correlations were clearly superior to those given by the neuroradiological images available, allowing to map the extent and anatomical location of astrocytomas or oligodendrogliomas. This made more safe resective surgery and more accurate stereotactic interstitial radiotherapy. Their experience in this field is summarized in a second important book, *EEG et SEEG dans les tumeurs cérébrales et l'Épilepsie*,[31] in which they described the topographic transitions between electrical silence inside glial tumors, slow waves, spiking, subclinical paroxysms, and seizure activity. This book also collected important data on simultaneous recordings of scalp-EEG and SEEG. As such it still provides, more than 30 years later,

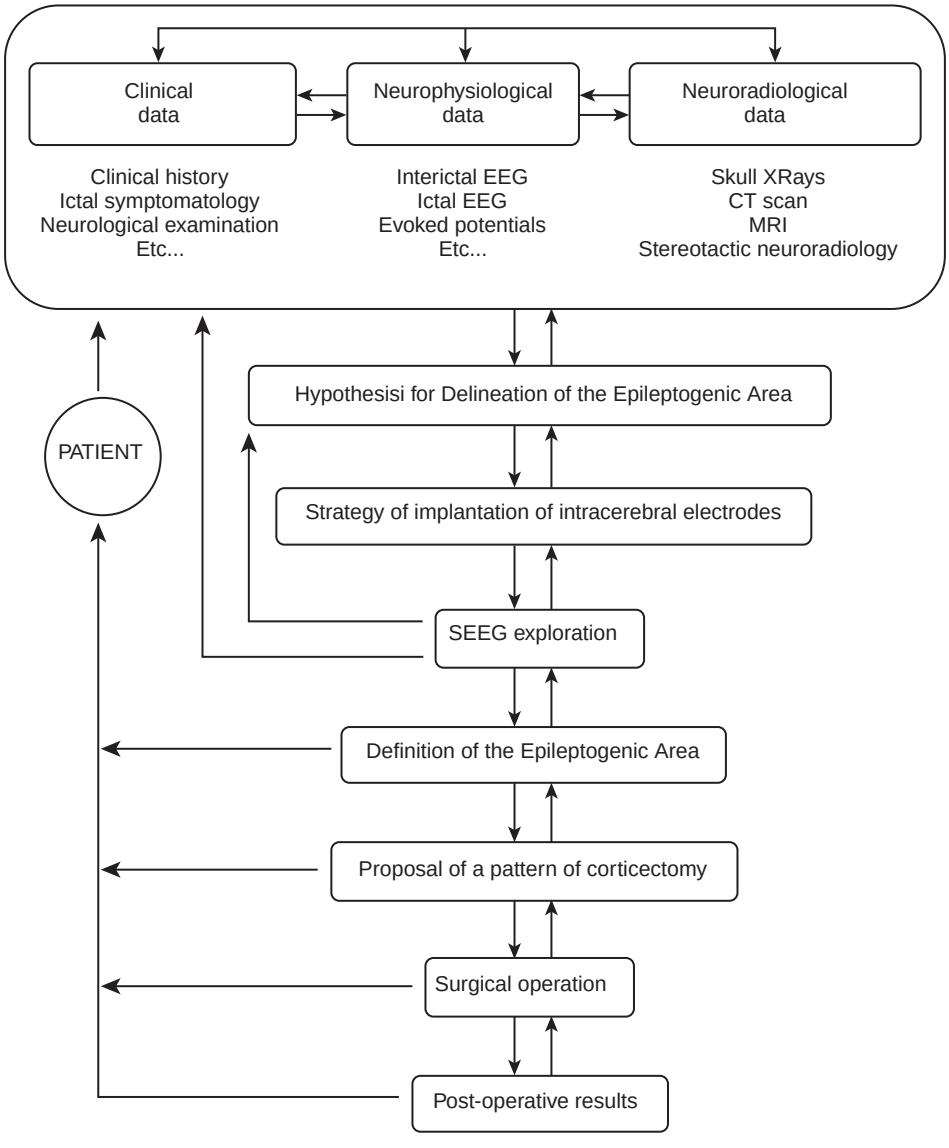

Figure 6.2 Schematic representation of the methodology used by Bancaud and Talairach for examining a patient for surgical treatment of epilepsy (modified)[19].

valuable information on what we record and what we miss using surface recordings.

From these early studies emerged the novel concept of the 'epileptogenic zone', a term which directly derived from the necessity to create a new definition – based on seizure recordings – of the brain area to be resected.[32] SEEG definitions of seizure onset were proposed, which could slightly vary from one structure to another (temporal limbic, neocortical …), but which all emphasized the existence of fast synchronizing discharges that might involve a single region, or distinct but interconnected regions. The epileptogenic zone was differentiated from the 'irritative zone' (the area occupied by interictal spikes) and from the 'lesional zone'. Indeed, Talairach and Bancaud[33] observed that the respective topography of these different zones were not fully overlapping. This led to a new type of surgery, based on a three-dimensional representation of the three zones on the basis of which, together with the results of electrical stimulation, the surgical plan could be carefully prepared and adapted to the individual patient's case.

Bancaud and Talairach rapidly understood that their method also represented a remarkable tool for studying 'normal' neurophysiology. Using intracerebral electrical stimulation, they brought new insights on the anatomo-functional organization of the supplementary motor area[18,34,35] and, with the help of P. Buser, worked on various aspects of motor systems. Buser was a neurophysiologist who was especially interested in the pyramidal system and sensory |polymodal afferents to the frontal cortex. One of the models he used was the startle reaction in the anesthetized cat. He began to work with Bancaud in 1964, and they developed together new concepts on the physiopathology of startle epilepsies,[36,37] Kojewnikow syndrome,[38–40] and post-anoxic myoclonus.[41] Also, using evoked potentials, they studied cortico-cortical connections and their facilitation inside the epileptogenic zone.[42–45]

The Sainte-Anne team becomes the Sainte-Anne school (1970–1990)

In 1970, the *Institut National de la Santé et de la Recherche Médicale* (INSERM) created the U97 research unit entitled

'Stereotaxic Functional Exploration and Surgical Treatment of the Epilepsies'. It was headed first by Talairach for 5 years, and then by Bancaud. Other people joined the Sainte-Anne group, among whom P. Chauvel from Rennes, and C. Munari from Bologna (Italy), who would both later have a major influence on the development of epilepsy surgery in France. The Sainte-Anne group was then composed of neurosurgeons (C. Munari, G. Szikla, J. Talairach), neurologists (A. Bonis, P. Chauvel, S. Geier, S. Trottier, C. Schaub) and researchers (P. Buser, J. Louvel, M. Lamarche, R. Pumain). During this period, the collaborative work of Talairach and Bancaud culminated in the general report presented in 1974 to *the Société de Neurochirurgie de Langue Française*, entitled '*Approche Nouvelle de la Chirurgie de L'Épilepsie*'. In this report, Talairach and Bancaud exhaustively specified the successive and multidisciplinary steps of their method, and described the surgical results obtained in 204 epileptic patients operated on during the 1957–1973 period, including 160 resections and 44 stereotactic destructions.[46]

During the 1970s, technical progress allowed to prolong the SEEG recordings. It was now possible not only to record seizures during the 'acute' phase in the operating theater but also in the laboratory. The advent of telemetry and video-recording were retrospectively matched with EEG signals, and this allowed a much better study of ictal clinical symptoms, such as 'automatisms'. Bancaud and coworkers were especially interested in gestural automatisms, and they identified correlations between particular gestural manifestations with anterior frontal lobe seizures,[87–89] as well as the characteristics that helped to distinguish them from gestural manifestations of temporal lobe origin.[90,91] In the search for mechanisms of automatisms, they also described the behavioural effects of anterior cingulate gyrus stimulation, which consisted in complex coordinated movements associated with mood alteration.[92] Some observations made at this time also suggested that an epileptogenic zone could be distributed between different lobes, thus leading to the concept of frontotemporal,[19] perisylvian,[93] and temporo-parieto-occipital epilepsies,[94] and therefore to a concomitant change in surgical strategy.[95] The continuous evaluation of the clinical features of partial epileptic seizures, thanks to SEEG results, progressively led to the refinement of seizure semiology and significant advances were achieved in the study of temporal and frontal lobe epilepsies.[46]

The method of Bancaud and Talairach generated considerable interest abroad and a number of physicians visited the Sainte-Anne group, coming from Argentina (Dr Betti), Austria (Dr Mempel), Belgium (Dr Petrov), Brasil (Dr Marino), Canada (Dr Saint-Hilaire), Chile (Dr Serrano), Germany (Dr Tomalske), Greece (Dr Prosalentis), Italy (Dr Signorelli), Japan (Drs Hori, Dr Takeda), Mexico (Dr Lopez-Gonzales, Dr Moises), Paraguay (Dr Bordas-Ferrer), Poland (Drs Sierpinsky, Dr Valencak), Romania (Dr Cinca, Dr Russu), Spain (Dr Manrique), Switzerland (Dr Bernouilly, Dr Wieser), Tchecoslovaquie (Dr Rektor), Turkey (Dr Oproic Ozdemir Aral), and the United States (Dr Zervas). In France, a number of neurosurgeons came at Sainte-Anne Hospital to learn stereotactic surgery. Some would play later a crucial role for the development of epilepsy surgery in Bordeaux (A. Rougier), Grenoble (A.L. Benabid), Marseille (J.C. Perragut), and Rennes (J.M. Scarabin).

Epilepsy surgery in France today (1990–)

During the last 20 years a number of epilepsy surgery centers were developed, first as an initiative of A. Rougier in Bordeaux (where P. Loiseau and P. Jallon had developed a comprehensive epilepsy program),[47] and then under the impulse of the most prominent pupils of Talairach and Bancaud: P. Chauvel (who started the centres of Rennes and Marseille in collaboration with J.M. Scarabin and J.C. Perragut, respectively), and the late C. Munari (who founded the centre of Grenoble with A.L. Benabid, and then moved to Milano).

Later, other centers were started, so that more than ten University Hospitals have specifically developed an epilepsy-surgery program (Figure 6.3). Most are using the SEEG method when necessary, mainly for adult patients. Both centres have developed not only clinical programs but also, in line with the spirit of Sainte-Anne School, research programs in which emphasis is placed on the value of clinical semiology and its integration through 'anatomo-electro-clinical correlations'. As a result, important contributions have emerged these last years from the French epilepsy surgery community including, among others: the SEEG investigation of hypothalamic hamartomas and focal cortical dysplasia;[48,49] the development of innovative methods for signal analysis to better understand how epileptogenic networks are organized;[50–53] the characterization of different subtypes of mesio-temporal lobe seizures and the identification of the role of the temporal pole and entorhinal cortex in a number of such seizures;[54–56] the recognition of the insular cortex as a potential key structure in seizure spread and seizure generation;[57–60] the delineation of the concept of 'temporal plus' epilepsies;[61,62] the development of new therapeutic approaches such as gamma-knife surgery,[63–65] sub-thalamic nucleus stimulation,[66,67] and SEEG-guided thermocoagulation.[68] In 1999 the first international epilepsy journal was started which was regularly published with an accompanying DVD to include video-EEG recordings; *Epileptic Disorders (www.epilepticdisorders.com)*, always in the search of refinement in the analysis of electro-clinical semiology.

In children, one of the first epilepsy groups to support epilepsy surgery was that of J. Aicardi (Hôpital Necker-Enfants Malades, Paris) in collaboration with the Sainte-Anne group (J. Bancaud, S. Trottier, and colleagues) for SEEG cases, and with the Neurosurgery Department (J.F. Hirsch and C. Sainte-Rose) of the Enfants-Malades Hospital. They contributed to the better individualization of surgical indications in Sturge-Weber syndrome,[69–72] as well as to a better evaluation of the effectiveness of 'lesionectomy' for different brain epileptogenic lesions.[73–75] The group of O. Dulac (Saint-Vincent-de Paul Hospital, Paris) also developed an epilepsy surgery program, in collaboration with the group of O. Delalande (Fondation Rothschild, Paris). They have a particular interest in large hemispheric lesions in young children with severe epileptic encephalopathies, and they were among the first to propose a modified technique for hemispherectomy, the vertical parasagittal hemispherectomy.[76,77] They contributed also to significant advances in the surgical treatment of hypothalamic hamartomas by extending the disconnection method for

Figure 6.3 Geographic distribution of epilepsy surgery centers in France. Four centers are located in Paris: *Sainte-Anne hospital* (F. Chassoux B. Devaux, E. Landré, B. Turak), *Hôpital de la Salpétrière* (C. Adam, M. Baulac, S. Clémenceau, S. Dupont), *Fondation Rothschild* (O. Delalande, M. Fohlen, C. Jallin), *and Hôpital Necker-Enfants Malades* (M. Bourgeois, C. Sainte-Rose). The remaining centers are located in *Bordeaux* (C. Marchal, A. Rougier), *Grenoble* (S. Chabardès, D. Hoffmann, P. Kahane, L. Minotti, E. Seigneuret), *Lille* (S. Blond, P. Derambure, N. Reyns, W. Szurhaj), *Lyon* (M. Guénot, J. Isnard, F. Mauguière, P. Ryvlin), *Marseille* (F. Bartolomei, D. Broglin, P. Chauvel, J.C. Perragut, J. Régis), *Montpellier* (P. Coubes, A. Crespel, P. Gélisse), *Rennes* (A. Biraben, D. Taussig), *Strasbourg* (S. Chassagnon, E. Hirsch, P. Kherli, M.P. Valenti), *Toulouse* (J.C. Sol, L. Valton).

this indication and by developing a stereoendoscopic approach.[77–80] They represent today in France one of the two major groups regularly dealing with epilepsy surgery in children.

Recently, surgery has been 'officially' recognized in France as being part of the treatment of drug-resistant partial epilepsies.[81] Also, following the results of a multicentric medico-economic study,[82] the French Ministry of Health accepted to re-evaluate the reimbursement cost for a SEEG evaluation (it was reimbursed less than 1500 Euros until early 2007 but was re-estimated to nearly 13 000 Euros). These are certainly important steps, and the available facilities now allow operation about 400 to 500 patients each year in French territory. However, as for other countries, a vast majority of epilepsy surgery centers mainly deal with adult patients, and epilepsy surgery in children remains one of the priorities in this field in the near future.

Such a priority was emphasized more than 10 years ago by C. Munari, when he organized in Paris a meeting specifically devoted to drug-resistant focal epilepsies in children.[83] Under his impulsion and in collaboration with C. Sainte-Rose, a multidisciplinary group, including adult and child neurologists, neurosurgeons, neuroradiologists, and neuropsychologists from various cities and French University Hospitals (Grenoble, Lyon, Paris-Robert Debré, Paris-Necker, Strasbourg, Rouen) started working together on a regular basis in order to better evaluate indications and surgical approaches for children with drug-resistant epilepsies. Meetings on a monthly basis facilitated the evaluation of an important number of children with focal epilepsies or epileptic encephalopathies. This 'multidisciplinary network' and regional collaboration undoubtedly accelerated access of children to various presurgical evaluations since it allowed to all participating medical groups to benefit from facilities available at the various centers, but not necessarily to all. Earlier access to surgery was also facilitated by the regular participation of the neurosurgeons in the analysis of the anatomo-electro-clinical data. The progressive development of a 'common language' between the various groups progressively diminished the number of children that needed SEEG recordings.

During the last 5 years, however, it became evident, following the expansion of epilepsy surgery indications, that the small number of centers dedicated to children could not cover the needs at a national level (60 million inhabitants). It is currently estimated that more than 500 children per year could benefit from epilepsy surgery while not more than 150 are effectively operated on. This remains true despite the fact that

the French social security system covers all medical expenses, including transport, a fact that enormously facilitated the way of working of the above-mentioned multidisciplinary group, since it allowed patients to move from one city to another for a more rapid access to various presurgical evaluation techniques. On the basis of this evidently difficult-to- accept situation, some of the members of the 'multidisciplinary network' (A. Arzimanoglou, E. Hirsch, P. Kahane, P. Ryvlin, and C. Sainte-Rose) elaborated in 2004 a project for starting a national reference center, now known under the acronym IDEE (Institute for Children and Adolescents with Epilepsy). IDEE was conceived as a university hospital-based institute that would combine four main characteristics:

1. a health service, with at least 14 monitoring beds (four of which dedicated to SEEG recordings), with a concentration of highly-qualified epileptologists (neurologists and child neurologists) and paramedics with a wide experience of video-EEG monitoring;
2. a clinical and fundamental research department, with the participation of all clinicians of the medical department and research units working on topics related to cognitive development and epilepsy;
3. a medico-social center, under the management of a major lay association, that will develop specific projects of global epilepsy care (neuropsychology, psychological support, speech therapy, education of parents and children on epilepsy management issues, epilepsy nurses);
4. a sector dedicated to industrial development of techniques and treatment approaches directly related to the missions of IDEE.

In 2006, the University of Lyon accepted to endorse the project for commissioning the institute and the agreement of the French health authorities was obtained. IDEE is expected to be functional early in 2010 and will have, among others, a mission of evaluation of medical practices and research production related to epilepsy surgery.

Concluding remarks

Epilepsy surgery in France has more than half a century of history. In 2007 almost all major university hospitals throughout the country comprise of units dedicated to adult epilepsy surgery. Despite this remarkable development, many of these centers still lack the necessary manpower to develop comprehensive epilepsy surgery programs and access to surgery may still take several months, even when clearly indicated. Epilepsy surgery for children is just terminating its neonatal period. The most important contribution of the 'French school' is undoubtedly the stereo-electroencephalography approach of depth recordings developed by Bancaud, Talairach, and their pupils.[85] This anatomo-electro-clinical approach largely enriched the international medical literature on issues related to seizure semiology and localization.

7 Epilepsy surgery in Italy

G Avanzini and L Tassi

Introduction

Italy is a country of 57 million inhabitants, subdivided into 20 different areas (regions) (Figure 7.1). Each region manages the health and the hospitals in its area under the superintendence of the Health Ministry. The state provides public health covering all Italian citizens for any medical or surgical treatment independently from their social, economic, ethnic, or religious condition. Citizens have their first medical contact with a family doctor (general practitioner) who decides, on the basis of the diagnosis to treat the patient or to send it to a first, second or third level hospital.

It has been evaluated that approximately 570,000 patients in the country are suffering from epilepsy and about 20,000 with a focal drug-resistant epilepsy could be candidates to epilepsy surgery. Most epileptic patients are currently treated in third-level centers, but despite the high density of specialized centers, about half are in the charge of general neurologists, pediatricians or general practitioners.

At the present time drug-resistant patients with focal epilepsies are referred to one of the two centers dedicated specifically to epilepsy surgery, from one of the regional epilepsy centers, after a diagnostic and pharmacological work-up. These two epilepsy surgery centers are located in the northern and southern part of Italy.

Historical development

From 1955 to 1970

After early attempts dating back to the beginning of the 40s, two main groups led by Franco Marossero and Carlo Alberto Pagni in Milano and by Victor Aldo Fasano in Torino[1,2] continued the task to implement epilepsy surgery by developing specific programs including the refinement of invasive presurgical methodologies such as 'electrodurographic' and 'stereo-electroencephalographic' recordings.[3,4,6]

The lack of a strict co-operation between neurosurgeons and neurologists and neurophysiologists specifically devoted to epilepsy and properly trained, resulted in poor outcomes and frequency of surgical complications.

Several patients were submitted to temporal lobectomy.[1,2,5] However, the absence of accurate anatomo-electroclinical correlations led to discouraging results and therefore epilepsy surgery became quickly discredited. As a consequence, neurologists and epileptologists tended to stick to the pharmacological treatment, even if it could not control the seizures.

From 1970 to 1994

Although epilepsy surgery was considered among the possible options of epilepsy treatment, in practice it only had a 'marginal' role. Once again the multidisciplinary approach to a complex pathology failed, no dedicated centers were created, and the neurosurgeons managed epilepsy inside neurosurgery departments.

A pioneering work in sensitizing the Italian epileptologist had been carried out earlier in Genova and then in Roma by Gianfranco Rossi and his group tried to outline the general guidelines for epilepsy surgery.[7–9,12]

In addition palliative surgery,[10,14] and lesionectomies, particularly in epilepsies associated with tumoral lesions,[11] were carried out by Isacco Papo in Ancona and by Giovanni Broggi in Milano. Later on, disconnective techniques and hemispherectomies were carried out.[18,19]

The Claudio Munari contributions to epilepsy surgery in Italy (1993–1999)

Claudio Munari, after a post-graduate certification in neurosurgery and in neurology in Bologna, and a period in Marseille, moved to Paris in 1977 and worked with Jean Bancaud and Jean Talairach at the Ste. Anne Hospital (Figure 7.2). In 1994, 17 years after his departure, he returned to Italy (Figure 7.3). His scientific and clinical training, both in neurology and neurosurgery, makes him a 'unique specimen' in epilepsy surgery: he could manage a patient from the first outpatient examination to the operating theater.

His entire life was devoted to his work addressed to the cure and to the care of patients; it was not infrequent to find him after 10 p.m, with his unfailing cigarette, at his desk reviewing EEGs, planning the *next* day (after) surgery or visiting patients. His entire professional career was aimed at contributing to the comprehension of epileptogenic mechanisms and to development and improvement of epilepsy surgery always with a great respect toward the patients and empathy for their problems.

The major contrast between the European (and particularly French) school and the US clinical approach, concerned the concept of uniqueness of each patient and of each epilepsy. The correlations between ictal symptomatology, anatomical data and the neurophysiological explorations permitted him to define, in a single patient, the so-called 'Epileptogenic Zone' and to carefully plan the surgical resection. His fluency not only in Italian but also in French and English languages had characterized many a discussion sometimes 'vigorous and excited' particularly on the relationships between the anatomical lesion and the epileptogenic zone.

Figure 7.1 Topographic map of Italy, subdivided into 20 different regions.

(a) (b)

Figure 7.2 Claudio Munari at the Ste. Anne Hospital. A: with Jean Bancaud, interpreting a EEG (the first from the left and the third from the left). B: in the operating theatre with Patrick Chauvel (the second from the bottom and the first from the bottom).

He transformed the Stereo-EEG investigation, inherited from Bancaud and Tailarach, in a methodological and systematic approach.[13,15]

In 1990 he left Paris to the Neurosurgery Service in Grenoble headed by Alim Louis Benabid, where, with his precious collaboration, he created an epilepsy surgery center.

When he moved to Milan in 1994, the first dedicated epilepsy surgery center was created in Italy. His strenuous activity was divided between Milano, Genova, Paris, and Grenoble, allowing the Center to rapidly attain international standard. He became, having been one of the founders, President of the Italian League Against Epilepsy (LICE) in 1996 (Figure 7.3), and he was with a number of commissions and task forces within the International League Against Epilepsy.

He was a magical and helpful 'maestro' to his numerous pupils teaching them how to learn and improve from their mistakes. He gave them the gift of a scientific methodology and the clinical, semiological, neurophysiological, and anatomical fundamentals to ensure the heritage of his work.[16,17,20]

Since his untimely death, on 2 October 1999, the epilepsy surgery center is dedicated to him.

Mechanisms of referral

Regional Centers of Epilepsy and the LICE (Lega Italiana Contro l'Epilessia)

The development of centers of excellence (second and third level) for the care of epileptic patients, adults and children, has occurred in almost all Italian regions. They are located in the hospitals or associated with University centers. The Italian League Against Epilepsy promotes and encourages the scientific

Figure 7.3 Claudio Munari in Italy, before and during his presidency of the Lega Italiana Contro l'Epilessia.

and professional training of the epileptologists, and supports the development of epilepsy surgery centers.

The degree of service offered at each center can vary from routine diagnostic, monitoring, and follow-up care to intensive monitoring.

Access of the epileptic patient to the epilepsy surgery centers is through referral by the neurologist, neurophysiologist, or neuropediatrician working in each center.

Although the existence of the epilepsy surgery centers is increasingly known, the benefits of surgical treatment are not yet sufficiently known and therefore too often the patients are referred too late to epilepsy surgery.

Epilepsy surgery: the present

'Claudio Munari' Center (Milan) and Neuromed (Pozzilli)

Nowadays two epilepsy surgery centers (Figure 7.4) are working in Italy. The first one in Milano, founded by Claudio Munari, with about 100 patients operated on per year. A multidisciplinary approach permits us to define the surgical strategy, and Stereo-EEG evaluation is available for more complicated epilepsies. A team of neurologists, neurophysiologists and neurosurgeons ensures the mandatory work-up in focal drug-resistant epilepsy.

The second center, located in Pozzilli (Isernia), is based on the same strategy and methodology, except that invasive investigations are carried out by subdural electrodes. About 100 patients per year undergo epilepsy surgery in Pozzilli.

The other centers

Other neurosurgery departments of the Istituto Nazionale Neurologico C. Besta of Milano and of the Universities of Siena, Bologna, Udine, Roma, in collaboration with the two main epilepsy surgery centers, include evaluation and surgical treatment of epileptic patients, mainly symptomatic. No invasive investigations are available, although long-term monitoring is frequently accessible.

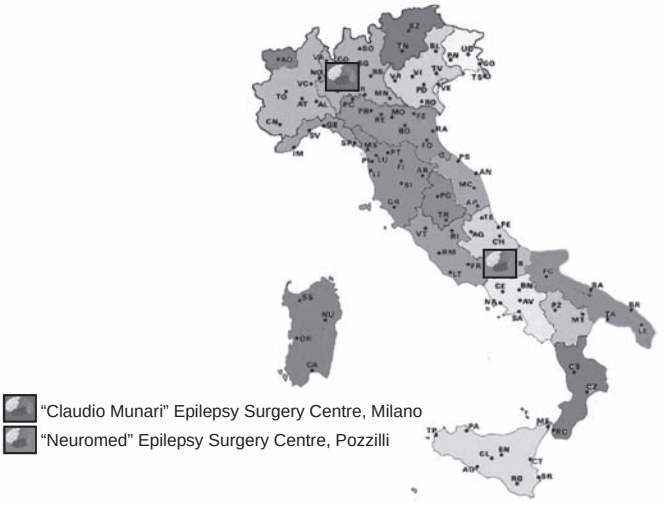

Figure 7.4 The location of the two dedicated epilepsy surgery Centers in Italy: the red one in the Northern part, and the green one in the South. (See Color plates.)

Conclusion

A dedicated epilepsy surgery center has only been operating in Italy since 1994, founded by Claudio Munari, and dedicated to him. A second center is functioning in Pozzilli, in the southern part of Italy. Unfortunately, the total number of patients does not exceed 200 persons per year, in comparison with thousands of patients needing surgical treatment.

A Commission of the Italian League Against Epilepsy is drafting a comprehensive guideline for epilepsy surgery and for pre-surgical evaluations.

From 1994, about 800 patients were operated on in Italy, and a network of epilepsy care centers is available to improve the medical, social, and surgical management of these patients.

8a Epilepsy surgery in Switzerland

HG Wieser and K Schindler

* Parts of the Zürich Section have been previously published by Fandino J, Wieser HG. Contributions of Hugo Krayenbühl and M. Gazi Yasargil to epilepsy surgery. In: HO Lüders, YG Comair (eds.) *Epilepsy Surgery*, Second Edition. Philadelphia: Lippincott-Raven 2001:43–53.[1]

The surgical forerunners in Switzerland

Theodor Kocher (1841–1917), well known as a surgeon awarded the Nobel Prize (1909), Hayazo Ito (1864–1929) and Harvey Cushing (1869–1939) worked in Berne, Switzerland (Figure 8a.1).

Cushing arrived at Berne one year after Ito left Kochers clinic for Kyoto in 1899. Cushing stayed 5 months (November 1900–March 1901) in Berne. William Osler and William Halstead, at the Johns Hopkins Hospital, had persuaded Cushing to spend a year in Europe. Osler himself was in England at the beginning of Cushing's trip, thus assuring that Cushing received many professional and social invitations. Cushing met Victor Horsley in London and Charles S. Sherrington in Liverpool. Following his stay in Berne, Cushing left to Turin (Italy) where he spent 4 weeks at the laboratory of Angelo Mosso. On Kocher`s suggestion, during his stay in Berne, Cushing engaged in a research project in the laboratory of the physiology department under the guidance of Professor Hugo Kronecker. Cushing studied brain stem control of systemic blood pressure during raised intracranial pressure (Cushing response).[2,3]

Ito, *the* pioneer of epilepsy surgery in Japan, the first professor of the second surgical department of Kyoto University from 1900 to 1924, spent over three years as a volunteer research fellow to Kocher and engaged in experimental studies on the relationship between intracranial pressure and epileptic seizures.[4,5]

Theodor Kocher considered the necessity of a 'surgical neurology' ('chirurgische Neurologie') as a specialty. In relation to epilepsy surgery he stated in 1893 that all traumatic epilepsies have to be submitted to surgery.[5] However, Switzerland needed another 20 years until the founding of the first department of neurosurgery in 1939 by Hugo Krayenbühl took place in Zurich, although Rudolf Krönlein, the successor of Prof. Billroth (well known for his classic types of gastrectomy cited in every textbook of surgery), must be mentioned as a pioneer in this field around 1900.[6]

Otfrid Foerster (1873–1941; Figure 8a.1 right), the 'foremost teacher and most learned authority in the field of neurology and one of the strongest personalities of his time in medicine' (statement by John F. Fulton in 1942) has historical connections to Switzerland, and, of course, many famous visitors, among them John Fulton, Wilder Penfield, Percival Bailey, Paul Bucy, Maclean M. Kennard, and W. Mahoney. Post-traumatic epilepsy due to war wounds had stimulated Foerster`s interest, and led to the neurosurgical removal of cerebral scar tissue by excision in all accessible parts of the cerebral cortex. A pioneer in epilepsy surgery, Foerster performed cortical stimulation under local anesthesia before resecting epileptogenic areas.[7] Together with Altenberger, Foerster recorded the first electrocorticogram of a brain tumor; he introduced hyperventilation to provoke epileptic seizures and coined the term 'psychomotor epilepsy'. Although we know that the technique of Foerster, the neurosurgeon self-trained in surgery, was not elegant or meticulous, in his world-famous work on cortical representation which he reported at the 100th anniversary of Hughlings Jackson in the ninth memorial lecture ('Electrical excitability of the human cerebral cortex', delivered at University College, London, April 2–30, 1931) he documented his mastery in the anatomy and physiology of the human central nervous system. Harvey Cushing honored him as 'surgeon-in-chief pro tempore'. It was 1931 in Berne that Foerster wrote the resolution asking the governments of the participating nations to create an academic representation of neurology at their universities. The first who received the Otfrid Foerster Award, one of the most prestigious awards of the German Society of Neurosurgery, was Percival Bailey in 1953. Wilder Penfield was honored by it in 1966, and Hugo Krayenbühl in 1973.[8–11] It should be mentioned here, that Penfield, who spent 'an interlude in Germany' with Foerster in Breslau,[12] had close contact to Hugo Krayenbühl*.

*Penfield dedicated his book *Epilepsy and Cerebral Localization*[13] on 9 July 1946 'to Professor Krayenbühl – with best wishes from his colleague Wilder Penfield'. The senior author has a letter from Krayenbühl to Penfield, dated 25 February 1976, in which Krayenbühl 'thanks for (WPs) kind letter of February 12, 1976'. After having expressed his 'delight to see Priscilla again ...' Krayenbühl continues discussing Penfield's book *The Mystery of the Mind* [14] praising WPs 'outstanding clinical neurophysiological research on the function of the brain'. Krayenbühl then quotes Walter R. Hess and Hans Fischer and finally he confesses that he adheres to Hess' statement 'that we have to content ourselves with the recognition that much exists and evolves in this world which is not accessible to our comprehension, since our cerebral organization is primarily devised so that it secures secure survival of the individual in its natural surroundings'.

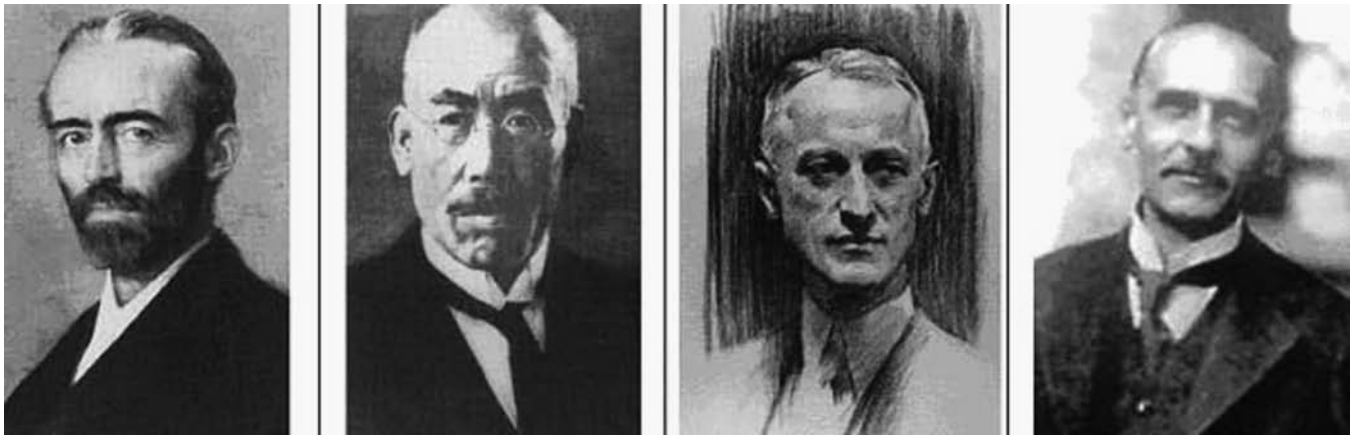

Figure 8a.1 From left to right: Portraits of Theodor Kocher (1841–1917), Hayazo Ito (1864–1929),[5] Harvey Cushing (1869–1939)[15] and Otfrid Foerster (1873–1941).[11]

Hugo Krayenbühl's legacy

The history and development of modern neurosurgery in Switzerland has been linked since the early beginning to the study and surgical management of epilepsy.

The idea of a ward for neurosurgical patients in Zurich became a reality when the old deaconess hospital located in the Heliostrasse called 'Krankenstation Hegibach' (Figure 8a.2 left) was given from the government to the surgical department of the 'Kantonsspital Zurich'. In 1936, in the uppermost floor of the building and under the far-sighted guidance of Krayenbühl, a ward specially dedicated to neurosurgical cases was opened. In 1939 Krayenbühl officially assumed the direction of the Division of Neurosurgery, still a part of the surgical department.

Krayenbühl was born on 3 December 1902 in Zihlschlacht, a small village located in Thurgau in Switzerland. He was the son of a well-known Swiss psychiatrist who was chief of the psychiatric hospital in Zihlschlacht. At home, during his childhood and adolescence, Krayenbühl was deeply influenced by discussions about the causes and treatment modalities of mental and neurological diseases. He started his medical training in Geneva in 1921, and continued his studies in Kiel (Germany) with the later renowned psychiatrist Manfred Bleuler. Krayenbühl returned home and graduated from the medical faculty of the University of Zurich in 1927. He began his nine-year postgraduate training in pathology, internal medicine, psychiatry, and general surgery in Zurich, and continued in neurology (Prof. K. Bonhoeffer) in Berlin, and in neurosurgery (1934–1935) in London with Sir Hugh Cairns.[16] After his return to Zurich in 1936 he worked as a 'Voluntärassistent' at the surgical department in Zurich under Paul Clairmont.

Krayenbühl's hard work during the following two years succeeded in convincing the faculty to establish a

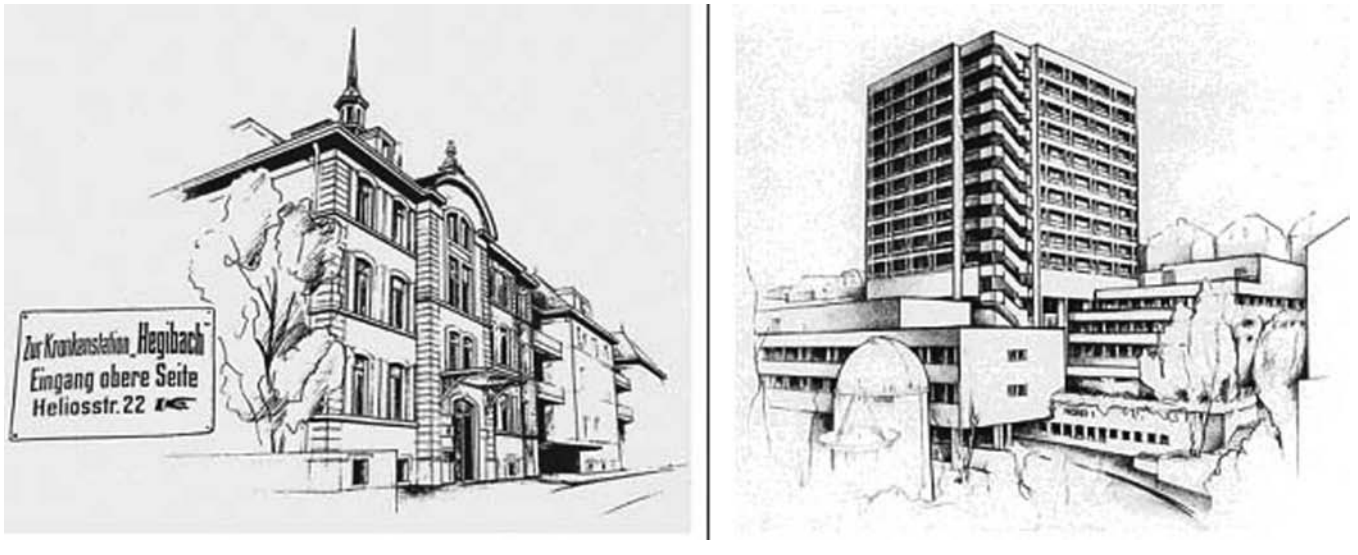

Figure 8a.2 Left: The neurosurgical ward at Hegibach started with a few beds during the year 1936. In 1939, it was recognized as a division of the Department of General Surgery under Professor Paul Clairmont (1875–1945). Later on, in 1945, an independent Department of Neurosurgery was created under the direction of Professor Hugo Krayenbühl. In 'Hegibach'the first installation took place of an EEG station during 1948 as a division of the neurosurgical department. During 1951 the Department of Neurosurgery moved to the new building of the Cantonal Hospital of Zurich (University Hospital) at the Rämistrasse where a new in-patient ward of the neurological clinic was opened. Right: In 1999 the neurosurgery moved to the new Nordtrakt II of the University Hospital Zurich, with theaters and the ICU on floor C, and wards on floors M and N. (Illustrations: P. Roth).

neurosurgical ward. Later, during the winter semester of 1944–1945, an independent Department of Neurosurgery was officially inaugurated. With this historical milestone, Krayenbühl became the first chief of a Department of Neurosurgery in Switzerland.

Krayenbühl's interest in epilepsy surgery was already apparent in his early career as a neurological surgeon. On 13 May 1941, he received the Venia legendi from the University of Zurich, based on ten original publications and the monograph 'Das Hirnaneurysma', an 84-page long manuscript published in the Swiss Archives of Neurology and Psychiatry. For his 'Probevortrag', an introducing lecture given to the members of the faculty, Krayenbühl chose the issue 'Epilepsie und ihre chirurgische Behandlung' (epilepsy and its surgical treatment). This reflected his interest in epilepsy and revealed the multidisciplinary nature of it. No other disease or human suffering could bring together so tightly different medical specialties as epilepsy. Influenced by his predecessors Victor Horsley (1857–1916) and Harvey Cushing (1869–1939) as well as Wilder Penfield (1891–1976), Krayenbühl succeeded in specifying a common path for neurologists, neurophysiologists, neuropsychologists, and neurosurgeons dedicated to the study and treatment of epileptic seizure disorders.

Krayenbühl was promoted to Professor Titularius on 30 April 1945, to Professor Extraordinarius ad personam on 23 September 1948, and to Professor Ordinarius on 16 April 1963.

His colleagues considered Krayenbühl, because of his huge and profound knowledge in neurology and his clinical skills, as a 'neurological surgeon'. Until 1952 all outpatients of the neurological clinic who required hospitalization for check-up or diagnostic reasons were admitted to the neurosurgical department. There were two reasons for this historical situation. First the new diagnostic techniques such as electroencephalography (EEG), pneumoencephalography (PEG), myelography, and angiography were locally introduced with great impetus by Krayenbühl. Second, an in-patient station at the neurological department was absent. Only eight years after the establishment of the neurosurgical department, the neurological department opened a ward for patients who required hospitalization for diagnostic purposes.

During the first 18 years, a total of 2336 patients with epilepsy were assessed and treated in the neurosurgical department under Krayenbühl. A brain tumor was causing the seizures in 343 patients (15%) and 608 patients suffered from a so-called 'Spätepilepsie', i.e., idiopathic epilepsy of the elderly. [17] This sample was described by several publications.[18, 19] Thereby, neurologists and neurophysiologists, founded a bank of knowledge at the neurosurgical department. Based on experimental studies on 'extrapyramidal epilepsy' and its pathophysiology, Krayenbühl defined its clinical features.[18]

With the introduction of an EEG-station in 1948 and the facilities in the new building of the 'Kantonsspital' (1951/2), surgery for epilepsy became routine in the daily activities of the department. The discovery and neurophysiological evaluation of many cases with 'psychomotor epilepsy' raised the interest of temporal lobe epilepsy and surgical management. Krayenbühl had been performing anterior temporal lobectomies with a standard technique since 1936, and started to use intraoperative electrocorticography (ECoG) in 1949. His surgical decisions were always based on the convergence of clinical features and EEG findings (Figure 8a.3). His meticulous technique did not differ much from that practiced since 1934 by Wilder Penfield at the Montreal Neurological Institute (MNI).[20, 21] The posterior line of resection of a nondominant anterior temporal lobectomy was the vein of Labbé, the temporal horn was punctured at the beginning of the operation via a small corticotomy in the middle temporal gyrus, and the uncinate gyrus was sucked away very carefully to remove the mesial structures of the temporal lobe.

In October 1951, Krayenbühl revealed his passionate interest in psychomotor epilepsy in a lecture he gave to the medical faculty of the University of Zurich. He presented his surgical series of patients with lesional and nonlesional epilepsy and increased his pupils' interest in temporal lobe epilepsy. Together with Hans Peter Weber, his intraoperative illustrator, Krayenbühl and his collaborators documented carefully each case with epilepsy (Figure 8a.4).

Krayenbühl developed his own concept of epilepsy surgery and he expressed his estimation of the work of his colleagues in London,[22] Paris,[23, 24] and Montreal.[20, 21]

Krayenbühl's absolute priority was to limit the exposure of the brain surface during surgery. The brain and its surrounding structures had to be carefully handled. Although together with Rudolf Hess he performed numerous electrical intraoperative stimulations, he was skeptical and showed distrust toward new invasive presurgical diagnostic methods, such as the SEEG, until he proved them and was convinced of their safety and efficacy. It is typical that he

wanted to see that depth electrodes had advantages over intraoperative recording (Figure 8a.5).

In association with distinguished neurosurgeons of Europe and the US, Krayenbühl engineered and founded the publication 'Advances and Technical Standards in Neurosurgery', its first issue appearing in 1972.

Krayenbühl was a gentle individual who stimulated his pupils and transmitted his philosophy to them. He left an indelible trace in all of them. His strictness and his demonstration of authority, sometimes led to outbursts of rage. According to Krayenbühl, 'One has to say to the people what they did wrong, what they did right is self-evident'. Many of his pupils and colleagues discovered a paternalism coming from their teacher. The strive for excellence in the daily work was his main occupation. His authoritative behavior was used only to serve.

In 1995 at the commemoration of Krayenbühl's death, Yasargil expressed, 'I still continue to learn from my teacher in my daily activities and decisions, and I am often involved in discussions with him, even in my dreams' (Figure 8a.6).

After 22 years as chairman of the Department of Neurosurgery, Krayenbühl retired in 1973, dedicating his last years to finishing ongoing projects and meditating about his life as a neurosurgeon, teacher, and philosopher. Professor Hugo Krayenbühl died on 1 January 1985, 83 years old.

The Zürich Neurology and Brain Research Institute

Twelve years after the first chair for neurology had been created for J.M. Charcot, (Paris 1882), Constantin von Monakow (1853–1930), who was seeing patients in a private praxis in Zurich since 1887, was elected as professor extraordinarius for 'hirnanatomische Fächer' (brain anatomy; 1 October 1894) (Figure 8a.7). In 1910 Monakow's private laboratory for brain research has been taken over by the Canton Zurich. From 1913 on there existed a 'Hirnanatomisches Institut' and a 'Neurologische Poliklinik',[25] but the first neurological ward was only available in 1952 under the successor of von Monakow, Miecyzyslav Minkowski (1928–1954). Monakow retired in 1927 and was succeeded by Minokowski in 1928 who was at the same time promoted to professor extraordinarius (with etat) and nominated director of the 'Neurologische Poliklinik' and the 'Hirnanatomisches Institut'.[26]

The 'Hirnanatomisches Institut', later called the Brain Research Institute, is also indebted to Krayenbühl. After the retirement of Minkowski as chief of the Neurological Clinic and director of the Institute in 1954, the prestigious Brain Anatomy Institute was almost shut down. Throughout the decade, with continuous negotiations with the University of Zurich and the Medical Faculty, Krayenbühl was successful in his efforts, and an additional academic position was created for the guidance of the Institute. Konrad Akert was appointed chairman in 1960, and the traditional research at the Institute was complemented with research in the pathogenesis of epilepsy (Figure 8a.8).[27]

The EEG Unit at the Neurosurgical Department

Krayenbühl, considering the new development of advanced neurosurgery, installed an EEG-station at Hegibach in 1948. Very soon Krayenbühl had recognized the importance of this

Figure 8a.6 Left: Portrait of Professor Hugo Krayenbühl (1902–1985), founder and chairman of the first neurosurgical department in Switzerland. Middle: Hugo Krayenbühl is congratulated on his 70th anniversary by HGW. Right: Hugo Krayenbühl during the celebration of his 80th birthday in Zurich accompanied by his pupils M. Gazi Yasargil and Konrad Akert, Director of the Brain Research Institute of the University of Zurich. Photo: P. Roth.

method for epilepsy and neurosurgery.[18,19] Intraoperative EEG recording from the brain (ECoG) was already considered an important tool for definition of the 'epileptic focus', according to the pioneer work of Penfield and Jasper in Montreal. At that time in Zurich, about one third of the patients admitted to the neurosurgical department presented with seizures. In 15% of the cases a tumor could be diagnosed as the cause of epilepsy.

The historical context at that time was optimal for the development of electrophysiology in Zurich. One decade of surgical experience in neurological surgery, the cumulated number of patients with epilepsy, an independent neurosurgical department, as well as the support of many brilliant colleagues, such as neurophysiologist and 1949 Nobel Prize winner Walter Rudolf Hess (Figure 8a.9, *left*), allowed Krayenbühl to initiate a very fruitful era of EEG in Switzerland. Krayenbühl assigned this task to Rudolf Hess (Figure 8a.9, *middle*), who was trained in 1947–1948 by Dr. W. A. Cobb at Queens Square National Hospital in London, Dr. Grey Walter, Bristol, and in 1957 by Dr. Herbert Jasper in Montreal. Rudolf Hess also engaged himself in experimental sleep studies (Figure 8a.9, *right*) and was responsible for the development of clinical electrophysiology in Zurich.

Hess recorded the first scalp EEG (in a 31-year-old patient K., in 1917) on 8 October 1948, and the first intraoperative ECoG on 18 May 1949, in patient Elisabeth. Krayenbühl performed this operation, while Rudolf Hess was fortunate to record a well-localized spontaneous ictal event (Figure 8a.10).

Hess himself pushed the only existing eight-channel EEG apparatus of that time from the ward to the operation room until the department moved to a modern building at the

Hess.

Rämistrasse in 1952. The operation room at this hospital, later called University Hospital, was designed and built according to modern standards and well equipped for intraoperative EEG recording and electrical stimulation.[29,30] Epilepsy surgery became a routine procedure. More than 500 lesional, nonlesional, temporal, and extratemporal resections were performed throughout two decades.

The method of stereo-electroencephalography (SEEG), as pioneered in Paris by Bancaud and Talairach in 1965,[23,24] was introduced in Zurich with the cooperation of Christoph Bernoulli, epileptologist, and Jean Siegfried, functional neurosurgeon. Bernoulli had been trained with the Saint Anne's team in Paris, and Siegfried at the same time in Montreal. The first, at this time 'acute' SEEG exploration was done on 20 February, 1970 (patient M.S. in 1959) with the help of Gabor Szikla (from the Saint Anne team; Figure 8a.11) who did the so-called 'répèrage', i.e., the neuroradiological examination under stereotactic condition, consisting of pneumencephalography, angiography, and ventriculography, and performed with the patient's head fixed in the Talairach frame (Figure 8a.12). Up to 1984 depth EEG long-term recordings had to be done hard-wired in the laboratory (Figure 8a.13).

Seven years later, in 1977, Bernoulli *et al.* reported a person-to-person transmission of Creutzfeld–Jakob disease after SEEG exploration.[31] The popularity of this technique hid under the shadow of this fatal experience and less invasive and less risky presurgical evaluation methods were looked for, developed, and favored whenever possible. Nevertheless, SEEG had allowed for a deepened understanding of the phenomenology and electroclinical features of partial epilepsy syndromes and in particular temporal-limbic seizures.[32] These stereoelectroencephalographic studies inspired the development of new surgical techniques for the treatment of the so-called mesial temporal lobe epilepsy syndrome. The good results obtained in Zürich with the microsurgically performed selective temporal lobe resections stimulated and inspired the later development and introduction in Zurich of the foramen ovale (FO) electrode, a semi-invasive method for preoperative assessment of mesial temporal lobe epilepsy, in 1983.[33] Since 1984 FO electrodes were used in Zurich in 272 patients. Most of them were studied with radiotelemetry, which was

introduced in 1986. The FO-electrode technique became popular worldwide.

Cerebral angiography and the study of cerebrovascular anatomy

Krayenbühl learned the angiographic technique from Cairns in Oxford (Cairns, who had worked at the London Hospital, returned to Oxford in 1937) and introduced it in Zurich in 1939. In 1941 he reported the first angiogram of a saccular aneurysm of the basilar artery and in 1952 he published his experiences in the monograph 'Cerebral angiography' together with Dr. H. Richter.[34]

On 4 January 1953, M. Gazi Yasargil began his training in neurosurgery with Hugo Krayenbühl and Gerhard Weber. Krayenbühl assigned Yasargil to develop the technique of percutaneous cerebral angiography. Until 1965 Yasargil performed percutaneous carotid, vertebral, and orbital angiography on several thousand patients. The analyses of these angiograms and injected arteries and veins on 200 cadaver brains concerning their variations and courses have been published in several books, among them: in 1957 'Vascular diseases of vertebral and basilar arteries'[35] and in 1964 'Cerebral angiography'.[36]

In this way, the pioneering work of Krayenbühl and Yasargil on cerebral angiography converged again with the study and surgical treatment of epilepsy. Fifty years after the

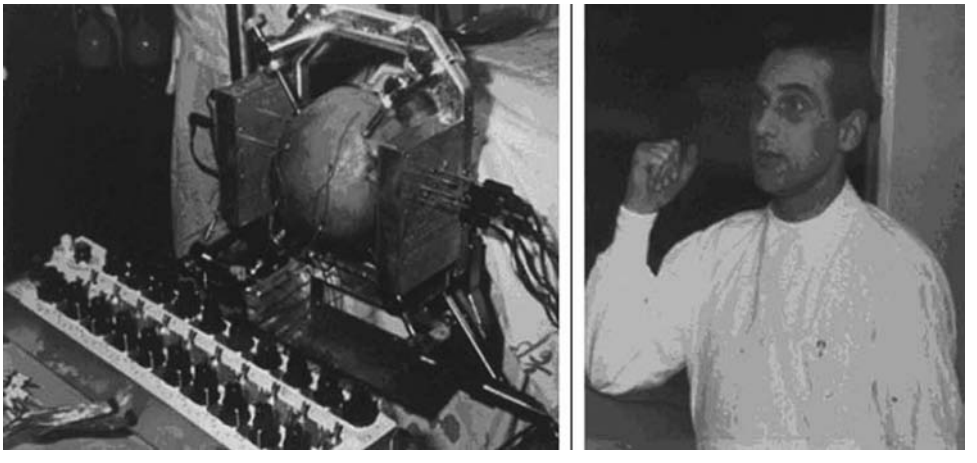

Figure 8a.11 Left: First 'acute' stereo-electroencephalography in Zurich 20 February 1970 (patient M.S. *1959) with the help of Gabor Szikla (right).

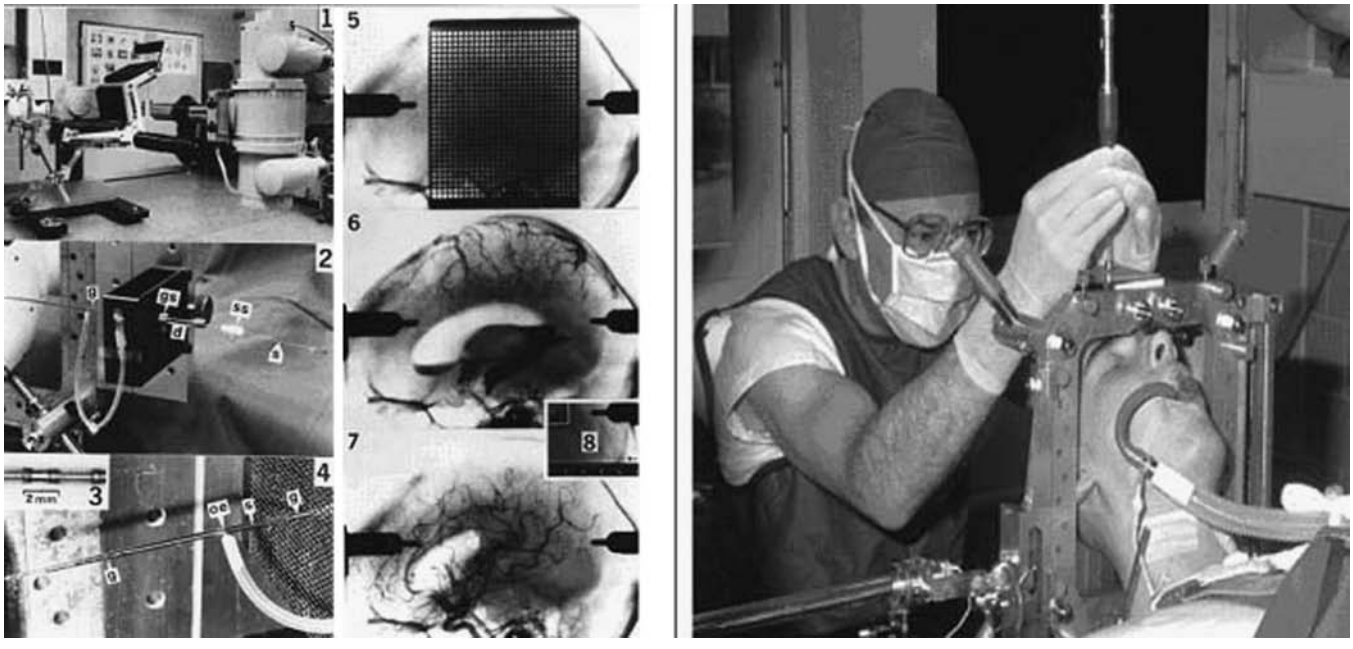

Figure 8a.12 Left: Illustration of the répèrage, i.e., neuroradiological examination under stereotactic conditions (1, 5–7) and insertion of the depth electrodes (2–4, 8). 1: Table of Alexander, 2 and 4: Electrode and insertion device mounted on the Talairach frame with the double grid. The guiding cannula (g) enters the bony orifice. Then the distance between the guide stopper (gs) and the end of the guide for the stylet was measured (d) and added to the calculated position of the stylet stopper (ss). To allow placement of the hollow-core electrode (see insert, 3) with mounted connector on the rigid stylet (s) between the grid and the patient's head, the double grid had to be removed by 6 cm. Photograph 4 shows how the guiding stylet was introduced into the lumen of the electrode (oe). Photographs 5, 6, and 7 show the lateral X-rays with the double grid in good centration (5), the veins (6), and arteries (7); the insert 8 shows the small burr hole for the depth electrode and one inserted depth electrode in the a–p view. Right: Trepanation for a depth electrode with the special drill.

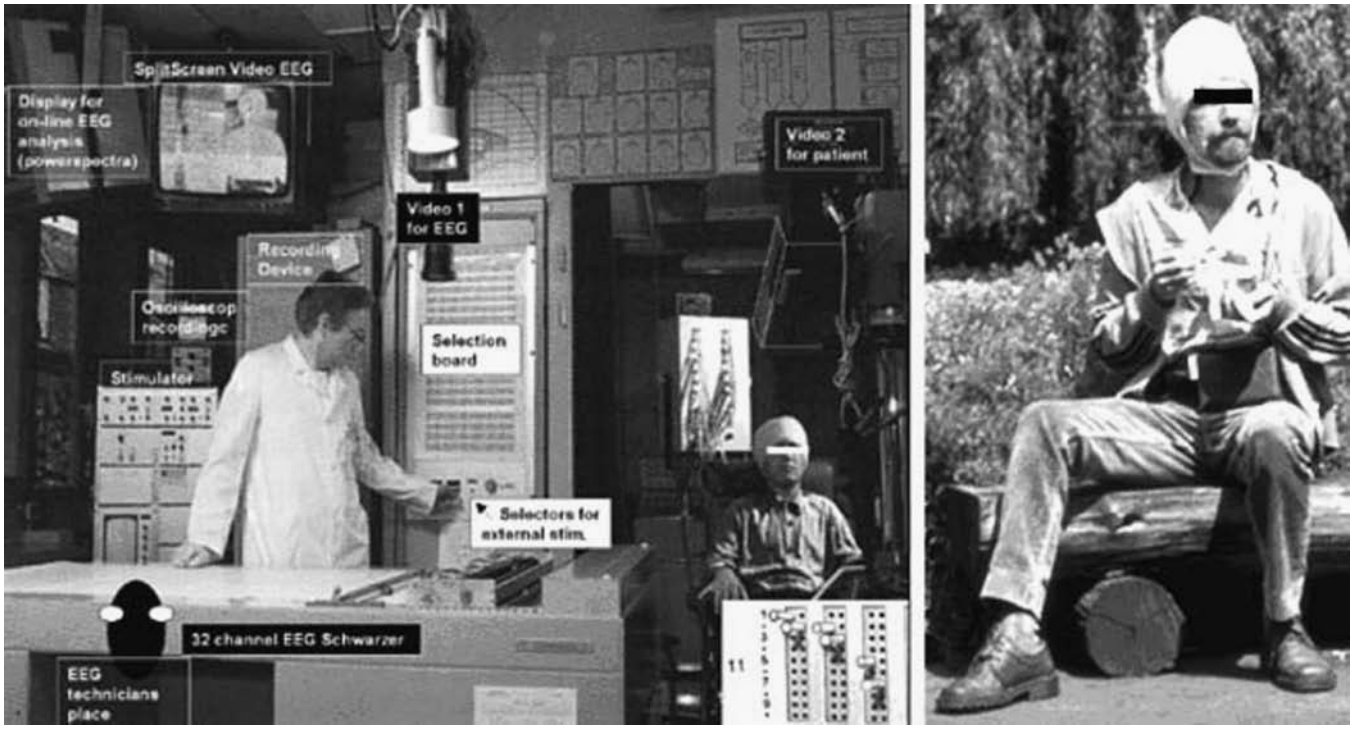

Figure 8a.13 Left: Photograph of the Zurich SEEG laboratory used in 1980 with a Faraday cage and the main parts of the recording and stimulation device. The selection board used the principle of a 'Kreuzschiene'(selection board), which allowed the composition of every conceivable combination of electrode contacts for recording and stimulation. There were 32 channels (horizontal) versus 17 × 10 signal entries (vertical). The insert (bottom, right) illustrates a detail of the selection board indicating that channel 1 records from contacts 1–2 of the depth electrode, channel 2 from contacts 2–3, etc. The lower part of the board hosts the selectors (two black rectangles) for external electrical stimulation. Right: First ambulatory depth EEG cassette recording 1984 (patient D.L.)

introduction of cerebral angiography in Zurich, another remarkable contribution of neuroradiology to epilepsy surgery was reported. In 1989 the introduction of the selective and superselective Amytal memory tests in Zurich allowed more exact presurgical language and memory investigations. The selective catheterization of the anterior choroidal artery in the so-called selective temporal lobe Amytal memory tests,[37] as well as branches of middle and posterior cerebral arteries supplying eloquent cortices in the so-called selective language Wada tests[38] was performed by Professor Anton Valavanis, chief of the Institute of Neuroradiology. Such selective co-injections of Amytal and a SPECT tracer became a routine procedure for selective Wada tests in Zurich. MRI replaced preoperative diagnostic and postoperative follow-up CT after epilepsy surgery in the Zurich series in 1983. The inclusion of new functional imaging methods, such as SPECT and PET in the presurgical evaluation of candidates for epilepsy surgery started in February 1988. More recently magnetic resonance spectroscopy (MRS) and functional MRI (fMRI) could be added.

Gazi M. Yasargil and the introduction of microneurosurgery

Krayenbühl highlighted 'the place of microsurgical technique in neurosurgical surgery' during the Fifth Sir Hugh Cairns Memorial Lecture of the British Society of Neurological Surgeons in London on 30 May 1969, 'I wish to emphasize, with Hugh Cairns, that surgery is and must be always an art, but its progress and thus its vitality depend on the maximum application to it of the methods and discoveries of science'.[39] This statement showed the immense and open foresight of a man who was already 67-years-old. In fact, it is easy to imagine how difficult it would be for a surgeon, after thirty years of surgical experience, to accept a better 'new way to do it'. In 1962 the Swedish cardiovascular surgeon Professor A. Senning, active in Zurich, was worried about thrombotic complications of leptomeningeal arteries after heart surgery using extracorporal circulation. He inquired whether a microvascular technique could be applied to solve the iatrogenic embolized arteries. Krayenbühl decided to send Yasargil to the United States to learn the microsurgical techniques, at that time mainly applied to peripheral neuro and vascular surgery. Theodor Rasmussen, Director of the MNI, recommended Professor R.M. Peardon Donaghy from Burlington, VT. Donaghy was already a pioneer in reconstructive vascular surgery, initiated at his clinic in 1960 by J. H. Jacobson. Yasargil went to the US in 1965 and spent a year in Donaghy laboratory. Here, he learned and developed microtechniques for the reconstruction of the brain arteries.[40]

The era Gazi M. Yasargil

Mahmut Gazi Yasargil (Figure 8a.14) was born in Lice, Turkey, on 6 July 1925. In order to study medicine, he left Turkey in 1943 and went first to Vienna and then to Jena where he studied in medical schools two semesters and then moved to Basle, Switzerland, where he graduated in Fall 1949. According to his intention to become a neurosurgeon he spent three months at the Basle Institute of Anatomy 'Vesalianum' and learned from Professor Josef Klingler the special dissection technique of the formaldehyde fixed cadaver brain. He continued these studies during his postgraduate training in the following three years.

His basic medical training was complemented with a year of psychiatry and neurology (Professor Max Müller, Münsingen), internal medicine (Professor W. Baumgartner), and general surgery (Professor W. Bandi) in Interlaken. In January 1953 he joined the Department of Neurosurgery at the University Hospital Zurich and started his training in Neurosurgery with Hugo Krayenbühl and Gerhard Weber. His first paper on neurosurgery titled 'Vertebralisangiographie' was published in 1955.[41] From 1958–1965 Yasargil was involved in stereotactic procedures for the treatment of movement disorders and of chronic pain using the Riechert–Mundinger stereotactic frame and the high frequency coagulation apparatus of O. Wyss and R.W. Hunsperger, developed at the Institute of Physiology, University of Zürich. In 1957 he spent some weeks in Freiburg/Breisgau (Germany) and 1960 four weeks in Paris with Prof. Jean Talairach. From 1965–1966 he spent 14 months in the laboratory of cardiovascular surgery at the University Vermont, Burlington, USA where amongst others R.M.P. Donaghy was pioneering microvascular surgical techniques. Before leaving Zurich he introduced Jean Siegfried to the field of functional neurosurgery.

Yasargil envisioned that the field of microneurosurgery developed for reconstructive neurovascular procedures (introduction of extracranial–intracranial anastomosis), would gradually encompass other vascular lesions, aneurysms, arteriovenous malformations, and brain tumors, and, eventually, involve the whole realm of neurosurgery. During difficult vascular procedures he expressed to Krayenbühl the necessity 'to see better'. Good illumination, unobstructed vision and a view of the whole operative field are essential to the surgeon. In the foreword of Yasargil's famous book '*Microsurgery Applied to Neurosurgery*'.[42] Krayenbühl points out, 'It is astonishing that the operating microscope came to be employed so late in the field of neurosurgery, since it has been an indispensable tool in the routine otologic surgery for four decades'. The historical invention and development of the bipolar coagulation done by Leonard I. Malis (chief of the Department of Neurosurgery, Mt. Sinai Medical Center, NY, from 1970–1991) accompanied by the introduction of a counterbalanced operating microscope stand and numerous microinstruments designed or re-designed by Yasargil (presented in a Zurich course in microsurgery, 14–20 November 1968), allowed the application of microtechniques in neurosurgery. Yasargil's contribution to neurosurgical literature culminates with his latest book in the series 'Microneurosurgery' in 1996.[43]

Gazi Yasargil introduced microtechniques to neurosurgery in 1967. The design and development of a counterbalance microscope stand (System Yasargil, SMED®); numerous microinstruments and new approaches became very fast the gold standard technique in vascular and tumoral neurosurgery and contributed to the development and technical improvement of epilepsy surgery. Over 3000 colleagues (neurosurgeons and other surgical specialists) from around the world were introduced to and trained in the techniques of

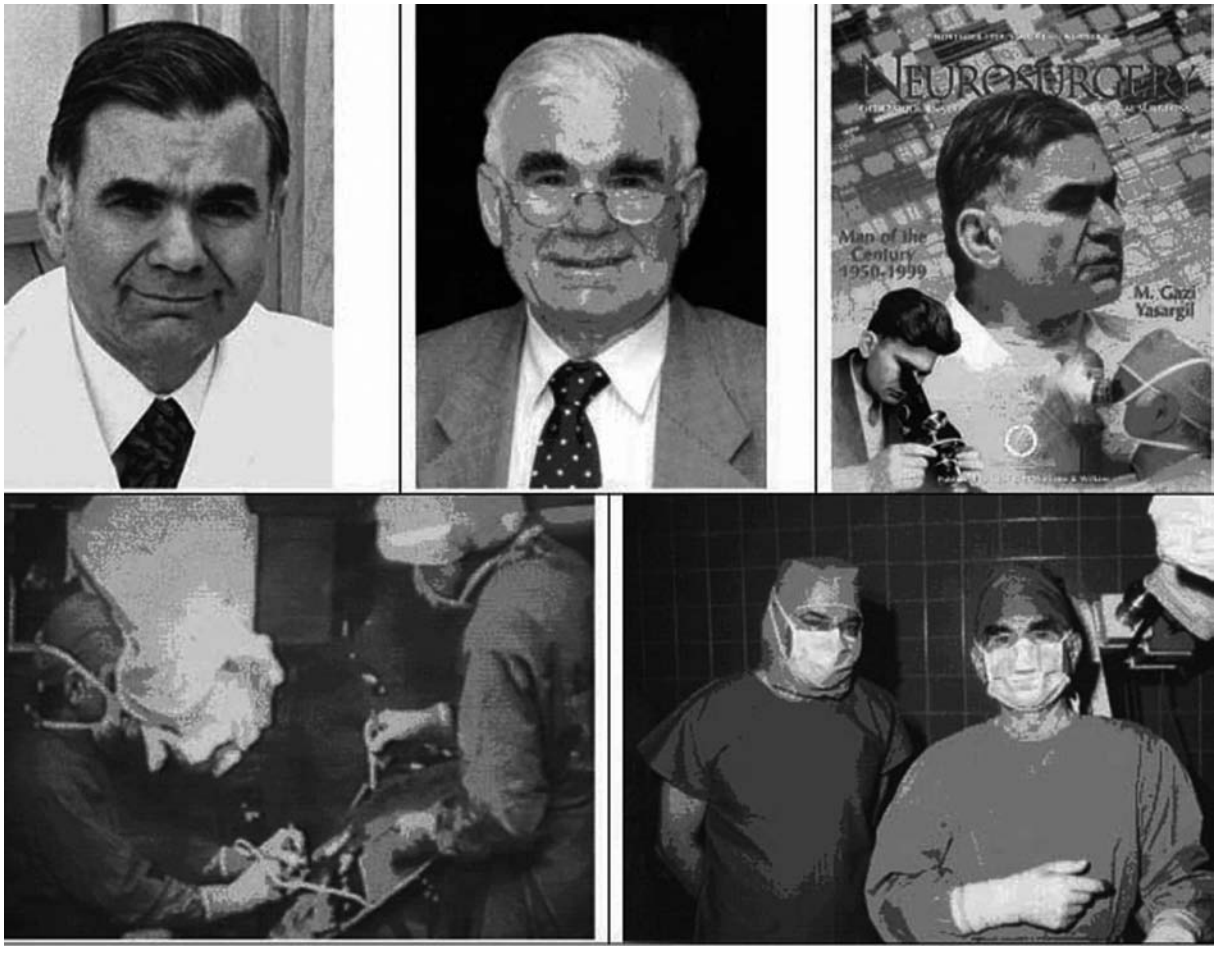

Figure 8a.14 Top: Gazi Yasargil at the beginning (left) and at the end (middle) of his career in Zurich. Right: Title page of the *Neurosurgery* 1999, vol.5, honoring M. Gazi Yasargil as Neurosurgery's Man of the Century. Bottom: Gazi Yasargil performing microneurosurgery and assisted by Diane Yasargil (left) and after his last selective amygdalohippocampectomy performed in Zurich (right).

microsurgery in Zurich. The development of the subarachnoid approaches allowed noninvasive explorations and complete elimination of extrinsic and intrinsic lesions of the CNS: 'the subarachnoid pathways are the route maps for microneurosurgery'. In more recent years, Yasargil's interest focused on 'autoregulated integral functional units' of the central nervous system. Observations and experiences in a large series of operated patients with vascular and neoplastic lesions led him to conceptualize the 'limbic–paralimbic' compartment.[44]

Yasargil retired in Zurich 1992 after completing 40 years of activities at the University Hospital of Zurich. He was appointed in 1994 at the University of Arkansas in Little Rock, AR (USA) as professor of neurosurgery (Department of Neurosurgery, chairman Prof. Ossama Al-Mefty), where he continues his academic and surgical activities. He received the Medal of Honor of the World Federation of Neurosurgical Societies during the XI International Congress of Neurological Surgery held in Amsterdam in 1997. Harvey Cushing (1869–1939) and M. Gazi Yasargil were selected as the Neurosurgery`s Men of the Century by the Editorial Board and the International Liasin ad Advisory Panel of Neurosurgery, the official Journal of the Congress of Neurological Surgeons.[45–49] Since then Yasargil has continued improving neurosurgical training[50] and to advice his pupils.[49]

The present

Yasuhiro Yonekawa, a graduate of Kyoto University, was sent by Prof. H. Handa (founder of the Department of Neurosurgery in Kyoto University) to Zurich (Figure 8a.15). To speak in Prof. Yonekawa's own words[51] he came to Zurich in 1970 as 'one of the many pilgrims' and trained with Prof. Yasargil from 1970–1976, at first as resident and later as a chief resident (Oberarzt). Yonekawa returned to Japan in 1976 and was nominated Director of the National Center for Vascular Surgery in Osaka. At the beginning 1993 he was called as Yasargil's successor to direct the Neurosurgery Department. In his most recent paper[52] Yonekawa speculates on the reasons for 'the final decision why and how a Japanese was elected' and came to the conclusion that one of the main reasons must be that he (Yonekawa) knows 'exactly how and what the Zurich school of neurosurgery is: style of working and tradition above all'. Indeed one of us (HGW) witnessed that the operative excellency was the decisive criterion for the succession of Yasargil in 1993. In his No Shinkei Geka article[52] Yonekawa gave a brief review of the history of the Zurich Neurosurgery department and devoted one paragraph to 'what is now going on?'. In this paragraph he lists 'epilepsy surgery' under number 4 [after # 1: Vascular neurosurgery, including Moyamoya angiopathy; # 2: Skull base tumors, deeply seated tumors, and # 3: Glioma-glioblastoma surgery. Under # 5 he mentions

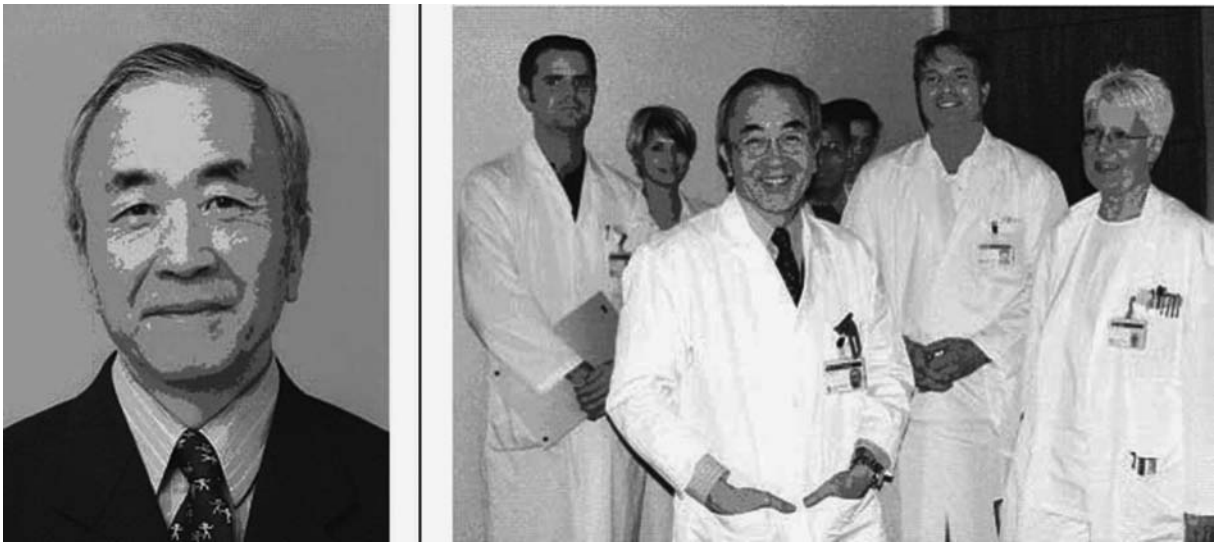

Figure 8a.15 Yasuhiro Yonekawa, chairman of the neurosurgical department of the University Hospital Zurich since 1993 with some of his collaborators in 2005 (right).

neuronavigation, open MRI, and neurophysiological monitoring, under # 6 neurosurgical intensive medicine. # 7 covers stereotactic surgery, # 8 postgraduate education and exchange of information and knowledge by international and regional meetings. In # 9 he mentions approaches of routine use developed recently besides selective extradural anterior clinoidectomy and SCTT (supracerebellar transtentorial) approaches. Under epilepsy surgery he addresses the selective amygdalohippocampectomy series[53] and his supracerebellar transtentorial approach[54] as well as the infratentorial supracerebellar approach for posterior hippocampectomy and intraoperative EEG monitoring[55] including ECoG and electrical cortex stimulation.[56] It should be mentioned that Prof Yonekawa re-introduced epilepsy surgery in the awake patient for cases with planned resections in highly eloquent brain areas[57] and by his en bloc resection of the hippocampus helped tremendously the experimental research.[58a,b]

Selective amygdalohippocampectomy

Prior to 1969, resective surgical therapy of temporal lobe epilepsies in Zurich was done by means of anterior two-third resections. Patients who underwent this operation met the following criteria: (a) drug-resistant complex partial seizures, and (b) spike foci well and consistently lateralized to one temporal lobe in surface EEG. Patients usually underwent PEG and ventriculography as well as carotid angiography; intraoperatively, ECoG confirmed the spike focus and the extent of resection was approximated according to it.[19] This approach had several shortcomings and the results did not entirely satisfy. Therefore, the method of SEEG, as mentioned before, was adopted and introduced in Zurich in 1970. From 1970 to 1974, the criteria, mode of exploration ('acute'), and stereotactic techniques, as well as the analysis methods of the depth EEG, were more or less identical to the Parisian approach,[23,24] i.e., a broad spectrum of patients with various types of focal epilepsies (temporal and extratemporal) were evaluated.

In patients with temporal lobe epilepsy, particularly in those cases in which a seizure origin had been identified within the mediobasal temporal lobe structures, the question arose in 1973 to perform a selective amygdalo-hippo-parahippocampectomy using a microsurgical technique. Gastaut had already stated in 1950 that the origin of temporal lobe epilepsy is in most cases rhinencephalic.[59] Paulo Niemeyer presented his experiences on 19 patients at the 2nd International Colloquium (Bethesda, Maryland, USA, 1958): he had successfully removed through a transventricular approach the mediobasal temporal lobe structures. In the subsequently appearing book based on this Colloquium (edited by M. Baldwin and P. Bailey), Niemeyer[60] gave credit to Riechert and Jung, who interrupted stereotactically the fornix, to J. Viana, who had removed the hippocampus in unselected epilepsy patients, and to Scoville and Milner.

A review of the history of epilepsy surgery documents that the surgical procedures for the treatment of epilepsy were dependent on, and related to the precise definition of the seizure focus.[61–64]

The microsurgical selective amygdalohippocampectomy introduced by Yasargil is the result of the experience gained since 1967 by microsurgical approaches in the treatment of aneurysms, AVMs and especially mesiobasal temporal tumors.[65–67] Yasargil was influenced by two main issues: first, he found that gangliogliomas, ganglioneuromas, astrocytomas, and AVMs confined to the mediobasal temporal lobe could radically be extirpated without recourse to lobectomy. Second, he noted that local removal of mediobasal temporal tumors and AVMs had been accompanied by fewer postoperative fits if the amygdala and parahippocampus were resected simultaneously.[66,67]

The development of the pterional craniotomy and its various refinements provided familiarity in exposing the proximal Sylvian fissure just above the limen insulae. The transsylvian route was readily adapted for exploration of the mediobasal superior lobe with approach to the amygdala and parahippocampal cortex. After gentle opening of the Sylvian fissure using sharp dissection, a 1–2 cm cortical incision in the sulcus insulae circularis pars inferior, lateral to M-1 and inferior trunc of M-2, is done to reach and remove the amygdala, to open the pia-arachnoideal layers, to explore the ambient and

crural cisterns, to identify the courses of the anterior choroidal and P1-segment of posterior cerebral artery, the optic tract, and the oculomotor nerve. The temporal horn is identified, dissected, and the hippocampus and parahippocampal gyrus are removed. This technique requires considerable microsurgical experience and, above all, familiarity with the regional anatomy, which can only be gained after 'meticulous cadaver microdissection'.[67] This technique has been somewhat underestimated by neurosurgeons who do not have enough experience in vascular microneurosurgery not realizing the great benefit of this selective technique considering its outcome with respect to seizures and neuropsychology. The manipulation and recognition of the vascularization of the amygdala, gyrus parahippocampalis, uncus, and hippocampus and regular variability has to be kept in mind during surgery.

In the last 10 years Yonekawa has steadily refined the posterior hippocampectomy for symptomatic posterior hippocampal epilepsies. Such lesions were difficult to approach with Yasargil's transsylvian technique. Today the posterior hippocampectomy (PHE) constitutes a remarkable large percentage of mesial TL resections at our hospital: 35 PHE versus 150 sAHE.

The criteria considered for the 'curative' selective amygdalohippocampectomy include (a) unequivocal unilateral medial temporal focal seizure onset at these structures associated with typical clinical symptoms and (b) contralateral hippocampal functions intact (special neuropsychological testing for learning and memory performance, selective temporal lobe Amytal testing, and presence of signs indicative of hippocampal atrophy and/or Ammon's horn sclerosis). A 'palliative' operation of this type might be indicated in cases where the primary seizure generating zone in the lateral posterior temporal neocortex cannot be removed without anticipated intolerable functional deficit, and where the ipsilateral hippocampal formation is rapidly involved by the ictal discharges acting as a 'secondary pacemaker'. In the time-period since 1975, 513 patients underwent selective amygdalohippocampectomy with satisfying results.[68–70]

Perspectives and final remarks

Professor Krayenbühl will be remembered as a teacher whose forethought and encouragement allowed the advances in neurosurgery and development of his pupils. Epilepsy, as the common meeting point of many medical disciplines has allowed neurosurgery to develop smoothly through the fields of EEG, neuroradiology and microtechniques throughout the last six decades.

New functional neuroimaging methods, such as SPECT, PET, magnetic resonance spectroscopy (MRS), fMRI, as well as less invasive surgical methods and techniques supported by real time imaging during surgery (like open MRI or frameless computer assisted stereotactic localization) have been introduced in Zurich in the last few years without ignoring the tradition and legacy of the predecessors.

Meanwhile epilepsy surgery and related research is done in several institutions in Switzerland. With the election of Professor Theodor Landis as chairman of the neurology in Geneva and his move from Zurich to Geneva the surgical program 'neurologie et neurochirurgie fonctionelle Vaud – Geneva' started in 1955. Margitta Seeck and Jean-Guy Villemure recently presented their first 150 patients consisting of pediatric (one third) and adult epilepsy surgery patients. This very active surgical program has at its disposal all modern presurgical evaluation methods, including 3T-MRI, PET, ictal SPECT including subtraction analysis SISCOM, fMRI and EEG-triggered fMRI, as well as high resolution EEG recordings with electric source imaging on the basis of up to 256 scalp EEG channels. They also use invasive and semi-invasive intracranial recording and perform all accepted curative and palliative surgical procedures, including functional hemispherectomy, selective amygdalohippocampectomy, tailored neocortical resections both temporal and extratemporal, and VNS.

Epilepsy surgery is also done in other university hospitals, such as Berne, and with a more limited approach in several other institutions and Cantonal hospitals. Today there is a very fruitful and close collaboration between the University Hospital Basle and the Swiss Epilepsy Center in Zürich on one hand and the epilepsy surgery program of the University Zurich on the other. Thus, as Wilder Penfield has masterly outlined in his biography 'No Man Alone'[12] epilepsy surgery in Switzerland has emerged to network collaboration. Reasons for this advantageous development of epilepsy surgery in Switzerland are:

(1) the availability of advanced non-invasive diagnostic tools to delineate epileptogenic lesions, epilepsy related functional deficits and to prove epileptogenicity;
(2) improved knowledge on surgically remediable epilepsy syndromes; and
(3) improved surgical techniques by means of microsurgery and the availability of intraoperative MRI and intraoperative monitoring, including recording and cortical electrical stimulation.

All these factors translate into better post-surgical outcome figures and a larger population of difficult-to-treat patients profiting from surgery. Although 'much has been reached at, more has to be done'! The Zurich team adheres to the principles of Hugo Krayenbühl to learn from failures ('one has to say to the people what they did wrong – what they did right is self-evident') and remains aware of Gazi Yasargil's statement 'each surgical action compromises not only science, experience, knowledge, and techniques, but also artistic, philosophical, and religious attitudes from a neurosurgeon'.

The Zurich team, in order to master neurosurgery, remains aware of Yasargil's statement: 'each surgical action comprises not only science, experience, knowledge, and techniques, but also artistic, philosophical, and religious attitudes from a neurosurgeon'.[41]

Acknowledgments

The Zurich authors are indebted to Mr. Hans Peter Weber and Mr. Peter Roth, scientific artists, whose work has helped many neurosurgeons understand the concept of microneurosurgery, and to Mrs. Simone Spring for compilation of the references.

8b Epilepsy surgery in Austria

C Baumgartner, T Czech, and O Schröttner

Development of epilepsy surgery in Vienna

Neurosurgery in Austria began at the turn of the 19th century when Anton von Eiselsberg (1860–1939) (Figure 8b.1a) removed a gliomatous brain tumor in the central region in 1904. The patient wasdischarged in excellent condition two months after surgery. After spending some time in Paris studying neurology under Charcot, von Eiselsberg began his surgical career under the famous Christian Theodor Billroth (1829–1885) in 1882 just one year after Billroth had performed the first successful gastric resection. Von Eiselsberg was appointed chairman of the First Department of Surgery of the University of Vienna at the Vienna General Hospital ('Allgemeines Krankenhaus der Stadt Wien') in 1901 (Figure 8b.1b). Subsequently, Vienna developed to one of the leading centers for neurosurgery at that time and even Harvey Cushing came to Vienna to learn from von Eiselsberg. In 1908, von Eiselsberg published a review of the first 23 brain tumors treated surgically in his department.

In 1910, when Harvey Cushing performed his first brain tumor surgery, von Eiselsberg already published his experience on 71 brain tumor resections [1]. Between 1901 and 1913 von Eiselsberg and his coworker Egon Ranzi (1875–1938) (Figure 8b.1c) operated on 168 brain and medullary tumors among them many patients suffering from focal epilepsy.[2] Von Eiselsberg's intense interest in neurosurgery is further reflected in 17 publications on neurological surgery out of his 95 major publications. In 1920, the anatomist Julius Tandler and Egon Ranzi published a book on the surgical anatomy and operative techniques of the central nervous system which was considered the international reference work at that time.[3]

Subsequently there developed an intense collaboration between Egon Ranzi from the Department of Surgery and Otto Marburg, Chairman of the Department of Neurology which culminated in a publication on 318 brain tumors treated surgically in Vienna (Figure 8b.1d).[4] In this seminal paper the authors mention epileptic seizures as one of the key symptoms for the diagnosis of brain tumors. They correctly disputed Victor Horsely's postulate that every patient with adult-onset epilepsy should be treated surgically. They presented a detailed table on 35 patients with epilepsy categorized according to epilepsy type, tumor type and tumor location. They pointed out the importance of an accurate history for the localization of the seizure-onset zone and the high reliability of Jacksonian seizures for localizing the seizure-onset zone to the central region. They reported on a patient with ictal aphasia with a tumor located in Broca's area. They also meticulously analyzed the temporal relationship between the onset of epilepsy and other symptoms and also reported on a subgroup of 8 patients suffering from long-lasting epilepsy without other symptoms. Concerning outcome they reported 20 patients with supratentorial tumors in whom the tumor could be identified during the operation and could be either totally or partially resected. While 10 patients died either early or late (within 6 months after surgery), 10 patients were considered as cured by the surgery, long-term results were available for 7 of them. The authors remarked that seizures stopped after surgery in some cases, while they were not influenced by the operation in others. They also reported that 8 out of 41 patients in whom a brain tumor was removed between 1901 and 1913 were still alive and fully functional after a follow-up for 7 to 15 years. Concerning epilepsy they already distinguished between two groups of patients, namely those whose seizures could be cured by surgery and those with persistent seizures due to some 'disposition to epilepsy'. [4]

While the experience with brain tumors in the First Department of Surgery accumulated to 500 cases in the meanwhile, failures, complications and surgical mortality remained high, which deeply concerned von Eiselsberg. He gave a critical lecture during the 50th Congress of the German Society of Surgeons in 1926 where he said 'as Billroth taught me to look for the causes of failure at my own doorsteps, I spent many miserable hours doing so, wondering why my results, when compared with the success achieved by the American surgeons, particularly Cushing, were so poor'.[5]

In 1931, Eiselsberg stepped down as chairman of the First Surgical department. He was followed by Egon Ranzi who delivered his inaugural lecture on the development and advances of neurosurgery in 1932.[6] Ranzi believed that the ideal neurosurgeon was one who combined the skills of the surgeon with the knowledge of the neurologist, as Cushing and Otfried Förster had done. He stressed the necessity of intense collaboration between neurology and neurosurgery. In 1938 Ranzi had to step down as chairman for political reasons and died in the same year. In 1939, Eiselsberg died in a railroad accident. Two other pioneers of neurosurgery in Vienna, Marburg and Hirsch, had to leave the country and immigrated to the Unites States.

Leopold Schönbauer (1888–1963) (Figure 8b.1e) became chairman of the Department of Surgery in 1939. He was the last living representative of von Eiselsberg's legacy. Schönbauer joined von Eiselsberg' team in 1916 and became increasingly interested in neurosurgery. In 1924 Schönbauer visited Harvey Cushing in Boston and spent 4 months there. Schönbauer became deeply impressed by Cushing's approach to neurosurgery, his skills

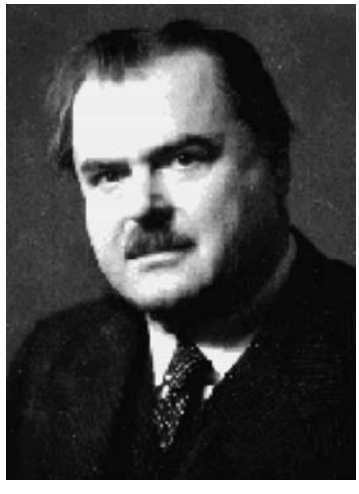
Figure 8b.1 a, Anton von Eiselsberg (1860–1939), chairman of the First Surgical Department at the University of Vienna 1901 to 1931. b, Historical view of the Vienna General Hospital ('Allgemeines Krankenhaus'). c, Egon Ranzi (1875–1938), chairman of the First Surgical Department at the University of Vienna 1932 to 1938. d, Title of the seminal paper on 318 brain tumors treated surgically in Vienna by Otto Marburg and Egon Ranzi submitted in 1920 and published in 1921.

and achievements. Schönbauer realized that any surgeon who wanted to achieve Cushing's standards must devote his efforts to neurosurgery exclusively which was not possible at that time in Vienna. Between 1930 and 1939 Schönbauer was head of the department of surgery in the Hospital of Lainz in Vienna where he established the first center of neurosurgical practice together with the famous neurologist Hans Hoff. They published a monograph entitled 'Hirnchirurgie' ('brain surgery') and operated on 10 brain tumors a month. Despite the help of Hans Hoff for the localization of tumors, postoperative mortality remained high averaging around 30%.[1,5]

Herbert Kraus (1910–1975) who started as a resident under Ranzi in 1935 became Associate Professor under Schönbauer and focused his interest on neurosurgery. Only his first seven publications dealt with general surgical themes, the ensuing 100 publications were devoted to neurosurgical subjects. In 1949 he visited several major centers in the USA. In 1964 he was appointed Chairman of the newly founded Neurosurgical Department of the University of Vienna. Heinz Brenner (born in 1926, a disciple of Schönbauer), Wolfgang Koos (1930–2000), and Josef Ganglberger (born in 1921) (Figure 8b.1f), who was trained in stereotaxic neurosurgery in Freiburg, Germany under



(e)

(f)

Figure 8b.1, Cont'd e, Leopold Schönbauer (1888–1963), chairman of the First Surgical Department at the University of Vienna 1938 to 1961. f, Josef Ganglberger (born in 1921) introduced stereotaxic treatment of epilepsy in Vienna.

Traugott Riechert, joined his team.[1, 5] Gangelberger introduced stereotaxic treatment of epilepsy in Vienna. He performed several stereotaxic fornicotomies, anterior comissurotomies, and amygdalotomies. In addition he recognized the critical role of pathways from the basal-lateral amygdala and the anterior temporal cortex via the ansa peduncularis and the pedunculus thalami extracapsularis to the medial nucleus of the thalamus for seizure propagation. He therefore carried out stereotaxic interruptions of this pathway on the rostro-ventral margin of the medial thalamic nucleus and could successfully treat several patients who were still suffering from seizures after fornico-and anterior comissurotomies. Ganglberger and coworkers also performed meticulous invasive electrophysiological studies during stereotaxic procedures studying evoked potentials and event-related slow potentials.[7-10] Kraus died from lung cancer in 1975. He was followed by Wolfgang Koos (1930–2000) who developed the department to a modern neurosurgical clinic.

Development of epilepsy surgery in Graz

At the University of Graz (Figure 8b 2a), the first neurosurgical unit was established within the department of surgery under Fritz Heppner (1917–2002) in 1950 (Figure 8b.2b). Heppner started his surgical training in Vienna in 1940 and completed his neurosurgical training under Herbert Olivecrona in Stockholm and under Sir Wylie McKissock in London.[1] Stereotaxic and functional neurosurgery was introduced in Austria in 1962 by his coworker Hans Erich Diemath (born in 1931). Soon after the establishment of neurosurgery as a separate discipline at the University of Graz in 1950, the surgical treatment of epilepsy began. Heppner and colleagues published several papers on the surgical treatment of epilepsy.[11–18] In 1987 they summarized their extensive experience on epilepsy surgery performed in Graz since 1950.[19] The indication for the first 28 patients was still vague, surgical procedures consisted of sympathectomy in 7 patients, corticotomies in 18 patients, meningolysis (subdurography) in 5 patients, and a probatory exploration in 1 patient. In 1954 the indications for epilepsy surgery became more clearly defined and included 'proof of medical intractability, a constant EEG focus, localization of the epileptic focus within a dispensable area of the brain, undamaged contralateral brain areas, and a sufficient IQ for social rehabilitation'. One hundred and fifteen patients underwent epilepsy surgery following these criteria between 1954 and 1985 including 6 hemispherectomies, 50 hippocampectomies, 6 fornicotomies, 40 anterior cingulectomies and 13 stereotaxic amygdalotomies. Six children aged 3 to 13 years with spastic infantile hemiplegia underwent hemispherectomies. Long-term follow-up was available in 3 children all of whom

Figure 8b.2 (a) Historical view of the Landeskrankenhaus Graz.

remained seizure free. One child died postoperatively from meningitis. Hippocampectomy was performed in 50 patients suffering from psychomotor epilepsy (Figure 8b.2c and d). In the first 40 patients a partial anterior temporal lobe resection with removal of the hippocampus was performed. The resection was limited to the hippocampus in the last 10 patients. In order to limit the formation of scar tissue and minimize trauma, a CO_2 laser beam method was applied. Long-term results were available for 34 patients, 18 of whom became completely seizure free. In 9 patients seizures were markedly improved, in 2 patients somewhat improved and in 3 patients seizures remained unchanged. Moreover, mental status and employment situation were improved postoperatively in the majority of patients. Stereotaxic fornicotomy was successfully performed in 6 patients who did not benefit from hippocampectomy. This method consisted of stereotaxic interruption of the fornix close to the anterior commissure with the rationale 'to prevent the spread of epileptic discharges from the hippocampus to the rest of the brain'. While 3 patients became seizure-free, the other 3 became manageable by antiepileptic drugs. Bilateral anterior cingulectomies, which were first described by LeBeau in 1948, were performed in 40 patients. In 3 cases the stereotaxic method was applied, in 8 cases the CO_2 laser beam method was used with vaporization of the anterior cingulate gyrus. In 17 patients long-term follow-up was available. Seizure-freedom could be achieved in 4 patients who displayed focal epileptic activity on the electrocorticogram in the area of the cingulum. In 5 patients marked improvement could be observed, 3 patients improved somewhat, and 5 patients remained unchanged. Emotional behavior was markedly improved in 6 patients, somewhat improved in 4 patients, and remained unchanged in 5 patients. Finally, bilateral stereotaxic amygdalotomies were performed in 13 patients suffering from epilepsy with an aggressive form of debility and resulted in a considerable improvement of psychic control in all patients.[19]

After Heppner's retirement in 1987, the department was led for 3 years by Peter-Wolf Ascher (born in 1939). In 1990, Gerhard Pendl (born in 1934), a student of Kraus and an upholder of von Eiselsberg's tradition, was appointed chairman of the department in Graz. In addition to completely reorganizing the department to modern standards, he introduced radiosurgery with the gamma knife in Graz in 1992.[1] Under the leadership of Gerhard Pendl and Oskar Schröttner pioneering work in the radiosurgical treatment of epilepsy including treatment of patients with mesial temporal lobe epilepsy, vascular malformations, tumoral epilepsy, and hypothalamic hamartomas was performed in Graz.[20–22] Furthermore the Graz group was the first to successfully perform callosotomies with the gamma knife.[23]

The modern area

The modern area of epilepsy surgery in Austria was introduced by Christoph Baumgartner (Neurology) who was trained at the Cleveland Clinic Foundation under Hans Lüders and Thomas Czech (Neurosurgery) at the University of Vienna in the Vienna General Hospital ('Wiener Allgemeines Krankenhaus') in close collaboration with the Neurological Department of the Krankenhaus Rosenhügel in 1992. In the following years epilepsy surgery centers were established at the Wagner-Jauregg Krankenhaus in Linz, the University of Innsbruck and the University of Graz. These centers offer all possibilities of modern presurgical evaluation and surgical techniques. A review of the activities of these four Austrian centers was recently published.[24]

9 Epilepsy surgery in the Nordic countries

K Källén, H Høgenhaven, KO Nakken, and R Kalviäinen

Four of the five Nordic countries have active epilepsy surgery teams, which are the Scandinavian countries (comprising Sweden, Denmark and Norway) and Finland. They are located in the northern part of Europe, partly surrounded by the North Sea and the Baltic Sea as illustrated in Figure 9.1. The four countries are in many aspects homogeneous with similar health care systems. The recruitment of patients for epilepsy surgery is exclusively dependent on the general social insurance system and is not influenced by the socioeconomic situation of the individual patient. Patients with severe and therapy-resistant epilepsy are referred to the centers with epilepsy surgery programs. Not only patients who are optimal surgical candidates are evaluated, but also mixed populations with diverse prognoses and chances for successful surgical outcome.

The four countries are small with a combined population of 24 million inhabitants; Sweden has nine million, Denmark and Finland more than five million each, and Norway four and a half million. Denmark and Norway have chosen to centralize their surgical programs to National Centers for Epilepsy Surgery while Sweden has a population-based regional referring system. The Swedish model is a decentralized model, with six centers at the regional university hospitals working in close collaboration, and with all centers participating in a national epilepsy surgery register for quality control. In Finland there are two centers with comprehensive epilepsy teams and epilepsy surgery programs. In Iceland, the fifth Nordic country, patients are sent abroad, mainly to the USA, for epilepsy surgery.

In this chapter the history of epilepsy surgery in the Nordic countries is described in detail for comparison of different ways of organizing epilepsy surgical programs in four developed countries with public health care systems.

Epilepsy surgery in Sweden

by Kristina Källén, Lund University Hospital

In Sweden, series of patients with difficult to treat epilepsy underwent epilepsy surgery during the 1950s, operated on by Olivecrona in Stockholm and by Jeppsson at the regional hospital in the southern part of Sweden, Lund University Hospital. A new phase of development was initiated by the neurosurgeon Herbert Silfvenius and collaborators at Umeå University Hospital in northern Sweden. Silfvenius, who had trained at Montreal Neurological Institute, initiated the modern era of comprehensive multiprofessional epilepsy surgery evaluation in Sweden and operated on 87 patients during 1980 to 1988. At this time epilepsy surgery was also revitalized in Lund, Göteborg, and Uppsala. From 1979 to 1994 a total of 430 epilepsy surgery procedures were performed.

During this period the future organization of epilepsy surgery in Sweden was extensively discussed. In contrast to the situation in Denmark and Norway, Sweden did not have a national epilepsy center and active epilepsy surgery teams were already developing at several university hospitals. Under the auspices of the Swedish National Board of Health and Welfare a group of experts produced background information concerning the national organization of epilepsy care in general as well as that of epilepsy surgery.[1] Criteria for a reference center for epilepsy surgery in Sweden were defined as: (1) a center with a multidisciplinary core team with a neurophysiologist, neurologist, and neurosurgeon; (2) access to a comprehensive epilepsy team with specialized personnel; and (3) access to other specialists such as neuroradiologists, neuropsychologists, neuropsychiatrists and a neurorehabilitation team. Furthermore, centers should have access to advanced techniques for video-EEG-monitoring and neuro-imaging and perform a sufficient number of diagnostic and therapeutic investigations yearly to keep and develop their competence. The importance of national and international collaboration was also emphasized.[1]

In order to evaluate the results of epilepsy surgery the Swedish National Board of Health and Welfare also requested an audit of the results from the operating centers from 1980 to 1990, which led to two scientific reports, one retrospective multicenter study focusing on surgical procedures and two-year seizure outcome, and one study of health-related quality of life two years after epilepsy surgery. These studies demonstrated that epilepsy surgery could be performed in Sweden with satisfactory results both concerning seizure outcome and quality of life.[2,3]

Based on these two reports, the Swedish National Board of Health and Welfare accepted the continuation of decentralized epilepsy surgery in Sweden but requested the construction of a national epilepsy surgery register, as one of the several Swedish quality control registers auditing health care. The experiences from the retrospective studies of epilepsy surgery in the 1980s were used in the creation of a prospective epilepsy surgery database. From the early 1990s and onwards, all six Swedish university hospitals (in Lund, Göteborg, Linköping, Stockholm, Uppsala, and Umeå) have provided specialized epilepsy care including epilepsy surgery, and there is a population-based regional referring system. Sweden has a population of nine million inhabitants and approximately 60,000 persons (0.7%), 50,000 adults, and 10,000 children, have active epilepsy.[4]

Figure 9.1 Map showing the Nordic countries and all centers with comprehensive epilepsy surgery teams. Denmark and Norway have chosen to centralize their surgical programs to National Centers, Sweden has a decentralized model with six centers at the regional university hospitals working in close collaboration, and in Finland there are two centers with epilepsy surgery programs.

All centers contribute to the Swedish National Epilepsy Surgery Register, which has a steering committee with participation from all centers. The register protocol includes data on medical history, investigational findings, side and site of the operation, histopathological diagnoses, complications during the pre-surgical evaluation or at surgery, and a two-year follow-up of seizure outcome, antiepileptic medication, and psychosocial data. It has recently been decided to prolong the prospective follow-up of all operated patients, and a five-year as well as a ten-year follow-up will be included in the register. The validity of the data collected from the centers is regularly checked by several systems. Intrinsic checkpoints within the database reject certain impossible combinations. An external revision is also performed: two epilepsy nurses visit all centers regularly and compare the data entered into the data base with the original data from the patient file for a random sample of the patients operated at that center. The items controlled in this external revision include side and site of operation, complications, neuropathological findings, and seizure outcome at the two year follow-up. So far, there have been no mismatches in the reporting on any of these central items.

The register is prospective since 1995 and has full coverage of every epilepsy surgery procedure in Sweden. Up to now it contains data on 924 patients, 668 have proceeded to surgery (418 adults and 250 children), while the remainder consists of suspended preoperative investigations and ongoing investigations. Temporal lobe resections dominate in the Swedish series (459 patients) as elsewhere, followed by extratemporal lobe resections (141 patients), and the remaining patients have undergone callosotomies, hemispherotomies, or multilobar resections. Intracranial recordings are performed in 20–40% of evaluations. During recent years the trend has been towards fewer invasive recordings.

There is a close network cooperation between the six centers, with regular workshops and case discussions. There are, however, differences between the centers both regarding number of operations and choice of and access to advanced investigational techniques. For example, PET is exclusively performed at Uppsala University PET-Centrum, while ictal SPECT is most extensively used in the program at Lund University Hospital. The register gives the possibility of a regular audit, with yearly reports sent to the Swedish National Board of Health and Welfare. The yearly reports are also distributed to all participating centers and discussed at the annual meetings.

The register is also the basis of scientific reports at a population-based national level. Two-year seizure outcomes are regularly analyzed in different patient populations and have been shown to compare well with results from international centers. As expected lesionectomies show the best results, with around 80% seizure freedom, followed by temporal lobe resections, where a relation with intellectual level has also been demonstrated.[5,6] In 325 patients who underwent temporal lobe resection 1990–99, 65% of the patients with IQ > 70 were seizure-free two years after surgery compared to 42% of the patients with IQ 50–69.[7,8] During the same time period 19 hemispherotomies were performed and 63% of these patients were seizure free at the two-year follow-up, while none of the five patients who underwent subtotal hemispherectomy obtained seizure freedom.[9]

One concern related to the decentralization of epilepsy surgery pertains to the risk for complications. An analysis of complications was therefore performed, based on data from the Swedish National Epilepsy Surgery register 1990–1995.[10] Complication rates were analyzed for 654 surgical procedures, 205 of which were invasive electrode procedures and 449 were therapeutic procedures. A complication was defined as minor if it resolved within three months and major if it affected activities of daily living and lasted longer than three months. The complication rates were shown to be low, minor complications were seen in 8.9% and major complications in 3.1%, which is quite comparable to the complication rates reported from big single centers.[11] It was also demonstrated that risk was related to age, patients younger than 35 years at surgery had a very low risk.

The Swedish National Epilepsy Surgery Register has also made it possible to study the referral trends over a ten-year period during the 1990s, a period when the epilepsy surgery programs were well established and had been very active.[12] At the beginning of this time period patients had often had their epilepsy for a very long time before being referred (median 20 years for adults). It was hoped that due to more information about the epilepsy surgery programs and better neuroimaging, patients would successively be referred earlier, but this was not the case during this ten year period. At the

end of the 1990s patients with temporal lobe epilepsy still had an epilepsy duration of around half of their lives before being referred for surgical evaluation. Even patients with lesions were treated 5–10 years for their medically resistant epilepsy before referral to the epilepsy surgery center. There has, however, been a tendency towards somewhat shorter mean epilepsy duration at referral since 2000. Regional differences are also apparent; there are four-fold variations in the regional utilization of epilepsy surgery between various Swedish counties, which cannot be accounted for by differences in number of referring neurologists or neuropediatricians. In total, the number of operations has diminished from a median of 78 epilepsy surgery procedures yearly during the 1990s (0.8–1.0 operations/100,000 inhabitants) to the present median of 50 during the 2000s (around 0.5/100,000 inhabitants yearly).

Epilepsy surgery in Denmark

by Hans Høgenhaven, Copenhagen University Hospital, Rigshospitalet

Surgery for temporal lobe epilepsy was introduced in Denmark at Copenhagen University Hospital, Rigshospitalet in 1960 by the neurosurgeon Kjeld Værnet. The criteria for selecting the patients for surgery were long-standing drug-resistant epilepsy and a preoperative unilateral temporal focus found on EEG, in accordance with the principles of Penfield (Montreal) and Falconer (London). The operation consisted of an *en bloc* anterior temporal lobectomy, usually going back to the vein of Labbé. Neurologist Inge Jensen followed up extensively all 74 patients operated upon in the first 10 years with special reference to neuropathology, social conditions and surgical outcome.[13] Interestingly, many of the observations and conclusions still hold true today. In her thesis 'Temporal Lobe Epilepsy' from 1977, she found that 64% were seizure-free at the time of follow up. If the group of patients with at least 75% reduction in seizure frequency was included, 83% of the patients derived benefit from surgery. The final conclusion of the thesis was that 'patients should be operated on as early as possible, and in all events as soon as their epilepsy had proven resistant to medication'. Despite the excellent results, the number of operations for epilepsy declined slowly through the 1970s and 1980s, partly because epilepsy surgery was confused with psychosurgery by the public.

Improved results and new enthusiasm from the major centers in North America convinced neurologist Mogens Dam to revitalize epilepsy surgery in Denmark in 1987. 'The National Epilepsy Surgery Group' was formed as a multidisciplinary team from several institutions, primarily involving Copenhagen University Hospitals and Dianalund Epilepsy Hospital. However, in 1993 Danish National Health authorities felt the need to regulate the activity, mainly due to epidemiological considerations. Denmark, with a population of 5.3 million people, was thought to be too small a country to generate enough patients to justify the implementation of highly specialized diagnostic and epilepsy surgical procedures. Also, at the time there was a lack of uniform internationally recognized and evidence-based standards for selection of patients, diagnostic and treatment procedures, safety and results. It was decided that intracranial diagnostic procedures should not be performed, leaving the Danish program for some years with a non-invasive protocol and the option of temporal lobe surgery only. Patients who met the borders of the protocol or had extra-temporal epilepsy were referred to international epilepsy surgery centers abroad, mainly in the USA (MINCEP, Mayo and Cleveland Clinics) and in Germany (Bethel, Bielefeld), and the costs were covered by the national health services. Although it was not the intention, one of the consequences of this regulation was that fewer Danish patients had epilepsy surgery than in the other Nordic countries.

Today, epilepsy surgery in Denmark is centralized at one center, 'The National Epilepsy Surgery Group' at Rigshospitalet, in close cooperation with Dianalund Epilepsy Hospital. The program now meets the recommended standards of a referral center outlined by the Commission on Neurosurgery of the International League Against Epilepsy (ILAE)[14] and has at its disposal all the necessary diagnostic modalities, i.e., long term video EEG monitoring, PET, SPECT, ECoG, Wada-test, highly specialized neuropsychological and psychiatric services, and dedicated MRI, including fMRI, as well as intracranial recordings and stimulations. The capacity of the program has been set at 40 operations (resective surgery) per year, i.e., 0.8 operations per 100,000, both children and adults.

For this program, the working definition of epilepsy surgery is 'an operation performed on the background of medically resistant epilepsy with incapacitating seizures, not caused by an etiology (ex: a tumor) which by itself sets the indication for operation.' This implies that some types of lesionectomies in epilepsy patients, as well as initial presurgical work-up, may be performed at other university clinics if they are in accordance with the epilepsy surgery protocol. However, if the epileptogenic zone has to be characterized preoperatively, the patients are referred to the National Epilepsy Surgery Group. In the presurgical evaluation all candidates have to follow a protocol that includes a neurological examination, ictal video scalp-EEG monitoring, and a cerebral MRI. PET, interictal and ictal SPECT, Wada-test, and fMRI are employed when necessary, followed by neuropsychological testing and an optional neuropsychiatric evaluation. If necessary, ictal video-EEG monitoring utilizing intracranial electrodes, is performed, with stimulation if indicated. Approximately one third of the patients referred to the program proceed to surgery. In the last decade 25% of patients have been children under the age of 18 years.

All patients who undergo epilepsy surgery will have postoperative evaluations by the National Epilepsy Surgery Group after 3, 6, and 12 months. One year postoperatively, all patients have a comprehensive evaluation, including a full neuropsychological examination and a quality of life assessment, and the need for rehabilitation is addressed. The postoperative outcome is documented using the classification of Engel. (An additional comprehensive evaluation after 24 months is under consideration.) At this time the adult patients are referred to the care of their local doctors, while the children stay in the program for several years.

The results of epilepsy surgery in the Danish patients, many of whom until recently have been operated on abroad, are comparable to international reports. Approximately 2/3 of patients with temporal lobe resections are seizure-free.

The complication rate in terms of permanent neurological or cognitive deficits is low.

The number of candidates referred has been slowly rising during the last 10 years. Currently, Danish patients have had epilepsy for an average of 17 years at the time of surgery, so the recommendation from Inge Jensen's thesis based on the operations performed in the 1960s that 'patients should be operated as early as possible' has not yet come true.

Epilepsy surgery in Norway

by Karl Otto Nakken, National Centre for Epilepsy in Sandvika

In 1949, Kristian Kristiansen at Ullevaal Hospital in Oslo introduced epilepsy surgery in Norway. He had been trained by Wilder Penfield at Montreal Neurological Institute, and for many years he was the only Norwegian surgeon who performed epilepsy surgery. When he retired in 1976, this activity was transferred to the National Hospital in Oslo (now Rikshospitalet University Hospital).

While lesionectomies in epilepsy patients are performed at all regional hospitals (Oslo, Bergen, Trondheim, Tromsø), 'pure' epilepsy surgery, i.e., removal of the epileptogenic zone, has for the last ~30 years been centralized to the Rikshospitalet University Hospital, in close collaboration with the National Center for Epilepsy in Sandvika. From a modest start, the number of patients undergoing epilepsy surgery has been fairly constant over recent years, approximately 30–40 operations per year.

With a population of 4.5 million inhabitants, about 32,000 persons are estimated to have epilepsy in Norway. About 30% of these have difficult-to-control seizures, and a considerable number of these patients are potential candidates for epilepsy surgery. After primary epileptological assessment at the local/regional hospital, those patients who have drug-resistant and disabling seizures are referred to the National Centre for Epilepsy. Here they undergo a comprehensive presurgical evaluation, including a clinical, neurophysiological, neuropsychological, and neuroradiological assessment. All candidates for surgery have a neurological examination, an ictal video scalp-EEG monitoring, and a cerebral MRI investigation according to an epilepsy protocol. Currently, all PET investigations are performed in Sweden (Uppsala University PET-Centrum). Only about 25% of these patients actually proceed to surgery. The approximate yearly number of presurgical investigations are shown in Table 9.1.

Table 9.1 Presurgical investigations in Norway

Type of procedures	Numbers per year
Neuropsychological assessments	40
Intracranial recordings	20
PET investigations	50
Ictal SPECT investigations	10
Wada-tests	40
fMRI investigations	10

While clinical, neurophysiological, and neuropsychological assessments are performed at the epilepsy center, the neuroradiological investigations, the Wada-tests, and the diagnostic and therapeutic surgery take place at Rikshospitalet University Hospital. Hence, the Wada-test is included in the presurgical diagnostic work-up, and for the time being fMRI cannot, in our opinion, fully replace this test. Specimens of resected brain tissue are examined histopathologically.

All patients who have had epilepsy surgery are followed up at the National Centre for Epilepsy 3, 6, 12, and 24 months postoperatively. Two years following surgery all patients have a comprehensive evaluation, including a clinical, neurophysiological, and neuropsychological assessment, and the postoperative results are classified *ad modum* Engel.[15] The need for further rehabilitation is assessed, and later on the patients are followed up by their local pediatricians /neurologists.

The results of epilepsy surgery in Norway compare well with what is reported from other epilepsy centers. Seizure freedom is achieved in ~70% of patients with temporal lobe resections, while ~50% of those with extratemporal resections become seizure free. The complication rate in terms of permanent neurological or cognitive deficits is low.

In our opinion, the psychosocial outcome of epilepsy surgery is a largely neglected field of research. Guldvog *et al.*[16] compared surgically and conservatively treated patients and found no evidence of significant psychosocial improvement after surgery, even in seizure-free patients or in patients with a marked reduction of seizures.

In our experience, focal surgery may be a good treatment option also in epilepsy patients with low IQ, provided the resections are performed relatively early after seizure onset.[17] Furthermore, among adult patients with speech localized to the left hemisphere, we have found indications of a gender difference in vulnerability to epilepsy surgery, exhibiting greater reduction in long-delay verbal memory in men operated in the left hemisphere compared to women.[18]

A few patients have had epilepsy surgery outside Norway. Some selected children with catastrophic epilepsy have undergone hemispherotomy in Germany (Bonn), and some few complicated cases have been operated in the US (Dartmouth Hitchcock Medical Center, New Hampshire).

Despite increased attention the recent years, epilepsy surgery is assumed to be under-utilized in Norway. We believe that at least 50 patients should be operated yearly in Norway, and it will be a great challenge in the years to come to further market this very effective treatment option.

Epilepsy surgery in Finland

by Reetta Kälviäinen, Kuopio Epilepsy Center

In Finland, the first 37 patients with difficult to treat epilepsy underwent epilepsy surgery between 1979–88 at Oulu University Hospital in a program led by the neurosurgeons Stig Nyström and Esa Heikkinen. Before initiating the first modern comprehensive multidisciplinary epilepsy surgery evaluation team in Kuopio in 1988, Neurosurgeon Matti Vapalahti and his team members (neurologists, neurophysiologists, and a neuropsychologist) were trained at the Montreal Neurological Institute. The second comprehensive epilepsy center was initiated in Helsinki in 1991, after Dr. Marja-Liisa Granström had been trained at the Cleveland Clinic, Dr. Eija

Gaily at the University of California in Los Angeles, and neurosurgeon Göran Blomstedt at Umeå University Hospital in Sweden. Currently the Finnish Ministry of Social Affairs and Health has recognized Kuopio and Helsinki as the two highly specialized centers in Finland for invasive diagnostics and surgery for patients with therapy resistant epilepsy. Finland has a population of 5.2 million inhabitants. Altogether 36,000 patients use current medication for epilepsy and about 9,000 patients use more than one antiepileptic drug indicating intractable epilepsy.

Between 1988 and 2005, altogether 333 therapeutic epilepsy surgery interventions have been performed in the Center in Kuopio University Hospital. Kuopio has concentrated in temporal lobe epilepsy and has performed the majority of temporal resections in the country (n = 248). The program has also included extratemporal resections (n = 33), callosotomies (n = 28), lesionectomies with corticography (n = 22), and hemisphereotomies (n = 2), 80% are adults and 20% children, about half of the patients referred for evaluation proceed to surgery. In the majority of adult patients with temporal lobe epilepsy, MRI and extracranial EEG-videotelemetry provides sufficient localization of seizure origin for making the decision about surgery. However in Kuopio altogether 40% of those temporal lobe epilepsy patients who have undergone resective surgery have needed preoperative invasive intracranial recordings (i.e. subdural and/or intracerebral depth electrodes). Indication for invasive EEG-investigations has been: suspected bitemporal epilepsy (52%); extratemporal (36%) onset of seizures; or remote structural lesion (12%).[19] Functional imaging methods (ictal-SPECT, PET, fMRI, MEG)[20] are also used to provide additional evidence, when needed. A special strength in Kuopio has been the intensive co-operation with the Department of Neurobiology of Kuopio University on research on epileptogenesis and molecular biology of epilepsy with direct clinical correlations and applications in surgical treatment.[21]

Kuopio Epilepsy Center has published long-term outcome results from a consecutive series of 140 adults with TLE operated on between 1988 and 1999.[22] The aim of surgery was defined preoperatively as: 'curative' for 74% (n = 103) of patients with unilateral TLE; or as 'palliative' for 26% (n = 37) of the patients. The palliative category included patients with bitemporal seizure onset (49%), multifocal epilepsy, dual pathology, or patients in whom the epileptic focus could not be completely resected. Outcome of surgery was assessed independently in unilateral TLE and in palliative patients due to the significant difference in expected outcome. The study demonstrated that patients without restricted unilateral seizure focus also may benefit from surgery and that the outcome of surgery improved significantly after introduction of the standardised MRI protocol (Table 9.2). Eighty-six percent of all seizure relapses occurred within one year after surgery, and late seizure relapse (>2 years after surgery) was observed in only 5% of all patients and was often preceded by a specific explanatory factor such as withdrawal of antiepileptic medication. In a multivariate analysis, unitemporal MRI abnormalities, early onset of epilepsy, or the predominance of focal seizures with impaired consciousness with focal ictal EEG, were identified as predictors for successful postoperative outcome.

The epilepsy unit in Helsinki University Hospital (Hospital for Children and Adolescents and Department of Neurosurgery) started in 1991 with pediatric epilepsy surgery, and since 1998 the team has also offered epilepsy surgery to adult patients in collaboration with the Department of Neurology. Between 1991 and 2005 a total of 187 therapeutic epilepsy surgery interventions had been performed in Helsinki. The program has included temporal resections (n = 72), extratemporal resections (n = 49), callosotomies (n = 34), hemispherotomies (n = 29), multiple subpial transections (n = 1), and radiotherapy of hamartomas (n = 2). During preoperative evaluation all patients were studied with video-EEG, 1.5 T MRI, and neuropsychology. When necessary ictal-SPECT, MEG (localization of interictal spikes and functional areas), FDG-PET, magnetic resonance spectroscopy, and/or invasive monitoring with subdural grids (n = 22) and strips (n = 3) is used during the presurgical work-up. Nearly all patients undergo psychiatric evaluation. The majority of the patients are children or adolescents (76%) and due to the heterogeneous population regarding syndromes and etiologies (including catastrophic epilepsies of

Table 9.2 Long-term postsurgical seizure outcome in 140 adult temporal lobe epilepsy (TLE) patients in Kuopio Epilepsy Center[22]

	Curative group with unilateral TLE (n=103)		Palliative TLE epilepsy group (n=37)
	Entire group (%)	Standardized MRI protocol (%) (n=59)	(%)
Seizure free	45	61	27
Persisting auras	12	11	3
Worthwhile outcome (Engel I-II)	68	74	62

early childhood) general outcome figures are difficult to evaluate. The team has, however, recently evaluated the two-year follow-up of cognitive outcome after pediatric epilepsy surgery.[23] Altogether 38 patients, between 3–17 years of age, were evaluated before surgery and six months and 2 years postoperatively. No significant change in verbal or performance IQ was demonstrated at group level. Lateralization, type of surgery, age, sex, and presurgical IQ did not affect outcome. In conclusion, epilepsy surgery in children and adolescents did not in general have a significant impact on cognitive development in a two-year perspective.

Medical intractability is defined as persistent seizures despite 2–3 maximally tolerated AED trials. In older children and adults medical intractability can be diagnosed in two years in most cases. However, the median duration of epilepsy in patients referred to presurgical evaluation at Kuopio Epilepsy Center has been 19 years.[22] In the future, emphasis should be put on early prediction of medically intractable temporal lobe epilepsy in children and adolescents, since early surgery probably improves the overall outcome, especially in younger patients. Further evaluation for long-term cognitive outcome is also warranted. The epilepsy unit in Helsinki continues to focus on pediatric epilepsy surgery, accepting pediatric patients from all parts of Finland and adults within their own catchment area. Kuopio Epilepsy Center continues to treat patients with medically refractory temporal or extra-temporal focal epilepsy of all ages from the whole country, especially focusing on getting patients referred earlier.

The future of epilepsy surgery in the Nordic countries?

Despite increased attention in recent years, epilepsy surgery is assumed to be under-utilized in the Nordic countries. Approximate yearly numbers of procedures in Sweden, Norway and Finland are shown in Table 9.3. Too few patients, especially children in the Scandinavian three countries, with severe, drug-resistant epilepsy, are referred to the centers for surgical evaluation, and many are referred too late, i.e., long after psychosocial problems have become irreversible. This situation is most probably not at all unique since there is a general concern that epilepsy surgery is underused. One reason for this underutilization of the resource of epilepsy surgery might be lack of knowledge about epilepsy within the medical profession[24] or lack of knowledge about the favorable results of surgical treatment of epilepsy within the neurological community. In a survey concerning the provision of epilepsy services in Europe which was undertaken by the ILAE Commission on European Affairs a few years ago, all countries but six stated that they had epilepsy surgery programs.[24] Lack of epilepsy surgery was more commonly reported from Eastern and Southern Europe, whereas several western ILAE chapters mentioned as a problem that epilepsy surgery was present but underused.

The epilepsy surgery groups in the Scandinavian countries together with Finland recently decided to organize a meeting for collaboration and the first Nordic epilepsy surgery meeting was held in Sweden in 2004. The second will be held in Norway 2006. In the future the epilepsy surgery groups in the Nordic countries plan to meet at regular intervals to learn from each other and expand their network cooperation for the benefit of the patients.

Acknowledgment

We want to thank Kristina Malmgren, professor in neurology at Sahlgrenska University Hospital in Gothenburg, for editorial help, and Kirsten E. Stabell, neuropsychologist at the National Centre for Epilepsy in Sandvika, for providing us with the number of presurgical investigations and surgical procedures in Norway.

Table 9.3 Yearly epilepsy surgery procedures in the Nordic Countries based on an average over a 10–15 year period

	Sweden (9 million inhab.)	Denmark (5.3 million inhab.)	Norway (4.5 million inhab.)	Finland (5.2 million inhab.)
Temporal lobe resections (selective AHE included)	41	14	25	19
Extra-temporal lobe resections	14	2	7	5
Mixed group Multilobar resections, hemispherotomies, MST, callosotomies, hamartomas (pure lesionectomies are also included in the mixed group in Finland)	14	4	3	7

Inhab. = inhabitants.

10 The development of epilepsy surgery in the Netherlands and Belgium

W van Emde Boas and PAJM Boon

The Netherlands[1]

In the Netherlands, initial development of brain surgery came relatively late. In his jubilee speech on the development of surgery during the last 30 years, at the occasion of the 25th anniversary of the Nederlands Tijdschrift voor Geneeskunde (NTvG) in 1882, J.W.R. Tilanus (1829–1914), professor of surgery in Amsterdam, does not yet even mention surgery of the nervous system[2] and, apart from the usual descriptions of trepanation in early general medical or surgical texts, up to 1890 no papers on surgical intervention on either the central or the peripheral nervous system had been published in the NTvG, then as now the main Dutch medical journal, nor by Dutch authors, in other medical journals or books.[3,4] This changed at the initiative of Cornelis Winkler (1855–1941), the first professor in psychiatry and neurology in the Netherlands and generally considered the founding father of modern Dutch Neurology (Figure 10.1).

First steps: the neurologist and the surgeon

Winkler studied medicine in Utrecht where he was greatly influenced by the strict scientific approach of ophthalmologist and physiologist F.C. Donders (1818–1889). Following graduation and obtaining a PhD degree on a thesis on Virus Tuberculosum 1879; and a brief period as clinical resident in The Hague, Winkler expressed to his former teacher the desire for a more research oriented position in Utrecht. Offered the position of reader in psychiatry, Winkler initially declined, considering psychiatry too philosophical and unscientific to his liking. After some clinical work with neurological patients in the clinic for internal medicine of S. Talma (1847–1918) and following visits to T. Meynert (1833–1892) and J. Wagner von Jauregg (1857–1940) in Vienna and to numerous German protagonists of the neuropathological oriented school of psychiatry and neurology, he became convinced of the advantages of teaching both neurology and psychiatry as a whole and accepted in 1885 the lectureship of psychiatry in Utrecht, followed in 1893 by the appointment to professor in psychiatry and neurology, the first such chair to be officially created in the Netherlands.'[5]

Winkler was well aware of the current clinical and experimental literature on the localization of brain functions and the application of these findings to clinical neurology and early on expressed his intention to follow the example of V. Horsley (1857–1916) and others and to focus attention also on brain surgery as a possible treatment for neurological disorders, notably in epilepsy patients with seizures comparable to those, induced by electrical stimulation of the cortex in animals by E. Hitzig (1838–1907) or described in humans by J. Hughlings Jackson (1835–1911).[5] As luck would have it, Winkler's appointment coincided with that of his friend and fellow student J.A. Guldenarm (1852–1905) as general surgeon in the Deaconess Hospital in Utrecht. According to Winkler, Guldenarm was a gifted and inventive surgeon, who made his own instruments, operated very neatly and with whom he felt sufficiently confident to try to remove brain tumours, '*a great endeavour, considering that we hardly knew what we were going to do*'.[5]

On 11 November 1889 they performed their first published surgery on a 54-year-old ex-soldier with a two year history of Jackson type seizures, beginning in the right leg and with fast neurological and mental deterioration during the last few weeks. Exploring the left frontocentral area, they partially resected an angiosarcoma from the left gyrus frontalis superior, lobus paracentralis, and gyrus centralis anterior. The patient survived the procedure and remained without seizures but with hemiplegia, aphasia, progressive loss of consciousness and increasing prolapsus cerebri before dying, three weeks after surgery.[6]

Between 1891 and 1893 Winkler and Guldenarm, together with A. Huysman, ENT surgeon, and H. Buringh Boekhoudt, resident to Winkler, published a series of five 'contributions to surgery of the brain' in the NTvG in which they provided meticulous detailed clinical histories of 15 patients (3 not operated) and discuss the value, possibilities and – often – impossibilities of surgical intervention in various neuropathological conditions.[6–10] Although epilepsy was not mentioned in the title of any of these five papers it was a major symptom in five and the primary indication for surgery in a further two of the twelve operated patients. The first of the latter was a 22-year-old man with an 11 year history of Jacksonian seizures in the left hand and arm who had a right frontocentral angioma removed by Guldenarm on 4 April 1890[6] and changed from >40 seizures a day to multiple days without seizures with a follow up of 7 years.[11] This patient was also published in a thesis 1891; by a Dutch physician, P.C. Th. Lens, defended however in Giessen and thus not really to be considered the first Dutch thesis on epilepsy surgery.[12] The second patient was a 19-year-old boy with an epilepsy history of 6 years, following a skull trauma at the age of 8 years. He became free of seizures, following extirpation of a calcified lesion from the left hand area[9] but died from

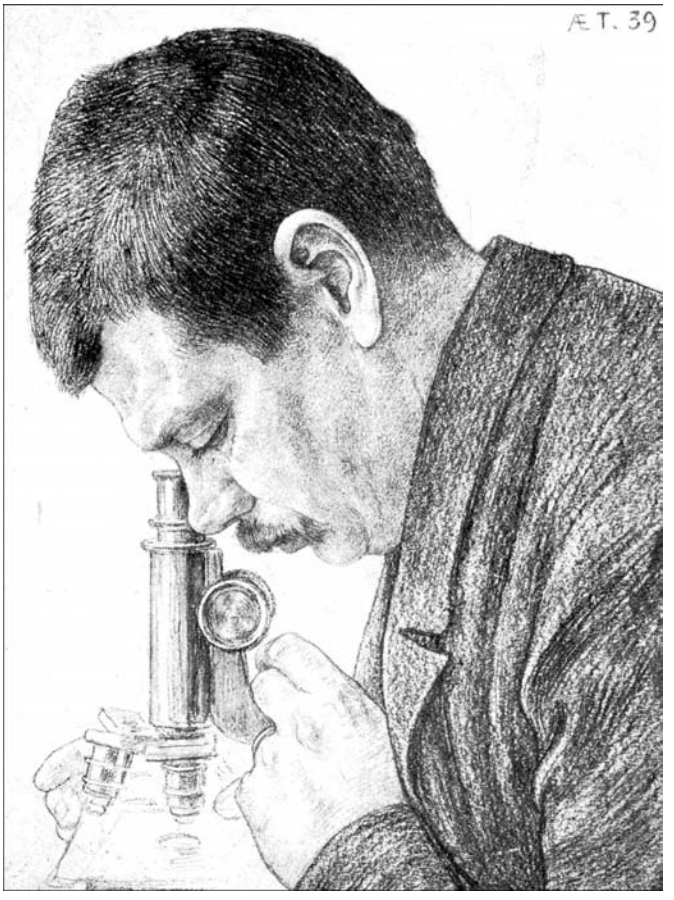

Figure 10.1 Cornelis Winkler (1855–1941). Pencil drawing by Jan Veth, 1896. The portrait was made just after Winkler resigned in Utrecht and before he moved to Amsterdam. While making this portrait Veth (1864–1925) proposed to Winkler to give art lessons to medical doctors, in order to improve the quality of the illustrations in their publications. The idea however was never realized.[5]

an occupational accident a few years later.[11] Some of the early tumor cases, including one patient with Jacksonian seizures, were collected and described in the really first Dutch PhD thesis on brain surgery, defended by Winkler's pupil R. S. Hermanides[13] and again in the NTvG.[14]

Surgical techniques are not dealt with in detail in these papers although there is some discussion about the relative advances of a bony versus a soft tissue closing of the trepanation area in certain circumstances. Some procedures were only performed '*after we had ascertained ourselves on the cadaver that the surgery was possible*'.[6] Major emphasis is given on the other hand to the problem of correct localization, prior to surgical intervention. The papers include some patients where Winkler failed to make a proper preoperative localizing diagnosis and he frankly admits that in at least one patient, in whom surgery failed, the obduction showed a right tentorium meningioma that, on correct diagnosis, could have been successfully removed.[6] Winkler strongly believed that, unless surgeons had extensive knowledge of brain anatomy and physiology, brain surgery should be guided by the neurologist as the one both to make the exact diagnosis and to decide about the indication for surgical exploration and the place and extent of the necessary trepanation. For the latter he developed a new method to enable the neurologist and the surgeon to estimate the position of the central and Sylvian sulci and of the targeted cortical gyri, using just two external reference points (the glabella and the protuberantia occipitalis externa) to create a grid of triangles, projecting over skin of the skull.[15] Since this system was based on comparative rather than absolute measurements it was considered to be more reliable than that of Horsley or others and the 'triangulation according to Winkler' (Figure 10.2) became the standard procedure for guiding the trepanation in the Netherlands for the next few decades.

Such was Winkler's enthusiasm for brain surgery that in 1895 he even published a long popular paper on the subject in *De Gids*, the most important cultural monthly magazine in the Netherlands. Despite the overall poor results (only 4 out of 18 operated cases still alive at the time of publication and only

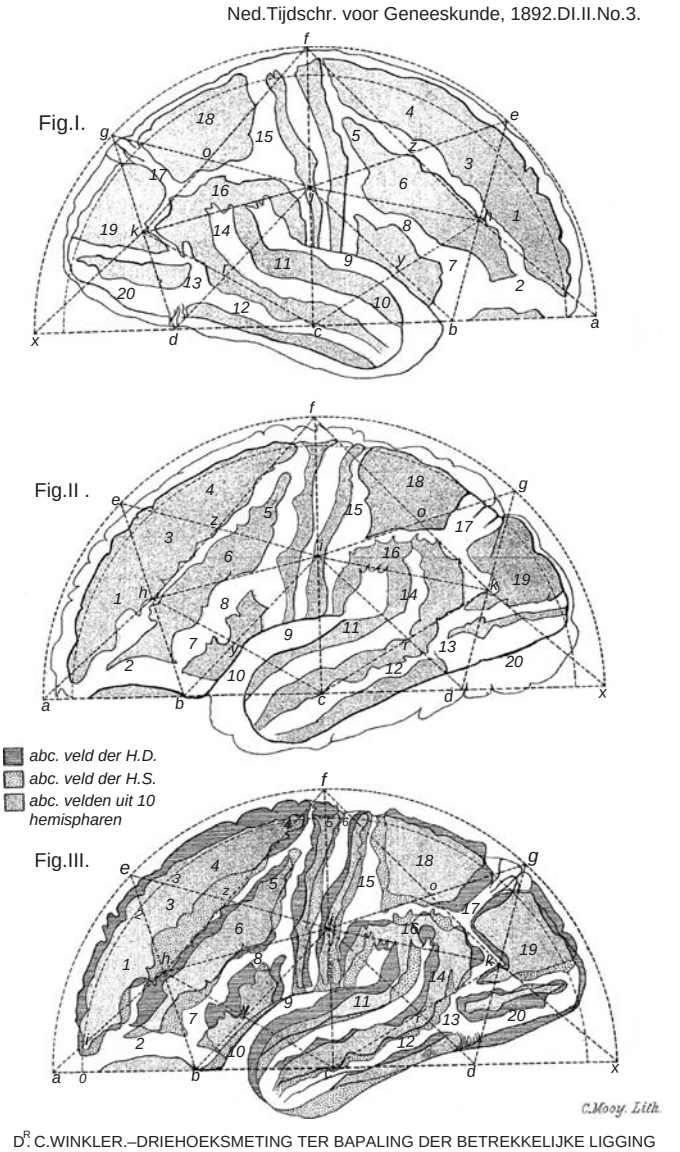

Figure 10.2 Winklers method of triangulation. By constructing a series of triangles, based on the line between the glabella and the protuberantia occipitalis and the perpendicular dissecting line at midpoint he obtained a reasonable estimate of the position of the underlying cortical structures. The drawing is based on studies on 10 adult subjects; the darkened areas and numbers indicate cortical areas or sulci that reliably will be found within that specific triangle (lithograph illustration of Winkler's paper[15] in the NTvG, Bohn: Haarlem, 1892).

two really cured) he argues for an aggressive approach since the patients, mostly tumor cases, have little to lose. For patients with epilepsy he considers the loss of some function to be preferred to the constant irritation of the cortex and the risks of the recurrent seizures. He discussed the use of electrical stimulation to identify the epileptic focus and the different surgical options. He preferred resection of the cortex, notably when abnormal on inspection, and did not think highly of the practice of just cutting around the suspected area in order to prevent seizure propagation. In an interesting last paragraph he commented on some early efforts on psychosurgery by Burckhart in Switzerland, which he rejected since he was of the opinion that one should treat the underlying disease in mental patients and not just the symptoms.[16]

In 1896, being refused a new clinic that was initially promised to him, Winkler resigned his position in Utrecht and within months accepted the newly created chair of Neurology and Psychiatry in Amsterdam where he would have ample access to clinical beds both for neurology and psychiatry and would be able to work together with J.K.A. Wertheim Salomonson (1864–1922), who already ran a clinic for neurology and electrotherapy, and in 1899 would be appointed to the first chair in neurology, electrotherapy, and radiography in the Netherlands. In Amsterdam Winkler continued his neurosurgical activities, together with the surgeons J.A. Korteweg (1851–1930) and J.A. Rotgans (1859–1948) and the professor in Internal medicine P.K. Pel (1851–1919), who also was actively interested in neurological diseases. Epilepsy initially remained a major indication. In 1897 Winkler's pupil H.H. van Eyk (1869–1930) obtained his Ph.D. on the first (and until Brekelmans[17] the last) Dutch dissertation to deal specifically with the surgical treatment of partial epilepsy[18] and in that same year Winkler, in recognition of his expertise in the field, was invited to lecture on 'Surgical intervention in the epilepsies' at the International Congress of Psychiatry, Neurology and Hypnology In Brussels.[11]

In his dissertation Van Eyk described 10 cases of predominantly posttraumatic epilepsy, nine of them operated and with clear improvement in five. In addition he summarized the data from the literature, 13 cases of epilepsy due to subdural haematoma and 100 cases of posttraumatic epilepsy, including 7 of his own, and showed that the best results were obtained in patients in whom a recognizable lesion could be removed. His case #9 concerns a 20-year-old man with a 2 year history of focal seizures, beginning in the left hand. A first exploration by Rotgans and Buringh Boekhoudt showed local thickening of the dura over the hand area, identified by electrostimulation by Wertheim Salomonson. Nothing was excised and there was no improvement. Following two further surgeries with temporary improvement the patient was operated upon a fourth time on 18 June 1897, this time with Winkler performing the electrostimulation. A seizure was provoked by stimulating the finger area '*which was photographically documented and found to be identical to the spontaneously observed seizures*', the first case of intracranial and intraoperative seizure monitoring? Following a local cortectomy the patient became paretic but also free of seizures for at least the next two months.[18]

At the congress in Brussels Winkler discussed 20 patients who had surgery, including two patients, successfully operated for 'reflex-epilepsy', due to peripheral nerve injury (one a cornea corpus alienum, the other a bullet injury of a branch of the trigeminal nerve), a clinical entity which certainly was not epilepsy but was generally accepted at the time and considered a good indication for surgical intervention.[19] In 13 patients partial epilepsy was the primary indication for surgery, in 5 the seizures were but a symptom of more serious neurological disease. According to Winkler posttraumatic cases had the best prognosis, tumor cases a varying outcome and infectious cases (Lues, TBC, otogenic abcesses) or alcoholic cases a poor prognosis. In cases without an external or internal scar and with a normal aspect of the cortex, cortectomy should only be performed if a typical seizure could be elicited from that area by electrical stimulation. For toxic epilepsies, even if manifesting with partial seizures, surgery was not indicated.[11]

Even at the time of the congress, however, the initial enthusiasm for epilepsy surgery (or even brain surgery in general) appeared to be lessening. In a comprehensive review of all neurosurgical interventions performed in the Netherlands between 1889 and 1900, published in the famous 3 volume series of A. Chipault (1866–1920) on the current state of neurosurgery in 1902, Winkler and Rotgans briefly refer to the earlier work but epilepsy is not mentioned anymore as a specific indication.[3] This appears to be in line with developments elsewhere. In a long letter from London where he was visiting a number of hospitals, Wertheim Salomonson describes his admiration for the surgical skills of Horsley but also mentioned that at that time, in 1898, Horsley had not operated for epilepsy in the last 18 months because of disappointing results.[20] Two conference reports and a review in the NTvG from the same period but citing predominantly German and Swiss sources also emphasized overall poor results of surgery for epilepsy[21–23] and W.J.M Indemans (1868–1932), a general practitioner in Maastricht, reporting one patient, operated with moderate success for posttraumatic partial epilepsy, actually complained that he could not find a surgeon willing to operate on a second case.[24] Winkler himself apparently lost interest and did not publish anything on epilepsy surgery afterwards although he remained involved in some cases later published by others.

Also the attitude of the surgeons to surgery on the nervous system was changing. While most of the surgeons with whom Winkler had collaborated in Utrecht and, after 1896, in Amsterdam, apparently had little problems with his approach by which they had to rely completely on the diagnostic and localizing acumen of the neurologist, J.E. van Iterson (1842–1901), with whom Winkler performed some surgeries in Utrecht, was the first to challenge this approach. In a 1899 paper on the present state of surgery effectively citing Winkler himself, he stated that:

> *The recognition and localisation of the pathology [in the brain] still is wanting and I am pleased to report that according to the first Dutch authority in this field [Winkler] this situation will not improve unless the surgeons themselves take up the diagnosis of brain disorders and stop acting only on guidance by specialists.*[25]

With this, van Iterson started a controversy that was to continue for the next three decades and would clearly influence the further development of neurosurgery, and thus epilepsy surgery, in the Netherlands. At the time, however,

his word was hardly heeded and for some time to come the neurologist remained either the active guide of the surgeon or, by reversing the situation sketched by Winkler, actually took over the scalpel and the trephine.

Intermezzo: the neurologist–neurosurgeon

Louis Jacob Joseph Muskens (1872–1937)[26] studied medicine in Utrecht and, significantly influenced by Donders and Winkler, early on decided for a career in physiology and neurology. After obtaining his PhD in 1896 on a thesis on the reflex mechanisms of the frog heart, supervised by T. Engelmann (1843–1909), successor [and son in law] of Donders, Muskens, on a travel grant provided by the Donders Society, spent two years in the USA where he visited and worked with C.L. Dana (1853–1935) in New York and H.P. Bowditch (1840–1911) in Boston. Stimulated by Winkler to further specialize himself he spent a next period in London in the National Hospital for the Paralysed and the Epileptic, working under W. Gowers (1845–1911) and notably, for 20 months, under Horsley in order to master the surgical skills necessary to render him independent from the general surgeon.[27,28]

In the USA and in London Muskens appeared to have developed his interest in epilepsy which to a large extent would mark his further career. Back in the Netherlands he instigated the founding, in 1902 in the Hague, of the 'Dutch Society Against Falling Sickness', which, contrary to the older 1882; 'Christian Society for the Care of Sufferers from the Falling Sickness', aimed to promote treatment rather than care of epilepsy. In the same year Muskens moved to Amsterdam in 1902 and took up a practice as specialist for nervous disorders, including the position (from its inception until 1918) of medical supervisor of the clinical and outpatient departments of the 'Amsterdamse Gasthuis Tegen Vallende Ziekte' (Amsterdam Hospital for Epilepsy), an initiative by the Amsterdam Branch of the Dutch Society and, in 1903, the first non-university-associated neurological clinic in the country. Together with the Hungarian J. Donath, Muskens, in 1908, founded the *Journal Epilepsia* and, in 1909, the International League Against Epilepsy (ILAE) of which he would remain active as general secretary for many years and which he helped to revive in 1937, after a long interruption of the ILAE activities following the turmoil of World War I.[29]

A prolific writer, Muskens published extensively about epilepsy, both from an experimental and a clinical view and with major emphasis on the social aspects and needs of persons with epilepsy. His vast clinical and experimental experience culminated in a major monograph on epilepsy, published in 1924 and translated both in German and in English.[30] Other subjects included the segmental distribution of the sensory input of the cerebral cortex, the anatomo-physio-pathology of upper brain-stem connections, subject of a second major monograph on the supra-vestibular system,[31] technical and clinical aspects of neurosurgery and a series of papers on the relation between neurology, neurosurgery, and psychiatry and the way those specialties should be taught to students and be practiced.

In 1906 Muskens was admitted as private lecturer on nervous diseases at the municipal university of Amsterdam and in his official public lecture advocated the further development of organ oriented (sub) specialties in medicine, a subject highly controversial at the time[32] (Muskens, 1906). In Muskens's view specialties should focus on the anatomy, physiology, pathology, conservative treatment options and surgery of specific organs, the central nervous system representing one of the most ideal organ systems for such an approach. Psychiatry was to be separated from neurology [in the Netherlands it was not until 1974 that this separation finally was realized] and the surgical approach to the nervous system was best left to the neurologist with specific surgical training (i.e., Muskens himself). Like Winkler had done before him Muskens published a series of 'contributions to the surgical treatment of the central nervous system' in the NTvG, the third including a number of patients with seizures and the last dealing specifically with posttraumatic epilepsy,[33–36] in addition to a large number of other papers or reports of clinical demonstrations of neurosurgical cases in Dutch or foreign journals. Unfortunately and contrary to the papers of his predecessor and teacher Muskens's patient descriptions are often rather short and, when repeated, as is often the case, factual data (dates, type of trauma, patient initials, patient age) differ in successive publications, in part probably due to the then current poor quality of proofreading and correction in association with very fast publication, but in part apparently due to either shoddy writing or – worse – 'massaging' the data. Moreover Muskens had a highly contentious style of writing and presenting, emphasizing presumed diagnostic errors or failed procedures by others and exaggerating his own activities and results. Repeatedly and usually with good arguments and in terms which in today's perspective would be considered too offensive for public discussion in print, his claims are refuted, his results doubted, his qualifications as a neurologist-surgeon denied, and his references identified as incorrect, not only by the general surgeons but notably also by his fellow neurologists and by the chief editor of the NTvG.[37–44] Although Muskens apparently was considered as sufficiently an expert to be invited by the Belgian Red Cross to assist in setting up a unit for war casualties with brain or spinal injuries in Antwerp[45] the chiefs of the university clinics in Amsterdam repeatedly refused to have Muskens operate in their clinics.[44] Significantly, the well-known Amsterdam neurologist C. T. van Valkenburg (1872–1962), who for a number of years was the medical director of Muskens's hospital, relied on other surgeons for his work on the sensory neuroanatomy of the human cortex, based on electrical stimulation during surgery.[46–48]

As far as epilepsy is concerned only few successful surgery cases eventually are listed in the chapter on posttraumatic and focal epilepsy and the surgical treatment of epilepsy in Muskens's 1924 monograph.[30] These include three of his favorite cases which he published and presented at many occasions, the first a patient with probably posttraumatic serous meningitis, operated in 1907 because of fast neurological deterioration, in whom the seizures were but a secondary symptom, and the second, a girl of 18 (cranial trauma at age 3 years) in whom Muskens, guided by sensory loss in the ulnar region of the left arm, ligated some 'abnormal pial veins' and claimed successful treatment of 'seizures' that by all his peers of the Amsterdam Neurological community, many of which previously had observed this patient, were consistently interpreted

as psychogenic events. Only the third represents a true epilepsy surgery success story: a female patient who following trauma at age 4 and two earlier surgical interventions by Winkler and Rotgans at the age of 4 and 16, finally was rendered seizure free by Muskens by removal of two tiny bone fragments, found under the previous bone flap and, when the seizures still persisted, in a second session a small cortisectomy from the area where habitual seizures could be elicited by electrical stimulation. The remaining 7 patients in the chapter, which purports to present 'a comprehensive report' of a lifetime experience include one non-traumatic tumor patient (presented to illustrate the limited value of surgery in those cases), one patient operated in 1910 but without clinical information ('all files lost') or follow up, other than that the patient was successfully employed as a marine officer, 1 patient, operated by others with poor results, 2 patients with less than a year of follow up at the time of writing, leaving only two more reasonably well-documented cases, successfully operated for posttraumatic epilepsy in 1913 and 1918.[30]

In the same period that Muskens was active, occasional reports indicated that, as before, some surgical procedures for posttraumatic or other symptomatic forms of epilepsy were performed by a general surgeons, assisted by a neurologist, generally with acceptable results for posttraumatic epilepsy and poor results for all other cases. These were not part of any organized program but in number and results appear equal or even superior to Muskens's activities. Not surprisingly Muskens academic career never progressed beyond his private readership and even as a neurosurgeon his real activities appear to have remained limited.

Looking back, Muskens remains a major figure in the development of epileptology and epilepsy care, both in the Netherlands and internationally.[26] For the actual development of either neurosurgery in general or epilepsy surgery in particular, however, this self proclaimed 'self operating neurologist' did relatively little and achieved even less.

A second start: the neurosurgeon and the neuro(physio)logist

Since otherwise the field remained in the hands of general surgeons with neither specific training nor interest in neurological disorders, the overall practice of neurosurgery in the Netherlands remained limited and of relatively poor quality for well into the first three decades of the 20th century. Yet increasingly the need for surgical treatment of some neurological disorders was felt and again it was a neurologist who took the initiative.

In 1923 Bernard Brouwer (1881–1949), who studied medicine in Amsterdam and then trained with Winkler, was appointed to the chair of neurology, now for the first time divided from psychiatry, in the city of his Alma Mater. For his surgical cases he worked with the general surgeons O. Lanz (1865–1935) and W. Noordenbos Sr. (1875–1954) but he was well aware of the gap between their results and those reported by others. Contacts with H. Cushing (1869–1939) and W. Dandy (1886–1946) during a lecture tour in the USA in 1926 convinced him that good quality neurosurgery was only possible in a special setting and by dedicated and undivided neurosurgeons with specific and adequate training. In Amsterdam he managed to convince the municipal authorities to have a new 100 bed clinic to be built, exclusively for neurological patients and including a fully equipped neurosurgical unit that could function independent of the general surgical clinic. While the clinic was being built Brouwer selected Ignaz Oljenick (1888–1981), a young resident surgeon, and sent him to Boston for training with Harvey Cushing. In 1929 Oljenick returned to Amsterdam and in September of that year the neurosurgical unit in the newly opened clinic started its activities.[1] As far as can be ascertained from his publications Oljenick did not perform any procedures specifically for epilepsy. His first trainee, however, would.

Arnaud Cornelis de Vet (1904–2001), studied medicine in Amsterdam and in 1929 applied for and obtained the position, offered by Brouwer, of resident in neurosurgery. De Vet thus became the first physician to be trained formally as a neurosurgeon in the Netherlands. After finishing his years of training with Brouwer and Oljenick and a study trip of several months to neurosurgical clinics in numerous European cities, De Vet in 1936 obtained his PhD, supported by Brouwer, on a thesis on the diagnosis of cerebral meningioma.[49] His material concerns a series of 36 operated and (with one exception, histologically verified) and two unoperated cases, including 17 patients in whom seizures were the major ($n = 13$) or a contributing symptom. Fifteen of these had their meningeoma removed, two died within a few days following surgery, and of the remaining 13 no follow up is provided. He points to the potential value but also the risks of ventriculography for the diagnosis of these (and other) intracranial processes but also emphasizes the need for a meticulous anamnesis and clinical work up and devotes a special chapter on the epileptic symptoms, found predominantly in patients with meningeoma over the convexity or the parasaggittal areas of the brain, and their localizing significance.

In the summer of 1936 De Vet left Amsterdam and moved to Wassenaar, a suburban village near The Hague where a former psychiatric clinic had been rebuild as the second non university associated hospital for psychiatric and neurological disorders, including the first non-university neurosurgical unit in the country. In the St. Ursula Clinic De Vet continued to pursue his interest in epilepsy as a possible target for surgical intervention and in 1938 he was appointed consultant neurosurgeon in the epilepsy clinic 'Meer and Bosch' in Heemstede.

'Meer and Bosch' was named after the stately mansion and the surrounding grounds, acquired in 1885 by the Christian Foundation for the care of Sufferers from the Falling Disease, founded in 1882, as living quarters for the clergyman-director. The institute, modeled after the Bodelschwing Institutions in Bielefeld, Germany, started in a small garden building at the premises of the founder, Lady A. J. M. Teding van Berkhout (1833–1909), in Haarlem but by 1938 had grown into a conglomerate of many buildings for housing, care, occupation or education, of adults and children with chronic epilepsy. Whereas care, provided by deaconess brothers and sisters, had been the original task of the foundation, the second quarter of the 20th century brought a shift towards a more medical oriented approach. In 1930 B. Ch. Ledeboer (1897–1959) was appointed as the first medical director, working together and not any more under the still prevailing clergyman director. Within a few years he managed to have a modern clinic built on the premises, with observation wards for adults and children, laboratories and even surgical facilities. In 1934 the

Queen Emma Clinic was officially opened and it was there that De Vet, starting 22 November 1938, practiced part time, in addition to his work in the St. Ursula Clinic. De Vet strongly believed in the value of ventriculography and designed a movable and translucent model of the ventricular system for better understanding of the movement of air through the ventricles and for illustrating and teaching puposes.[50,51] He advocated that every patient with epilepsy should have at least one diagnostic encephalogram and from the register of surgical procedures of the Queen Emma Clinic[52] it is clear that he practiced what he preached.

From the 377 procedures performed between November 1938 and February 1942, less than 40 appear to have involved real neurosurgical interventions, including five resections of cortical scars or areas from which seizures could be elicited. Others concerned lesiectomies (glioma, angioma, meningioma, etc.) which De Vet himself did not consider 'epilepsy surgery'.[53] The vast majority of the procedures were suboccipital ventriculgraphies, usually performed by A. Verjaal (1910–1973), the later Professor of Neurology in Leiden but then first assistant to Ledeboer, the remainder some 20–30 bi-occipital trepanations for direct puncture of the ventricles, performed by De Vet, Verjaal assisting. In 1942 the clinics in Heemstede closed and all patients returned home in order to prevent the German occupation forces and their Dutch collaborators to take over the management of the clinics. The St. Ursula clinic remained active. Occasional surgeries for epilepsy, either as the main symptom or as a secondary phenomenon, were also performed elsewhere since neurosurgical departments by this time also had been established in other university clinics in the Netherlands. In the Valerius Clinic, associated with the Free University of Amsterdam, general surgeon C. van Gelderen actually performed some interventions, including a tumor case with seizures, guided by some of the earliest electroencephalographic (EEG) recordings performed in the Netherlands.[54] These early Dutch endeavors in the field of EEG by physicist L.J. Koopman, psychiatrist L.J. Franke, and physiologist J. ten Cate were discontinued, due to war conditions (Jonkman[1]).

After the war the neurosurgical activities in Heemstede were resumed but according to the register it was not until 1949 that some real surgical intervention, other than diagnostic procedures was performed. In that year de Vet was joined by Otto Magnus, who, due to the vicissitudes of war had worked in Zurich with W.R. Hess (1881–1973), and then trained in Neurology in London. In 1947 De Vet had suggested that Magnus, rather than starting a residency in neurosurgery, should pursue his earlier neurophysiologic interest and acquaint himself with electroencephalography (EEG). Following two more years of training in Montreal with H. Jasper (1906–1999) and W. Penfield (1891–1976), Magnus returned and introduced EEG both in Wassenaar and in Heemstede. Magnus also introduced acute electrocorticography (ACoG) as a regular procedure for epilepsy surgery and according to the register, from June 1949 to September 1954 17 cortical excisions, guided by ACoG were performed, either by P. Hanraets, pupil and later associate of De Vet or by De Vet himself, who has his last entry on 23 September 1954. After that time no neurosurgical procedures were performed in Heemstede and on arrival of A.M. Lorentz de Haas (1911–1967) as successor to Ledeboer the operating room, which had remained in use for minor surgeries, was closed. All epilepsy surgery activities thus were moved to Wassenaar but Magnus remained head of the EEG department, both in Wassenaar and in Heemstede, acting as a liaison between the two clinics until 1968.

In an early report, specifically mentioning epilepsy, De Vet reported 80 cases of epilepsy admitted to the clinic in Wassenaar between 1936 and 1938, 63 of them being symptomatic cases. No mention was made concerning number of surgeries or outcome.[55] In 1949 he reported on 105 operated patients with a good outcome (comparable to Engel I and II) in 50%. Most patients had lesions. In 15 patients he removed small areas of normal looking cortex where seizures could be elicited and from those 15 only 4 had a satisfactory outcome.[53] In 1962 Magnus compared the results of the first 45 procedures with ACoG with those of the earlier series and found them to be more or less equal[56]. In his last paper on the subject[57] De Vet however emphasised the value of ACoG in cases of non-lesional temporal lobe epilepsy. From a total series of 213 patients, operated for epilepsy in the period 1936–1969, 78 could be identified with psychomotor epilepsy, where 33 of these turned out to have a lesion. From the remaining 45, all operated with the help of ACoG by Magnus, 18 became seizure free and another 13 showed major improvement, an outcome far superior to the 1949 results.[53]

In 1969 De Vet retired from the St. Ursula Clinic and after his departure the interest in epilepsy surgery quickly diminished. Only a few procedures were performed in the following years and in the new Westeinde Hospital in The Hague to which the neurological and neurosurgical departments were moved in 1979 no epilepsy surgery was performed any more. By this time however the torch had already been taken over by another team, already evident in De Vet's 1972 paper[57] where he discussed the options of stereotactic intracranial EEG investigations, advocated its application in cases of bitemporal lobe EEG foci and illustrated his point by an X-ray picture of a skull with multiple intracerebral and subdural electrodes, 'Courtesy Prof. Dr. W. Storm van Leeuwen'.

Consolidation: The Dutch Collaborative Epilepsy Surgery Programme

Reference to stereotactic procedures had already been made by De Vet before. Like other neurosurgeons of the period he had been actively involved in psychosurgery and, well aware of the major drawbacks of both open or closed leucotomy techniques, he recognized the potential advances of multiple and successive microcoagulations, performed through chronic indwelling micro-electrodes, but considered the technique as yet insufficiently developed.[58] By the time of his retirement this had changed.

Willem Storm van Leeuwen (1912–2005) studied medicine in Leiden and specialized in physiology and neurophysiology with G. J. J. Rademaker (1887–1957). In 1945 he obtained his PhD on a thesis on cardiac arrhythmia, elicited by experimental injury of the central nervous system. Supported by a Rockefeller Fellowship he then spent some years in the UK with Lord Adrian in London and with W. Gray Walter in Bristol, where he obtained his training in EEG.[59] On returning to the Netherlands Storm van Leeuwen was one of the driving forces behind the further development of clinical

neurophysiology in the Netherlands. Following alternating appointments in Leiden and Utrecht he finally settled in Utrecht in 1959 as director of the department of clinical neurophysiology and of the department of brain research of the Medical Physical Institute (MFI) of the National Dutch organization for applied physical research (TNO). The fortuitous situation of clinical neurophysiologists such as Storm van Leeuwen, Magnus, and Portugese born Fernando Lopes da Silva, whom Storm van Leeuwen had brought to Holland from the UK, collaborating with physicists as Anton Kamp in Utrecht and Henk van der Tweel (1915–1997) in Amsterdam, resulted in major advances in recording techniques and equipment, innovative early methods of computer analysis, and the development of miniaturized radiotelemetry with depth electrodes which was to be decisive for the further development of psychosurgery and, in its wake, also of epilepsy surgery in the Netherlands.

Following some pioneer stereotactic coagulation procedures by a group of Dutch and Belgian neurologists and neurosurgeons, including Arthur Sonnen (1932–2000) and Jan van Manen [60] in 1971, largely through an initiative of Harry Meinardi and the Dutch National Commission for Epilepsy Research (CLEO) a working group for neuro-physio-surgery was constituted to discuss all Dutch patients for whom psychosurgical interventions were considered.[61] Medical, social and ethical impact of such interventions were considered to exceed the individual responsibility of individual doctors and requiring peer review and as such the working group, although initiated by some of the core members, soon obtained formal recognition by the Dutch health authorities. Storm van Leeuwen held the chair. Members were neurologists, psychiatrists, clinical neurophysiologists, and neurosurgeons actively involved in psychosurgery and came from different clinics in the Netherlands as well as from the Dutch speaking part of Belgium. Since gross leucotomy by that time was totally discredited the method of choice was chronic stereotaxic microcogulation as originally advocated by Crow *et al.*[62] but employing the electrodes developed originally for animal experimentation by Kamp and Lopes da Silva. Since at the onset it was clear that evaluation of epileptic patients for possible surgery would require comparable electrode types and stereotactic techniques it was decided that the activities of the working group should also include epilepsy and that epileptologists should participate.[61] Special multistranded depth electrodes and subdural wire and reed multi-electrodes were developed at MFI and a method was developed for the stereotactic implantation of two to six intracerebral electrodes, aimed at the hippocampus, amygdala and mesio-frontobasal cortex, combined with 8–16 narrow subdural reeds, guided by hand and fluoroscopy over wide areas of the lateral and basal frontal, temporal and centroparietal cortex of both hemispheres, all electrodes introduced through just two small bifrontal trephine holes[63] (Figure 10.3).

Although reaching fewer intracerebral sites than the orthogonal stereotactic approach, developed by Taillairach and Bancaud,[63] the Dutch approach performed excellently[64] and had the advantage of better access to the surface cortex bilaterally with less risk for intracerebral hemorrhage and with relatively minor surgical trauma, compared to the subdural strip and grid methods, developed shortly afterwards in the USA. All procedures, including those on patients from Belgium, were performed in Utrecht by neurosurgeon C.W.M van Veelen.

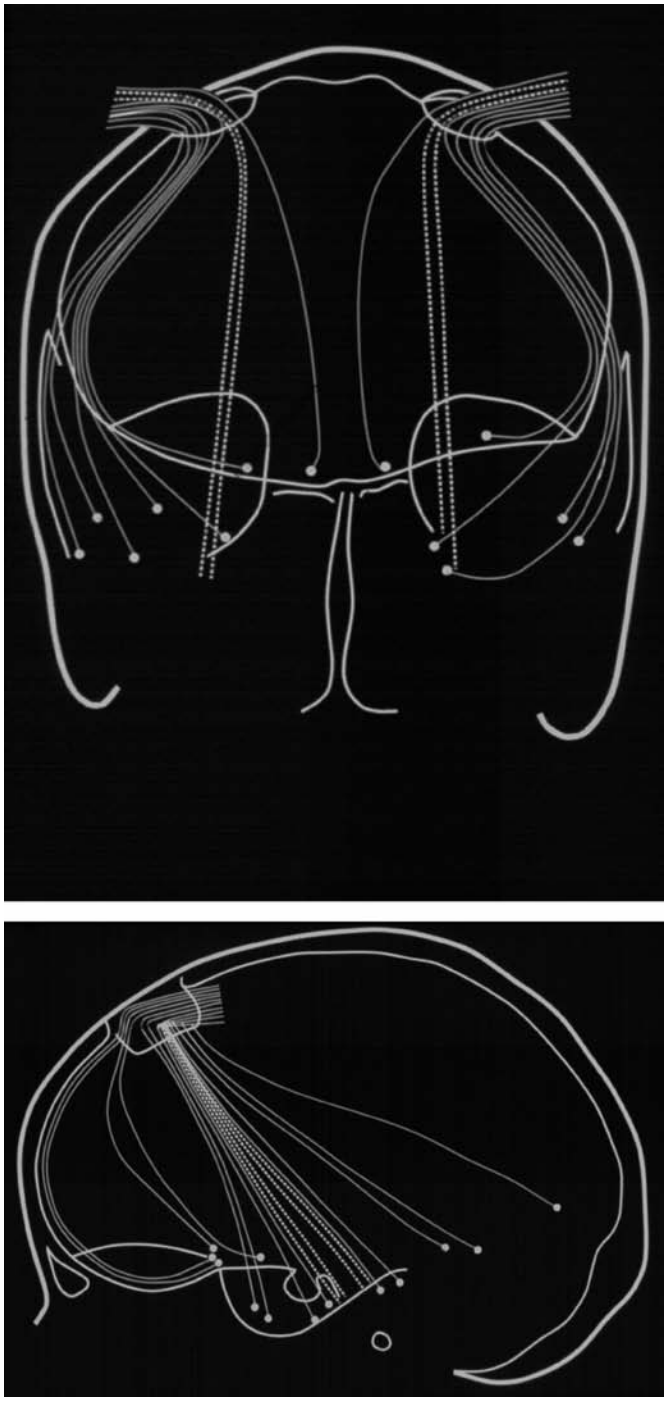

Figure 10.3 (a, b) Frontal and lateral scheme, drawn after postimplantation X-ray of a patient with bilateral subdural wire and reed electrodes (continuous lines) and four depth electrodes (dotted lines) in the mesilimbic structures, all electrodes implanted through small bifrontal trephine holes according to the method, developed by the group of Storm van Leeuwen, Lopes da Silva, and Van Veelen.[62]

Initially psychosurgery constituted the brunt of the working group's activities. Although at the time of Storm van Leeuwen's retirement in 1979 the number of such cases, was dwindling, the workgroup activities continued, stimulated by the arrival of C. D. Binnie, London and Cambridge trained clinical neurophysiologist, who in 1976 had taken up the position of director of the department of clinical neurophysiology at 'Meer and Bosch'. There he had created the first telemetric long term EEG and video monitoring unit in the country

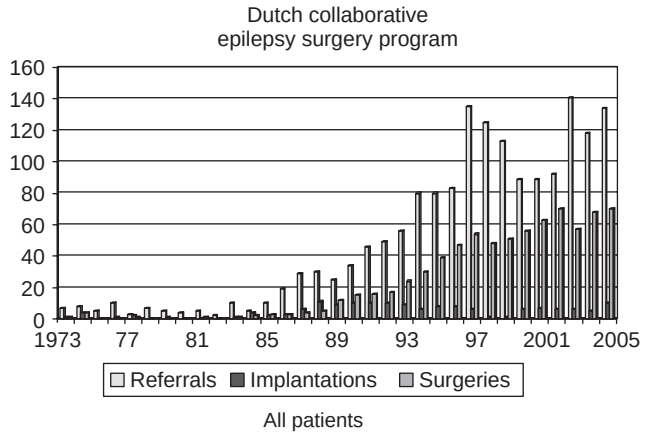

Figure 10.4 Dutch Collaborative Epilepsy Surgery Program activities 1973–2005: all patients A total of 1656 patients has been referred and evaluated resulting in 775 resections. 160 patients had intracranial recordings (135 bilateral or unilateral depth and subdural electrodes, 25 subdural grids).

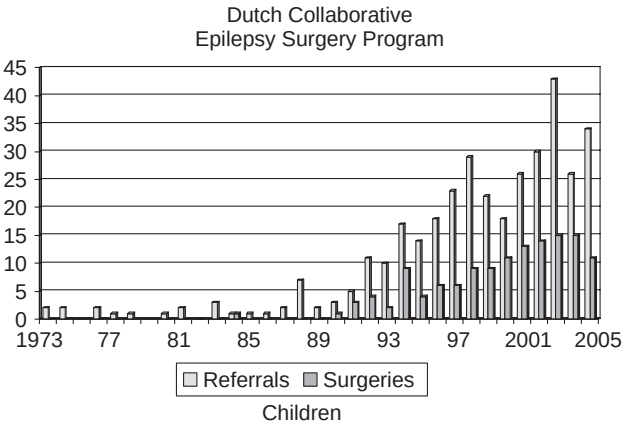

Figure 10.5 Dutch Collaborative Epilepsy Surgery Program activities 1973–2005: children, up to the age of 16 years. 357 children were referred of which 133 had surgery, with one exception all since 1990. Surgical procedures range from limited lesionectomies or partial resections to structural or functional hemispherectomies and a small number of anterior callosotomies.

where he could accommodate even depth implanted patients, who at that time could not be monitored in Utrecht.[66]

The emphasis now changed from psychiatry to epilepsy, at first still at a very low pace but, following the appointments, in 1985, of A. C. van Huffelen as successor of Storm van Leeuwen and of W. van Emde Boas on the position of Binnie, who returned to the UK, the program quickly expanded (Figure 10.4).

In 1989–1990 Van Emde Boas spent 5 months for additional training with F. Andermann and P. Gloor (1923–2003) in Montreal and on his return in Heemstede expanded the capacity for presurgical evaluation by creating a new 'non-hospital but home-like' three bed epilepsy monitoring unit, where, weather permitting, patients, including those with implanted electrodes, could be recorded, even while sitting outside in the garden. Van Huffelen, at the same time, prepared a medical technology assessment project and obtained government funding for the period 1990–1992.

The final report of this project, supervised by Van Huffelen, Van Veelen, and Van Emde Boas, was offered to the Dutch health authorities in 1993 and resulted in formal acceptance – and thus formal albeit hardly sufficient third-party payment – of epilepsy surgery, including the necessary presurgical evaluation for up to an initially 50 patient maximum per year, Utrecht Academic Hospital being the only recognized hospital allowed to perform these operations in close collaboration with the three specialized Dutch epilepsy centers.

By that time the constitution and procedures of the working group had drastically changed. With monitoring facilities now also available in the Epilepsy Centers Kempenhaeghe in Heeze and the Dr. Hans Berger Clinic in Breda, more clinical neurophysiologists and neurologists attended the meetings in Utrecht together with the neuropsychologists, responsible for pre- and post-surgical assessment and the Intracarotid Sodium Amytal test.[67] A second monthly meeting was organized in Heemstede for the clinical neurophysiologists only for a collective review of all the seizures, video and EEG, of the patients to be discussed in the next plenary session in Utrecht, where a brief summary would be presented. Other neurosurgeons joined van Veelen and pediatric epilepsy surgery, already practiced on a limited scale, got a major impetus when O. van Nieuwenhuizen, shortly afterwards to be appointed professor of child neurology in Utrecht, joined the group in 1991 (Figure 10.5).

Special MRI protocols were developed[68] and PET and occasional SPECT studies[69] were performed in selected patients, the former first in collaboration with the University clinic in Liege (Belgium)' and later in the Free University in Amsterdam, where in 1997 Magneto Encephalography (MEG) also became available. After lifting of the earlier imposed restrictions the university hospitals of Maastricht and of the Free University in Amsterdam joined the workgroup activities in 1997 and 2002.

While the number of referrals and surgeries steadily increased, until levelling off around 2002 (Figure 10.5) the number of intracranial investigations sharply dropped, then started to rise again following the introduction of Grids recordings in Utrecht under the supervision of Heemstede trained F. Leijten. Initially some Belgian patients continued to be referred to the Dutch program but this came to an end following the development of epilepsy surgery in Gent and elsewhere in Belgium.

Collaboration between programs on both sides of the border continued however, notably in the field of research in addition to multiple contacts between the Dutch program (since renamed 'National Working Group for Epilepsy Surgery' [LWEC] within the Netherlands and 'Dutch Collaborative Epilepsy Surgery Program' [DCESP] for international purposes) and international circles. Members of the group actively participated in many international meetings and van Emde Boas and van Nieuwenhuizen acted as commission members for the commission on epilepsy surgery and the subcommission for pediatric epilepsy surgery of the International League Against Epilepsy. Between 1973 and 2005 775 patients had been operated, the last overall results (on 338 patients operated up to 1998) published by van Veelen in 2001.[70] An overview of the papers published by participating workgroup members and associated research programs (Appendix) can be obtained through Pub Med.

Vagal nerve stimulation never was part of the activities of the LWEC although some of the member epileptologists and surgeons were or are involved in early pilot studies and in the current multicenter program for a limited number of VNS implants per year, accepted by the health authorities and coordinated by G. Hageman (Enschede) for adults and M. Majoie (Heeze) for children.

Growth of patient numbers and the increased complexity of presurgical work up of individual patients and of traffic in the densely populated Netherlands have made the process of regular, now two per month, general meetings in Heemstede and Utrecht an increasing burden on the participants and some members of the LWEC have advocated the creation of local teams, leaving only the most difficult cases for broad discussion in the central group. A team consisting of neurologists, neurophysiologists, neuropsychologists, and neurosurgeons from the University of Maastricht and Epilepsy Center Kempenhaeghe has started its activities in 2005, reviewing cases from the southern part of the Netherlands; the first resective procedures have recently been performed in Maastricht. However, it takes expertise also to recognize 'easy cases' inasmuch as these exist and the LWEC intends, with the development of teleconferencing techniques, to continue to monitor, coordinate, and guide all epilepsy surgery activities in the Netherlands.

Belgium

At the end of the 16th century Jean Baptiste van Helmont (1577–1644), the founder of the Iatrochemical School, which looked to chemical explanations of vital phenomena, from Leuven, was the first to write about the underlying mechanism of epilepsy in the Low Countries. He attributed epilepsy to a dysfunction of the orifice of the stomach where a duumvirate of stomach and spleen was thought to regulate functions of life. However, he also acknowledged that seizures could be provoked by strong emotions affecting the sensitive soul.[71] In modern times, it was only after 70 years of its independence from the Netherlands in 1830 that Belgium saw some early efforts in surgical treatment of patients with epilepsy. Crocq[72] mentioned 13 mostly posttraumatic cases from nine authors in his 1902 review and in that same year Lowie from Eecloo reported another patient at a major Flemish meeting.[73] Yet these activities, and comparable ones in the years to follow, remained isolated cases, performed by general surgeons and not incorporated in a structured program. The interest in neurosurgery and epilepsy in Belgium dates from immediately before the World War I. In 1905, Van Gehuchten began to film neurological and psychiatric patients, among some with epileptic fits; the original nitrate movies have survived and represent in fact the first Belgian films. The Great War, with 90% of the country under German occupation, represented a period of scientific stagnation. Only in Flanders Fields did some surgeons acquire great experience in traumatology. Noteworthy is the contribution by De Page who designed a special electromagnetic device used for removing deep seated shrapnel and bullets from the brain.[74] As the capacity of (neuro)surgical care on the battlefield was very limited, the Belgian Red Cross called upon the services of Muskens from The Netherlands to help setting up a unit for central nervous system war injuries in 1914. Immediately after the World War I, Paul Martin was the first Belgian surgeon who went to the USA for training in neurosurgery with Harvey Cushing and became head of the surgical laboratory at Harvard University. He later returned to Belgium to become the first professor of neurosurgery at the University of Brussels.[74] In the meantime, Van Gehuchten had joined forces with Jean Morelle, a neurosurgeon who had also trained in the USA and set up a nucleus of neurosurgery within the general surgery department at Leuven. A similar attempt was made at the University of Liège, where Christophe, who had worked with Frazier, Adson and Cushing, became lecturer in neurosurgery in 1933, probably the first of his kind in Europe.[74] However, the first independent neurosurgical departments were founded only after the World War II but initially there was no special interest for epilepsy surgery.

In fact, specialized epilepsy care in Belgium as such did not start until in the fifties of the 20th century. In 1955 academical neuropsychiatrists from the Universities of Gent, Brussels, Leuven, and Liège and other interested professionals founded the Belgian National League against Epilepsy. The league has survived to date but currently serves as an umbrella organization of two active regional leagues (one Flemish-speaking and one French-speaking) reflecting the federal nature of the Belgian state. According to a review by Sorel, by the end of the fifties in-patient facilities for epilepsy patients were available in neurological departments of 59 hospitals throughout the country.[75] In about 10 neurosurgical units nationwide occasional epilepsy surgery procedures were performed. In the late sixties and early seventies two institutions for residential care of refractory epilepsy patients were founded in Pulderbos and in Ottignies. Pulderbos, located in the Flemish-speaking part of the country, emerged from collaboration between the University Hospital of Leuven and a major health care provider. The 'Centre Neurologique William Lennox' was founded in 1972 and is associated with the French-speaking 'Université Catholique de Louvain'.

The first reports in the international peer-reviewed literature of epilepsy surgery in Belgium originate from Liège where in the mid-sixties A. Waltregny, a neurosurgeon and clinical neurophysiologist, performed experimental and human studies using invasive EEG recording based on the teachings of Gastaut and Bancaud in France.[64,76] Relatively few resective procedures were performed, however, without further contributions to the international epilepsy surgery literature. Many patients eligible for surgery were referred to epilepsy surgery centers in France, The Netherlands, and Western Germany.

In the beginning of the eighties P. Tugendhaft and J. Brotchi at Hôpital Erasme, an academical hospital associated with the French-speaking 'Université Libre de Bruxelles', performed a series of invasive EEG recordings using the methodology of Wyler from the USA. and initiated the first epilepsy surgery series in Belgium.[77] Neuropsychological assessment and intracarotid amytal procedures were routinely performed.

In 1990, the first comprehensive epilepsy surgery center in Belgium was established at Ghent University by P. Boon, and L. Calliauw, chair of neurosurgery at Ghent University Hospital. P. Boon, a neurologist and clinical neurophysiologist, trained at Winston-Salem, NC with Penry and at

Yale University with Williamson and Spencer. Soon E. Thiery, professor of neuropsychology at Ghent University and E. Achten, neuroradiologist at Ghent University Hospital, joined the team. Their collaboration resulted in the first multidisciplinary epilepsy surgery team in Belgium, evaluating and operating increasing numbers of patients and performing clinical research.[78,79] The first combined placement of depth and subdural electrodes in patients requiring invasive EEG recording, the first implantation of a vagus nerve stimulator in Belgium, and the first long-term treatment with amygdalohippocampal deep brain stimulation for temporal lobe epilepsy in Europe were all performed by their team. Over time the group in Gent came to include K. Vonck, a neurologist with special expertise in neuromodulation and D. Van Roost, a functional neurosurgeon with long-standing experience in epilepsy surgery, who trained with the neurosurgical team of Schramm at Bonn University Hospital.[80,81]

At about the same time, the team from the 'Université de Liège' headed by G. Franck and B. Sadzot, who had trained in Baltimore, USA, established a positron emission tomography unit in which patients with refractory epilepsy were systematically investigated. Most of these patients were referred from the Dutch Collaborative Epilepsy Surgery Programme in Utrecht.[69,82]

In the late nineties W. Van Paesschen, a neurologist who trained with Duncan and his group in London and J. Van Loon, a neurosurgeon, started with presurgical evaluation and epilepsy surgery at the 'Katholieke Universiteit Leuven'. Their group has a strong focus on non-invasive diagnostic tools such as ictal SPECT.[83] This was quickly followed by similar initiatives to establish epilepsy surgery programs at the 'Université de Liege' (headed by B. Sadzot and T. Grisar), the 'Cliniques Universitaires St-Luc' in Brussels (headed by K. Van Rijckevorsel and C. Raftopoulos), and in the 'Centrum voor Epilepsie en Psycho-organische Stoornissen', a private initiative in Duffel (headed by R. Hauman). The already active programme at 'Hôpital Erasme', Bruxelles, now directed by B. Legros and P. Van Bogaert, during the same period expanded its activities.

A major breakthrough in terms of acceptance by the health authorities and funding by the national reimbursement agency was the establishment of 'Reference Centers for Refractory Epilepsy' in 2000. Strict criteria were defined with regard to the necessary availability of technical infrastructure, human resources and neurological and neurosurgical expertise for academical centers to be recognized as a referral center for epilepsy surgery. The main purpose was to concentrate know-how in a limited number of centers, guarantee high quality standards and limit the costs. Only patients treated in such centers got reimbursement for presurgical evaluation and surgical procedures for refractory epilepsy.

After an initial phase during which six centers were recognized in 2000, presently four Reference Centers for Refractory Epilepsy are active in Belgium: in Gent (Universitair Ziekenhuis Gent), Leuven (Universitair Ziekenhuis Gasthuisberg), and two in Brussels (Hôpital Erasme, Cliniques Universitaires St-Luc). All have dedicated epilepsy surgery teams and follow a similar presugical evaluation protocol. In each center, video-EEG monitoring, 1.5T or 3T optimum MRI facilities, PET, SPECT, and neuropsychological assessment are available. Biannually, in each center quality and performance parameters are assessed by the national reimbursement agency. In 2003–2004, 300 patients annually underwent presurgical evaluation (including invasive video-EEG monitoring in 20 patients) resulting in 70 resective procedures and 60 implantations of a vagus nerve stimulator in patients who were not eligible for resective surgery.

Presurgical evaluation and epilepsy surgery are a strong impetus for performing clinical and experimental research. Epilepsy research in Belgium has basically followed the same timelines as the clinical development of epilepsy care described above. While scientific reports on epilepsy surgery related work were scarce until the 1980s, clinical researchers from Gent, Leuven, Bruxelles, Louvain and Liège have been increasingly active. Among the most published topics in the past 15 years are EEG source localization (Gent), optimal structural magnetic resonance imaging (Gent, Leuven), functional magnetic resonance imaging (Gent), PET (Liège), ictal SPECT (Leuven), magnetoencephalography (Gent), seizure anticipation (Gent, Leuven), antiepileptic drug research (all centers), vagus nerve stimulation (Gent), and deep brain stimulation (Gent, Bruxelles).[80–89] The groups from Gent and Liège have experimental animal facilities providing many relevant epilepsy animal models and they are active in the field of basic neurophysiology, neurostimulation and stem cell applications in epilepsy.[90–93]

11 History of epilepsy surgery in the Middle- and East-European countries and Russia

P Halász

Epilepsy surgery in the Middle- and East-European region and in Russia developed under the influence of the USA and of the French schools. In the majority of countries a strong neurosurgical school developed at the beginning of the 20th century, and epilepsy surgery was built up with a more or less delay on a double basis: on classical neurosurgery and on independently developing clinical neurophysiology. The two disciplines have been amalgamated by the emerging clinical epileptological knowledge throughout the world in the multidisciplinatory assessment of epilepsy surgery. In these countries the development of epilepsy surgery was severely hindered by the information blockade due to the realm of the antidemocratic political power and to the delayed application of the contemporary neuroimaging techniques due to economical reasons. Presently the development of epilepsy surgery practice reached the international standards of leading centers in the world in Poland, Czech Republic and Hungary.

Poland

In the second half of the 19th century surgical treatment was directed to vascular surgery, mainly on the sympathetic system, according to the theory that the disturbance in blood supply, especially vasospasm, was the direct cause of the epileptic seizure. R. Baracz in 1888 and 1893 published papers 'On the ligation and resection of the vertebral arteries and the resection of sympathetic nerve for treatment of spontaneous epilepsy'. In the same year (1893) J. Bogdanik published a similar paper 'On the resection of sympathetic nerve in treatment of spontaneous epilepsy' and found improvement after such operations. Later on this procedure was applied by Raum and others as well.

Later it was held that epilepsy is the consequence of the collection of cerebrospinal fluid on the surface of the brain in various kinds of cysts and can be treated by trephination and decompression. Decompressive trephinations were used by Baracz in 1890, Krajewski in 1894 and 1899, Schramm in 1899, and Raum in 1900. A. Domaszewicz and J. Zaczek published the paper (1922): 'On the surgical treatment of epilepsy with personal experience' describing the operative findings and the results of the decompressive craniotomy.

Founder of the modern Polish neurosurgery was Jerzy Choróbski (1903–1986), head of the Department of Neurosurgery in Warsawa. He was Penfield's pupil spending several years working with him and started neurosurgery in Poland in 1935. At the beginning, during World War II and directly after, he performed several procedures for removing brain scars in cases of posttraumatic epilepsy, so important at that time. As soon as conditions after the war allowed and necessary equipment was obtained, among others EEG apparatus, he carried out the first surgery of focal, cryptogenic epilepsy on 27 November 1957 by temporal lobectomy. Diagnosis was derived from the clinical picture, PEG, EEG, and was proved intraoperatively by electrocorticography and brain electrostimulation. Later Choróbski was doing mostly temporal resections or, in special cases, hemispherectomy.

The epilepsy surgery team included L. Stępień and J. Bidziński (neurosurgery), T. Bacia (electrophysiology), all trained at the Montreal Neurological Institute and J. Wislawski (neuropathology). After Choróbski's retirement, the next head of the Department, Lucjan Stępień, continued this work with the above mentioned co-workers. Anatomical hemispherectomy was replaced by functional hemispherectomy. Extensive electrophysiological non-invasive investigations included various pharmacological activations and whole night physiological sleep. New diagnostic methods were consequently introduced: the Wada test (1960), psychological examination, invasive diagnosis as stereotactically implanted chronic electrodes, chronic epi- and subdural electrodes (Bidziński and Bacia in 1974). PEG was replaced by CT and NMR, and isotope studies were introduced. The results of their work were published in several publications with very long follow-up of several hundred patients and presented at international meetings.

Beyond resective surgery, other methods, such as stereotactic lesions (amygdala, Forel's field, Bidziński in 1981) and cerebellar electrostimulation (Bidzinski and Bacia in 1981) were tried with questionable results.

The Next head of the Department, J. Bidzinski, continued epilepsy surgery and introduced anterior callosotomy and vagal nerve stimulation in Poland (1990). The present head of the Department, Prof. A Marchel with co-worker A. Rysz, are continuing the tradition of epilepsy surgery in this department with electrophysiology.

As the surgical treatment of epilepsy became more popular, new neurosurgical centers started to offer surgical treatment. E. Mempel in Warsawa for many years did stereotactic

amygdalotomy in patients with emotional disturbances in epilepsy and introduced acute stereoEEG in 1968. Since 1961, Z. Huber in Poznań has performed several temporal lobectomies in adults and recently in children. Specially important was the establishment of an epilepsy surgery center for children at the Children's Hospital, Mother Health Center in Warsawa, in 1995 (head, M. Roszkowski.), and at the Children's Hospital in Lodz, in 2001 (head, L. Polis). In these centers children are treated up to 16 years of age. Recently two more neurosurgical departments joined the centers doing epilepsy surgery: in 2002 the Department of Neurosurgery in the Ministry of Administration Hospital in Warsawa (head W. Maksymowicz) and in 2004 the Department of Children's Neurosurgery Medical University in Katowice (head M. Mandela).

Russia

Epilepsy surgery in Russia and the former Soviet Union dates back to the end of the 19th and the beginning of the 20th centuries. In his 'clinical lectures' published in St Petersburg in 1898, A. Tauberg described cases of surgical treatment of 'cortical epilepsy' after brain trauma. F. Rein (1897) published a paper 'Results and indications for the surgical tratment of Jacksonian epilepsy'. V. A. Muratov considered Jacksonian type seizures to be the indication to surgery. S. Timopheev (1913) and L. Pusepp (1919) reported long-term follow up of patients operated because of 'Jacksonian epilepsy'.

There were also several attempts to treat non-focal epilepsies surgically at that time. Various types of operations has been suggested, including operations on the autonomic nervous system. Later the idea of surgical treatment of focal epilepsies was supported by the famous Russian neurosurgeon N. Burdenko.

Since the middle of 20th century epilepsy surgery has been developed in several regions of the Soviet Union: in St Petersburg Bechterewa, in Tbilis, Georgia (P. Saragishvily and P Chencheli), in Kiev, Ukraine (A. Romodanovĺ), in Sverdlovsk (now Ekaterinburg) (D. Shefer), and in Omsk (Yu. Savchenko). Stereotactic methodology of the Paris school was the basis of surgical interventions in these centers. Several papers and books dedicated to epilepsy surgery have been published in the Russian language by the above-mentioned authors.

Presently in Russia, epilepsy surgery is being performed in St Petersburg (V. Bernsev), Ekaterinburg (A. Shershever), Viatka (B. Bein), and Omsk (A. Savchenko) on a considerable number of patients. The basic diagnostic disciplines, the diagnostic system used, the participation of neuroimaging methods in the presurgical procedure are deviating in several aspects from the contemporary European and USA epileptological standards. Evidence based evaluation of the results have so far not been published.

Five years ago a joint surgery program was established in Moscow between the Department of Neurology and Neurosurgery of the Russian State Medical University and the Institute of Neurosurgery, based on a multidisciplinary team. This team decided to join to the contemporary epilepsy surgery programs in Europe using the same standards, evaluation and surgical methods. More than 400 patients have been evaluated and from them 58 patients selected for presurgical evaluation, 30 patients were operated, mainly on the temporal lobe, with good results.

Romania

The founder of Romanian neurosurgery was Prof. Dimitrie Bagdasar, trained in Prof. Cushing's Department in Boston, and the first dedicated neurosurgical department in Bucharest was founded by him in 1935. His follower Prof C. Arseni was the next determining leader in neurosurgery until 1989.

The modern era of Romanian neurosurgery was introduced by Prof. Al. Constantinovici and later by Prof. A.V. Ciurea. In 1993, a large neurosurgical hospital was established in Bucharest, named 'Bagdasar-Arseni', having departments for general neurosurgery, pediatric nerosurgery, spine neurosurgery, and adult neurosurgery. In March 2005 a neuroimaging department was added.

Epilepsy surgery is still restricted to resective procedures of standard temporal lobectomies (3–4 yearly), a few tailored temporal surgical procedures (5–7 yearly) and 3–4 extratemporal resections yearly, in the last three years.

Within this hospital a multidisciplinary team is starting to perform epilepsy surgery together with the Romanian National Reference Center of ILAE ruled by Dr. R. Rogozea. They are equipped with video-EEG, SPECT, and 1.5 Tesla MRI, using special 'epilepsy protocols', they recently introduced cortical mapping by subdural electrodes, and transcranial magnetic stimulation. They do not have as yet PET, fMRI, or MEG.

Czech Republic

Epilepsy surgery in the Czech Republic (at that time part of Czechoslovakia) started in departments of neurosurgery of Medical Faculties of Charles University in Prague and Hradec Králové. Since 1956 patients with epilepsy were operated in the Department of Neurosurgery of Faculty of General Medicine of Charles University and the Military Hospital in Prague. There were two young associate professors (Šourek and Vladyka) deeply interested in epilepsy. At first they performed excisions of cortical foci and temporal lobe resections. Stereotaxic operations were introduced later.

At the beginning surgery was performed only in patients with intractable epilepsy lasting for tens of years. Therefore the number of successful outcomes was relatively low but it increased with the shift to patients with a shorter history of therapy resistant epilepsy. Šourek and Vladyka introduced a method of local cooling of the temporal lobe with the aim to open the blood–brain barrier and then apply intravenously a bolus of an antiepileptic drug. Until 1974 they used this method on 71 patients and approximately 25% of them remained seizure free, unsuccessful operations also represented 27% of patients and the remaining patients exhibited different degrees of improvement.

The number of neurosurgery departments interested in epilepsy progressively increased so that there are at present at least seven departments performing more or less frequent

epileptosurgical operations (Prague, Brno, Hradec Králové, Plzeň, and Olomouc).

Modern techniques, including video-EEG studies and intracranial explorations, were introduced during the 1990s. The Homolka Center in Prague had been educated primarily in English-speaking countries, and subdural recordings were the dominant method of invasive explorations (62%). The Epilepsy Center Brno was based on the model of a French school using the stereo-EEG method when invasive intracranial detection was necessary (92%). A recent analysis of the surgical results of the two centers in 248 adult patients with post-surgical follow-up of at least two years displayed Engel I in 58.9%, Engel II in 15.5%, Engel III in 13.3%, and Engel IV and V in 11.3%.

Turkey[2–6]

Epilepsy surgery has a relatively long history in Turkey although a modern teamwork approach was started during 1990s. Prof. Kenan Tukel (Figure 11.1) who was a pupil of Penfield and Jasper in the Montreal Neurological Institute established the first EEG lab in the early 1950s in Istanbul University. However, the first case report related to epilepsy surgery was published from Hacettepe University Medical Faculty, Ankara in 1960 by V. Turkmen and A. Erbengi. It was about a patient with infantile hemiplegia operated by hemispherectomy. The first electrocorticography (ECoG) during surgery was applied again in the same hospital in 1965 where epilepsy surgery gained speed with the efforts of O. Kalabay and V. Bertan from the departments of neurology and neurosurgery. In 1986, A. Erdem performed extratemporal cortical resections guided by ECoG in Ankara University. After being trained by G. Yasargil in Zurich, A. Erdem in Ankara and later E. Ozyurt in Istanbul introduced selective amygdalohippocampectomy in the early 1990s. Epilepsy surgery teams working in a multidiciplinary fashion were established in 1993 in Hacettepe and 1995 in Cerrahpasa Medical faculties and have continued since then with addition of different centers including Gazi University, Istanbul Medical Faculty, Marmara University and others.

Estonia[7–11]

The founder of the national school of neurosurgery in Estonia was Professor Ludvig Puusepp (1875–1942) who operated 318 epileptic patients during 1901–1920. Thereafter, the summary of operations in 1921–1930 (1–5 cases per year) were published.

During the following years the number of operations have fallen dramatically, primarily due to effective medical treatment. In Tartu, EEG has been available since 1961, intraoperative electrocorticography (ECoG) since 1967, computerized tomography scanning since 1983, and magnetic resonance imaging since 1992. In 1996, the measurement of AED concentration just became available for routine use.

Long-term video-EEG has been available in Tartu since 2003. In recent years all patients for epilepsy surgery were investigated in long-term video-EEG (only scalp-electrodes). An average of two patients per year has been operated, all typical MRI-positive hippocampal temporal lobe epilepsies. ECoG was performed in 50% of the cases.

Figure 11.1 Dr. Kenan Tükel as a member of the Montreal team in 1952.

Latvia[12–17]

Episodical epilepsy surgery in the case of symptomatic disease (mainly tumors) in the territory of Latvia was performed at the beginning of the 20th century (A. von Bergmann, P. Klemm, L. Bornhoupt, E. von Schwartz in Riga's 1st Hospital). During the 1920s and 1930s neurosurgical operations in 3 hospitals in Riga were performed by general surgeons (V. Minz, J. Jankovsky, P. Mucenieks, A. Udre, P. Stradins, K. Dolietis *et al.*), and in rare cases neurosurgical operations were made for cerebral disease with epilepsy.

In the year 1939, K. Dolietis became the first certified neurosurgeon in Latvia and operated several patients with symptomatic epilepsy. At the end of the World War II, K. Dolietis emigrated to Sweden.

Development of neurosurgery continued in Riga's 1st Hospital; in 1946, the Clinic of Neurology and Neurosurgery was opened (A. Liepukalns and K. Arajs).

In 1969 I. Purins organized the Neurosurgical Center on the basis of P. Stradin's Clinical Hospital in Riga. Soon after that T. Apinis and Z. Grinbergs, doctors of this hospital, made the first steps to specialized epilepsy surgery after practices in the clinics of Moscow and Leningrad. The main method for epilepsy surgery was temporal lobectomy. Sometimes intraoperative cerebral surface electrodes were used for more precise diagnosis of the lesion locus.

Other types of operations were frontal lobotomies, gyrotomies, callosotomies; some hemispherectomies were also performed. Fifteen operations of intracranial superficial hypothermia in patients with epilepsy did not give any influence to the disease course.

A total of 145 operations for epilepsy were registered in this hospital during the period from 1974 to 1988. Epilepsy surgery in other hospitals of Latvia at this time was not very significant. Recently epileptic patients were selected for surgery in two neurosurgical departments of Riga: in the Clinical Hospital 'Gailezers' and in the P. Stradin's University Hospital. The surgery for symptomatic epilepsy due to cerebral tumors, dysplasias, heterotopias, mesial sclerosis etc. is accentuated; the number of operations of such type is approximately 20–30 per year. The new technologies (neuronavigation and invasive electrode techniques) are also used in the epilepsy surgery.

Lithuania

The first specialized neurosurgery unit in Lithuania was established in 1951 at Kaunas Clinical Hospital (Kaunas University Hospital at present). The start of epilepsy surgery took place in 1974 when the first temporal lobe resection was performed by doctors Henrikas Juozakas and Vytautas Paškauskas. Since 1976 subpial cortical suction, and since 1978 stereotactic hippocampo-amygdalotomy have been introduced, the latter also being performed nowadays. The stereotactic method for epilepsy surgery has been introduced and is still being developed by docent Juozas Šidiškis. In 1980 the Neurosurgery Clinic was established in Kaunas, with six specialized neurosurgery units. The Unit of Functional Surgery was a specialized unit for epilepsy surgery and microneurosurgery, with Professor Egidijus Jarûemskas as the Head until 1998, and Dr. Jonas Gelūnas until 2001. Professor E. Jaržemskas was the one who developed epilepsy surgery in Lithuania. Also, he was the founder and the president of the Society for Epileptology of Lithuania, which joined ILAE as a chapter in 1995. In 2001 the Neurosurgery Clinic was reorganized, and a specialized unit for cerebral surgery was established, with the Sector for Epilepsy Surgery included and headed by Dr. Arūnas Žobakas.

The diagnostic method implanted depth electrodes was introduced in 1982, and the use of subdural electrodes for the localization of the epileptogenic focus in 1989. Sleep EEG and video-EEG for presurgical diagnostics have been introduced at Kaunas University Hospital since 2000. The development of comprehensive presurgical multidisciplinary evaluation is one of the strategic plans at Kaunas University Hospital for the near future.

Hungary[18–21]

Kálmán Sántha and István Környey, friends and legendary personalities in the Hungarian history of neurology contributed equally to establish neurosurgery in the 1930s in Szeged and later in the 1940s in Pécs and Debrecen. István Környei was educated in Boston and Ann Arbor, Kálmán Sántha (Figure 11.2) in Montreal by W. Penfield, supported by the Rockefeller fellowship. Sántha, together with Cipriani, was the first to provided evidence that during an epileptic seizure it was not vasoconstriction (as was stated in the theory of Mayer) but just the opposite procedure, an important elevation in blood flow, that occured (Sántha, Cipriani, and Penfield 1938) (Figure 11.3). This work should be held as a first move toward the contemporary development of the ictal SPECT method. The first decisive steps of Hungarian epilepsy surgery were taken by J. Hullay in Debrecen, a pupil of Sántha, who reported on 50 temporal lobectomies as early as 1958.[18,19] Later in the 1970s in the same institution (Department of Neurology, Medical University of

Debrecen) within the framework of the epilepsy surgery program, invasive presurgical monitoring with the Bancaud–Tailerach stereotactic methods was carried out on several patients.[20]

The new wave of modern epilepsy surgery was started in the 1990s with the foundation of a 'Co-operative epilepsy surgery program' in which under the leadership of the National Institute of Psychiatry and Neurology, Epilepsy Center, several neurological institutions, and the National Institution of Neurosurgery participated including the Bethesda Children Hospital where a video-EEG monitoring unit has been working since 1997.[21] The number of patients involved and operated using the presurgical protocol is 20–30 yearly. The overwhelming majority of surgical interventions are partial temporal lobectomies in therapy resistant MTLE syndrome, but a few extratemporal surgeries are done yearly with invasive presurgical evaluation by subdural strips and grids. Results of temporal lobe surgery are illustrated in the Figure 11.4. In 2005 a new epilepsy surgery program was started in Pécs in the Neurological Clinic of the Medical University.

Acknowledgments

I am really grateful to Prof. Alla Guekht (Russia), Prof Jerzy Bidzinski (Poland), Prof. Pavel Mares and Prof. Ivan Rektor (Czech Republic), Dr. V. Ciobotaru (Romania), Prof. Cigdem Özkara (Turkey), Prof. Milda Endziniene and Dr. Arunas Zobakas (Lithuania), and Dr. André Öun (Estonia), for providing essential information not easily obtainable / elsewhere.

12 Epilepsy surgery in Canada

W Feindel

The Montreal School

From 1934, Wilder Penfield with his surgical partner William Cone, their associates and many successors, developed at the Montreal Neurological Institute a center that became known world-wide for its systematic surgical treatment, research and teaching related to epilepsy (Figure 12.1).[1–6] Following Victor Horsley's pioneer efforts,[7] many surgeons in North America ventured to operate on patients suffering from seizures related mostly to cerebral trauma or tumors.[8,9] But their reports were often a litany of failures. Harvey Cushing had treated patients with seizures by surgery under local anesthesia and was the first to report mapping by electrical stimulation of the sensory cortex.[10] But Cushing centered his main interest on brain tumors, noting in 1932 to Wilder Penfield his former student,

> at all events, you can see that I, too, just thirty years ago was extirpating a cortex for epilepsy. If I had the industry and ability that you and Foerster combine, I might have gone ahead with it and made something of it. But I soon dropped it for things I thought I could do better.[11]

While at Columbia-Presbyterian Hospital in New York, in the 1920s, Penfield had taken a special interest in the problem of how a wounded brain heals, hoping that a better understanding would lead to improvement in excision of brain lesions, such as the post-traumatic scars associated with epilepsy.[5,11] He pursued this interest by going to Madrid in 1924, where he studied with Ramon y Cajàl's brilliant student Pio del Rìo-Hortega the role of neuroglia and microglia in brain healing, tumors and inflammation.[12]

As the first English speaking pupil of the Cajal school of neurohistology, Penfield returned to New York and applied his unique expertise to neurosurgical problems, and especially to epilepsy. Then in 1928 during his transition between New York and taking up neurosurgical practice in Montreal, he spent six months with Otfrid Foerster in Breslau. Here he learned the technique of electrical stimulation of the cortex with the patient awake under local anesthesia. He also took advantage of his familiarity with the Spanish methods to study the histology of the meningo-cerebral cicatrix in a dozen patients, mostly with head injuries, upon whom Foerster had operated for seizures.[13]

In September 1928, Penfield arrived in Montreal on the invitation of Edward Archibald to take over his neurosurgical practice at the Royal Victoria Hospital associated with McGill University. Archibald had been a student in 1906 of Sir Victor Horsley and Sir William Gowers at the National Hospital, Queen Square, and thus became the first surgeon in Canada to focus on neurosurgery. In 1908, he published the 375-page monograph on 'Surgical Affections and Wounds of the Head' in Bryant and Buck's *American Practice of Surgery*.[90] It was the same year that Harvey Cushing's extensive review of 259 pages on neurosurgery appeared in Keen's *Surgery: Its Principles and Practice*.[91] But Archibald began to take greater interest in thoracic surgery, in which he would become one of the American leaders. He also turned to the problem of post-graduate surgical education and directed his influence to establishing the American Board of Surgery.

Earlier at McGill University, William Osler was a keen protagonist for the emerging specialty of neurosurgery. From 1869 to 1884 he performed a thousand autopsies at the Montreal General Hospital. Among these, he reported many examples of neurological disorders, including epilepsy.[14,15] In commenting on the first operation for a brain tumor performed by Rickman Godlee in 1884 at London, Osler compared his own case where a post-mortem examination in 1883 disclosed a small glioma in the leg center of the cortex. This had caused Jacksonian seizures for twelve years, eventually ending in a fatal bout of status epilepticus: 'an instance', Osler wrote, 'in which operation would have been justifiable and possibly have been the means of saving life'.[16] Osler's spirited humanism and his positive attitude toward brain surgery influenced the field of neurosurgery through his friendships with both Harvey Cushing and Wilder Penfield.[17,18]

The Royal Victoria Hospital, Montreal (1928–1934)

In November 1928, two months after Penfield moved with his surgical partner William Cone from New York to Montreal, he performed his first operation at the Royal Victoria Hospital for focal epilepsy. (Figure 12.1) The young patient (RM) had fallen from a horse ten years earlier when he required surgery for a right-sided subdural hematoma and brain contusion. He developed seizures with increasing frequency, from 5 to 20 a day.

Eventually, this complex post-traumatic epileptogenic lesion required three operations to control these intractable seizures. At the first procedure, a small area of cortex was

Figure 12.1 Wilder Penfield (left) and William Cone, the neurosurgical partners, at the Royal Victoria Hospital, 1932.

excised near the motor strip that was defined by stimulation. The attacks continued. A second exploratory craniotomy followed a few months later to expose the frontal lobe on the opposite side; no abnormalities were found so no removal of any sort was made. For the third and final operation, three years later, Stanley Cobb and William Lennox came from Boston as consultants. Cobb's sketch and Penfield's comments (in bold letters) show the sites of the stimulation responses and delineates the thin scarred cortex of the temporal area that was widely resected (Figure 12.2).

Penfield referred to this as his first temporal lobectomy for seizures. He had applied stimulation and excision techniques learned in Foerster's clinic at Breslau (Foerster and Penfield, 1930b) In the first few years after operation, the patient had a greatly reduced number of seizures. After starting dilantin in 1939, his attacks numbered four in the next 13 years.[20]

In 1930, Penfield listed the neurosurgical cases for the preceding two years at the Royal Victoria Hospital. Among the 325 operations carried out by him and William Cone, there were fourteen examples of surgery for focal epilepsy. The successful transfer to Montreal of the laboratory of neurocytology, which they had started in New York, was already attracting students from the United States and abroad. During this period Penfield edited for publication a three volume multi-authored work destined to become a neurological classic, *Cytology and Cellular Pathology of the Nervous System*.[21]

The Montreal Neurological Institute

After a refusal and several delays, the Rockefeller Foundation responded in 1932 to the proposal of Wilder Penfield and McGill University for a Neurological Institute 'to provide,' Penfield hoped, 'a center for neurological thought that would serve the whole continent.' He envisaged clinical neurology and neurosurgery carried on in the same building that contained laboratories for research in neuropathology, neurophysiology and the anatomy and psychology relating to the nervous system.[22]

The Montreal Neurological Institute (MNI) opened its doors in 1934. An interesting hybrid, it was unique in its time, a 50-bed hospital for patients with neurological disorders, combined with a research center for the scientific study of the nervous system and a teaching Department of Neurology and Neurosurgery for McGill University.

With the provision of endowment by the Rockefeller Foundation of $1,000,000, further support garnered from generous citizens in Montreal as well as ongoing pledges by the City and Provincial governments for hospital support, the stage was set and the actors were in place to carry out Penfield's master plan.[5,20,23] Penfield and his surgical partner, William Cone, expanded their studies on the histopathology of brain scars and brain tumors with an enthusiastic and ever growing team of young assistants. They made persistent efforts to treat intractable epilepsy caused by trauma or tumors, applying the Foerster technique to score some brilliant successes. At multidisciplinarian weekly conferences, seizure patterns of patients were scrutinized in great detail, catalogued, and matched with the type and location of the lesions predicted by X-ray and EEG and as revealed and photographed at operation. Meticulous analysis of hundreds of stimulation points were plotted out to constitute brain maps of the sensory and motor areas that gave more detail than the earlier maps published by Horsley, Foerster, Krause, and Cushing.[24,25] These findings extended eventually to the definition of speech areas[26] and to the complex problem of how the brain remembers.[27,28,29]

Maximal removals of frontal tumors and scars causing epilepsy resulted in surprising retention of intellectual functioning in the patients as determined by.[29,30] Hebb's studies on Penfield's patients also activated the field of clinical neuropsychology which at the MNI over many years has been of critical importance for the pre- and post-operative evaluation of patients.[31]

Cortical stimulation: the homunculus

In 1937, Penfield with Edwin Boldrey reviewed 163 patients, who were operated upon under local anesthesia and in whom the motor-sensory responses to cortical stimulation were carefully plotted. These composite stimulation maps became familiar in the numerous publications from Penfield and his team over the years. Their report marked also the first appearance of the 'homunculus' (Figure 12.3) who would later appear in several guises (Figure 12.4) to highlight the cortical localization subserving anatomical regions of the body (Penfield and Rasmussen, 1950; Penfield and Jasper, 1954).

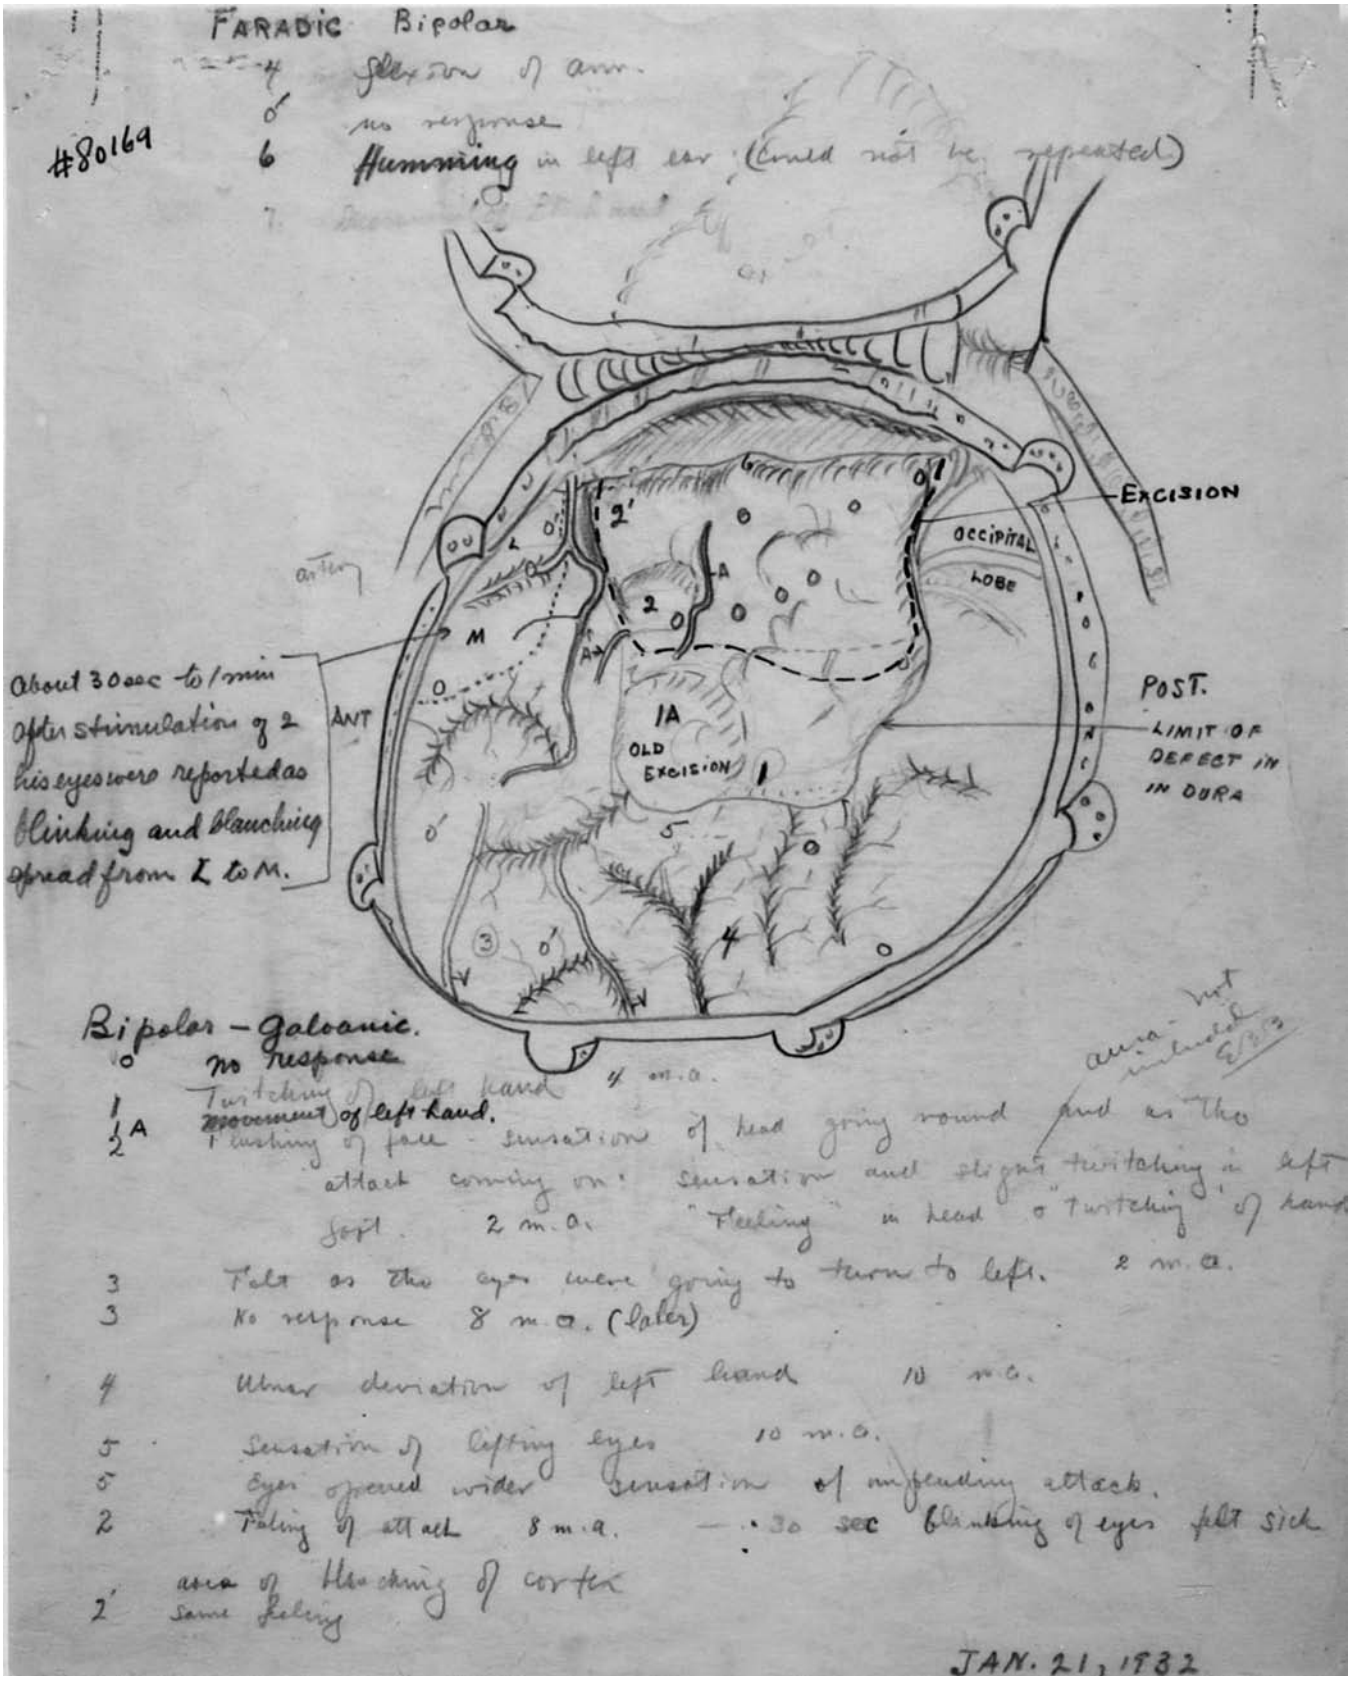

Figure 12.2 Penfield's sketch and notes during the operation on patient R.M. The brain is upside down as viewed by the surgeon, with the frontal lobe to the left. Two excisions, outlined by dashed lines, include a small area in front of the motor cortex (1A) and a much larger resection of the temporal lobe shown in the upper part of the sketch. Penfield's notes are in bold script; the notes in finer lettering and possibly some of the details of the sketch are in Stanley Cobb's hand.

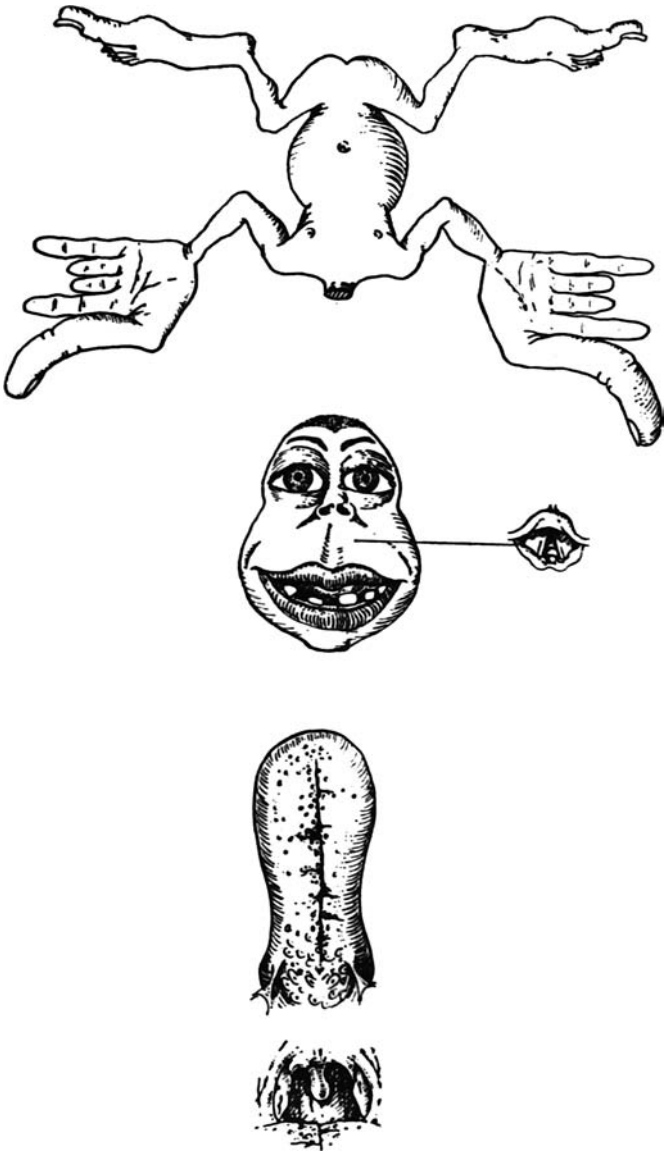

Figure 12.3 Homunculus appearing first in the article by Penfield and Boldrey in 1937, to illustrate the relative size of body parts represented on the motor cortex as defined by electrical stimulation at operation.

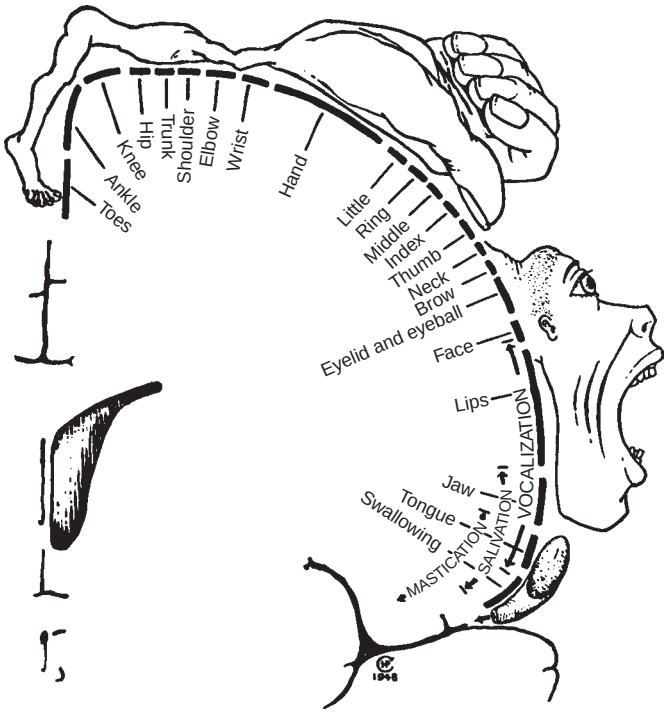

Figure 12.4 A later version of the homunculus, with reference to the representation in the motor cortex, from the studies of Penfield and Rasmussen in 1948.

Herbert Jasper and the advent of electroencephalography

A chance encounter at Brown University in 1937 led Penfield to bring Herbert Jasper to Montreal to apply the new techniques of electroencephalography (EEG) and electrocorticography (ECG). Jasper with Carmichael in 1935[93] had reported on the application of Berger's new technique of EEG, in the same year that the Boston group led by Gibbs had noted its value in epilepsy.[32] EEG refined the task of localizing the site of origin of seizure discharge by recording spikes and sharp waves that were pathognomonic for epilepsy.[33] This greatly improved the selection of patients with focal seizures for surgical treatment. ECG mapped the localization of seizure activity during surgery by recording directly from the cortex and by monitoring stimulation responses. The application of the new technology to epilepsy resulted in a long series of clinical studies by Penfield, Jasper and their associates. Jasper's background in psychology and electrophysiology also generated at the MNI an expansion in neurophysiological research which over the years elucidated the complex mechanism of epilepsy and sharpened the criteria for surgical treatment.[34] Jasper's chapter in the monograph by Penfield and Erickson of 1941 on *Epilepsy and Cerebral Localization* provided the first comprehensive review of the use of EEG and corticography in the diagnosis and surgical treatment of epilepsy.[94]

Numerous monographs and publications by Penfield with his associates, Jasper, Kristiansen, Rasmussen and a long list of neurosurgical Fellows, continued to document from 1934 to 1950 much detailed evidence for the successful surgical treatment of focal epilepsy at the MNI.[20]

Surgery for temporal lobe seizures

The anterior and lateral temporal cortex

The emergence at the MNI in the early 1950s of surgery for seizures related to the temporal lobe opened a new era for what has now become the most frequent surgical approach for the surgical treatment of epilepsy. There were several phases in the development of such surgery, each distinguished by a substantial increase in knowledge about the pathophysiology of seizures arising from the temporal lobe. Penfield and Flanigin[35] reviewed 68 temporal lobe operations carried out over the decade from 1939 to 1949, which had arrested or controlled seizures in over one-half of the patients. The resections in this series were limited mainly to the anterolateral temporal cortex; in only 10 cases was the uncus removed and in only two was a part of the hippocampus also removed. Bailey and Gibbs[36] in the meantime performed antero-lateral cortical removal in a series of patients, with no encroachment on

mesial temporal structures because Bailey was aware of the severe behavioral deficits in monkeys after bilateral mesial temporal ablations as reported by Klüver and Bucy[92] beginning in 1939.[37] This limited anterolateral approach was also supported by the pre-operative localization offered by EEG, either antero-lateral temporal, anterior Sylvian, or fronto-temporal.[38] Related experimental studies at the MNI were thus directed to clarify the connections of the temporal pole.[39,40] This is also well illustrated by similar antero-lateral temporal localization of ECG foci registered by Jasper and two young neurosurgeons[41] in 39 of the same series of patients reported by Penfield and Flanigin in 1950. In only a few patients was ECG abnormality detected in the inferior and mesial part of the temporal lobe. (Figure 12.5).

The mesial temporal region

The success rate of just over 50% in the two major surgical series, reported from Montreal by Penfield and Flanigin[35] and from Chicago by Bailey and Gibbs[36] indicated that resection limited to the antero-lateral temporal cortex did not eliminate all the epileptogenic tissue in many patients. Indeed in some cases persistent seizures led Penfield to persevere and carry out a second operation. In these, he extended the resection, under electrocorticographic control, sometimes posteriorly along the lateral temporal cortex (if on the nondominant side for speech) and also included more of the uncus and hippocampus.[20]

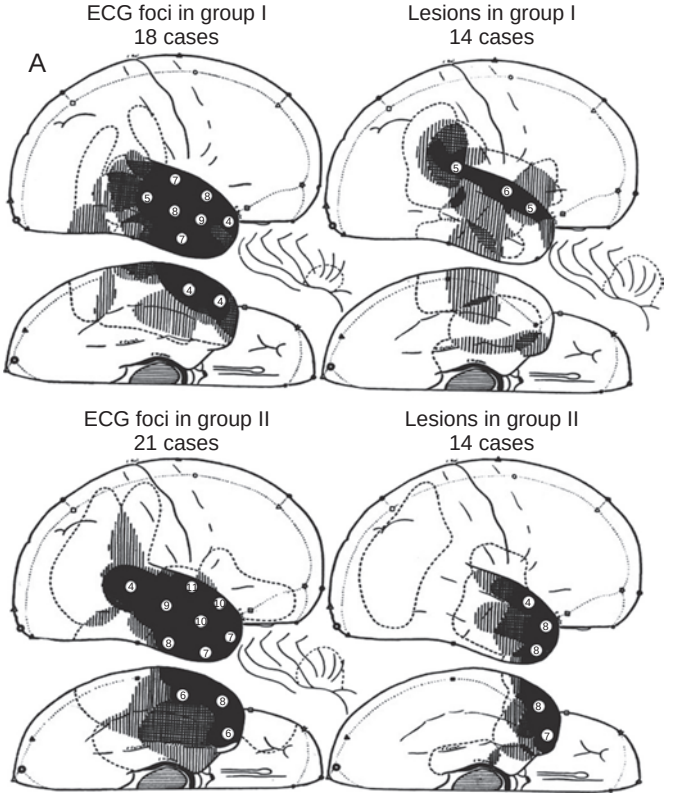

Figure 12.5 Localization of ECG foci and lesions reported by Jasper, Pertuiset, and Flanigan in 39 patients operated upon for temporal lobe seizures by Penfield. The maximum changes, areas indicated in black, involve mainly the antero-lateral cortex of the temporal lobe.

A second phase in the surgical approach to temporal lobe seizures unfolded rapidly in the early 1950s. Clues from experimental animal studies by Gastaut *et al.*[42] and Kaada[43] and from stimulation at operation[44,45] pointed to the mesial and inferior surfaces of the temporal lobe for the origin of the epileptic attack. Penfield noted instances where stimulation in the uncinate region produced auras of the patients' attacks. In one such instance, a seizure with automatism was recorded consisting of low voltage fast activity followed by 3 per second waves to spread from the stimulation point to involve a wide region of the temporal cortex. (Figure 12.6). These findings led Penfield in this case to extend his resection to include the mesial temporal region.

Stimulation responses from the claustro-amygdaloid complex

The most convincing evidence that the mesial temporal region was a crucial zone for the generation of temporal lobe seizures came in a third phase of surgical studies. This was the reproduction of the patient's habitual auras and other typical features of these attacks by anatomically directed depth stimulation or stimulation under direct vision at operation within and around the amygdala involving also the ventral claustrum and the anterior insula.[46] The resulting seizure discharges on corticography were seen to spread rapidly to encompass not only the temporal cortex but the exposed frontal parietal cortex.

In 1951, the surgical findings in the first patient in this series, initiated convincing evidence for the role of the amygdaloid region in temporal lobe seizures.[27]

Case report

Patient P.S., Age 26

He had a difficult birth and, from the age of 12, attacks which began with a vision of colored lights, a 'shock in the head', after which he became unresponsive, fumbled with his clothes and would later have no memory of his actions during this period. Pre-operative EEG study showed abnormal spike activity over the lateral and inferior temporal regions on the right side. At operation, a depth electrode was directed through the second temporal convolution 3.5 cm from the tip of the temporal lobe toward the region of the amygdala. One of his typical small attacks was produced with the electrode tip deep in temporal-insular sulcus, with electrodes recording from the lateral and inferior surface of the temporal lobe (Figure 12.7). Epileptic spikes were suddenly replaced by low voltage rapid activity, the patient was seen to stare and become unresponsive to questioning, while he plucked at the anaesthesist's coat and made chewing movements. His appearance was much like that seen in his habitual attacks. The electrographic changes lasted a minute and a half, at which time the patient appeared to have recovered, but seemed unaware of the attack (Figure 14.7). There was smallness and toughness of the first temporal convolution and mesial temporal region, as well as a zone of gelatinoid tissue about the size of a small walnut deep in the temporal lobe, lateral and inferior to the ventricle and encroaching on the amygdala. Microscopically, this showed dense astrocytic gliosis. On later review, the neuropathologist interpreted this as a grade I astrocytoma. Resection included

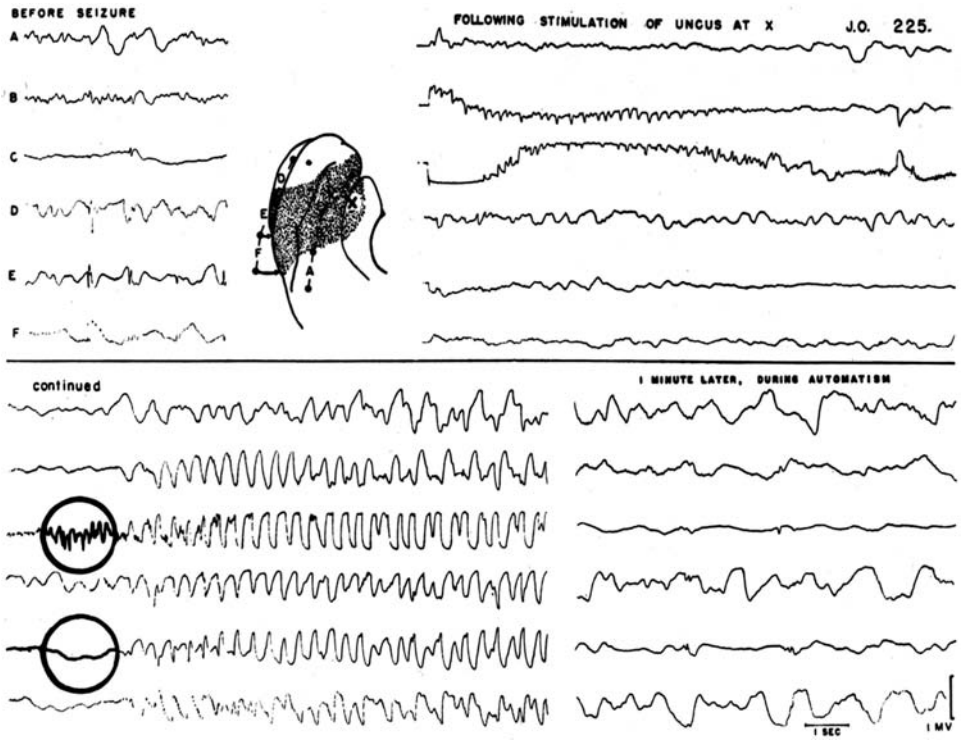

Figure 12.6 ECG recording at operation by Penfield. After stimulation of the uncinate region, a seizure discharge was recorded from a wide area of the inferior temporal cortex.[4,41]

6 cm. of antero-lateral cortex, as well as the mesial temporal region (amygdala; hippocampus) harboring the lesion. The patient continued free of attacks for 37 years later, with no reappearance of the tumor.

The role of the claustro-amygdaloid complex

In 15 other patients from that same study, similar features of automatism and amnesia were reproduced by stimulation in the peri-amygdaloid region (Figure 12.8). This first examination of stimulation and electrographic responses from the human amygdala demonstrated its role in visceral responses such as fear and its critical relation to recent memory.[46] It was noted that these findings corresponded to the localization for 'a particular variety of epilepsy' that had been proposed by Hughlings Jackson and others, just before the turn of the century:

> the discharge-lesions in these cases are made up of some cells, not of the uncinate gyrus alone, but of some cells of different parts of a region of which this gyrus is part – a very vague circumscription, I admit – the uncinate region.[47]

The rich network of connectivity subtended by the amygdala offered a valid explanation for many of the characteristic clinical features of 'uncinate' attacks described by Jackson.[27] Thus, the patient's epigastric aura, sometimes associated with a sense of fear, was reproduced from stimulation either of the amygdala itself or of the adjacent anterior insular cortex, which would later be shown to be physiologically associated with gastric movement.[48] The various emotional, autonomic, and visceral responses likewise seemed explicable because of the robust anatomical pathways then known from the amygdala to the septal and hypothalamic regions. The initial feature of brief tonic movement with some temporal lobe attacks could be effected by the amygdaline efferent pathways to the striatum; chewing and swallowing movements could be explained by connections with the brain stem. The interference of the epileptic discharge with memory recording, characterized by the profound postictal amnesia, could reasonably be related, it was proposed, to the amygdala–hippocampal connection as well as the projection of the amygdala to the reticular system of the brain stem.[49] Curiously, stimulation of the hippocampus directly at operation in the Montreal experience rarely produced such responses, even though epileptic abnormality might sometimes be recorded from the anterior part of the structure.[50]

Thus, this evidence indicated that the amygdala and the juxtaposed gray matter, including the ventral claustrum and the anterior insular cortex, could generate temporal lobe seizures; this provided a physiological hypothesis that explained for the first time many of the clinical aspects of these attacks (Figure 12.9a, b). It also indicated that the peri-amygdaloid zone should be removed in the surgical resection in order to produce the most beneficial outcome. This critical role of the peri-amygdaloid region in mesial temporal seizures became confirmed in many later studies, as summarized for example in the monograph by Gloor in 1997.[51]

Incisural sclerosis

The pathological counterpart of this physiological hypothesis was offered in a concurrent study by Earle, Baldwin, and Penfield in 1953.[52] They introduced the concept of incisural

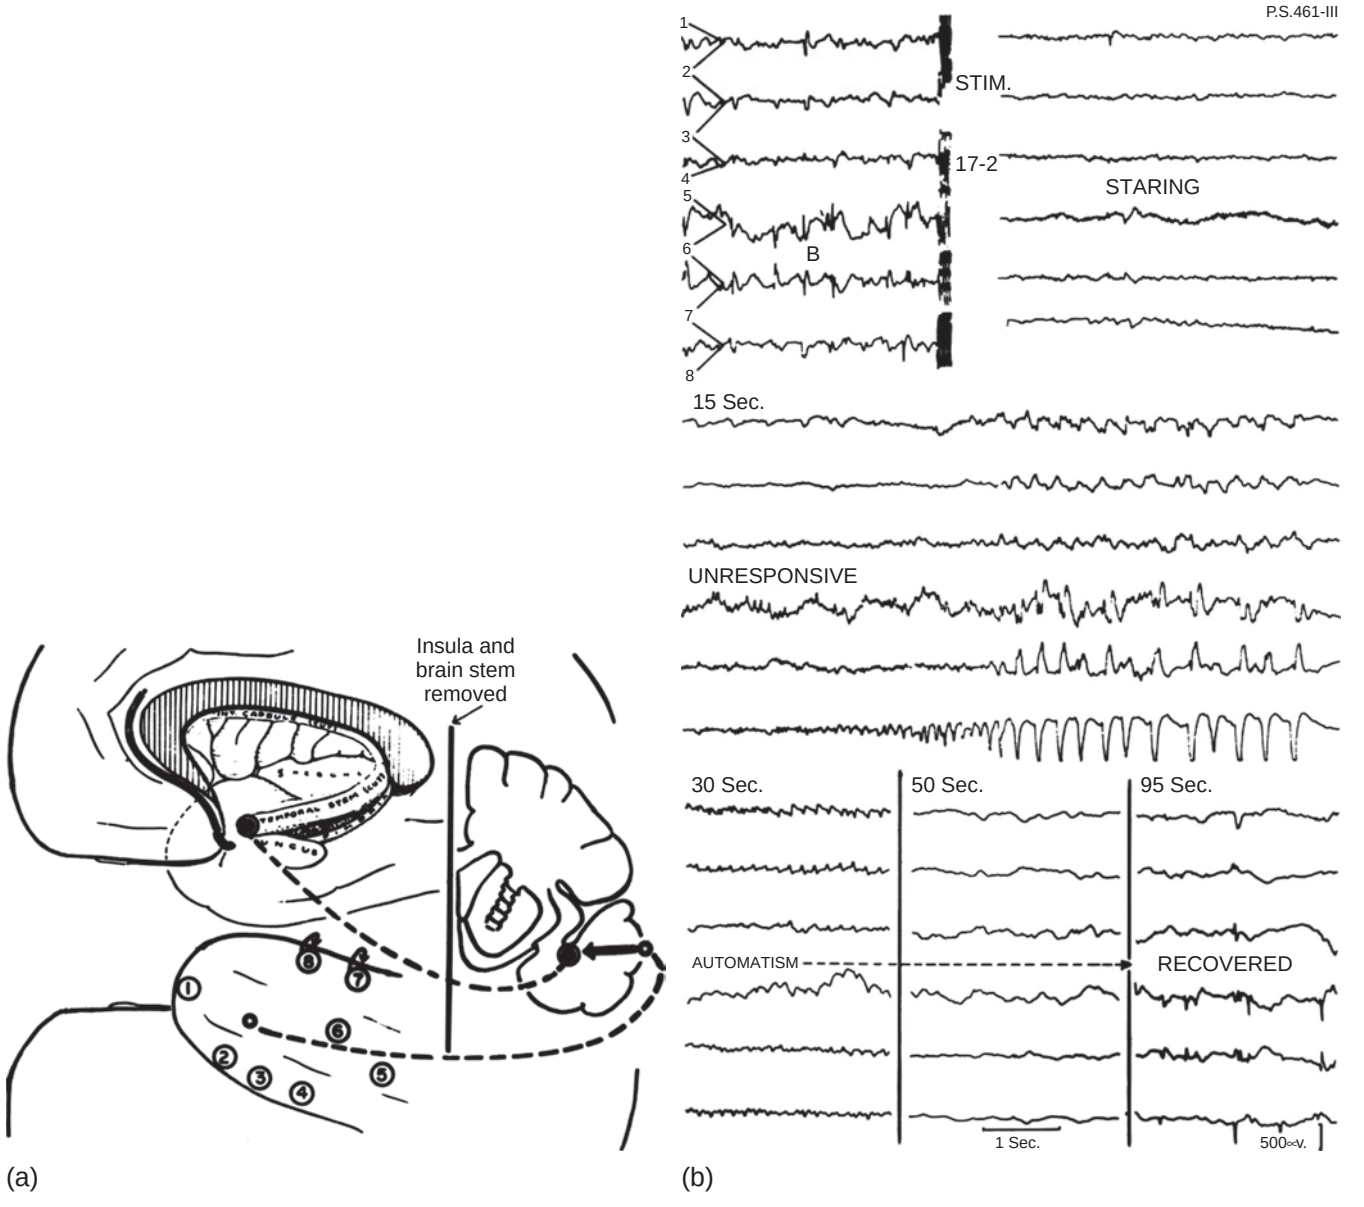

Figure 12.7 (a) Brain drawing to show electrode positions (in numbered circles) and depth stimulation in the amygdaloid region (black circles) from patient P.S.[27] (b) ECG showing rapid low-voltage activity from the temporal lobe and then return of the prestimulation spike activity. The patient had automatism and amnesia for the episode. Compare with Figure 14.6.[27]

sclerosis, which they postulated was due to herniation of the mesial part of the temporal lobe over the tentorial edge associated with increased intracranial pressure during a difficult birth (Figure 12.10). They considered this to cause injury to the hippocampal region, both by direct compression of the tissue and by arterial and venous vascular compression with resulting ischemia. Although they did not emphasize this, the uncus with the contiguous amygdala and entorhinal cortex are even more likely to herniate into the prepeduncular space and to be subject to compressive damage.

Application of the Montreal procedure

Based on these new findings from stimulation results and pathological studies, a radically different surgical approach was developed, with excision not only of the anterolateral cortex, but also removal under direct vision of the mesial part of the temporal lobe to include the amygdala, hippocampus and entorhinal cortex. Details of this operative technique were first described by Penfield and Baldwin in 1952[53] (Figure 12.11) and revised in 1961 by Penfield *et al.*[54] With the application of this approach, successful surgical outcome improved from 50% to 65%.

From 1953 onward, many neurosurgical centers, often involving surgeons and scientists who had studied at The Montreal Neurological Institute, took up the procedure of temporal lobe resection for the treatment of seizures. A colloquium on advances in the surgical treatment of temporal lobe epilepsy, organized by Gastaut and his associates in Marseilles in 1954, gave an opportunity for Penfield to provide an overview of the early experimental and surgical results of his team, which firmly established the important role of the mesial temporal region in the pathogenesis and surgical treatment.[55] The extensive monograph of 1954 by Penfield

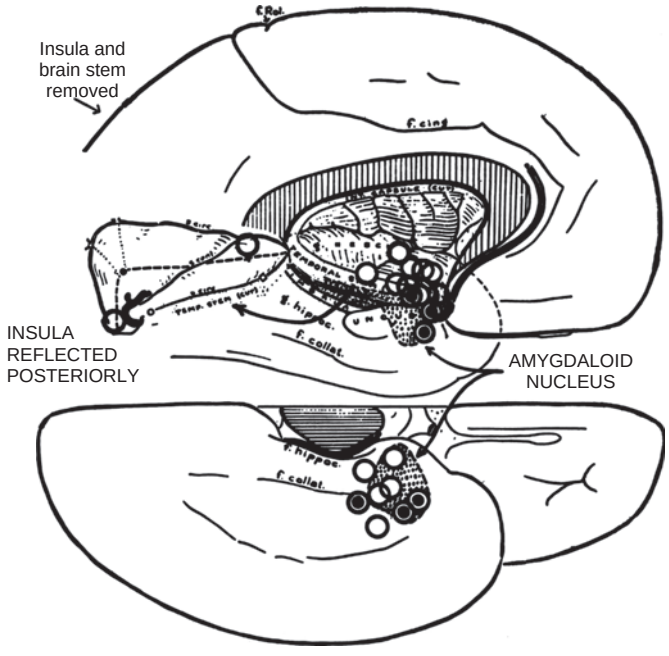

Figure 12.8 Sites of stimulation from 16 operations that produced features of temporal lobe seizures such as epigastric area, fear, memory disturbance, automatism and amnesia.

and Jasper reviewed this Montreal experience.(Figure 12.12) A second colloquium sponsored by Maitland Baldwin and Pearce Bailey[56] in 1958 at the National Institutes of Health, USA, extended and confirmed the significance of subtotal temporal lobectomy, including particularly the mesial temporal structures, for treating temporal lobe seizures.[57]

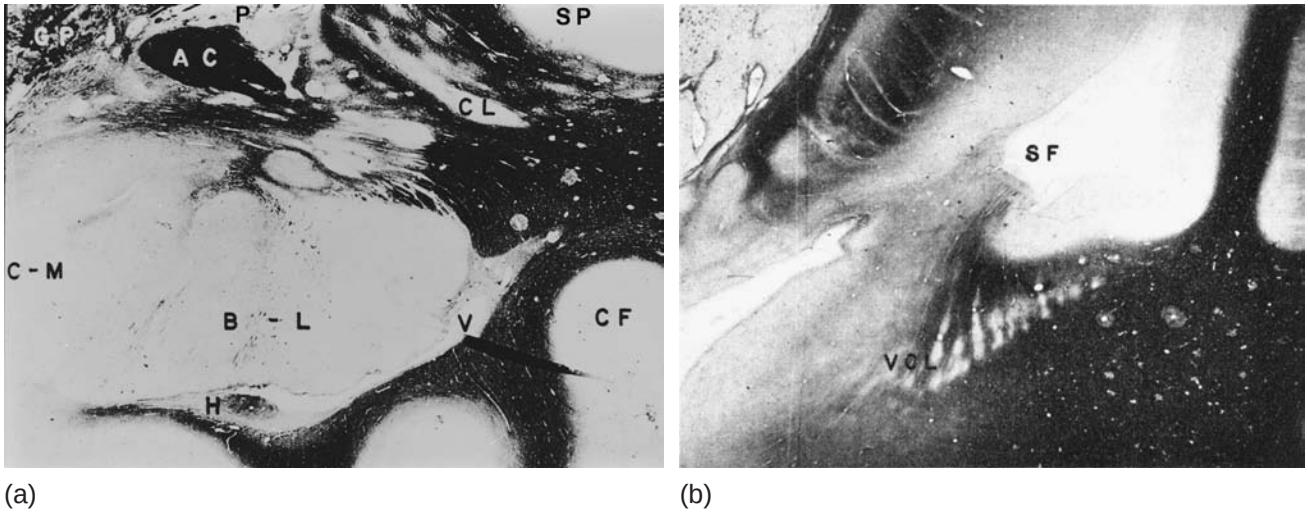
Memory deficit with bilateral temporal lesions

Scoville and his group at Hartford[44] had also produced stimulation responses from the uncus which resembled some features of temporal lobe seizures. This induced him to carry out bilateral resection of the mesial temporal region by a subfrontal approach in a few patients with epilepsy. One of these patients, H.M., who has since become noteworthy in the annals of neuropsychology, developed a severe deficit in recent memory.[58] This was similar to the syndrome that had been reported earlier by Milner and Penfield[28] from the MNI series, in three patients after unilateral temporal excision in the presence of what later became recognized as bitemporal mesial temporal pathology, especially involving the hippocampus.[59,60] These findings, together with the initial observation by Feindel and Penfield[27] that stimulation of the amygdala evoked ictal amnesia, directed attention to the important role of the mesial temporal structures in memory mechanisms.[28]

Toward a surgical cure

The surgery of focal temporal seizures, augmented by many contributions, has become one of the most successful therapeutic measures in modern neurosurgery.[61,62] Many thousands of patients have had the benefit of such surgery. The patterning of the surgical resection in order to obtain the most satisfactory surgical outcome and at the same time to minimize neurological deficit continues to be examined currently in over 100 neurosurgical centers.[23,62] A vast literature has now become available on the anatomy, physiology, pathology, and cognitive aspects of the temporal lobe.[63–68] Gloor summarized this field in 1997 in his masterly monograph on the temporal lobe and limbic system.[51]

The developments in EEG such as sphenoidal recordings and computerized-video monitoring greatly enhanced the pre-operative localization of the epileptogenic region.[69] The increasing use of detailed neuropsychological evaluation by Milner and her associates and the application of the intracarotid amytal test developed by Wada and Rasmussen for defining lateralization of speech and memory function proved to be invaluable adjuncts.[28,69,70]



(a) (b)

Figure 12.9 (a) Enlarged view of the claustro-amygdaloid complex which shows the Sylvian fissure (SF), claustrum (CL), anterior commissure (AC), globus pallidum (GP), centro-medial and baso-lateral nuclei of the amygdala (C-M, B-L) hippocampus (H), ventricle (V), and collateral fissure (C-F).[27] (b) A more anterior coronal section shows the Sylvian fissure (SF) and grey matter of the ventral claustrum (VCL). This section relates to the site of the depth stimulation.[27]

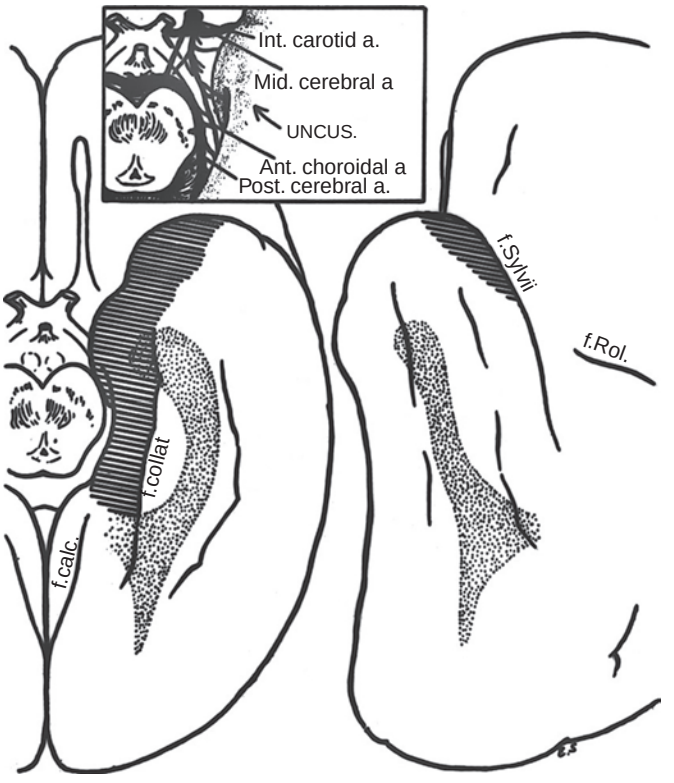


Figure 12.10 Drawing to show the region of sclerosis and the mesial blood vessels involved in tentorial herniation of the uncinate region, for example, during abnormal birth.[52]

Surgical techniques have become refined and selection of patients for the surgical procedure has grown far more enlightened.[71–73] Amygdalo-hippocampectomy introduced by Niemeyer in 1958[74] and adopted enthusiastically by Wieser and Yasargil in 1982,[75] has yielded an excellent surgical outcome and may well prove on evidence to become the resection of choice in selected patients.[72]

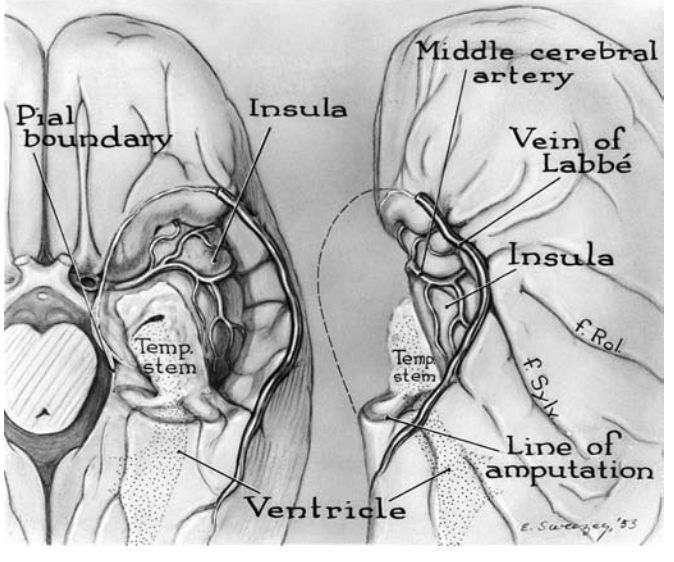

Figure 12.11 Drawing to show subtotal temporal lobectomy that includes the amygdala and up to 4 cm of the hippocampus as well as the antero-lateral temporal cortex, as described by Penfield and Baldwin in 1952.[53] This operation became widely adopted.

Figure 12.12 Wilder Penfield (seated), and Herbert Jasper photographed in 1954 on the publication of their monograph, *Epilepsy and the Functional Anatomy of the Human Brain*.

Further surgical evidence from the MNI[76] indicates that temporal corticectomy with radical resection of the amygdala and uncus but with minimal removal of the hippocampus can achieve an excellent surgical outcome in 65% of patients (Figure 12.13a) At the same time the relative sparing of the hippocampus reduces the possibility of deficit in memory function which had been assigned by Milner and others[31,69] to varying degrees of damage to the hippocampal regions.

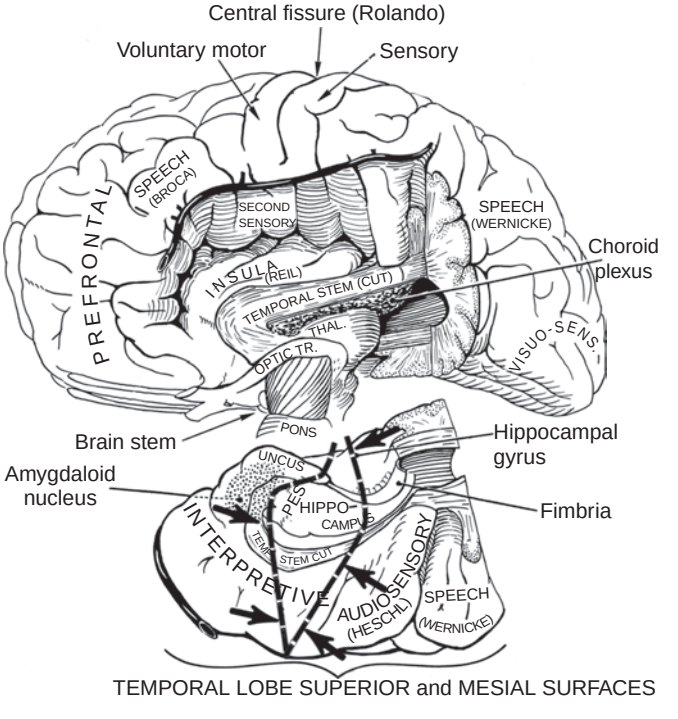

Figure 12.13 (a) Anatomical dissection of the temporal lobe to show cortico-amygdalectomy (hatched line on the left) compared to cortico-amygdalo-hippocampectomy (hatched line on the right).[76] (b) Post-operative MRI to show radical excision of the amygdala and minimal removal of the hippocampus.[9]

The acquisition at the MNI of magnetic resonance imaging (MRI) in 1985 gave a significant new dimension to the selection of patients for operation by identifying small structural lesions in the temporal lobe in more than 25% of patient and also the presence in another 30% of patients of mesial temporal sclerosis involving the hippocampus and later demonstrated also to include the amygdala and entorhinal cortex.[73,77,78] MRI also provided the *sine qua non* for monitoring the exact anatomical extent of the surgical resection to compare with the type of surgical outcome reported from different centers.[20] In the span of fifty years covered by this review, the effective control of temporal lobe seizures by surgical treatment has thus improved from 50% to almost 90%, with minimal morbidity and mortality.[71,79] The role of mesial temporal sclerosis in the pathogenesis of temporal lobe seizures is now widely recognized.[68] The significance of the amygdalo-hippocampal region in the physiopathology has been well substantiated from many stimulation studies,[80,81] and by greater detail available on the anatomy and pathology of these structures.[82–84] Marked improvement based on limited excision of the hippocampus but radical resection of the amygdala and minimal cortical ablation has been achieved in the surgical cure of temporal lobe seizures.[76]

Contributions from the Toronto school

Kenneth McKenzie trained with Harvey Cushing at Boston in 1923 and returned to establish the first neurosurgical unit in Toronto in 1924.[15,85] He performed the first hemispherectomy for seizures in 1936. He reported the case in 1938 at a meeting of the American Medical Association. The patient, a 16-year-old woman, had seizures from infancy and progressive hemiplegia. After operation she was seizure-free and lived with her family for another 23 years. McKenzie's experience antedated by 14 years the series of 12 patients with seizures treated by hemispherectomy by R.A. Krynau and published in 1950. McKenzie never published his case but the patient was studied and reported by Williams and Scott[86] in 1939 in relation to autonomic responses following hemidecortication.

At the Sick Children's Hospital in Toronto, Stobo Pritchard established a comprehensive neurological clinic for childhood epilepsy. On his foundation the pediatric neurosurgeons of the Toronto school, especially Harold Hoffman, developed an active center for surgical treatment of epilepsy in the 1970s.

Epilepsy program at London, Ontario

In 1977 Warren Blume, a neurologist and epileptologist, and John Girvin, a neurosurgeon and neurophysiologist, both trained at the MNI and McGill, established an Epilepsy Unit, coordinating a multidisciplinary team of health care professionals. Although somewhat in the shadow of the illustrious team led by Drake, Barnett, Ferguson, and Peerless, who were world-leaders in the cerebrovascular field, the Epilepsy Unit developed successfully over the next two decades. A convincing milestone in the long record of evidence for the effectiveness of surgery for temporal lobe epilepsy was reported by the London group from an ingen-ious randomized trial comparing medical treatment with surgical treatment at this unit from July 1996 to August 2000.[87] From a study of 80 patients divided into two groups, they found that 64% of the 36 patients operated upon by temporal lobe resection were free of seizures compared to 8% in the group assigned to medical treatment, an eight-fold benefit.

The pre-operative investigation and selection for surgery in this London project evidently followed the same lines as those practiced for many years at the Montreal Neurological Institute. The pattern of surgical excision, based on the procedure introduced by the Montreal group in the 1950s,[53] included the antero-lateral temporal cortex and the mesial structures, especially the amygdala and hippocampus.[88] Thus the London study was another vindication of the successful results of surgery reported from the MNI over a period of 50 years and documented in extensive long-term follow-up studies by Rasmussen and many colleagues. These demonstrated a post-operative outcome of 65% of patients seizure-free and over 85% showing significant improvement in regard to seizure control.[89]

Other Canadian centers

Neurological and neurosurgical trainees from the Montreal Neurological Institute and McGill introduced neurosurgical treament for epilepsy in many other Canadian cities, including Edmonton, Saskatoon, Vancouver, Calgary, Winnipeg, and Halifax.

Returning to Montreal, the major neurosurgical unit at Notre-Dame Hospital affiliated with the University of Montreal and first established in 1947 by Claude Bertrand, who had trained with Penfield and Cone at the MNI, became a world center for functional neurosurgery. This included the operative treatment of epilepsy.

Although many children with focal epilepsy had been treated over the years at the MNI by Penfield and his team, in the 1970s an active group dealing with childhood epilepsy was established through the efforts of Preston Robb, head of neurology, and Kathleen Metrakos in charge of EEG. José Montes after completing his training at the MNI developed one of the most active centers at the Montreal Children's Hospital (MCH) for the surgical treatment of epilepsy in children.

Conclusion

This historical outline highlights the contributions in Canada that enhanced our basic understanding of the surgical treatment of epilepsy. From 1934 to 1984 the MNI was headed by three successive Directors who were neurosurgeons with a persisting interest in epilepsy surgery (Figure 12.14). Trainees in neurosurgery, neurology, EEG, neurophysiology, neuropsychology and neuroimaging from the MNI have translated the benefits of surgical treatment throughout Canada and to many other countries around the world. In particular, many of the major centers for epilepsy surgery in the United States were established by MNI graduates.

Since the early 1970s, the revolutionary advances in brain imaging have elucidated the pathological and neurochemical changes in epilepsy and also provided elegant three-dimensional visualization to the surgeon for pre-operative diagnosis, precise anatomical navigation during operation and exact monitoring of the surgical resection to correlate with clinical outcome.

13 A brief history of epilepsy surgery in the United States

PJ Connolly, DD Spencer, and AA Cohen-Gadol

If I wished to show a student the difficulties of getting at the truth from clinical experience, I would give him The History of Epilepsy to read.

Oliver Wendell Holmes[1]

The history of epilepsy treatment revolves around individuals who through their ingenuity and innovation have elucidated the understanding of epilepsy pathophysiology. In the following chapter, we will review some of the contributions of these key individuals from the United States of America.

Benjamin Winslow Dudley

Dudley who had earned his MD from University of Pennsylvania, traveled to England and France to learn the art of surgery and trephining. When he returned to Kentucky in 1818, he became the first American to perform surgery for epilepsy and the first surgeon to ever publish a series (five) of epilepsy surgery patients. He conducted surgery for post-traumatic epilepsy. All five patients in his series survived, three were seizure free and the other two had decreased seizure frequency.[2] Dudley attributed his success to the 'good clean air' of the Kentucky frontier.

Harvey W Cushing

The history of modern epilepsy surgery in many ways reflects the history of neurosurgery in the late 19th and early 20th centuries. During his training, Cushing (considered to be the father of modern neurosurgery) went abroad in 1901, where he visited Horsley but he was not impressed by Horsley's speedy surgical techniques. Upon his return to the United States and expansion of his practice at Peter Bent Brigham Hospital in Boston, Cushing established the safety of intracranial surgery and neurosurgery training programs. He had a particular interest in surgical treatment of brain tumors. He demonstrated the localizing value of epileptic syndromes although he had no special interest in electrophysiology. He trained many future leaders in epilepsy surgery including Percival Bailey and Wilder Penfield.

Bailey and Gibbs

As early as 1938, Frederic and Erna Gibbs along with Lennox had suggested the idea of operating on an electrical focus responsible for epilepsy in the absence of a structural lesion. In 1948, the Gibbs studied 300 patients' EEG findings associated with psychomotor seizures localized to the anterior temporal lobe.[3] They convinced Percival Bailey (who was trained by Cushing) to perform anterior temporal resections for psychomotor epilepsy. By 1954, Bailey had operated on 72 patients with a five year follow-up and concluded that 'major convulsions are abolished or greatly reduced in half of the cases.' The hippocampus and hippocampal gyrus were spared in these operations.[4] The Gibbs' and Bailey's efforts were one of the earlier attempts at surgical treatment of non-lesional epilepsy.

More recent generation of epilepsy surgeons in the United States

Earl Walker's[5] physiological studies on the brain and more specifically thalamus provided further data regarding electrophysiological mechanisms underlying epilepsy. Arthur Ward[6,7] was the first to perform intracellular recordings from human epileptic neurons. His demonstration of temporal lobe electrophysiology responsible for epilepsy further complemented Crandall's[8] pioneering work in chronic depth electrode recordings. An amalgam of Falconer's demonstration of anatomic abnormalities and Crandall's analysis of corresponding electrophysiological characteristics has founded our current comprehension of temporal lobe epilepsy. The more complex electrophysiology responsible for extra-temporal epilepsy has partly delayed our more detailed understanding of mechanisms involved in extra-temporal epilepsy syndromes.

Other surgical procedures for epilepsy

Hemispherectomy was initially described by Dandy in 1928 for gliomas, and used by Krynauw[9] in 1950 for children with epilepsy and infantile hemiplegia. As was mentioned previously, Rasmussen described 'functional hemispherectomy' which further minimized the complications associated with an anatomic hemispherectomy. Based on Horsley's and Erickson's observations regarding the importance of corpus callosum in transferring epileptic discharges between hemispheres, Van Wagenen and Herron performed the first corpus callosotomy in 1940.

As the first part of the 20th century demonstrated the efficacy of epilepsy surgery; the second part of century defined who would be likely to benefit most from surgery and also expanded the repertoire of surgical technique: callosotomy,[10] focal cortical resection,[11] multiple subpial transactions.[12] Multiple subpial transaction was first described in 1989.[12] The technique has been applied successfully to epilepsy foci in eloquent cortex by severing the 'horizontal' or traversing fibers while preserving the descending fibers, therefore; isolating the route of seizure spread. In addition, application of intracranial monitoring strategies has made epilepsy surgery available for patients with focal epilepsy and non-structural abnormalities.

Other procedures such as vagus nerve stimulation (VNS) (approved in 1997) has been used for patients with generalized seizures who have typically bilateral or non focal epileptiform activity on EEG and are not candidates for resective surgery. The mechanism of action of VNS is not known, but it may reduce seizure frequency with a similar efficacy as those of new generation of anticonvulsant drugs. Another new procedure for intractable generalized seizures is deep brain stimulation in the anterior nucleus of thalamus.[13] The anterior thalamus is known to play a role in seizure propagation. This is a novel treatment for patients with generalized seizures, who are not typically candidates for resective surgery. The future treatments in epilepsy will depend on a better understanding of the cellular phenomenon and networks involved in seizure generation.

Neuroimaging and epilepsy

The evolution of imaging modalities has significantly expanded the application of surgery through improved localization of seizure foci. In 1930s, Penfield used ventriculography, pneumoencephalography and angiography to evaluate epileptogenic mass lesions. MRI scanning was a significant advance due to its high resolution of soft tissues revealing anatomic details and pathologic signal changes with striking clarity. Multiplanar imaging allowed visualization of medial temporal and neocortical structures in anatomically useful cross sections.[14] With the advent of MRI, there was a preoperative correlate to EEG. Hippocampal sclerosis and atrophy on the side of seizure origin was found to effectively predict seizure remission.[15] Furthermore, the degree of hippocampal resection was found to affect seizure outcomes.[16]

Further evolution of imaging modalities including functional MRI, positron emission tomography and single photon emission computed tomography have further facilitated delineation of more subtle areas of structural and metabolic abnormality. Regions of electrographic abnormality have become correlated with areas of radiographic abnormality as disclosed by magnetic resonance imaging. Localization of a 'seizure generator' by two independent methods has improved the likelihood of obtaining a surgical cure. Functional imaging coregistered with structural and electrographic data has become an important tool in epilepsy surgery.[17]

Conclusions

In the present chapter, we reviewed an abbreviated history of epilepsy surgery in the United States. We highlighted the milestones in the development of epilepsy surgery which began with an understanding of cortical electrical activity and its role in epilepsy. Advances in electrical localization, beginning with scalp EEG recordings and shortly followed by cortical and depth recordings, have enhances our preoperative localizing power, significantly increasing the effectiveness of epilepsy surgery. Further improvement in our treatment paradigms is possible with multicenter trials and understanding the networks and molecular basis of epilepsy.

14 Epilepsy surgery in Latin America

J Godoy, AC Sakamoto, and ALF Palmini

Although waxing and waning, interest in epilepsy surgery appeared in Latin America shortly after this therapy was introduced by Penfield's pioneering work at the Montreal Neurological Institute. The first systematic resective surgeries for epilepsy were performed in the region in the 1940s.[1] For decades, this treatment was used mainly in isolated, anecdotal cases or performed in very small series, having included almost all its modalities: temporal and extratemporal resections, hemispherectomies, callosotomies, lesionectomies, stereotaxia, and amigdalo-hippocampectomies.[2–4] During the last 15 years several systematic epilepsy surgery programs have been established in the region, including some centers that use advanced techniques. However many Latin-American countries still have not performed any epilepsy surgery and some even lack the facilities for a complete patient presurgical evaluation. As in the rest of the world, the actual number of epilepsy surgeries represents a very small fraction of the total number of patients that need this type of therapy. Certainly one of the main challenges on this regard is to make this treatment available to the whole region.

Three are two major difficulties for the development of epilepsy surgery in Latin America. The first is economical limitations and the second the unawareness of the usefulness of surgical treatment and its proper timing within the neurological and neurosurgical community. Although unified by a common language and socio-cultural roots, Latin America is a continent where healthcare systems coexist with major differences not only between countries but also within a same country. According to World Bank data,[5] per capita income in Latin America ranges from US$400 in Haiti to US$6,230 in Mexico, while health expenditure per capita ranges from as low as US$29 per year in Haiti up to US$361 per year in Uruguay, compared to US$5,274 in the USA. This latter figure is higher than the total per capita income of almost all countries in the region. The impact of the economical development on epilepsy care is shown by the fact that the five countries with the highest income in the region have established epilepsy surgery programs while none of the five poorest countries have them. In this context of economical constraints it is easy to understand that there are quite a number of priorities that compete for health resources and explains why epilepsy surgeries are virtually nonexistent in public health systems in the region, with very few exceptions. On this regard, a major political step in favor of the development of epilepsy surgery in Latin America was made on September 9, 2005, in Santiago, Chile, where the 'Latin-American Declaration on Epilepsy' was read on behalf of several international organizations, including ILAE, IBE, WHO, and UNICEF, as part of the 'Epilepsy out of the Shadows' global campaign. This declaration included a statement calling to warrant availability and access to 'surgery and all forms of effective treatments'.[6]

Even more critical than the economical restrictions is the need for well-trained medical professionals who not only make epilepsy surgery programs technically feasible but also inform and teach local and regional neurological communities about this modality of therapy, and promote changes in healthcare systems for setting up the epilepsy surgery programs. Indeed all current epilepsy surgery centers in the region are led by epileptologists and neurosurgeons trained at top world-class epilepsy centers, mainly the Montreal Neurological Institute and the Cleveland Clinic. Probably the best contribution first-world epileptologists can do for the further development of epilepsy surgery in Latin America is to train physicians and other professionals in the different disciplines needed in this field.

Precursors

Before the development of modern neurophysiological techniques, surgery was performed in Latin America mainly for post-traumatic epilepsy.[2,7] Usually, the site of an obvious structural lesion or simply the site of a head injury was selected for resection. Preoperative investigations were very limited because no EEGs were performed. Some patients were operated on based only on clinical history and plain skull X-ray findings (fractures, depressions, etc.).

It is surprising to know that this approach was occasionally used in Latin America as early as the end of the 19th century. Razetti *et al.*, in Venezuela, and Maldonado *et al.*, in Colombia, operated on patients with jacksonian post-traumatic epilepsy, in 1893 and 1897, respectively;[8] in 1894 Navarro,[9] in Montevideo, Uruguay, operated on a patient who developed frequent seizures after a head injury with a skull depression. He used a silver plate as a craneoplasty; the patient developed a right hemiplegia and remained with seizures for a few days, improving afterwards and being able to return to work 6 weeks later.

Argentina

The first systematic epilepsy surgery attempts were made almost 50 years ago in this country. In 1957, Ghersi *et al.*[10] reported a series of 25 patients with no demonstrable structural lesion who underwent temporal lobectomies or gyrectomies based on clinical history, surface EEG, and intraoperative corticograms (performed before and after the

initial resections in all cases). Although all patients improved significantly (40–80% seizure reduction), none was completely cured; their series also included some hemispherectomies which had good outcomes. Pardal *et al.*[11] performed stereotaxic surgery on six epileptic patients in 1960 and reported good outcome in all of them. A few years later the group of Basso and Betti,[3] from the University of Buenos Aires, using Bancaud and Talairach's technique, implanted electrodes for acute or chronic recordings in 61 patients, 36 of whom had temporal lobe epilepsy. They explored the amygdala, hippocampus, temporal cortex, thalamus, and other structures; in some patients they produced thalamic injuries and in others they destroyed epileptogenic areas with yttrium (Y-90) or performed amygdalo-hippocampotomy. Unfortunately, detailed preoperative and follow-up protocols were not provided. These authors also used combined surgical approaches, which included stereotaxic treatment for temporal lobe epilepsies and, in case of failure, topectomy of the affected cortex or temporal lobectomy.[3] In 1977 Chescotta *et al.*[12] reported a group of 62 epileptic patients on whom amygdalotomies and fornicotomies were performed; a significant improvement was obtained in 66% of the patients. Costales and Ferrarese[13] from Bahía Blanca, Argentina, presented a case report on a patient with a refractory status epilepticus successfully treated with temporal lobectomy.

Nowadays, there are four groups performing epilepsy surgery in Argentina. The group of Pomata, working in Buenos Aires at Juan P. Garrahan National Pediatric Hospital and at the FLENI Institute, started epilepsy surgery in 1995 (Pomata H, personal communication). Up to 2005 their series included 158 temporal and 139 extratemporal lobe surgeries, 34 hemispherectomies (2 of them anatomical), 35 callosotomies, and 13 vagal nerve stimulators. These authors reported part of their experience in 2001,[14] describing 60 children with extratemporal epilepsies, treated with resections, disconnections, and in one case, hemispherectomy; 10 of these patients underwent invasive evaluations; the one year follow-up showed that 38 patients were on Engel's class I. They also presented a small group of patients with Rasmussen encephalitis who underwent hemispherectomy,[15] and additionally described a 6 year-old child with refractory status epilepticus successfully treated with multiple subpial transection.[16]

Another epilepsy surgery program in Buenos Aires is located at the Hospital Italiano where Rabadan *et al.* have performed epilepsy surgery since 1999. They reported part of their series in 2000.[17] As of 2005 they have operated on 35 adult patients, including temporal and extratemporal resections as well as callosotomies (Rabadan A, personal communication). Also in Buenos Aires, at the Ramos Mejia Hospital, Kochen, Silva, Seoane, and Consalvo continued the work of Basso and Betti.[18] They introduced Video-EEG monitoring in 1996, invasive studies in 2001, and started extratemporal resections in 2003. They have also performed some callosotomies and vagal nerve stimulation since 2001 (Kochen S, personal communication).

Outside the capital city, epilepsy surgery has been performed in two provinces. One in the northern city of Cordoba, where Bulacio, Sfaello, and Muñoz started an epilepsy surgery program at The Santisima Trinidad Children's hospital and at the Center for the Study and Treatment of Epilepsy and Sleep Disorders (Bulacio J, personal communication); they have practiced temporal and extratemporal resections in a small group of patients since 2004. In Mendoza city, the above-mentioned neurosurgeon Pomata has also performed temporal and extratemporal resections in children (Pomata H, personal communication).

Bolivia

In this country, cortical resections were reported in post-traumatic epilepsies by Enriquez in 1959.[7] In his series, no EEG recordings were practiced and therefore patients were operated on based only on clinical history and plain skull X-ray findings, mainly guided by fractures and depressions. This same author also described the use of suboccipital pneumoencephalography for treating epilepsies after central nervous system infections, but no controlled results were reported.[7] There are currently no established epilepsy surgery programs in Bolivia not are these known surgical treatment attempts in the past.

Brazil

In the largest Latin-American country interest in epilepsy surgery goes back to the 1950s, and the most important and original contribution from the Brazilians to this field was made by the neurosurgeon Paulo Niemeyer Soares, one of the founders of the Brazilian League against Epilepsy, who also made contributions in several other neurosurgical pathologies, including Parkinson's disease surgery (Figure 14.1).[19] Niemeyer, who started to work at the Santa Casa de Misericordia Hospital, in Rio de Janeiro, initially as a general surgeon, was the first to propose and to perform amygdalohippocampectomies for the treatment of temporal lobe epilepsy. He used a transventricular approach, a technique that he presented for the first time in Washington in 1957, and later described in more detail in a book chapter.[20] In 1973 his group presented a

Figure 14.1 Dr Paulo Niemeyer Soares, brazilian neurosurgeon who first described amygdalohippocampectomy in 1957 (courtesy of Americo Sakamoto, MD).

series of 42 patients who underwent amygdalohippocampectomies,[4] reporting satisfactory results in 74% of the patients, after a follow-up period ranging from 6 months to 10 years; this figure was similar to the one the same group had obtained in 35 temporal lobectomies with resections tailored according to post-ablation electrocorticographic recordings.

In order to better understand the meaning of post resection epileptiform discharges he eventually left in place tiny copper electrodes over the operated cortex and performed post-surgical recordings.[19] These electrodes were externalized through small trepanation holes and after finishing the recordings were simply pulled out. With this technique, he soon realized that there was an immediate post-operative worsening of the frequency of epileptiform discharges, an effect that vanished in hours or a few days. Many years later this finding was replicated in a prospective study by Cendes *et al.*,[21] in a group of amygdalohippocampectomy patients; these authors coined the term 'Niemeyer effect' to describe this phenomenon. Niemeyer and his group also performed the first electrocortical recordings in Brazil in the early 1950s, using a single channel Garcier electroencephalograph.[19]

While Niemeyer's pioneering work in the field of epilepsy surgery was developed as part of his extensive practice as a general neurosurgeon, more recent initiatives in Brazil already embraced the idea of a comprehensive epilepsy surgery program, involving a multidisciplinary team including neurologists, neurosurgeons, psychologists, technologists, and more recently, neuroradiologists, psychiatrists, social workers, and physicists.

According to this principle the first Brazilian epilepsy surgery center was established in the 1970s, at the Hospital das Clinicas da Universidade de São Paulo, in the city of São Paulo, led by neurosurgeon Raul Marino Jr., who started a program mainly focused on treating diffuse epileptic encephalopathies through corpus callosotomy.[22] In the 1980s the second epilepsy surgery center was implemented at the Instituto Neurologico de Goiânia, led by neurologist Paulo C. Ragazzo, who was trained at the MNI and had previously participated in the team from the Hospital das Clinicas da Universidade de São Paulo.

It was really in the 1990s that the field of epilepsy surgery experienced major developments in Brazil. Two major reasons were of paramount importance in this move to provide the country with epilepsy surgery centers at the level of first-class centers of the developed world, not only in terms of infrastructure and methodologies, but also in terms of results for both adult and pediatric patients.[23,24] The first reason was the return to Brazil of well-trained physicians who established new epilepsy surgery centers and introduced state-of-the-art methodologies for the presurgical evaluation and selection of surgical candidates, as well as for the surgical treatment itself. Two new centers were implemented in that decade, one at the Pontificia Universidade Católica, in Porto Alegre, in the early 1990s, under the leadership of the neurologists André L.F. Palmini (trained at the MNI) and Jaderson C. da Costa (trained in pediatric neurology at Boston Children's Hospital), and the second at Hospital das Clinicas de Ribeirão Preto, Universidade de São Paulo, in Ribeirão Preto, State of São Paulo, in the mid 1990s, under the leaderships of the neurologist Américo C. Sakamoto (trained at The Cleveland Clinic Foundation, Cleveland, USA, and Epilepsy Center Bethel, Bielefeld, Germany) and neurosurgeon João A. Assirati Jr. (extensive neurosurgical training in various centers in the USA). The second and more important reason was the establishment of a national epilepsy surgery program in 1994, within the public health system, sponsored and coordinated by the Health Department. This program was created after joint effort from the Brazilian League of Epilepsy, the Brazilian Society of Clinical Neurophysiology, and the Brazilian Society of Neurosurgery, all of them active participants of a committee named directly by the Minister of Health. The main objectives of this committee were three-fold: (a) to establish a nationwide epilepsy surgery program, (b) to implement internationally accepted medical standards, and (c) to compromise maximal resources and minimal costs. In order to achieve these goals a two-steps strategy was implemented, which included strict criteria for accreditation of epilepsy surgery centers based on minimal requirements and clearly defined guidelines for indication of epilepsy surgery (temporal and extratemporal resective surgery, hemispherectomy and callosotomy).

After completion of the first 10 years of experience (1994–2004), the program was shown to be highly successful in many different aspects. It started out in 1994 with three initially accredited centers (Hospital das Clinicas da Universidade de São Paulo – São Paulo, Instituto Neurologico de Goiânia – Goiânia, and Hospital São Lucas da Pontifícia Universidade Católica – Porto Alegre), and progressively expanded to the current eight centers distributed in different geographical regions, seven of them connected to academic institutions dedicated not only to medical assistance but also to education and research. In recent years many other epilepsy surgery centers were established and reached accreditation status: at the Hospital das Clinicas da Universidade Estadual de Campinas, in Campinas, under the leadership of the neurologist Fernando Cendes who was trained at the MNI, at the Hospital da Universidade Federal de São Paulo, in São Paulo, under the leadership of neurologists Américo C. Sakamoto and Elza M. T. Yacubian (trained at the National Institutes of Health, Bethesda, USA), at the Hospital das Clinicas da Universidade Federal do Paraná, in Curitiba, under the leadership of the neurologists Luciano de Paola (trained at the University of Minneapolis) and Carlos S. Silvado; and at Hospital Regional, in São José do Rio Preto, under the leadership of neurologist Lucia H. Marques (trained at Universidade Estadual de Campinas). Other emerging centers are currently applying for accreditation as epilepsy surgery centers, in an organized process led by the Health Department.

The nationwide implementation of this program was able to assure universal access to epilepsy surgery in Brazil, to increase 13 times the total number of epilepsy surgery per year, to increase 2.7 times the number of epilepsy surgery accredited (or in final stages to be accredited) centers, to increase 5 times the number of surgeries per center per year, to boost the scientific development in the field of epileptology, and equally important, to create a network of centers with full capacity of training young Brazilian professionals in the area of epilepsy surgery, warranting the expansion and continuity of the program in the country, and consequently, the future of epilepsy surgery in Brazil.

Chile

In this country there is also a lengthy history on epilepsy surgery. Alfonso Asenjo, who is recognized as one of the founders

of Latin American neurosurgery, was actively involved in promoting this therapy more than 50 years ago. He established in 1950 the Instituto de Neurocirugía e Investigaciones Cerebrales de Chile (currently The Asenjo Institute), one of the first teaching and investigation centers in neurosurgery in Latina America, where hundreds of neurosurgeons have been trained, from Chile and other South and Central American countries. Asenjo worked with Carlos Villavicencio, a neurophysiologist trained in Montreal between 1939 and 1941 under Wielder Penfield[25] and who started electroencephalography in Chile in 1944, in a room called 'Hans Berger', at the Instituto de Neurocirugía, in Santiago. In 1951 they published,[2] a series of 221 epilepsy surgery patients, although only 96 of their patients had lesions without surgical indication *per se*, most of them frontal and mainly post-traumatic. Preoperative investigations included repeated surface electroencephalograms (EEGs), plain skull X-rays, cerebral angiograms, pneumoencephalograms, and ventriculograms; intraoperative corticograms and electrical stimulation were performed for tailoring the resections. The authors reported significant improvement or complete control in up to 69% of the patients. Other surgical procedures were also practiced at that time, such as hemispherectomies, performed in 1954 at the same institution;[25] The group continued to perform epilepsy surgery for some years but with a progressive decay in interest. A new impulse came at this center in 1990 when a pediatric epilepsy surgery program started, under the leadership of Lilian Cuadra. Up to 2004, they have operated on more than 100 children, mainly using temporal lobectomies and callosotomies (Cuadra, personal communication), entirely supported by public funds.

Another center with a long history in epilepsy surgery in Chile is the Hospital de la Universidad Catolica, where epilepsy surgery was initiated in 1962 led by Cristian Vera, a neurosurgeon trained at the Montreal Neurological Institute from 1956 to 1961; anecdotically, he had the opportunity to assist in the last epilepsy surgery that Penfield performed at the MNI. In Chile, Vera himself not only performed the surgery but also the electrocorticograms, using a portable eight-channel Hofner equipment, going back and forth from the operation table to the EEG machine. His group, that included Luis F. Quesney as a novel student, who later became a distinguished epileptologist, performed both temporal and frontal resections as well as hemispherectomies. Patients were also evaluated with surface EEG, skull X-rays, pneumoencephalography and an amytal test (Vera, personal communication). They also operated at the Hospital Psiquiatrico in Santiago, to where they eventually moved the only EEG machine they had. In some patients, before the resections, they made recordings from the amygdala, using implanted gold electrodes while at the same time tested memory.

Again, interest decayed and no epilepsy surgeries were performed for almost 20 years, until 1990, when a new program was started by the neurophysiologist Godoy, trained at the Cleveland Clinic, and the neurosurgeon Torrealba;[26] this program had an additional impulse in 1996, when Campos, neurosurgeon trained in Bonn, joined the group. At this center temporal and extratemporal resections are performed and patients undergo prolonged Video EEG monitoring, and when needed, evaluation with subdural grids or foramen ovale electrodes.[27,28] In addition to high resolution MRI, SPECT (ictal and interictal) are performed and more recently PET scanning.

Several stereotaxic techniques were used in the past both at the Asenjo Institute and at the Santiago's Psychiatric Hospital.[29] In this latter center this epilepsy surgery was performed in the 1960s and 1970s, led by Mario Poblete (L. Aranda, personal communication).

Colombia

In Colombia, Sierra *et al.*[30] reported in 1960 a Sturge–Weber–Dimitri patient with intractable epilepsy, successfully treated with hemispherectomy; he had no seizure recurrence, even after complete anti-convulsant withdrawal. Gutierrez-Lara *et al.*[31] performed stereotaxic surgery in 15 children between 1973 and 1976. Patients underwent Forel campotomy, amygdalotomy and, in those with associated hyperkinetic syndrome (probably meant attention deficit disorder), hypothalamotomy; they described good results in 8 patients, with a 6–18 month follow up.

One of the largest, oldest and most significant epilepsy surgery program in Latin America has been developed in Cartagena de Indias, Colombia by Jaime Fandiño-Franky.[32,33] It is worth mentioning that a huge personnel effort has been put by Fandiño-Franky, who has been able to overcome all kind of difficulties and established a comprehensive epilepsy program supported by non-governmental entities for more than 20 years. In 1996, an international workshop on specific aspects of epilepsy in the developing world was organized by ILAE Commission of Epilepsy in Developing Countries, during which it was stated that 'Fandino-Franky inspired the entire Workshop when he described his experiences'.[34] He was trained in Sweden and shortly after his return to Colombia got actively involved in epilepsy. Fandiño-Franky performed the first anatomical hemispherectomy in Colombia in 1981 and in 1989 founded an epilepsy hospital (Hospital Neurologico) that belongs to the Colombian League Against Epilepsy; the same year his group performed the first callosotomy and the first anterior temporal lobectomy. As of 2005 they have performed 680 epilepsy surgery procedures, including temporal and extratemporal resective surgeries, callosotomies, hemispherectomies (anatomical and functional), multiple subpial transections etc. This comprehensive program also includes a nicely developed rehabilitation program (Fandiño-Franky, personal communication).

Other efforts have also been made in Colombia. In Bogotá, Nariño *et al.* developed an epilepsy surgery at the Hospital Central de la Policía and at the Palermo Clinic. They have already operated on 45 patients, including some with invasive studies (Nariño, personal communication).

Costa Rica

Epilepsy surgery has been performed only recently in Costa Rica. Sittenfeld and his group at the Hospital Doctor Carlos Saenz, have operated on 45 children since 200l. the group includes callosotomies, temporal lobectomies and extratemporal resections; some patients required invasive studies. At 2-year follow-up the authors report Engel's class I outcome

in 2/3 of their patients, both temporal and extratemporal groups as well as significant seizure reduction in 8/17 callosotomies practiced on children (Sittenfeld, unpublished work).

Cuba

An epilepsy surgery program was created in 2000, at the International Center for Restorative Neurology (CIREN) in Havana,[35] where they have started to perform video-EEG monitorings in 2000; the first surgical procedures, temporal resections, began in 2002 and later a few callosotomies have been performed. The medical team, which includes neurophysiologists, epileptologists, neuropsychologist, and neurosurgeon, was trained at the MNI. Patients are evaluated with surface video-EEG monitoring, neuroimaging, and SPECT; Wada tests are not performed (Bender, personal communication).

Dominican Republic

In this country there were no known epilepsy surgery treatments in the past. Since 2003 Video-EEG monitoring has been practiced at the Corazones Unidos Clinic, in Santo Domingo City where anecdotical extratemporal resections have been performed recently (Santos-Viloria, personal communication).

Ecuador

There has been no known epilepsy surgeries performed in Ecuador. Just recently Video-EEG monitoring was started at the 'Hospital Metropolitano', in Quito, the capital city, by the epileptologists Abad and Pesantes and the neurosurgeon Varsallo, trained in epilepsy surgery in Freiburg, Germany (Pesantes J, personal communication).

Mexico

The first communications about epilepsy surgery in Mexico date back to the early 1950s and were performed by Manuel Velasco Suarez, one of the most distinguished Mexican neurosurgeons. In 1951 he founded the Mexican League Against Epilepsy and later, in 1964, the National Institute of Neurology and Neurosurgery (Mexico City).[36]

Later, a pioneering work on deep brain stimulation has been developed since the mid-1980s by two other neurosurgeons, Francisco and Marcos Velasco, from the Instituto Mejicano de Seguridad Social Medical Center. They proposed centromedian median thalamic nuclei stimulation for the treatment of patients with intractable generalized tonic-clonic seizures,[37–39] using this therapy for up to 2 years, through a special device they had developed; they described good outcomes in generalized seizures but not in generalized tonic nor complex partial seizures. These same authors also reported the use of subacute electrical hippocampal stimulation, with either depth or subdural electrodes, in 10 patients who had withdrawn anticonvulsants for 48–72 hours; after a stimulation period of 2–3 weeks the patients underwent anterior temporal resections. With this method seizures were abolished in seven of these patients and even the interictal spiking was reduced significantly.[40] The Velascos have also reported on the use of bilateral cerebellar stimulation in a group of five refractory epilepsy patients, in a double-blind controlled study which used the same patients as controls, and obtained a statistically significant seizure reduction.[41]

An epilepsy surgery program that uses a more conventional approach was established in Mexico City, at the National Institute of Neurology and Neurosurgery, where temporal and extratemporal resections are performed, using intraoperative electrocorticography and cortical stimulation whenever appropriate. A 2-year follow-up report of 100 resective surgeries in temporal lobe epilepsy was presented in 2004, showing seizure free outcome in 84% of the patients.[42] At this center, vagal nerve stimulation was also implemented for refractory epilepsy in 2001.[43] Pella *et al.*, also in Mexico City, established an epilepsy surgery program at the Angeles del Pedregal Hospital in 1995. They have performed more than 100 surgeries, in both children and adults, including temporal and extratemporal lobectomies, callosotomies, and radiosurgical procedures (Pella *et al.*, personal communication).

Recently epilepsy surgery has been developed at the Instituto Potosino de Neurociencias, in San Luis de Potosí. Villalobos *et al.*[44] reported their experience in a group of 40 patients, children and adults, who underwent resective surgery.

Peru

Esteban Rocca, a neurosurgeon trained under the Chilean Alfonso Asenjo in the 1940s, founded the Neurosurgery Unit at the Hospital Obrero in Lima in 1947.[45] Working with Juan Franco, a neurosurgeon trained in Chile and the USA, he performed resective surgeries in 1955, using corticograms as guidance.[46] However, details of the surgical procedures and results were not presented. In Arequipa, a southern Peruvian city, Ortega and Gamero[47] in 1973 reported on 30 intractable patients with generalized seizure disorders that were treated with surgical section of the genu of the corpus callosum and anterior white commissure; significant improvement or complete control was achieved in 90% of these patients. No epilepsy surgery programs are currently established in Peru.

Uruguay

Alejandro Schroeder, the founder of Uruguayan neurosurgery, introduced the EEG and initiated epilepsy surgery at the Instituto Neurologico in Montevideo. He was initially trained in central nervous system histology in Hamburg, Germany and later he had the chance to work with Ostrid Fester in Breslau; after this latter experience he became interested in neurosurgery, starting his practice in 1930.[9] In 1949 he reported the first Latin-American series on lesionectomies at the Third South American Neurosurgery Congress held in Buenos Aires, Argentina.[1] It included ten patients studied preoperatively with surface EEG and cerebral angiograms; intraoperative electrocorticography was also performed and used as the main criterion for guiding surgery, since resections were done only when corticograms showed spikes, which was the case in the seven patients. The authors stated

that, after clinical and EEG studies, 'we mark on the skin the epileptic focus as exactly as possible'. Also in Montevideo, Arana Iñiguez, a neurosurgeon trained in Santiago, Chile, and Boston, USA performed one of the earliest hemispherectomies in Latin-America.[9] In 1961, Bogacz *et al.*[48] studied 62 patients with unilateral temporal lobe foci, using nasopharyngeal and sphenoidal electrodes. Seven of these patients underwent invasive studies with deep electrode threads for 24 hours, followed by temporal lobectomy.

As has happened in many other countries, no further epilepsy surgeries were performed for decades and only recently has an epilepsy surgery program been started in Montevideo at the Instituto de Neurologia del Hospital de Clínicas, led by Alejandro Scaramelli. Up to date they have performed 17 temporal lobectomies using non-invasive techniques (Scaramelli, personal communication).

Venezuela

Arminio Martinez *et al.*[49] working at the José María Vargas Hospital, in Caracas, the capital city, started temporal lobectomies in 1955, following the Montreal Neurological Institute approach, including the use of intraoperative electrocorticography and electrical stimulation; up to 1972 they had operated on 13 patients, reporting complete control in 9 and improvement in 2 patients. The same group performed the first hemispherectomy in Venezuela in 1959. After several decades Scholtz and Ponce, at the same Vargas Hospital, performed some other epilepsy surgery procedures. In 2000, Soto, *et al.* established a new epilepsy surgery program, working at the Domingo Luciani University Hospital and the Floresta Medical Institute where they have performed temporal and extratemporal resections, callosotomies, and vagal nerve stimulations (Soto, personal communication).

Concluding remarks

The history of epilepsy surgery in Latin America parallels the rest of the world. Very early attempts to develop this therapy following the Montreal Neurological Institute's approach can be found in several countries of the region. The pioneering work of the Brazilian neurosurgeon Paulo Niemeyer Soares, who proposed almost 50 years ago the selective amygdalohippocampectomy, a technique still used nowadays, is a good example of the interest Latin America has historically shown in epilepsy surgery.

More recently in the region, epilepsy surgery has followed the extraordinary development in first-world countries, including the area of neuroimaging. Unfortunately, Latin America has also great diversity in the organization of the health system and the breach between the number of patients needing epilepsy surgery and the actual amount of surgeries performed is certainly much larger than in developed countries. Only Brazil has a nationwide epilepsy surgery program and this experience, in this respect, probably has unique features, due to its universality (available to every citizen independent of socioeconomic status), high medical standards at minimal costs (strict definitions of human and technical requirements, and surgical protocols), and a controlled and organized accreditation system (supervised by Health Department and medical societies) which could be seen as an example not only for developing but also to developed countries.

15 Epilepsy surgery in Africa

MF Moodley and EL Khamlichi

Introduction

Epilepsy is the most common chronic neurological disorder estimated to affect at least 50 million people worldwide; 80% of whom reside in developing countries.[1] In Africa where 50% of the population is under 16 years of age, the prevalence is even higher making epilepsy a significant health and socio-economic burden.

Africa is the second largest continent with 35 million square kilometers and more than 800 million people distributed in 52 different countries.[2] Seventy-five percent of people with epilepsy in Africa receive inadequate or no treatment at all. Paralleling the enormous geographic, cultural and economic differences in this continent the neurological and neurosurgical services are equally diverse. Limited financial resources, illiteracy, social instability, war, lack of prioritization, poor health system infrastructure, and inadequate supplies of antiepileptic drugs in concert hinder the delivery of appropriate treatment. Furthermore, the vast majority of Africans still live in villages and there is a significant rural/urban divide in epilepsy services, with the vast majority of neurologists and neurosurgeons being concentrated in the major cities. Belief in supernatural causes and traditional treatment of epilepsy in Africa further contribute to the under-utilization of available medical services, to discrimination and social isolation.

Epidemiology and etiology of epilepsy

In Africa preventable causes of epilepsy (central nervous system infections, head trauma, poor antenatal and perinatal care) are more frequent resulting in greater disability and mortality in Africa than elsewhere.[3] The high incidence figures for epilepsy in developing countries is significantly attributable to symptomatic epilepsies caused by a host of parasitic and infectious diseases that are largely absent in industrialized countries.[4–6] Neurocysticercosis, for example is frequently found in people with epilepsy in developing countries and in South Africa it is a major cause of seizures in both children and adults.[4,7] Furthermore, in South Africa, 50% of children with recurrent seizures had had their first seizure before the age of 2 years, and 32% and 11% of the patients studied had a history of perinatal complications and meningitis respectively.[6]

Epidemiologic studies from North Africa are scarce, but in general, prevalence and incidence of epilepsy are much lower, perhaps because of a lower rate of infection than in Sub-Saharan Africa, better medical infrastructures, and more trained medical personnel in the North than in Sub-Saharan Africa.[8]

Despite the advent of modern anti-epileptic drugs in the last three decades, 30–40% of patients with epilepsy have intractable seizures. Almost half of these patients are potential surgical candidates and of these carefully selected patients, chance of freedom from seizures after surgery is in the range of 60–75%. If we consider the high number of African patients with refractory epilepsy, the cost of the anti-epileptic drugs, hospitalization, and the economic conditions of the majority of patients, it becomes clear that surgical treatment is more cost effective than sustained pharmacotherapy.

Epilepsy surgery has thus become readily adapted in many developing countries with limited resources like Brazil, China, India, and Turkey.[9,10] These all argue in favor of the development of epilepsy surgery programs in Africa, and African neurologists and neurosurgeons should develop epilepsy surgery programs with the knowledge that the success of epilepsy surgery depends more on well-trained clinical teams, than on high-level technology.

Contribution of Africa to the history of epilepsy and epilepsy surgery

Epilepsy is an ancient disorder, well described in many early civilizations with remarkable descriptions of epileptic attacks in early Babylonian texts of medicine (1000 BC)[11] Despite this very ancient description, the concept of epilepsy etiology has remained for centuries dominated by supernatural views, considering seizure attacks as a divine visitation (religious concept), or with an invasion of the body by evil spirits (superstitious concept). Consequently the treatment was not medical but spiritual with religious and/or various social approaches. The contributions of Africa, particularly the Northern part, to the history of epilepsy had been significant in the Middle Ages, between the 9th and 13th centuries, the golden age of the Arab–Islamic civilization, which extended at the time around the Mediterranean Sea. Among some outstanding individuals with medical knowledge, two individuals stand out: Abu-Bakr Al Razi, 'Rhazes' (830–923) and Hussein Ibn Sina, 'Avicenna' (980–1037), who left us the best descriptions of epilepsy.[12]

In his huge monograph ('Alkanun FiTib', Rules of Medicine), Avicenna described different types of epilepsy syndromes: tonic-clonic seizures, absence and focal seizures including focal-motor seizures, with its typical extension from the toes to the proximal lower limbs and from the fingers to the proximal upper limbs, and known today under the name

of Jackson, who described it 800 years later.[13] In Avicenna's monograph he also described many symptoms which can occur before or after a seizure which we now recognize as auras and postictal phenomena.

The interesting point in this historical manuscript is that Avicenna, referring to Hippocrates, mentions the concept that epilepsy is a brain disease and that seizures result from an invasion of the frontal lobes by a noxious substance which then propagates towards the posterior part of the brain and later to the spinal cord and the peripheral nerves. This propagation engenders generalized seizures. He considered these seizures of the body as resulting from a contraction of the brain which is necessary for the expulsion of noxious substances, and comparing also these contractions of the brain to the contractions of the stomach during hiccup or vomiting in order to 'chase noxious food'.[13] This medical knowledge about epilepsy and many other brain diseases that excelled between the 9th and the 13th centuries in Fez and Marrakech (Morocco), in Kairouan (Tunisia), and in Cairo (Egypt), was later transmitted to Europe in the 14th and 15th centuries, where it would be improved to prepare the Renaissance movement of neurology in the 18th and 19th centuries and the modern era of epilepsy.

As far as African neurosurgery is concerned it is well known that during the pharaonic era, neurosurgical procedures like trephinations were widely used in the whole continent, practiced and taught by healers in African tribes.[14] The technical concepts of this trephination are based, to a great extent, on the descriptions of Arab physicians of the Middle Ages.[14]

Of the many outstanding Arab physicians it was mainly Abulkassim Al Zahraoui (Abulkassis) who was the pioneer of neurosurgery. He is credited with devoting a volume of his treatise (made up of 30 volumes) to neurosurgery, a precise description of many aspects of neurosurgical pathology, its treatment, instruments and neurosurgical techniques.[14] In Kenya, the traditional art of skull trephination, passed down from generation to generation, and is still practiced by the Kisii tribesmen in the highlands of the South Nyanza District of Kenya.[15] As recently as 1982 a local daily newspaper featured an article entitled 'Skull Surgeon Who Never Went to Medical School'. This story focused on one of the well-known practitioners of trephination since 1955 having learned it from his grandfather. He claimed that he had performed hundreds of these procedures and that most of his patients had already been treated at hospitals without success.[15]

He added, 'Doctors in Kenya are not able to open the skull the way I do, and when a patient goes to them full of broken bones in the head, the treatment is often incomplete.' Neurosurgeons in Kenya encounter patients who have undergone this procedure. The openings in the skull vary from a few centimeters to removal of the entire vault. Trephinations were made for ritual or therapeutic purposes. It is speculated that they were intended to free the body from devils and spirits. It is thus easy to imagine that epileptics, in many African cultures viewed as possessed, underwent these trephinations.[15]

It is interesting to note that despite these significant contributions and the fact that this land was the birth place of our early human ancestors the vast majority of its population has not yet been part of the great technological/industrial revolutions that has occurred in many other parts of the world. Thus, the challenges facing Africa in the domain of medicine remain immense.[16]

Neurosurgical practice developed in many African countries only during colonization, together with the development of the health system as soon as the European colonizers came to these countries. Initially, neurosurgery was practiced in the departments of general surgery either by general surgeons or rarely by neurosurgeons themselves.[14]

Modern neurosurgery was introduced and started to develop in most African countries in the early 1960s, and the teaching of this subspecialty in many African universities began between 1960 and 1970, soon after their independence. However, in South Africa neurosurgery as an independent discipline commenced much earlier at the Groote Schuur Hospital in Cape Town with the return of Hermann de Villiers Hammann from Munich, Germany in 1946.[17]

Neurosurgery for intractable epilepsy, on the other hand, was practiced even earlier as the late 1940s. Roland A. Krynauw, a neurosurgeon from the Department of Neurosurgery, Johannesburg Hospital in South Africa pioneered hemispherectomy for children, adolescents and young adults with intractable seizures accompanying infantile hemiplegia.[18] Over a 5-year period he performed hemispherectomies on 12 patients with intractable seizures accompanying infantile hemiplegia with remarkable success. Epilepsy, either focal or generalized, was present in 10 of the 12 patients and in all these patients epileptic manifestations ceased in the post-operative period without any sedative medication. Furthermore, marked improvement in personality, behavior, and mental function was noted in all cases. His success with hemispherectomy soon attracted world wide attention to this neurosurgical procedure for intractable seizures.[18]

Management of epilepsy in Africa

While remarkable progress has been made worldwide in the second half of the 20th century in the diagnostic evaluation of neurological diseases, including epilepsy, in Africa this development was mainly-in the more affluent North and South Africa and remains restrained in the rest of the continent by the poor socio-economic conditions. In many countries in Sub Saharan Africa neurological and neurosurgical services are nonexistent creating a broad divide – 'From excellence to total absence'.

Fortunately, EEG is available in the majority of countries in Africa (82.4%), however, the availability of other investigations are limited in the majority of African countries.[19] Video EEG monitoring is available in 25.7% of African countries, 18 African countries have no CT scanners, 13 countries have only 1 CT scanner for each country and only 13 other countries have more than 2 CT scanners. Only North African countries and South Africa have an adequate number of CT and MRI scanners.[19–21] In addition, even in those countries with neuroimaging equipment, the majority of the population who live in rural areas do not have access to this equipment, because of limited economic resources and a lack of medical insurance. In the absence of these advanced technologies, most of the common causes of symptomatic epilepsy cannot be diagnosed in many countries in Africa.

The management of epilepsy in Africa is highly influenced by the socio-cultural misrepresentation of epilepsy. Consequently,

less than 20% of patients will seek medical attention after their first seizure, the other 20–30% will seek a healer or marabout (holy temple) for traditional treatment.[22] The remaining 50–60% will not seek any treatment. This delays diagnosis and treatment, with more than 50% of patients seeking medical help one year after their first seizure, and 30% 5 years after their first seizure.[23,24]

The mainstay of pharmacological treatment throughout Africa is phenobarbital, which has two main advantages: reliability of supplies and affordability with 50–80% of treated patients being on phenobarbital.[25] Most of the other older anticonvulsants like phenytoin, carbamazepine, valproic acid, and benzodiazepine are available in secondary and tertiary hospitals. The 'new' anticonvulsants discovered in the last 15 years are generally not available in the vast majority of countries in Africa. In South Africa on the other hand, it is available in most tertiary and quartenary hospitals and also in private clinics but cost is again a prohibitive factor for its widespread use.

Epilepsy surgery in Africa

Epilepsy surgery is a well accepted, safe and effective alternative treatment for patients with medically intractable epilepsy in developed countries.[26,27] However, in addition to appropriate technologies for pre-surgical evaluation, the success of epilepsy surgery depends on availability of well-trained clinical teams made up of neurologists, neurosurgeons, clinical neurophysiologists, neuropsychologists, and neuroradiologists, components not easily available in developing countries.

In the 1990s, 10 of 142 developing countries conducted epilepsy surgery and by 2000, 26 such countries have reported results of epilepsy surgery in carefully selected patients and this number is gradually increasing.[10] In Africa most of these reports emanate from the two extremes of the continent, the more affluent North and South Africa with almost the entire rest of the continent still experiencing a significant delay in the development of neurosurgery. The challenge is resource allocation in competition with other demands, in particular primary healthcare. A survey conducted in 1998 under the hospices of WHO, found only 565 neurosurgeons for a population of over 800 million (ratio of 1 neurosurgeon to 1,352,000 people).[20] The world wide ratio is 1 neurosurgeon to 230,000 people with 1 neurosurgeon to 121,000 people in Europe and 1 Neurosurgeon to 81,000 people in North America.[2] The distribution of neurosurgeons in the African continent shows that the majority are located in North Africa (Egypt 165, Algeria 130, Morocco 80, Tunisia 25) and South Africa (86). Consequently the total number of neurosurgeons in these countries is 486 for a total population of 174 million, with a ratio of 1 neurosurgeon to 358,000 people. Between North and South there are three countries that have between 8 and 15 neurosurgeons (Nigeria, Senegal, and Kenya), and the majority of other countries have between 1 and 5 neurosurgeons, with no neurosurgeons at all in 11 countries. Therefore, the ratio in Sub-Saharan Africa is 1 neurosurgeon to 7 million people. The biomedical equipment available has almost the same distribution.[2]

A local training program in neurosurgery is currently available only in North African countries and in South Africa. Most young neurosurgeons in the rest of Africa are trained outside the continent, mainly in Europe. Currently in South Africa there are a few centers in Cape Town, Johannesburg and Durban that have impressive pre-surgical technology and clinical teams who perform epilepsy surgery in carefully selected patients. (personal communication Roger Melville and James Butler). Subdural electrode placements, temporal lobectomies, and cortical resections account for the bulk of the surgery performed. Multiple subpial resections and functional hemisperectomies are also performed occasionally (personal communication Roger Melville).

In Morocco it took many years to find motivated people to create a multidisciplinary team and to commence epilepsy surgery which only began in February 2005. Surgical procedures so far have included temporal lobectomies and simple structural lesion surgery.

Faced with the reality of a scarcity of human and technological resources, is there room for epilepsy surgery in developing countries like those in Africa? Because of the high prevalence of epilepsy in Africa, the high cost of sustained pharmacotherapy, its medical intractability, and the high frequency of symptomatic epilepsy, epilepsy surgery offers a potential treatment to rescue a large number of patients with epilepsy in Africa.

Moreover, these are the reasons behind the development of many epilepsy surgery programs in countries with limited resources, like Brazil, China, and Turkey and these programs have demonstrated that surgery is more cost effective than sustained pharmacotherapy.[9] In addition, surgery will have a positive impact on the mental capacity of epileptic patients and of society in Africa, allowing patients to conceive of epilepsy as an organic disease originating from the brain, which can be cured with surgery. Even with limited technological and human resources carefully selected patients from an abundance of surgical candidates, the teams achieve outcomes comparable to those in the developed world with direct epilepsy surgery costs at a fraction of those in the developed world.

Future of neurosurgery and epilepsy in Africa

More than 80% of the 50 million people suffering from epilepsy around the world live in developing countries like those of Sub-Saharan Africa where the vast majority do not receive any modern treatment or are not even identified.[28] The main reasons behind this treatment gap are poor health care systems, illiteracy and cultural beliefs especially in Sub-Saharan Africa. Some other potential causes of this treatment gap are a lack of prioritization of epilepsy as a public health issue, inadequate preventative programs and a high prevalence of epilepsy in Africa.

Regarding the 'surgical treatment gap' in epilepsy there is a great divide – well catered for in North African countries (Egypt and Morocco) and South Africa and almost non-existent in the rest of the continent.[10,29] If we consider the proposed ratio by H. G. Wieser of 1 epilepsy center for 7 million people as estimated in developed countries, Africa with more than 800 million people, needs more than 100 epilepsy surgery centers making the bridging of the surgical treatment gap in

epilepsy in Africa an impossible dream.[10] The main problem to overcome is the scarcity of neurosurgeons and neurologists in the majority of African countries. Without their expertise it becomes difficult to organize any multidisciplinary team to solve the huge challenge of reducing the treatment gap in epilepsy between Africa and the developed world. Pioneering African neurosurgeons should develop neurosurgery in their countries by encouraging local training programs which remain the major pillar in the development and quicker promotion of neurosurgery in their countries as exemplified by North African countries and South Africa. African trainees in developed countries generally are not keen to return, and when they return do not have the resources which they have trained with rendering them ineffective or demoralized and thus paving the way for the growing 'brain drain' from Africa to Europe and North America.

The second main problem is to convince the political authorities and health planners that epilepsy is a public health issue, despite other high priority health demands, as in most African countries epilepsy and neurosurgery in general seem to have a very small place on public health priority programs.

Neurologists and neurosurgeons as advocates for patients with epilepsy should sensitize other individuals including non-medical professionals, patients and community Non-Governmental Organization (NGOs) to apply pressure on governments, health planners, and decision makers so that proposals for building sustainable training programs are put in place.

Epilepsy care development in Africa can also benefit from international cooperation and the help of international institutions like the WHO, the ILAE, and the International Bureau for Epilepsy (IBE). These three institutions make a major collaborative effort through the global campaign against epilepsy 'Out of the Shadows', which was launched in 1997 'to improve acceptability, treatment, services and prevention of epilepsy worldwide in order to address discrimination against people with epilepsy and to diminish the treatment gap in the developing regions of the world.'[1]

Three other institutions can efficiently help epilepsy programs in Africa: The World Federation of Neurosurgical Societies (WFNS), the World Federation of Neurology (WFN), and the Pan-African Association of Neurological Sciences (PAANS).[30] These institutions can help at different levels: at the information level by sending reports on the epilepsy care situation in Africa to governments and universities in African countries; at the training and research levels by organizing courses, seminars, and granting fellowships to young African doctors to be trained in neurology and neurosurgery. In 1998 the WFNS initiated the creation of the 'WHO Africa Sub-Committee in Neurosurgery,' which prepared a report on the state of neurosurgery in Africa, which was presented to the WFNS and the WHO working group in Neurosurgery in 1999,[20] resulting in the creation of the 'WFNS Foundation For Training Young Neurosurgeons from developing countries' in 2002. It also created the first reference center in the Department of Neurosurgery at the University Hospital in Rabat to train young African doctors, and the Mohamed V University of Rabat arranges and insures their training.

Conclusion

Epilepsy remains an important public health problem in Africa. With its high prevalence and the lack of appropriate diagnostic and therapeutic facilities it represents an important economic and social burden in the majority of African countries. The main constraints widening the treatment gap in epilepsy include lack of knowledge about epilepsy, cultural attitudes especially in rural people, poor advocacy for neurosurgery at governmental level, and the limited human and material resources in the majority of African countries.

The optimistic element, however, is the existence of neurosurgical centers of excellence at the two extreme parts of the continent, namely North and South Africa. Neurosurgeons in these areas can integrate epilepsy surgery in a fairly rapid way in their centers, using non-invasive pre-surgical investigations to successfully select the patients with intractable epilepsy. With the combined effort of North Africa and South Africa and substantial support for African neurosurgery from the international community, the development of neurology and neurosurgery in Sub-Saharan Africa can be improved and the treatment gap in epilepsy can be filled.

16a History of epilepsy surgery in Southeast Asia

S-H Lim

Overview of epilepsy surgery in Southeast Asia

Southeast Asia (SEA) covers an area of about 4 100 000 square kilometers containing the following countries: Brunei, Cambodia, Indonesia, Laos, Malaysia, Myanmar, Philippines, Singapore, Thailand, and Vietnam. As of 2007, there are more than 580 million people living in this region. If the epilepsy prevalence rate is 5 per 1000 population, SEA would have around 2.9 million people with epilepsy (PWE). If a quarter of these PWE are medically refractory, more than 700 000 of them could be evaluated for epilepsy surgery. However the epilepsy surgery treatment gap is huge in SEA.

An informal survey conducted by the author in 2003 (unpublished data) showed that <150 epilepsy surgeries were performed for adult and pediatric patients in SEA in the 1990s and early 2000s, mainly in Thailand, Singapore, Malaysia, and Indonesia, with fewer cases in the Philippines. 80–90% of these surgeries, were temporal lobectomy (standard anterior temporal lobectomy > selective amygdalo-hippocampectomy) while the rest were lesionectomy, neocortical resection, corpus callosotomy, hemispherectomy, and implantation of vagus nerve stimulator (VNS). Similar to the results in countries belonging with developing economies, 60–70% of temporal lobectomy patients achieved Engel Class I seizure outcome, while another 10–15% had rare seizures or worthwhile improvement.

These surgeries were performed at tertiary referral centers, established in the late 1980s in Thailand, early 1990s in Singapore, and in the second half of the 1990s in Malaysia, Philippines, and Indonesia. There are currently 1–4 centers per country, located in capital cities. Each centre has 1–5 epileptologists and 1–2 neurosurgeons with special interest and/or trained in epilepsy surgery. Many centers perform long-term video-EEG monitoring and structural MRI routinely. The usage of SPECT, Wada Test, MRS, neuropsychological testing, and psychiatric assessment is variable. Intracranial EEG recordings are rarely performed and PET study is only available in two countries. To date, there is no epilepsy surgery program in Brunei, Cambodia, Laos, Myanmar, or Vietnam.

There are common issues in SEA that continue to retard the development of epilepsy surgery in this region. Costs of evaluations and surgery are relatively high in most countries. Socially and culturally, many patients were reluctant to undergo cranial surgery for a condition not considered immediately life-threatening by these patients and their family. This tied in with the perception by the lay that cranial surgery is oftentimes morbid and considered an extreme intervention. Family support in SEA was relatively strong, thereby obviating the need for independence and self-support. Many patients in the rural areas are still probably undiagnosed and not informed of the epilepsy services available in the country. Public transport services in big cities are fairly prevalent and convenient. The need to be seizure free to drive was not as pressing as in other countries like the United States.

The following sections describe the development of epilepsy surgery in Indonesia, Malaysia, Philippines, and Singapore. The epilepsy surgery programe in Thailand is briefly mentioned here as the details are described in Chapter 19.

History of epilepsy surgery in Indonesia

Indonesia is the largest country in Southeast Asia with a population of 224 millions and has the largest pool of epilepsy patients who require epilepsy surgery. However, there was no epilepsy surgery program till the end of the 1990s. Unlike other SEA countries where epilepsy surgeries are driven by trained epileptologists, surgery for epilepsy in Indonesia was initiated by a neurosurgeon, Dr Zainal Muttaqin from Semarang, Indonesia.

Dr Muttaqin, influenced by the blooming of epilepsy surgeries in other parts of the world, developed an increasing interest in epilepsy surgery in the middle of the 1990s. To increase the awareness of clinicians and lay-public in epilepsy surgeries, he organized an epilepsy surgery symposia at national and regional neurology scientific meetings, at which Prof T Hori from Japan was a keynote speaker. He also started writing review articles on surgery for epilepsy in Indonesian language medical journals. He then decided to acquire the skills of epilepsy surgery and traveled to Hiroshima, Japan many times between 1996 and 2001 to learn epilepsy surgery from Dr Kazunori Arita and Prof Kaoru Kurisu, at the Hiroshima University. With their help, the first case of left temporal lobectomy was performed in 1999. Surgery was performed based on clinical information suggestive of temporal lobe seizures and MRI evidence of left temporal sclerosis. Another 10 cases were operated in 2000–2001, all based on clinical history suggestive of TLE semiology and unilateral hippocampal structural abnormality on MRI.

Due to the limitation of financial resourses, most of the MRI machines were of 0.5 Tesla in strength, including the only centre (Diponegoro University Hospital) that performed epilepsy surgery. Only a few hospitals affiliated to universities had acquired 1.5 Tesla machines which are not used for presurgical evaluation. Prolonged EEG recording with video monitoring facility is still lacking, thus it is not part of presurgical evaluation protocol. Even for routine EEG recording, most of the machines were 10 channels, though a few of the nonepilepsy surgery centers have acquired 20–32-channel EEG machines with video recording capability. There is also a lack of trained electroencephalographers (EEGers) in Indonesia. Between 2000 and 2006, there were three adult neurologists who received 6–12 months of training, mainly in routine and noninvasive long-term EEG monitoring and clinical epileptology. Other issues included inconsistent presurgical evaluation protocols, postoperative follow-up mainly by neurosurgeon, no other trained neurosurgeon, as well as late identification and referral of intractable cases. As such, decision for surgery was made mainly by Dr Muttaqin, very often based mainly on the findings obtained from low-resolution MRI imaging.

Despite the above-mentioned limitations, more than 100 patients had epilepsy surgery between 1999 and 2006. Over 90% had temporal lobectomy with removal of mesial structures, mainly for patients with mesial temporal sclerosis. A few patients had a Wada test and subdural grid recording (in those with normal MRI). One patient had intraoperative ECoG. For those with temporal lobectomy that had 12–82 months of follow-up, about 75% had Engel's class I seizure outcome and two-thirds of these patients could have their AEDs withdrawn. A few patients had lesionectomy, multiple subpial transaction, functional hemispherectomy and corpus callosotomy.

History of epilepsy surgery in Malaysia

Malaysia has a population of 28 million people but only had one 'one-stop' epilepsy surgery center in the 1990s and early 2000s. The adult epileptologist who pioneered the epilepsy surgery programme in Malaysia was Professor Raymond Azman Ali. He was trained by Prof David Fish in video-EEG monitoring, presurgical evaluation, and neuroimaging at the Institute of Neurology, Queen Square, London, from 1992 to 1994. At the same time, a neurosurgeon, Prof Benedict Selladurai, was also trained at the institute by Prof David Thomas and Mr. William Harkness in epilepsy surgery.

Upon returning to Malaysia in 1994, they together started the epilepsy surgery programme in 1995 at the Universiti Kebangsann Malaysia Hospital. The first operation was performed on an 11-year-old boy with a dysembryoplastic neuroepithelial tumor in the mesial temporal region, who became seizure free. When they announced the successful operation in one of the national newspapers, interest in epilepsy surgery amongst PWE increased tremendously. Not all surgical patients were from the same hospital, as many were referred from other major hospitals, including Kuala Lumpur Hospital and University Malaya Medical Centre. The hospital was supportive in upgrading the neurophysiology laboratory and neuroimaging service. However, they did not have a stand-alone epilepsy surgery centre, in-patient ward or epilepsy nursing staff. They also employed neuropsychologists interested in epilepsy. One of the psychiatrists went on to subspecialize in neuropsychiatry. In 2000, Prof Lai-Choo Ong, a pediatric neurologist, received training in Royal Melbourne Children's Hospital under the supervision of Dr Simon Harvey. Another adult neurologist, Dr Hui-Jin Tan, is currently being trained in clinical epilepsy.

EEG facilities included a video-EEG monitoring unit using scalp and sphenoidal electrodes. A few patients had intraoperative ECoG. They have not developed intracranial EEG capability. As for neuro-imaging capability, they have 1.5 T MRI machine and are able to add MRS to their evaluation protocol. Ictal SPECT was rarely performed. Neuropsychological evaluation was routine, but there was no expertise in performing WADA tests.

Standard anterior temporal lobectomy was started in 1996, followed by selective amygdalohippocampectomy and lesionectomy in 1999. Hemispherectomy, corpus callosotomy, and implantation of vagus nerve stimulator were started in 2001. Between 1996 and 2006 around 75 cases of anterior temporal lobectomy and 15 cases of selective amygdalohippocampectomy were performed with 70% of these patients achieving Engel's Class I seizure outcome. Two patients had hemispherectomy and both became seizure free. Twelve patients had lesionectomy and 55% achieved Class I seizure outcome. There were three cases of corpus callosotomy and one VNS and all had Class IV seizure outcome.

The main challenges encountered in developing the epilepsy surgery programme were lack of full-time staff (epileptologists, epilepsy neurosurgeons, neuroradiologists, neuropsychologists, nurses, and neuroanaesthesiologists). Currently only one centre performs a consistent number of epilepsy surgeries. Even then, the infrastructure for this 'one-stop' centre is underdeveloped.

History of epilepsy surgery in the Philippines

The Philippines have a population of 87 millions. There are 3–4 hospitals offering epilepsy surgery since the late 1990s. With the continued return of clinicians trained in epileptology and subsequently in epilepsy surgery, the comprehensive epilepsy program was established in 1997 at the St. Luke's Medical center. This center is one of the premier private hospitals in the country with the necessary resources to support the epilepsy surgery program. The center had a 'multidisciplinary team' composed of the following members: epileptologists, an epilepsy surgeon (Dr Annabelle Chua), neurophysiologists, psychiatrist, nurses, EEG technicians, and dieticians. The objective of the program was not only to evaluate patients and their suitability for epilepsy surgery, but also to offer overall better management and control of patients with difficult to control seizures.

The Epilepsy Monitoring Unit at the St. Luke's Medical Center is a three-bed unit capable of offering 2-hour and prolonged video-EEG monitoring. In addition, there are three other one-bed units in other hospitals with in-house epileptologists trained in video-EEG monitoring, namely the University of the Philippines-Philippine General Hospital, the Philippine Children's Medical Center, and the Makati Medical

Center. Epilepsy clinics were established in two training hospitals: the University of the Philippines-Philippine General Hospital and the University of the East-Ramon Magsaysay Medical Center.

Presurgical evaluation included CT scan, MRI, PET scan, video-EEG, neuropsychological evaluation and WADA test. For the latter, this is being done only at St. Luke's Medical Center, with its performance being limited by the difficulty in procuring amobarbital from the United States. There was also intracranial electrode placement, extraoperative monitoring, intraoperative ECoG, and mapping of eloquent cortex.

Most patients who had resective surgery had either hippocampal sclerosis or lesion such as tumors and vascular malformations. Detailed information on the number and types of surgery, as well as seizure outcome were not available.

History of epilepsy surgery in Singapore

Singapore is the smallest country that provides epilepsy surgery in SEA. It has a population of 3.6 million, and thus the number of potential surgical candidates is considered relatively low.

An epilepsy surgery programme was established in Singapore in 1992 after the return of an adult neurologist, Dr Shih-Hui Lim, from the Cleveland Clinic Foundation (CCF). With the sponsorship of the Ministry of Health, Singapore, Dr Lim completed a formal clinical fellowship in epilepsy and clinical neurophysiology under the supervision of Prof Hans O Lüders from 1989 to 1991. He also obtained board certification by the American Board of Clinical Neurophysiology. A year later, another adult neurologist, Dr Michael WL Chee, also sponsored by the Ministry, completed similar training at CCF from 1990 to 1992. In addition, Dr Prem Kumar Pillay, a Singaporean doctor receiving his neurosurgery residency training at CCF in the late 1980s and early 1990s, was trained in epilepsy surgery by Dr Isam Awad. In the early 1990s, a pediatric neurologist, Dr Wei-Ling Lee received pediatric epilepsy training at Toronto Children's Hospital in Canada as well as at the CCF. In the mid-1990s, Dr Ngai-Kun Loh, an adult neurologist spent a year and Dr Kheng-Kooi Tan, a neurosurgeon, spent a few months at CCF. Dr Andrew Pan, an adult neurologist, was sent by Ministry of Health to CCF from 1999 to 2001 to be trained in Epileptology and Sleep Disorders. Thus the epilepsy surgery programe in Singapore in the first 10 years was considerably influenced by the philosophy of Dr Lüders. In 2003, Dr Nigel Tan received his epilepsy training with Prof Sam Berkovic at the Comprehensive Epilepsy Program at Austin Health. His return added value to the existing epilepsy surgery programme.

One-Bed video-EEG monitoring unit was first set up at Tan Tock Seng Hospital in 1992 and at Singapore General Hospital in 1993. Scalp and sphenoidal electrodes were used routinely. Most patients were monitored for 4–5 days after stopping medication, with an aim of recording at least three seizures. Due to administrative and logistic reasons, early postictal SPECT was carried out during office hours at the Singapore General Hospital. For those who had postictal SPECT had interictal SPECT during the monitoring period. All patients had structural MRI (1.5 T) which included oblique coronal images with flash/gradient echo, T2-weighted, and FLAIR sequences. Volumetric study was performed as part of the research. MRS was introduced towards the end of the 1990s. FMRI for language lateralization was started in the early 2000s, mainly for research purposes. From 2005, structural MRI using a 3.0 T MRI machine became more common. WADA tests were performed routinely in the 1990s and infrequently in the 2000s. Neuropsychological and psychiatric assessments were routine. Decision for surgery was made mainly based on structural MRI findings, scalp EEG data, and analysis of semiology of recorded seizures. As long as there was no discordant information, good candidates would proceed with resective surgery. Depth electrodes implantation was performed only once in 1994 to lateralize seizure onset. Chronically implanted subdural grid electrodes and extraoperative cortical mapping were carried out in four patients with nonlesional extratemporal lobe epilepsy in 1994 and 1995. Due to the poor seizure outcome from these cases, better MRI imaging facilities, avoidance of performing resective surgery in patients with no lesion on MRI, as well as constraint of doctors' time, invasive intracranial EEG recordings were rarely performed in the 2000s.

As expected from a center conducting mainly noninvasive presurgical evaluation, temporal lobe surgeries (standard anterior temporal lobectomy cases were more than selective amygdalohippocampectomy) and to a lesser extent, lesionectomy, were the most commonly performed surgeries. Corpus callosotomy, extratemporal resective surgery, hemispherectomy and implantation of vagus nerve stimulator were much less frequently performed.

Between 1992 and 2002, more than 110 patients had temporal lobectomy, 12 had lesionectomy, four had corpus callosotomy, three had extratemporal resection, two had hemispherectomy and seven had VNS implanted. They have been followed-up for an average of 8.5 years (range 5–15 years). There was no death or irreversible complications from surgery or intracranial EEG recording. Of those who had temporal lobe surgeries, about 66% had Class I seizure outcome (including 2 patients who had re-operation), 20% had worthwhile improvement (>90% seizure reduction) and the rest had no significant change (<90% improvement). Seizure outcomes from other surgeries were less than satisfactory (Class III and IV) and this had led to further reduction in these surgical procedures in the last 5 years.

History of epilepsy surgery in Thailand

Thailand has a population of 67 million people and has the oldest epilepsy surgery programme in SEA. It also had the largest number of epilepsy surgery cases performed (>300) in the last 10 years. As described in Chapter __, the were two eras of epilepsy surgery in Thailand: the era of general neurosurgery before the 1990s and the era of epilepsy surgery as a specialty after the 1990s. For the latter, detailed neuroimaging and clinical neurophysiology information became an integral part of the presurgical evaluation process. Professor Sira Bunyaratavej and Professor Pongsakdi Visudhipan from Ramathibodi Hospital played an important role in the development of the new epilepsy surgery era in the 1990s.

The major epilepsy surgery center in Thailand is the Chulalongkorn Comprehensive Epilepsy Program (CCEP) at Chulalongkorn University Hospital, Bangkok, Thailand, led by Dr Chaichon Locharernkul, an adult epileptologist and Dr Teeradej Srikijvilaikul, an adult and pediatric neurosurgeon. Dr Chaichon was trained in presurgical evaluation by Prof GA Ojemann and Prof GE Chatrain at University of Washington at Seattle, USA and by Dr A Ebner at the Bethel Epilepsy Center in Germany. Dr Srikijvilaikul was trained by Dr WE Bingaman at CCF. Other team members included Drs Tayard Desudchit, Krishnapundha Bunyaratavej, Chusak Limotai, and Jakrin Loplumlert, all had formal training in USA (three at CCF). Together, they offered the most comprehensive presurgical evaluation, including the routine use of SISCOM and 3.0 T MRI.

Other centers providing epilepsy surgery programme were located at Pramongkutklao Hospital and Bangkok General Hospital. Both centers were established by Dr Yotin Chinvarun in 2001 and 2002, respectively. Dr Chinvarun was an adult epileptologist trained by Prof Sam Berkovic in Australia. Members in his team included Dr Siraruj Sakoolnamarka and Dr Dittapong Boonnampol (both were adult and pediatric neurosurgeons), as well as Dr Chachrine Nabangchang (a pediatric epileptologist). This is the only center in SEA that provided gamma knife surgery for epilepsy.

Acknowledgments

The author greatly appreciates the following persons who have given the above information: Dr Zainal Muttaqin from Indonesia, Dr Raymond Azman Ali from Malaysia, Dr Annabelle Chua from the Philippines, Drs Pongsakdi Visudhipan, Chaichon Locharernkul, and Yotin Chinvarun from Thailand.

16b Epilepsy surgery in India

DK Lachhwani and K Radhakrishnan

Although trephination as a treatment for epilepsy might have been practiced in ancient India more than 4000 years ago,[1] the first modern epilepsy surgery in India was undertaken in the year 1952.[2] As has happened elsewhere in the world,[3] surgical treatment of epilepsy in India went through three phases: an initial enthusiasm (1951–1970), followed by a period of decline and a recent resurgence (from 1995). In this chapter, we intend to trace the evolution of epilepsy surgery in India along with a brief biographical sketch of the pioneers who contributed to its early development, and discuss in detail its present state and future perspectives.

The beginning

The modern era of neurosurgery in India commenced with the establishment of the first department of neurosurgery by Dr. Jacob Chandy (Figure 16b.1a) in 1949 at the Christian Medical College, Vellore, in the erstwhile state of Madras (present Tamil Nadu) in southern India.[4] After completing his medical education at Madras Medical College, Madras and Masters in Surgery at the University of Pennsylvania, Philadelphia, Chandy underwent neurosurgical training at the Montreal Neurological Institute during 1945–1948 under Dr. Wilder Penfield. After a brief assignment with Dr. Theodore Rasmussen, who was then setting up a neurosurgery department at Chicago, Chandy returned to India and joined the Christian Medical College, Vellore in 1949. One year later, Dr. Baldev Singh (Figure 16b.1b) joined Chandy as a neurologist. After completing his medical graduation, Singh joined King Edward Medical College, Lahore in 1922, where his initial interest in neuroanatomy developed. During his training in neurology at the National Hospital, Queen Square, London, Singh was fortunate to work with Kinnear Wilson, Lord Brain and McDonald Critchley. Reading about Berger's rhythm, stimulated Singh to undergo a training course in electronics and construct an indigenous apparatus in the 1940s to record the electrical activity of the brain of experimental animals. Singh went over to Gibbs's laboratory at Chicago in 1950 and spent the year, where he met Dr. Percival Bailey and participated in EEG recording on epilepsy patients on whom Bailey operated. This training proved useful to Singh to develop an epilepsy surgery program at Christian Medical College, Vellore. Coinciding with Penfield's visit to Christian Medical College, Vellore, the first epilepsy surgery in India was performed on Aug 25, 1952 by Chandy on a 19-year old male patient with infantile right hemiplegia. Singh was in the operation theater supervising the EEG recording.

At that time, 150 km north of Vellore, in the city of Madras, the second department of neurosurgery in India was being developed by Dr. B. Ramamurthi (Figure. 16b.1c). After a brilliant undergraduate education, he secured Master of Surgery and Fellowship of the Royal College of Surgeons of Edinburgh in 1947. Ramamurthi received his initial training in neurosurgery at Newcastle, UK. He subsequently visited various neurosurgical centers in Europe and spent four months with Penfield at the Montreal Neurological Institute. In October 1950, Ramamurthi joined the Madras General Hospital and Madras Medical College and started the department of neurosurgery, which he later developed into the Institute of Neurology, Madras.[5] Ramamurthi was helped with the EEG recording by Dr. T. S. Narasimhan (Figure 16b.1d), a neurosurgeon and electroencephalographer practicing in the city of Madras, who also held an honorary attachment in the Madras General Hospital. The first epilepsy surgery at the Madras General Hospital was done by Ramamurthi in 1954.

Incidentally, the four pioneers who were involved with the early development of epilepsy surgery in India – Chandy, Singh, Ramamurthi, and Narasimhan – started the Neurological Society of India in 1951 at Madras.[5] While three of them passed away, (Narasimhan in 1959, Singh in 1998, and Ramamurthi in 2003), Chandy expired on June 23, 2007.

Initial enthusiasm

During the 1950s, 1960s, and the first half of the 1970s, several patients with uncontrolled epilepsies were operated at Christian Medical College, Vellore,[2,6,7] and Institute of Neurology, Madras.[8–10] The localization of the epileptogenic focus was based on seizure semiology as obtained by history, and data from scalp interictal EEG and radiological investigations available then such as skull radiograph, pneumoencephalogram, and carotid angiogram. At the Christian Medical College, Vellore, while local anesthesia was favored during the first decade and half, most of the subsequent surgeries were performed under general anesthesia.[6,7] Pre- and post-resection electrocorticogram (ECoG) was routinely done using surface and depth electrodes. Cortical stimulation to map motor and language areas and induction of seizures intraoperatively were practiced when indicated. In a recent retrospective analysis of the clinical profile and outcome of 141 patients operated for intractable epilepsy at Christian Medical College, Vellore (a majority of them during 1950s, 1960s, and first half of the 1970s), 102 (73%) had temporal

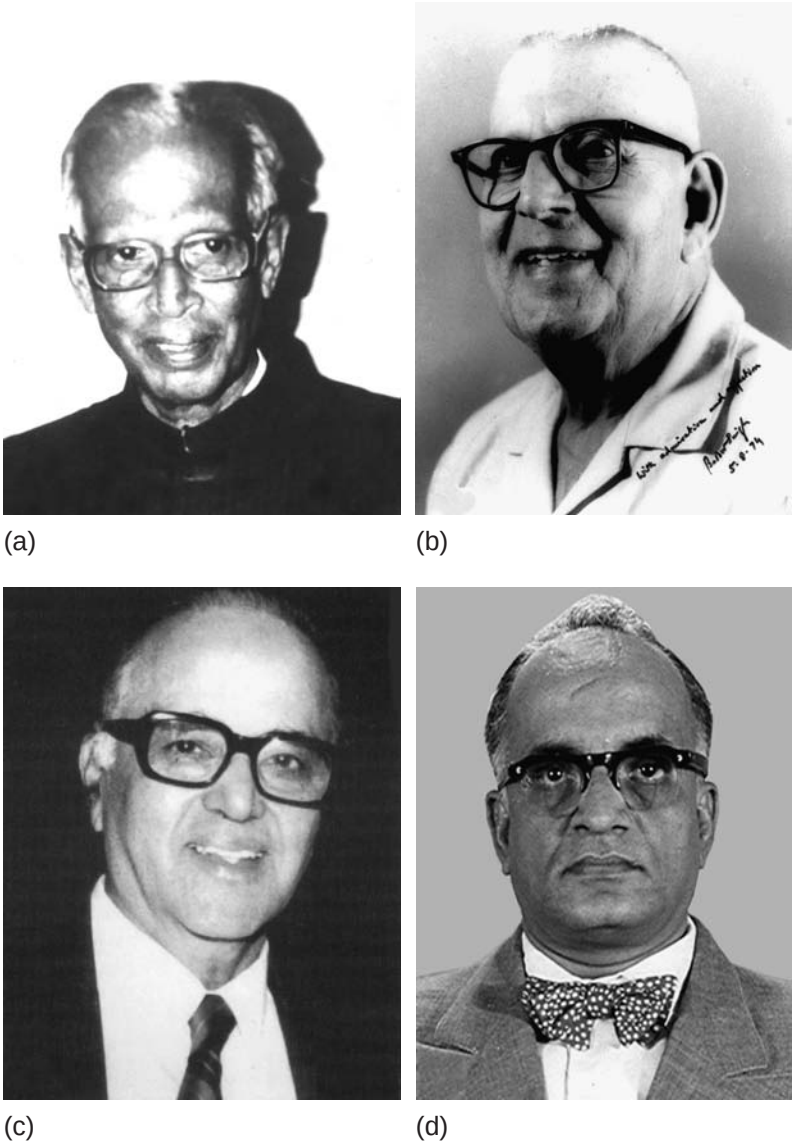

Figure 16b.1 The pioneers who contributed to early development of epilepsy surgery in India. (a) Professor Jacob Chandy (1910–2007). (b) Professor Baldev Singh (1904–1998). (c) Professor B. Ramamurthi (1922–2003). (d) Dr. T. S. Narasimhan (1913–1959).

lobe, 23 (16%) had extratemporal, and 16 (11%) had multifocal seizures.[11] The surgical procedures undertaken for TLE were lesionectomy (28 patients), temporal lobectomy with amygdalotomy (25 patients), temporal lobectomy with amygdalotomy and hippocampectomy (10 patients), amygdalotomy alone (15 patients), and lesionectomy with amygdalotomy in one case. For extratemporal epilepsies, lesionectomy was done in 24 patients and lobectomy for 2 patients. For multififocal epilepsy, 12 hemispherectomies and 4 stereotactic anosotomies were performed. The overall outcome was assessed as total or near total seizure control in 53% of patients and a worthwhile improvement in 20% of patients.[11]

In the mid-sixties, functional neurosurgery was established in the Institute of Neurology, Madras and stereotactic procedures for focal and generalized seizures were practiced.[5] Stereotactic lesions were made in the amygdalohippocampal region for TLE and in the central medial nucleus of the thalamus, the field of Forel, and in the internal capsule for generalized seizures and infantile spasms.[8–10]

The decline

In the mid-seventies, epilepsy surgery took a dramatic downward trend in the country. Thus, 100 out of the 102 patients with intractable TLE operated on at Christian Medical College, Vellore, until 1990,[11] were performed before 1980.[7] The retirement from active service of Chandy and Ramamurthi from the centers they almost single-handedly developed, less than expected post-operative seizure outcome, availability of more effective antiepileptic drugs, and stigma associated with epilepsy surgery due to its mistaken identity with psychosurgery collectively contributed to this decline.

The resurgence

The recognition in the 1990s that a majority of patients with medically refractory partial seizures have surgically remediable lesions that can be identified by relatively simple non-invasive studies such as magnetic resonance imaging (MRI) and scalp recorded interictal and ictal EEG has resulted in the evolution

of epilepsy surgery programs in developing countries with results comparable to that of developed countries.[12,13] A recent survey revealed that, in 26 of 142 (18.3%) developing nations, at least one center regularly conducted epilepsy surgery.[14] One of the authors (KR) returned to India in 1994 after having had training at the Epilepsy Program, Mayo Clinic, Rochester, MN and developed the R. Madhavan Nayar Center for Comprehensive Epilepsy Care at the Sree Chitra Tirunal Institute for Medical Sciences and Technology, a tertiary referral center, situated at Trivandrum, the capital city of the South Indian state of Kerala.[15] Since mid-1995, this center has undertaken, on average, 66 epilepsy surgeries per year. Almost simultaneously, epilepsy surgery programs were started at the All India Institute of Medical Sciences, New Delhi, and National Institute of Mental Health and Neurosciences, Bangalore. During the last decade, these three centers together have undertaken nearly 1000 epilepsy surgeries, which is five times more than the epilepsy surgeries performed in India during the previous four and half decades.

Present state

The success of epilepsy surgery is dependent upon the early identification of potential surgical candidates, and selecting from them, ideal candidates destined to have a postoperative seizure-free outcome.[16] Two basic requirements must be fulfilled before an epilepsy surgery program can be introduced in any geographical region: existence of a level of medical infrastructure to identify epilepsy patients with medical refractoriness, and a comprehensive epilepsy care organization where such patients can be subjected to a multidisciplinary evaluation to decide about surgical candidacy.

There are only about 800 neurologists for the 5–10 million persons with epilepsy in India. While 70% of the people with epilepsy in India reside in rural areas, almost all the neurologists practice in urban areas.[17] A majority of patients with epilepsy in India and other developing countries are therefore treated and followed-up by primary- and secondary-care physicians, who have little knowledge about the recent trends in the management of epilepsies. To many of them, epilepsy is still an incurable chronic disorder. Epilepsy clinics in a developing country set-up have to cater to a large number of patients with very limited skilled personnel. Overcrowding with patients and the consequent overburdening of the service providers, make time available for clinical assessment of individual patients very limited.[18] A frequent difficulty encountered in identifying medical refractoriness among patients with chronic epilepsy in developing countries is that, although many drugs have been used, none were given for sufficiently long periods and in adequate dosages, either alone or in proper combinations.[19] These factors contribute to considerable delay in the identification of prospective surgical candidates.

Epilepsy surgery centers in developing countries will lack the full range of state-of-the-art technologies such as single photon emission tomography (SPECT), positron emission tomography (PET), and magnetoencephalography usually available in centers in the developed world to perform non-invasive presurgical evaluation.[20] In India, patients or their families will have to bear the cost of epilepsy care. Although the total direct cost of presurgical evaluation and surgery in developing countries amounts to a small fraction of the cost incurred in the Industrialized World, this expenditure is beyond the reach of the majority.[21] Very few patients in India can afford the cost of intracranial electrodes used for invasive evaluation. In order to become cost-effective, epilepsy surgery centers in developing countries will have to achieve excellent results by selecting candidates destined to have a seizure-free outcome using locally available limited technology and expertise, without compromising on patient safety.[21] Because of these reasons, the process of selection of patients for epilepsy surgery in India to some extent differs from that of developed countries.

Patients with medical refractory epilepsy belong to different categories depending upon the degree of complexity involved in presurgical evaluation and the post-operative seizure outcome.[22] The prototype of a surgically remediable syndrome is mesial TLE with hippocampal sclerosis (MTLE-HS), which constitutes more than half of those patients with medically refractory epilepsy worldwide.[23] Non-invasive evaluation utilizing history, high resolution MRI, scalp video-EEG, and neuropsychological findings can identify patients with mesial temporal lobe epilepsy and those with other circumscribed, potentially epileptogenic lesions, 70–90% of whom become seizure-free following resective surgery.[16,24] Selected mesial temporal lobe epilepsy patients with consistent unilateral temporal interictal epileptiform abnormalities may not even require ictal video-EEG recordings.[25] Patients with large epileptogenic lesions involving primarily one hemisphere, and those with diffuse epileptic encephalopathies and multifocal disease can be selected for functional hemispherectomy or hemispherotomy and corpus callosotomy, respectively, based on non-invasive data.[22] Patients with extratemporal partial seizures, disorders of cortical development, and those with normal MRI will require extensive, sometimes repetitive studies with PET, SPECT, and intracranial electrode placement, which escalate enormously the cost of presurgical evaluation.[20] Even with these expensive evaluations, in this group of patients, the postoperative outcome is often not favorable.[26,27] A stepwise approach by initially operating on best outcome patients and reserving more difficult to treat patients to a later date as experience develops will help each center to understand its capabilities and limitations and to move forward.[21]

As detailed below, in evolving the most productive epilepsy surgery program in India today, the R. Madhavan Nayar Center for Comprehensive Epilepsy Care, Trivandum, has given due emphasis to address the above special issues relevant to epilepsy care in developing countries.

R. Madhavan Nayar Center for Comprehensive Epilepsy Care, Trivandum

The center is named after the late R. Madhavan Nayar, a pioneering industrialist of Kerala, who donated a generous sum of money to start a comprehensive epilepsy care program.[15] Three neurologists, two neurosurgeons, two neuroradiologists, a psychologist, a psychiatrist, and a medical social worker spend 25–50% of their working time with the epilepsy program. A three-patient video-EEG monitoring facility performs on an average 300 long-term monitoring studies

annually. A facility to do functional studies, spectroscopy, and T2 relaxometry was added recently to the 1.5 Tesla MRI already available.

Patients are classified according to their income into four categories; while the poorest group (~15% of patients) receives totally free treatment, the richest group (~30%) will have to bear the total hospital charges, and the intermediate groups pays 50–75% of the incurred actual cost. The center is sustained by the income generated through patient charges and by the financial support received from the Government of India for caring for the underprivileged. In addition, a local patient organization, Epilepsy Self Help Group, chips in with financial assistance for the needy through the donations it receives.[15]

The first epilepsy surgery (anterior temporal lobectomy with amygdalohippocampectomy) at the R. Madhavan Nayar Center for Comprehensive Epilepsy Care was undertaken on March 20, 1995. The patient was a 25-year-old gentleman with left mesial temporal sclerosis and medically refractory complex partial seizures. The important milestones of the surgical program and the break up of 706 epilepsy surgeries performed upto December 31, 2005 are provided in Tables 16b.1 and 16b.2, respectively. prior to September 2001, all the candidates were selected by non-invasive protocol utilizing history, clinical examination, interictal and ictal scalp EEG, high resolution MRI, and neuropsychological evaluation data, and all surgeries were done under general anesthesia. Nearly 90% of the patients operated during this period had MTLE-HS or MRI identified other focal lesions not adjacent to eloquent areas. Sphenoidal electrodes were inserted during long-term video-EEG monitoring of patients with suspected TLE only when initial scalp recorded ictal EEG pattern is poorly visualized or contaminated by movement artifacts.[28] Wada test was undertaken only in those patients in whom dominant extended temporal lobe resection is planned and in whom neuropsychological testing has revealed bilateral or discordant memory dysfunction. Even in patients with apparent TLE and normal MRI, careful analysis of the non-invasive data could identify favorable surgical candidates.[29] Such strategies prevented unnecessary escalation of the cost of temporal lobe epilepsy surgery. The non-invasive presurgical evaluation data of every patient is thoroughly discussed in the weekly patient management conference to collectively decide about surgical candidacy and to decide about further evaluation strategy in those with discordant features (Figure 16b.2).

Table 16b.1 Major milestones of the R. Madhavan Nayar Center for Comprehensive Epilepsy Care, Trivandrum

1st epilepsy surgery	March 20, 1995
100th epilepsy surgery	October 28, 1997
200th epilepsy surgery	April 22, 1999
300th epilepsy surgery	October 5, 2000
400th epilepsy surgery	March 25, 2002
500th epilepsy surgery	August 1, 2003
600th epilepsy surgery	September 24, 2004
700th epilepsy surgery	November 24, 2005

Table 16b.2 Epilepsy surgeries undertaken at the R. Madhavan Nayar Center for Comprehensive Epilepsy Care, Trivandrum from March 1995 through December 2005

Procedure	No.
Temporal lobe resections	588
Extratemporal resections	70
Corpus callosotomy	18
Hemispherectomy/hemispherotomy	30
Total	706

With the experience gained through the initial five years, intraoperative ECoG, subdural and depth electrode placements, and intraoperative and extraoperative cortical stimulation and mapping was started in 2001. These procedures have helped us to select patients whose epileptogenic zone could not be localized by non-invasive means and those with lesions such as malformations of cortical development close to eloquent areas. The R. Madhavan Nayar Center for Comprehensive Epilepsy Care is presently the only center in the country performing invasive presurgical evaluation. Upto December 31, 2005, 18 patients underwent long-term monitoring with bilateral temporal depth electrodes and 25 patients with subdural grid and strip electrodes placements. The Wada test is being replaced by functional MRI. During the last year, more restricted resective procedures such as selective amygdalohippocampectomy through subtemporal approach were being increasingly undertaken. Functional hemispherotomy is preferred to hemispherectomy for extensive unihemispherical lesions.

The step-wise evolution of the epilepsy surgery program at the R. Madhavan Nayar Center for Comprehensive Epilepsy Care as outlined above is illustrated through some case scenarios in Figure 16b.3.

Out of 351 patients with MTLE-HS operated on between March 1995 and March 2002 and have completed 2 years or more of post-operative follow-up, 286 (81.5%) are seizure-free, and 132 (37.7%) of them have been completely weaned off the antiepileptic drugs. During the median follow-up period of 4 years following surgery, out of 34 patients with tumoral TLE, 27 (79%) achieved a completely seizure-free state. Out of 46 patients with lesional extratemporal lobe epilepsies, 25 (55.6%) were seizure free during a median post-surgery follow-up of 4 years. Of the 6 patients operated for hypothalamic hamartoma through a transcallosal interforniceal approach, two were completely seizure free and three had more than 75% reduction of the seizures. Out of the 21 patients who completed ≥1 year of follow up following hemispherectomy/hemispherotomy, 18 patients (90%) became seizure free and 2 patients had more than 75% seizure freedom.

One patient died a few hours following an uneventful anterior temporal lobectomy, the cause of which remained obscure. Three patients, following anterior temporal lobectomy, developed disabling hemiplegia due to vascular injury. An abscess at the site of an intracranial grid electrode occurred in one patient, who made a recovery without sequel following

surgical drainage and antibiotic therapy. The rest of the complications were either minor or transient.

Other epilepsy surgery centers

The All India Institute of Medical Sciences, New Delhi has undertaken 273 epilepsy surgeries from April 1995 through December 2005, the break-up of which is given in Table 16b.3. Among the 121 patients operated for refractory epilepsy at the National Institute of Mental Health and Neurosciences, Bangalore, between 1998 and December 2005, 90 had anterior temporal lobectomy, 30 had lesionectomy, and 1 had corpus callosotomy. Detailed post-operative outcome data from these centers are not yet available, although preliminary results are comparable to those from the R. Madhavan Nayar Center for Comprehensive Epilepsy Care, Trivandrum.[30,31] The following centers in India have performed less than 50 epilepsy surgeries, during the last five years, Nizam's Institute of Medical Sciences, Hyderabad, CARE Hospital, Hyderabad, KEM Hospital, Mumbai, Jaslok Hospital, Mumbai, Poona Neurological Institute, Poona, Jahanghir Hospital, Poona, Postgraduate Institute of Medical Education and Research, Chandigarh, and Lourdes Hospital, Kochi. The National Hospital, Colombo, Sri Lanka has a very successful epilepsy surgery program and has offered surgery to nearly 60 patients in the last 3 years. The R Madhavan Nayar Center for Comprehensive Epilepsy Care, Trivandrum has actively participated in the development of the Sri Lankan program.

Future perspectives

In India, with over one billion inhabitants, there are approximately one million persons with medically refractory epilepsy; among them as many as one-quarter to one-half are potential surgical candidates. However, no more than 150 epilepsy surgeries are currently being performed per year in India. Thus, only a minuscule of potential surgical candidates in India and other developing countries ever get a chance to undergo presurgical evaluation. The lack of availability and affordability has resulted in an enormous gap in developing countries between number of patients who could be benefited from epilepsy surgery and those who actually receive this treatment, which can only be minimized by developing more centers in the country, where epilepsy surgery can be undertaken.

The out-of-pocket payment for epilepsy surgery (including non-invasive presurgical evaluation) at the R. Madhavan Nayar Center for Comprehensive Epilepsy Care is Rs. 50,000 (US$1200).[21] With invasive evaluation the cost would escalate to two to threefold of this amount. The computed direct total cost for caring a patient with refractory temporal lobe epilepsy from age 26 to 60 years works out to be Rs. 200,000 (US$5000).[21] The results from R. Madhavan Nayar Center for Comprehensive Epilepsy Care, Trivandrum and other epilepsy surgery centers in India show that over 70% of patients will be seizure-free following surgery for temporal lobe epilepsy, and there is a 30% chance that they will be

completely off antiepileptic drugs within 2 years following surgery.[12,30] Even with new antiepileptic drugs, complete seizure freedom occurs in only less than 10% of temporal lobe epilepsy patients.[32] A seizure-free person could be better employed, achieve an improved quality of life, and often becomes a productive member of society. Therefore, surgical treatment of refractory temporal lobe epilepsy is definitely a better cost-effective option than continued medical treatment even in developing countries. Epilepsy centers in developing countries could effectively use these statistics to obtain governmental subsidies and non-governmental financial supports for implementing and sustaining epilepsy surgery programs.

Conclusions

In order to become cost-effective, epilepsy surgery centers in India will have to achieve excellent results by selecting candidates destined to have a seizure-free outcome using locally available limited technology and expertise, without compromising on patient safety. The recent experience from epilepsy

surgery centers in India illustrates that this goal can be accomplished by selecting patients whose epileptogenic zone can be unquestionably established, based on history, high resolution MRI, and interictal and ictal scalp EEG findings such as those with MTLE-HS, and those with circumscribed potentially epileptogenic lesions. A stepwise approach by reserving more difficult to treat patients at a later date as experience develops, or by referring them to a better-equipped center, will help each center to understand its capabilities and limitations and to move forward. It is encouraging to note that, despite major challenges, in the last decade, several epilepsy centers in India have not only successfully implemented epilepsy surgery programs, but have also produced results comparable to that from developed countries at a fractional cost.

17 Treatment of epilepsy in Australia

A Mohamed

Introduction

Despite a relatively small population, Australia is the sixth largest nation in area following Russia, Canada, China, the United States of America, and Brazil. It is a very dry continent with most of the population living in its coastal margins. It is a federation of six states and two territories. The largest state, Western Australia, is about the same size as Western Europe.

Over 60,000 years before the arrival of European settlers in 1788, Aboriginal and Torres Strait Islander peoples inhabited most areas of the Australian continent. There were an estimated 300,000 Indigenous Australians living on the continent. Today, the population of Australia is slightly over 20 million and concentrated in large cities around the coast (Table 17.1).

Epilepsy and illness in the indigenous population

Aboriginal groups prior to European settlement were traditional hunter and gatherer communities and had enviable health in terms of nutrition and leisure. They lived in small closed groups of kin. The population numbers depended on availability of water and other essential resources. These groups followed up a more or less nomadic lifestyle. Most aboriginal groups were spread sparsely over the continent that mitigated against the spread of disease. These small groups followed a seasonal pattern of movement within a defined territory to which they had spiritual ties. Periodically, they would congregate in large numbers for ceremonial purposes or seasonal abundance of some food store at a particular site.[1]

In aboriginal culture prior to European settlement, sorcery or black magic provided an explanation of illness, pain, or death where the cause was not known or obvious. The explanations were always personal or spiritual. Someone or some spiritual powers performed black magic on the victim because of animosity or because the victim had broken a taboo. Aboriginal healers were able either to restore health or at least the group, via sorcery, could retain equilibrium. Not to know the cause of the illness or death was a disturbing factor in the psychological and social life of the group – therefore an acceptable explanation was necessary to enable the community to readjust itself to the events and go about its business.[2] The sick were kept tranquil in a familiar environment with their own people about them hearing familiar voices and passed away in peace with their own kind when death was upon them.[1]

The aboriginal healer symbolically extracted a bone, quartz, or other stone from the patient's body or would bring back the wandering soul through rituals, and all was well. If the patient could not be healed, both the patient and group would prepare for death. The patient was also in a condition of high suggestibility and was ready to realize the idea suggested by the aboriginal healer. If told that he was healed, he would be reassured and prepare for improvement. Likewise, if a doctor suggested that death was inevitable, the patient would think of the spirits of the departed, turn his face to the wall, and prepare for death.[2]

There is no evidence that aboriginal culture placed a premium on abnormality or the epileptic. There was no reverence for epileptic patients as found in other cultures.[2]

Aboriginal medicine men, far from being charlatans, were men of high degree and had degrees in the secret of life beyond that taken by most adults. This required discipline, mental training, courage and confidence. Their positions commanded respect, and they were men of outstanding personality. In addition, the psychological health of the group largely depended on their powers, and they specialized in the working of the human mind.[2]

Despite some notable improvements in the past 20 years, the health status of aboriginal people remains of great concern. They carry a double burden of disease – not only disease of poverty but increasingly disease characteristic of a Western lifestyle. Leading causes of death includes cardiorespiratory diseases, accidents and to moving trauma, suicide, violence, and cancer.[1] Incidence of epilepsy existing in the Aboriginal community is at least of the same proportion as the rest of Australia (1–2%). However this is probably an underestimate due to lifestyle factors such as alcoholism, substance abuse, and injury.

History of epilepsy in Australia after European settlement

The early history of the treatment of epilepsy in Australia closely followed the path paved in the UK because of the close relationship between the two countries. Australia's geographical isolation and low population density were compensated for by a tradition of overseas travel by doctors to undertake postgraduate studies in Europe.

As with many European countries, during the 19th century, it was customary for epileptics to be institutionalized as they were thought as unfit to be at large. Epilepsy was thought to be a precursor of insanity. Many with brain disorders were institutionalized in prisons side-by-side with felons. In early Australian European settlements, the incidence of epilepsy in the prison population varied from 7 to 13%.[3] The conditions in the prisons were grim and poor and it was not until later in

the 19th century where most people with epilepsy were managed in asylums for the mentally ill.[3]

Towards the end of the 19th century, in the two large colonies of the time, New South Wales and Victoria, the decision was made to manage epileptics in institutions for the mentally ill.[3,4] The very first asylum was created in 1811 in Castle Hill in the outskirts of Sydney. The second asylum outside New South Wales opened in 1848 at Yarra Bend in Victoria, although many sufferers were still managed at home by family and local doctors.[5] Poverty, strained family relationships, and unemployment often played in large part in incarceration of these patients. Conditions in these asylums were very poor. Many of these patients suffered from a large number of physical illnesses including tuberculosis.[6] In Sydney, patients in one institution (Galdesville Hospital) were dying from typhoid and infectious diseases due to inadequate sewerage.[4]

Early in the 20th century, there was a shift of attitudes that allowed the liberation of epileptics to asylums. This change in attitude together with campaigns by medical practitioners and activists led to a number of government inquiries[4] that in turn led to the development of epileptic colonies in Sydney and Melbourne. In Sydney, moral therapists spearheaded these reforms. Work was created for epileptics and seen as a therapeutic instrument.[3] Attendance of church was encouraged and libraries and newspapers were furnished for the patients.

Prior to Hughlings Jackson's postulate that epilepsy was disease of the cortex, a variety of causes were hypothesized for seizures. These included alcohol, worms, anxiety, and masturbation.[3] In the late 18th century, medical treatments of epilepsy in Australia included:[3]

- Quiet rest, the feet placed in hot water and mustard bath
- Shaving of the scalp
- Mustard plaster to the back of the head
- Cooling of the head by a mixture of spirit of vinegar and water
- Bleeding in letting five fluid ounces of blood at a time
- Leeches to the temples
- Blister to the nape of the neck
- Use of prolonged chloroform anaesthesia
- Morphia
- Bromides introduced by Dr. Smith in 1873
- Blistering where local limb auras occurred.

At this time the treatment for epilepsy in the USA included bromides, arsenic, quinine, cod liver oil, iron, and hysterectomies.[7]

The concept of epilepsy as a disease of the cortex was introduced to Australia in a paper in 1886 by John Springthorpe.[8] He also recommended a systematic approach to treatment. This included removal of any irritants: bromides, zinc oxide, belladonna, atropine, cannabis, digitalis, and a Seton tie at the back of the neck. The Seton tie was a silk or cotton twine that was inserted through a large flap of skin and left there until a chronic running sore was created with drainage of pus from around the seton.[9]

The surgical treatment of epilepsy was first detailed by Dr. John Maund[10] in 1856 and later by Dr. Poulton in 1890.[11] In 1856 a patient with post-traumatic epilepsy who had an old depressed skull fracture and had failed medical therapy was treated successfully with trephining and removal of the bone at the side of the fracture – this occurred prior to the introduction of antiseptic techniques in cranial surgery by Horsely in 1880s.[3]

The beginnings of epilepsy surgery in Australia

Peter Bladin created the first epilepsy center in 1969 at the Austin Hospital in Melbourne. This was a nationwide service that provided the first comprehensive epilepsy program in Australia. Between 1969 and 1991 this program performed over 200 temporal lobectomies for refractory epilepsy.[12] In the late 1970s and early 1980s epilepsy centers were also established in three other Melbourne hospitals.

In the early 1970s in Sydney, a lavishly equipped and staffed Brain Research Institute at Rozelle Hospital was established, where psychiatrists, neurologists, and neurosurgeons worked together to select patients for psychosurgery. Part of the work-up involved the insertion, under stereotactic guidance, of recording electrodes into the hippocampus and amygdala. They were particularly interested in rage attacks, and whether these were due to epileptic activity in the amygdala. In the late 1970s there was public disquiet over such surgery (Figure 17.1). A royal commission was called that led to the shut down of this unit. The first comprehensive epilepsy center in Sydney was established in 1977 in Royal Prince Alfred Hospital[13] (Figure 17.2) with centers at Prince Henry

and Westmead Hospitals being established soon after. Between the years 1990 and 1997, 226 temporal lobectomies and 40 extra temporal lobe surgeries were performed at the three adult epilepsy centers in Sydney (personal communication).

Epilepsy surgery for refractory epilepsy in children were first performed at The Royal Children's Hospital in Melbourne in 1979 and in Sydney in 1988. An epilepsy surgery center was established in Western Australia in 1989 and by 2002, 122 patients were assessed for surgery.

Conclusion

There is little known of the treatment of epilepsy by the aboriginal population prior to European settlement.

(a)

(b)

Figure 17.2 Epilepsy monitoring unit at Royal Prince Alfred Hospital in 1990.

However, various sources suggest that the aboriginal had good health and a spiritualistic approach to illness. The treatment of epilepsy in Australia after 1788 paralleled that seen in Europe and in particular in the UK due to the close ties between the two countries. Epilepsy surgery, first pioneered in Melbourne, has become available at a number of epilepsy centers in a country with a large geographical area, and its population concentrated in large coastal cities.

18 Epilepsy surgery in Korea

BI Lee

Traditional oriental medicine

Historically, Korean traditional medicine largely adopted the Chinese medicine since its beginning about 5,000 years ago. 'Fifty-two Diseases', the earliest Chinese medical record written 3,000 years ago, described symptoms of epilepsy and its treatment consisting of 'repeat bathing with fluid containing a brain pill' called '腦 丸藥(腦: brain, 丸: tablet, 藥: drug)'. This indicated that ancient Chinese doctors had already known that epilepsy was originating from the brain. Despite their clear insight on the origin of epilepsy there has been no record describing any surgical treatment of epilepsy throughout the prolonged history of Chinese medicine. The major treatment modality of epilepsy in Chinese medicine consisted of various prescriptions using herbs, minerals, and materials from animals, and various procedures such as acupunctures, massages, and moxacautery. In the early 16th century, Dr. Joon Huh, the father of Korean traditional medicine, wrote a book called '東醫 寶鑑 (東: east, 醫: medicine, 寶: gems, 鑑: book)', which had summarized his clinical experiences as well as previous medical knowledge available in Korean and Chinese medical literature. He classified epilepsy into eight types based on charateristic symptoms, age of onset, and the traditional concept of etiopathogenesis. The book, which is still regarded as the textbook of Korean traditional doctors, has described more than 300 prescriptions and various procedures applicable to different types of seizures but none for the surgical treatment of epilepsies.[1]

Era of Western medicine

Western medicine was first introduced by Dr. H.N. Allen (Figure 18.1) in 1884, who was the medical missionary from the North Presbyterian Denomination. He built a Royal Hospital called '濟衆院' (House of Universal Helpfulness, Figure 18.2) in 1885 by the sponsorship of King Kojong of Lee Dynasty. which was the first hospital practicing western medicine in Korea. In 1886, Dr. Allen started his medical education which was succeeded by Dr. Avison. He was the first principal of 濟衆院醫學校 (Chejungwon Medical School) and trained several assistant students. Among these, seven students had graduated in 1908 who were the first Korean medical doctors. In 1900, Mr. Severance in Cleveland, Ohio, donated $15,000 for the construction of a modern medical school and hospital which was opened in 1904 (Figure 18.3). The new medical complex was named the Severance Hospital and Medical School in memory of his generous contribution. In 1959, Severance Medical School was united with Yonhee University to form Yonsei University.[2] Korea was colonized by Japan from 1910 to 1945 and the Korean War occurred from 1950 to 1953. During the period, Korean society was seriously abandoned and most post-war medical activities were heavily dependent upon US aid. The modern medical management of epilepsy was initiated by Dr. L. Robinson (Figure 18.4) who was also an American medical missionary. She treated a girl suffering from epilepsy with phenytoin in 1963 and organized a mobile epilepsy clinic in association with Korean neurosurgeons and psychiatrists in 1964. These activities generated great hope among many patients and their families to organize the 'Rose Club', which did take initiatives of social movement as well as medical care for epilepsy. The rising phase of the Rose Club reached its peak during the 1970s and the first International Bureau Workshop for Epilepsy was held in the Severance Hospital on December, 1974. The Rose Club had grown to a huge social organization holding approximately 100,000 patients and their families and became a local chapter of IBE in 1979. Starting from 1980, the Korean economy had risen rapidly and most antiepileptic drugs became widely available in community hospitals. During this transitional period, the epilepsy care in Korea has gradually shifted from the Rose Club to community hospitals and the activities of the Rose club had gradually transformed into that of a lay

people's organization. In 1982, the Korean Neurology Association was established to start a nationwide training program of neurology residents. In 1988, an epilepsy clinic was opened at Yonsei University Medical Center (Severance Hospital), which was the beginning of a specialized program for the care of epilepsy in Korea. In 1996, the Korean Epilepsy Society was organized and the major part of the Rose Club became the Korean Epilepsy Association, which has greatly promoted the quality of epilepsy care in Korea.

Era of epilepsy surgery

Dr. C.K. Lee (Figure 18.5), a neurosurgeon who had a postdoctoral training at the Montreal Neurological Institute in Canada, started epilepsy surgery from 1966 and published his surgical experiences of 51 cases suffering from intractable epilepsies in 1972.[3] His surgical technique was the electrocoagulation of the preoccipital cortex. He considered that the preoccipital cortex was the main pathway of spreading ictal discharges and its interruption by electrocoagulation should be beneficial for the amelioration of seizures. He recorded electrocorticography (ECoG) before the electrocoagulation and observed its change after intracortical injection of procainamide to predict surgical outcome (Figure 18.6). Among 51 patients, 3 patients became seizure free and 26 patients achieved a significant improvement after the procedure. In 1980, Dr. D.S. Chung and his colleagues at Catholic University started epilepsy surgery and published their surgical experience consisting of seven cases of corpus callosotomy and eight cases of selective amygdalohippocampectomy in 1989.[4] Nine patients showed significant improvement and none got worse. In this series, they did not perform any dedicated presurgical evaluations but their surgery was undertaken on the basis of clinical judgment, routine scalp EEG, and CT scan. The modern epilepsy surgery program employing the protocol of advanced presurgical evaluation was initiated at the Severance Hospital of Yonsei University Medical

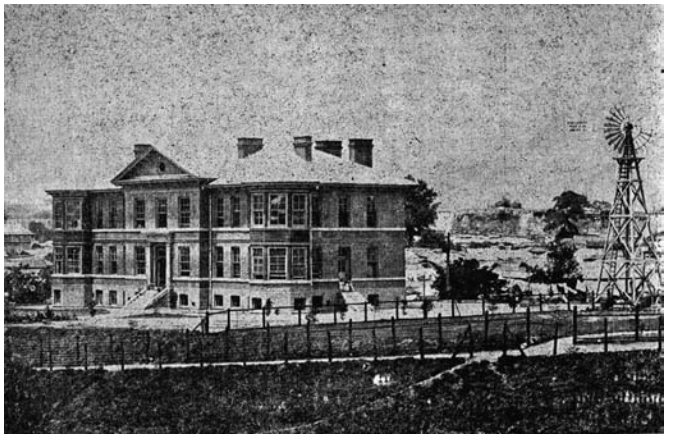

Figure 18.3 Severance Hospital and Medical School in 1904, which was built with the generous donation of Mr. Severance in Cleveland, Ohio. This building was located in Do-dong, Seoul. In 1995, this building was replaced by a 20-storey office building (Yonsei Severance Building) for the purpose of finacially supporting Yonsei University.

Baseline electocorticogram of a patient showing multiple spikes at both preoccipital (leads 1, 2 and 3) and motor (leads 4, 5 and 6) areas (a) electrocorticograms showed no suppression of epileptiform discharges from the preoccipital region during (b) and after (c) procainization of the motor cortex. Electrocorticograms from the motor cortex showed the clear response during (d) and after (e) the procainization of the preoccipital cortex.

Center in 1988 by Dr. B.I. Lee and K. Huh who had returned to Korea after their completion of training in neurology (University of Minnesota) and epileptology (Cleveland Clinic and University of Georgia) in the USA. In the early 1990s many young neurologists and neurosurgeons with an interest in epilepsy surgery started to have fellowship trainings abroad and established surgery programs in major university hospitals upon their return to Korea.

Current status of epilepsy surgery

With the opening of a specialized epilepsy care program at Yonsei University Medical Center in 1988, epilepsy sugery has become rapidly recognized as an effective therapeutic measure for patients suffering from medically intractable epilepsies. In addition, the wide availability of MRI and EEG telemetry systems encouraged the organization of surgery programs in major university hospitals in Korea. During the late 1990s, 12 centers performed about 500 cases of epilepsy surgery annually and their surgical experiences started to appear in international epilepsy journals. However, the flourishing activities of many surgical centers had gradually declined from the year 2000, largely relating to the emergence of failure cases, shortage of patients requiring only basic presurgical evaluations, tough competitions among centers, and financial restrictions of presurgical evaluations imposed by National Health Insurance. As PET, SYSCOM, and advanced MR

technologies became available in the late 1990s, advanced imaging technologies became the forerunner of interhospital competitions and centers not equipped with these facilities faced great restrictions in their activities to close their surgical programs. At present, seven centers are mantaining their surgical activities and the number of surgical cases has diminished to around 350 cases per year (Table 18.1). Compared to the gradual decrease in the number of resective surgeries, there has been a trend to increase implant of vagus nerve stimulation (VNS) for its simplicity, safety, and broad indications as well as its coverage by National Health Insurance. Deep brain stimulations (DBS) is also applied in a few centers despite its experimental stage of develop-ment. Magnetoencephalography (MEG) has become available recently.

19 Epilepsy surgery in Thailand

T Srikijvilaikul, C Locharernkul, and A Boongird

The history of epilepsy surgery in Thailand can be divided into the era before and after 1990. Before 1990 was the time of modern neurosurgery establishment by Thai pioneer neurosurgeons. After 1990, advanced epilepsy surgery has been established in Thailand in parallel with the development of a comprehensive epilepsy program with standard and state-of-the-art clinical practice.

History of epilepsy surgery in Thailand before 1990s

Modern neurosurgery in Thailand began after a number of neurosurgeons returned from formal training in the USA in the late 1960s and established neurosurgical services at Siriraj and Chulalongkorn hospitals, the first two medical schools in Thailand. Pioneers on epilepsy surgery in the country were distinguished neurosurgeons, namely Professor Sira Bunyaratavej and Professor Charas Suwanwela.

Due to the lack of computer technology and advanced imaging at that time, localization mainly relied upon clinical information, namely detailed history taking, highly precise neurological examination (Figure 19.1) and surface electroencephalogram (EEG) (Figure 19.2). Early imaging included skull series, scintigraphy or isotope brain scan, cerebral angiography, pneumoencephalograhy, and after the mid-1970s, computerized tomography (CT). The surgical outcomes varied among patients. Surgical treatment of epilepsy was mainly resection of structural lesions causing seizures such as tumors, abscesses, vascular malformations, and depressed skull fracture scars. However, a few operations for intractable epilepsy were also performed. Hemispherectomy for a Sturge–Weber patient was first done by Professor Sira Bunyaratavej in 1966 (Bunyaratavej S, personal communication). Stereotactic amygdalotomy was performed in a case of temporal lobe epilepsy by Professor Charas Suwanwela in 1977 (Suwanwela C, operative record).

At King Chulalongkorn Memorial Hospital, modern surgery of the brain was first established in 1963 by Professor Charas Suwanwela. Granted by the prestigious Anandamahidol Foundation under His Majesty King Bhumibol Adulyadej of Thailand, he finished his neurosurgical residency training from North Carolina and certified American Board of Neurological Surgery in 1961. He began modern neurosurgical therapy for Thai people at the Bangkok Bank Building (Figure 19.3). Early brain surgeries regarding epilepsy were mainly surgical removal of intracranial space occupying lesions producing seizures as well as other neurological symptoms. However, the number of brain operations directed toward the correction of epileptic seizures was modestly reported.

There were at least three patients who received cicatrectomy for their long-standing epilepsy. Two cases had refractory seizures from undiagnosed depressed skull fractures long after their head injuries. One of the two was a hospital worker who had become seizure free after the cortical scar was completely removed and with antiepileptic drugs maintained. Another patient suffered from a brain abscess close to the motor area. Intractable epilepsy developed one year after the abscess was drained.[1] After the fibrous wall of the healed abscess was removed, his seizures were abolished without any post-operative neurological deficit.

One hemispherectomy was performed on 13 November, 1989 by Professor Charas Suwanwela on a patient with cerebral hemiatrophy (Davidoff–Dyke syndrome) (Suwanwela C, personal communication). A 9-year-old boy suffered from very frequent desperate seizures and mental deterioration. Left hemiatrophic limbs with good motor powers were noted on examination. His CT scan revealed small right hemicranium with dilated ventricles. After one year of unsuccessful antiepileptic drug therapy, modified anatomical hemispherectomy was performed on the right cerebral hemisphere. Post-operatively, his seizures decreased significantly to 1–2 attacks per month resulting in much relief of his caregivers. Although left-sided hemiparesis was acquired from surgery and a wheelchair was

Figure 19.1 Professor Charas Suwanwela, a distinguished physician of early modern neurosurgery in Thailand, performing a highly precise neurological examination on a Thai patient in the 1970s.

Figure 19.2 Professor Tongchan Hongsaladarom, a pioneer neurologist and electroencephalographer of Thailand, with the first 'Grass' paper EEG machine at EEG laboratory, Chulalongkorn University Hospital in the early 1960s.

needed, his postoperative reduction in seizures was greatly appreciated by his family. His condition has remained the same during the regular follow-up period of over 10 years.

There was a study on focal convulsions from small cortical lesions by Suwanwela C *et al.* (unpublished data). Twenty-two patients who had epileptic attacks from lesions within the cerebral cortex were analyzed. Lesions larger than 2 cm in diameter were surgically removed. Among these cases, brain abscess were found in two patients and cysticercosis in one patient. However, conservative treatment was found to be the option in most patients since periodic brain CT disclosed spontaneous resolution in many cases and cysticercosis was postulated to be the cause of these vanishing granulomas. The authors recommended observation and follow-up instead of doing resective surgery in these epileptogenic infectious lesions.

Figure 19.3 The Bangkok Bank Building, ideally designed for neurology, neurosurgery, and psychiatry services on each floor in its three-storied structure was opened in 1960. Early neurosurgery, of the 1960s to modern epilepsy surgery of the 21st century took place here in its long evolutionary history. Now the location of the Chulalongkorn Comprehensive Epilepsy Program.

Development of epilepsy surgery after the 1990s

The era of comprehensive epilepsy surgery program starts from early 1990, after a few young Thai neurologists and neurosurgeons returned from their full epilepsy trainings in distinguished western epilepsy centers. Brought back were the technical know-how in modern epilepsy presurgical evaluation, state-of-the-art in surgical techniques and their enthusiasm in relieving epilepsy burden in Thai epileptics. A group of clinicians established the first comprehensive epilepsy program under a university hospital environment in 1994 known as Chulalongkorn Comprehensive Epilepsy Program, or CCEP (Table 19.1) with the second author being the founder and the director of the program.

During this period, surgical treatment for epilepsy relied upon neurophysiologic data and advanced imagings. The first temporal lobectomy series for intractable epilepsy was introduced by Professor Sira Bunyaratavej and Professor Pongsakdi Visudhipan in July 1993.[2]

The epilepsy society of Thailand has been established by Professor Pongsakdi Visudhiphan and committee since 1996. The aim of the organization has focused on identification of surgical candidates for intractable epilepsy and educated both clinician and non-clinician workers to understand the options of epilepsy surgery and other medical aspects of epileptic patients care. This organization has consistently maintained policy and enrolled as a member of the International League Against Epilepsy (ILAE) in 1997 and the International Bureau for Epilepsy in 2004. The organization was honored to host the 5th Asian and Oceanean Epilepsy Congress in 2004.

Other than CCEP and Ramathibodi hospital, there have been other epilepsy surgery services established in Bangkok, namely the Phramongkutklao Hospital and the Prasat Neurological Institute. However, CCEP has been considered the only advanced comprehensive epilepsy surgery center in Thailand since 1994.[3,4] The details of CCEP development will be described in this chapter.

The strategies

Thailand, as a developing country, has adapted its own pattern of epilepsy surgery development. Due to its 64 millions population in 2004, with accordingly high numbers of epilepsy cases, low average income per capita, and limited resources (Human Development Index rank 74 by United Nations Development Programme's *Human Development Report 2006*), the surgical program development has aimed to serve most patients under cost-effective, sustainable, and self-sufficient economic strategies.

In order to utilize resources as effective as possible, CCEP has been developed in four progressing phases, starting from the *optimizing medical treatment phase* (phase I, 1994–1996), the *presurgical evaluation development phase* (phase II, 1997–2000), the *basic epilepsy surgery phase* (phase III, 2001–2003) to the phase of *surgery using advanced techniques* (phase IV, 2004–present). The presurgical work-up using minimal standard procedures was developed step-by-step as necessary, to reach the target of rationale and economic practices.

II (Thai) Genetic studies in Thai epileptic patients with AED allergy	2006	CCEP, King Chulalongkorn Memorial Hospital, MOPH and National Health Security Office signed MOU on development of epilepsy clinics in main hospitals throughout Thailand using CCEP as a training model, establishing online epilepsy registration and referral system for epilepsy surgery Implementation of the issue 'Epilepsy and the Law' in Thailand

* First time developed in Thailand.
† First time performed in Asia.

Only international standard presurgical and surgical techniques have been used at the CCEP. Experimental therapeutic procedures and those unproven efficacy by evidence-based reviews were not used during the program development.

The optimization of medical treatment at the initial phase has reflected pictures of inappropriate medical treatment of epilepsy long being practiced among Thai general practitioners. Among the most common examples were inadequate adjustment of antiepileptic drug (AED) types and doses to reach the maximal effectiveness (40.9%), inappropriate choice of AEDs due to unclassified seizure types (17.4%), and early AED polytherapy (10.8%). Continuing use of failed drugs was found in a small proportion (2.4%) since sub-therapeutic dosing has been acquainted in most clinical practices.[5]

After phase I, the burden of truly medically intractable epilepsy was able to be determined. At phase II when needs have been clearly realized, standard presurgical diagnostic facilities have been successively developed. The introduction of surgery for high-yield remediable syndromes at phase III has eliminated fear and doubt of this new approach among Thai epileptics. The good surgical outcomes have gained dramatic acceptance and subsequent yearning for surgery from patients all over the country. The success of surgery has also brought public attention and continuing donation to the program. When discordant cases from basic evaluations have accumulated, advanced techniques have been developed at phase IV. Epilepsy surgery dealing with incongruent cases then began using relevant high cost, invasive diagnostic or intraoperative techniques. Many epilepsy presurgical and surgical techniques developed at CCEP have been considered for the first time ever in the medical history of Thailand.

The structure

CCEP, located at Bangkok Bank Building, King Chulalongkorn Memorial Hospital, Thai Red Cross Society is run as a charitable organization under the university hospital environment. CCEP comprises multidisciplinary medical staff of the Faculty of Medicine, Chulalongkorn University. CCEP has a structure of two arms developed in parallel, namely the medical technology arm and the community arm, with one heart, i.e. the program has been privileged to be under Royal patronage.

The medical technology arm development

A specialized epilepsy clinic was first established in September 1994. The clinic provided evidence-based medical treatment for epilepsy out-patients to achieve the best seizure control and to define medically intractable cases. Subsequently, standard presurgical evaluation facilities have been developed. A well-equipped two-bed epilepsy monitoring unit (EMU) comprised of 24-hour video EEG telemetry was first established in 1997 (Figure 19.4). Special electrode placement over true anterior temporal regions according to the international 10–10 system (T9T10, FT9FT10, F9F10)[6] has been routinely used in adults since late 1997. Sphenoidal electrode placement was first performed in January 1999.

The first epilepsy case management conference for surgical selection was conducted in June 1997 followed shortly by the first CCEP epilepsy surgery. Lesionectomy for right temporal ganglioglioma was performed on 16 June, 1997 by Professor Charas Suwanwela, rendering the patient seizure free for more than 9 years and AED totally discontinued for more than 7 years.

Figure 19.4 Epilepsy monitoring unit (EMU) equipped with long-term video/EEG telemetry was established in 1997. A 128-channel digital video/EEG analogue for cortical stimulation mapping and the four-bed facility were completed in 2004.

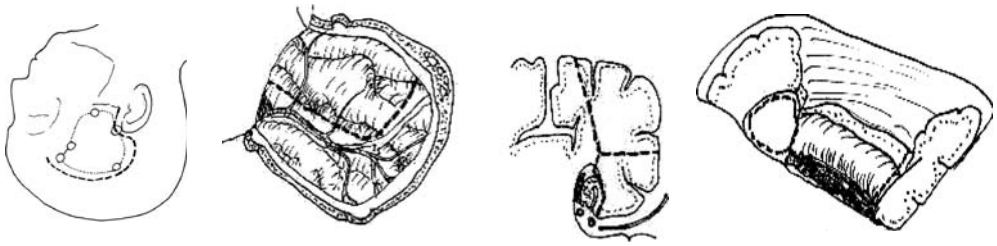

Figure 19.5 The first anterior temporal resection with amygdalo-hippocampectomy in a Thai MTLE patient (drawing by Professor Charas Suwanwela, the CCEP senior neurosurgeon, October 1999).

A 1.5 tesla high resolution MRI was first used for epilepsy in 1998.[7] Epilepsy protocol (thin cut on temporal lobes with planes parallel and perpendicular to hippocampal long axis) has been used. Fluid attenuation inversion recovery (FLAIR) technique has been added to routine epilepsy protocol since January 1999. Three-dimensional and reformatted software was developed in 2000 for detection of subtle cortical dysplasia. Magnetic resonance spectroscopy (MRS) and functional MRI (fMRI) for hand motor function were also developed in 2000.

Single photon emission tomography (SPECT) began in May 1998.[8] ^{99m}Tc-Ethyl Cysteinate Dimer (ECD) has been used for ictal and interictal injections. Ictal SPECT was limited only to official hours when ECD and scanner were available. A 3-head gamma camera scanner was first used in January 1999 which produced satisfactory high resolution images.

Thai language Wada test was invented by Tayard Desudchit *et al.*[9] Intracarotid amytal injection was, for the first time, performed to lateralize memory and speech functions in a Thai TLE patient in September 1999.

All epilepsy presurgical evaluations were completed and the first temporal lobectomy on intractable epilepsy from hippocampal sclerosis (HS) was performed at CCEP on 14 October 1999 by Professor Charas Suwanwela (Figure 19.5) which rendered the patient seizure free for over 7 years.

Surgical series that followed were the most prevalent and the most beneficial surgically remediable syndromes. These mainly included concordant temporal lobe epilepsy (TLE) with unilateral HS and localization related (focal) epilepsies from circumscribed tumors. Almost every candidate underwent the multidisciplinary presurgical evaluation and epilepsy conference. Mesial temporal lobe epilepsy (MTLE) is the most common adult epileptic syndrome operated, comprised of up to two-thirds of medically intractable cases, from which good surgical candidates can be found in 68% of cases.[10] The yield of excellent surgical outcome (>90% seizure freedom) in early surgical series had gained wide public acceptance. Subsequently, patients came to CCEP for surgical evaluation by information from others rather than by public information or referral system. The success in surgery obviously improved post-operative quality of life and relieved psychosocial stigmas of seizure-free patients. Many have become helpful volunteers of the program or even CCEP staffs in the expanding epilepsy service. Unfortunately, in early 2000, such success was acknowledged among the patient themselves rather than among medical personnel.

In 2001, a short course on epileptology was held by CCEP in Bangkok for education and training of general practitioners and physicians in related fields. The first book on epileptology was published in Thai to distribute recent advances and CCEP experiences in intractable epilepsy management to medical professions. A mobile epilepsy training module on epilepsy for rural doctors was conducted in 2001 in four main regions of Thailand, with partial funding from the Thai Ministry of Public Health (MOPH). In 2002, the first Clinical Practice Guideline (CPG) in Epilepsy and Manual on Epilepsy Surgery were published for Thai medical personnel for awareness and early referral to an epilepsy surgical center.

Surgeries were later performed in highly concordant TLE by using fewer resources as well as in less concordant cases. MRI and 24-hour video/EEG monitoring remains the minimal standard for presurgical evaluation of concordant right mesial TLE. The duration of hospital stay for monitoring was shortened significantly as skills in video/EEG recording and interpretation increased. Unnecessary SPECT and Wada tests were limited. The average scalp video/EEG monitoring period of 9 days in 1999 was reduced to 7.7 days in 2003 and 5.5 days in 2005.

Personnel training as well as technology development for advanced surgery have been conducted according to the CCEP plan. The Cleveland Clinic Foundation (CCF) Cleveland, Ohio, the University of Washington Regional Epilepsy Center, Seattle, USA, and the Bethel Epilepsy Center (BEZ), Bielefeld, Germany have contributed greatly to CCEP in such objectives and have created strong collaboration between the centers until now. The Chulabhorn Foundation under Professor Doctor Her Royal Highness Princess Chulabhorn's patronage has, for the first time, granted a qualified neurosurgeon (the first author) for 2-year epilepsy surgery fellowship training at CCF in 2001 to 2003. Invasive monitoring, cortical functional mapping as well as some aspects on neuropsychological tests, are among the transferred technology from BEZ to an adult epileptologist and two technicians from CCEP in late 2003.

Since then, expansion of advanced techniques has taken place at CCEP, most of which is the first time in Thailand. The first transcallosal resection of hypothalamic hamartoma was successfully done in September 2002.[11] Vagal nerve stimulation (VNS) was first implanted on 12 May, 2004 in a patient with Lennox–Gastaut syndrome. The first invasive EEG monitoring (IEM) and cortical stimulation mapping using subdural grid and strip electrodes was performed on 15 November, 2004, in a refractory TLE patient who had failed gamma knife radiosurgery at a private hospital, resulting in seizure freedom for more than 2 years.[12]

The worldwide shortage of sodium amytal in 2003 urged CCEP to study the use of propofol for the Wada test. The first intracarotid propofol procedure was performed on 22 October, 2004 with good results.[13] Digital video/EEG

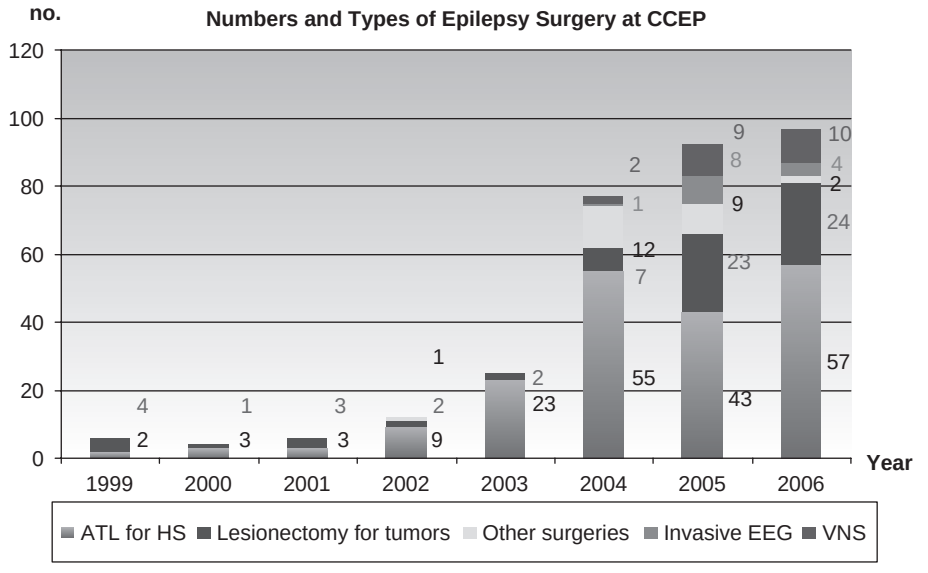

Figure 19.6 Numbers and types of epilepsy surgery at CCEP from 1999 to 15 December, 2006. The total numbers have reached 325 cases. The surgeries have been greatly increased since 2004, including cases receiving invasive EEG implantation.

telemetry, subtraction of ictal and interictal SPECT co-registered to MRI (SISCOM) and neuropsychological testing in Thai language are among other diagnostic facilities developed in parallel to the above advanced surgical techniques.

First multiple subpial transection (MST) was performed on 26 December, 2005 in a case of left insular cortical dysplasia with diffuse ictal onsets over eloquent frontotemporal regions. [18]FDG-PET was first used as a part of presurgical evaluations in July 2006. First depth electrode implantation was done on 21 August 2006 in a discordant unilateral MTLE patient.

Neurosurgical pathology also revealed many interesting epilepsy substrates from CCEP series. Many cases such as Rasmussen's encephalitis and desmoplastic infantile ganglioglioma (DIG tumor) were first reported in Thailand.[14] A case of low-grade hypothalamic neuronal tumor with gelastic/dacrystic seizure found at CCEP has never been reported in the world medical literature.

The number of surgical cases has tripled in 2004 (Figure 19.6). Anterior temporal lobectomy for HS is the most performed operation until now. Surgery on difficult cases with poorly defined epileptogenic zones such as cortical dysplasia (CD), bitemporal disease, and non-lesional epilepsy have increased in 2005. Moreover, the time after video/EEG monitoring to surgery, as well as the duration of hospital stay after surgery, has been reduced significantly in the last 3 years.

The community arm

Public activities have developed in parallel to medical technology. Serial public campaigns via media and magazines along with initial excellent surgical outcomes have dramatically converted initial fear and doubt in epilepsy surgery among the Thai population into the voluntary seeking of surgical therapy at the CCEP. The number of patients registered to the center has been increasing continuously to reach 3000 patients in 2006.

The 'Light for Life Foundation for Epilepsy' was founded in August 1999 as a charitable organization giving continuous financial support to low-income epilepsy patients. The foundation provides expenses for new AEDs, transportation, presurgical and surgical interventions including VNS supplies. Additional support was provided by the Thai MOPH with CCEP negotiation, i.e. funding for some anterior temporal lobectomy individuals from 2002 to 2004 and for VNS from 2004 to the present time.

A study from CCEP has shown that epilepsy surgery has magnificent impacts on the patients' QOL after surgery, when evaluated by occupational achievement and income acquisition.[15] Of the 111 adult epileptic patients operated between January 2002 and December 2004, an overall seizure free rate of 83% was obtained. There were 62% reduction of the unemployment rate, 43% increase of the postoperative professional achievement, and 48% increase of the average annual income per capita, when compared to the preoperative period ($p<0.001$), especially among seizure-free patients. The study proclaimed the worth of epilepsy surgery in terms of cost-effectiveness and the individual's dignity as well as emphasized the need of expansion of the surgery in Thailand, especially in those who have surgically remediable syndromes.

The CCEP website, www.thaiepilepsy.org, and 24-hour phone lines were open for consultation from patients as well as from the medical professions in 2000. A Thai novel written by a nation-renounced novelist in 2003 based on experience of a seizure free lady has subsequently brought better understanding toward epilepsy and its surgical aspects.

The Royal support

Thai monarchy is the center of merit for all Thai's hearts. The CCEP has had the privilege of Professor Doctor Her Royal Highness Princess Chulabhorn's patronage since August 1999. HRH Princess Chulabhorn, the youngest daughter of Their

Majesties King Bhumibol Adulyadej and Queen Sirikit of Thailand, received her Ph.D. degrees in biochemistry and toxicology, as well as her M.D, and Ph.D. in oncology.

HRH has followed Their Majesties' footsteps in promoting education, health, and sustainable development for the country. She also expressed her compassion on epileptic patients and her interest in expanding epilepsy surgery opportunity for them. HRH's concern at the tremendous suffering of epilepsy patients is echoed in Her speech:

> 'I have seen people under epileptic attacks and I feel much sympathy for them. When they came out of their seizures, they often felt embarrassed, as they were surrounded by gazing people. Although people would try to help them, they were unable to communicate. Afterwards, they would live with fear of unpredictable attacks. Many have lost their jobs. My heart goes out to these epilepsy patients. I deeply wish that they could become free of seizures.'

The special Thai ceremony of gratitude was performed under HRH's attendance in July, 2001 by persons who have become seizure free. The occasion signaled their good QOL and their willingness to become helpful social members after successful epilepsy surgery.

The 'Nom Klao Vocational Rehabilitation Project', another program under HRH's supervision to provide epileptics with handicraft skills to augment their income and dignity, was organized in 2003.

Education and training also play a major role in epilepsy surgery development in Thailand. On the Auspicious Occasion of HRH's 48th Birthday Anniversary, the CCEP organized the national Princess Epilepsy Congress (PEC2005) for audiences of all levels in the country. A scientific program on advanced epilepsy surgery, including lectures from invited world epilepsy experts, and workshops were opened for MD as well as for nurses and EEG technicians. A public program including psychosocial aspects of epilepsy, issues related to law, literatures, and arts have successfully extended the dimension of epilepsy interest into public and media.

Surgical series in Thailand and outcomes

There were few reports of epilepsy surgery in Thailand. In 1999, P. Visudhiphan *et al.* reported 70% seizure-free outcome following temporal lobectomy in 14 pediatric patients during 1993–1998. There were various kinds of pathologies in the report including hippocampal sclerosis, gliosis, tumor, and cavernoma.[2]

CCEP surgical series began with highly concordant temporal lobectomy and later developed to include all kinds of epilepsy surgeries, i.e. resection, palliative surgery, invasive EEG implantation, and vagal nerve stimulation (VNS).[16] Since 1997, CCEP has had a series of more than 300 epilepsy surgery patients.

Various epilepsy operations have been performed both in adults and children at CCEP. Up to December 2006, surgical substrates of temporal lobe resection have included hippocampal slerosis (HS) ($n = 172$), benign tumors ($n = 36$), cortical dysplasia (CD) ($n = 4$), cavernoma and arteriovenous malformation (AVM) ($n = 10$), hamartoma ($n = 1$) and gliosis ($n = 4$). Extratemporal resection was done on tumors ($n = 3$) and CD ($n = 5$). The rest were multilobar resection for CD ($n = 3$), corpus callosotomy ($n = 6$), functional hemispherectomy ($n = 10$), and removal of hypothalamic hamartoma ($n = 6$).

Twenty-one VNS had been implanted by December 2006. Some patients show modest reduction of seizures but have moderate improvement of emotional control, learning ability, awareness and communication. So far, subdural grid electrodes have been implanted in 12 patients, depth electrodes in 1 and bitemporal subdural strips in 4 with satisfactory results.

The outcome of 72 temporal lobectomy patients for hippocampal sclerosis who have at least 1 year follow-up are seizure free (Engel I) 60 cases (83.4%), almost seizure free (Engel II) 6 cases (8.3%), and worthwhile improved (Engel III) 6 cases (8.3%).[17,18] The results are comparable to an internationally published series. Epilepsy surgeries are increasing as more surgical candidates are identified by advanced diagnostic techniques and awareness of epilepsy surgery is expanding among patients and medical personnel.

Current situation of epilepsy surgery in Thailand

Epilepsy surgery has gained acceptance and expectation among patients with epilepsy in Thailand up until now. Nevertheless, drawbacks regarding inadequate knowledge in epilepsy surgery among personnel in local hospitals have affected proper timing and process of referral to a surgical center. The government has supported the CCEP 'New Life Project' by providing a budget for 300 upcoming epilepsy surgical cases from October 2005 to 2008 with a plan to expand more than 30 epilepsy clinics nationwide using CCEP as a prototype. As a result, more patients are expected to get access to standard presurgical evaluation and effective surgery by overcoming obstacles of limited referral to an epilepsy tertiary center.

Epilepsy surgery is gradually expanding in other medical institutes and private hospitals in Bangkok as well. However, up to now CCEP has been accepted as the only advanced comprehensive epilepsy surgery center serving patients from all parts of the country with routine highly standard protocol. Apart from the public communication and campaigns through the media in the early days, patients are now gaining their awareness of epilepsy surgery service among themselves. Its expansion has been supported mainly by charity funding under HRH's patronage and partly by the government sectors. Nevertheless, there are still large numbers of surgical candidates waiting to be evaluated and operated nationwide.

The epilepsy fellowship in Thailand has recently been established and approved by the Royal College of Physicians of Thailand (RCPT). CCEP is the first and only institution approved as an epilepsy fellow training center in 2005. The first fellowship started on June 1, having two fellows per year on a 2-year program. In the near future, as there are more trained epilepsy focusing physicians, suitable surgical candidates are anticipated to be better recognized and properly referred to the tertiary epilepsy center.

Projections into the future

CCEP is the pioneer in the development of epilepsy surgery in Thailand and has become an advanced epilepsy center at this stage. For sustainable development, education and training in epilepsy need to be distributed widely and continuously throughout the country. Basic epilepsy surgery needs to be developed as satellite regional centers in remote parts of Thailand to include more surgical remediable patients. Early and appropriate referral for surgery should be a promise.

Patient selection for surgery using minimal diagnostic facilities is another future expectation. As experience and confidence grow, epileptologists in a tertiary center can improvise presurgical evaluation to reduced cost and process but yet achieve good surgical outcome. Researches and development on this issue will be needed. On the other hand, some advanced investigations may substitute invasive and expensive work-up in a tertiary center, for example, fMRI for Wada test or PET scan for invasive EEG monitoring.

A national cyclotron and positron emission tomography (PET) center has been established at Chulabhorn Research Institute (CRI) Cancer Hospital in 2006 as a powerful diagnostic facility for cancer, epilepsy, and other diseases. The concept of sharing cyclotron and PET/CT scanners among surrounding medical schools and hospitals has been appraised by the International Atomic Energy Agency (IAEA). After its opening in July 2006, PET has improved localization of epileptogenic zone and identified more surgical candidates in certain epileptic syndromes, such as discordant TLE, non-lesional TLE and bitemporal disease.

Frameless deep brain stimulation (DBS) was first operated at King Chulalongkorn Memorial hospital in August 2005 for Parkinson's disease and dystonia. Although DBS for epilepsy is still an experimental approach, CCEP is ready for epilepsy application if this new modality proves effective in the future. However, upcoming advanced technologies should be wisely considered to fit the need and economical status of Thailand.

Parts of this chapter have been delivered as the Keynote Lecture by C. Locharernkul under the attendance of HRH Princess Chulabhorn and as a core lecture by T. Srikijvilaikul, at the Princess Epilepsy Congress 2005, Bangkok, 22–24 October, 2005.

20 History of epilepsy and seizure classification

T Loddenkemper and HO Lüders

Terminology and definitions

Epilepsy

In ancient medical science the word 'epilepsy' was used to depict both the disease and its attacks. The presentation of the attacks defined the condition: 'Epilepsy is a convulsion of the whole body together with an impairment of the leading functions'.[1] Frequently, the Greek term 'epilepsie' initially did not refer to the disease itself, but only to the actual attack or the epileptic patient. The term epilepsy derives from the Greek term 'epilambanein' which means to seize. The disease itself was called 'the sacred disease'.[2] Interestingly, John of Gaddesdon provides a different translation, suggesting that the word derives from 'epi', above and 'ledo', injure; that is injury to the upper parts, that is, the head.[3] Concepts and terminology of epilepsy have been changing throughout the centuries. With the advent of additional technologies and knowledge, previous terms required either redefining or introduction of new terms became necessary. Based on a recent ILAE publication:

> epilepsy is a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one epileptic seizure. Elements in the definition of epilepsy include history of at least one seizure, enduring alteration in the brain that increases the likelihood of future seizures, and associated neurobiologic, cognitive, psychological, and social disturbances.[4]

Epileptic seizure

Seizures have been documented for more than 3000 years.[5] Since then abundant descriptions and explanation models can be found in the literature. The separation of both the actual attacks and epilepsy as a disease dates back to John Hughlings Jackson. Jackson's definition of a seizure still provides the basis for the understanding of seizures to the present day. According to Jackson:

> A convulsion is but a symptom, and implies only that there is an occasional, an excessive, and a disorderly discharge of nerve tissue on muscles. This discharge occurs in all degrees; it occurs with all conditions of ill health, at all ages, and under innumerable circumstances.[6]

This definition has not changed much in the last 130 years. According to the International League Against Epilepsy (ILAE) an epileptic seizure 'is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain'.[4] Elements defining an epileptic seizure include 'mode of onset and termination, clinical manifestations, and abnormal enhanced synchrony'.[4]

Epileptic syndrome

The concept of epilepsy syndromes is relatively young. Although several authors in the literature attempted to delineate epilepsia proper from epilepsy related to other medical condtions, the terms epilepsy and epilepsy syndrome have frequently been used synonymously. Epilepsy syndromes based on presumed etiology have all been described within the last 150 years, including West syndrome, Rasmussen encephalitis, or Lennox–Gastaut syndrome. The first definition of epilepsy syndromes can be found in the 1985 epilepsy classification proposal.[7] This is the first proposal that officially differentiates between epilepsy and epilepsy syndrome. Here epilepsy syndromes have been defined as:

> an epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together. The signs and symptoms may be clinical (e.g., case history, seizure type, modes of seizure recurrence, and neurological and psychological findings) or findings detected by ancillary studies (e.g., EEG, X-ray, CT, and NMR). In contradistinction to a disease, a syndrome does not necessarily have a common etiology and prognosis.[7]

In a revised proposal in 2001, the definition has been shifted to: 'A complex of signs and symptoms that define a unique epilepsy condition. This must involve more than just the seizure type: thus frontal lobe seizures *per se*, for instance, do not constitute a syndrome'.[8] Idiopathic, symptomatic, and probably symptomatic epilepsy syndromes are differentiated. A syndrome is perceived as a different entity than genuine epilepsy as a disease. This is 'a pathological condition with a single specific, well-defined etiology. Thus, progressive myoclonic epilepsy is a syndrome, but Unverricht–Lundborg is a disease'.[8]

Understanding of epilepsy through the ages

Mythical approach: from ancient times to Hippocrates and Galen

Hippocrates book on the 'sacred disease' localized epilepsy in the brain and fought mysticism and superstition, that epilepsy is not a sacred but a medical condition. Ancient definitions included the one by Aretaeus defining epilepsy as an 'illness of various shapes and horrible'.[1] One of the earliest definitions of epilepsy in antiquity was ascribed to Erasistratus:[1] 'Epilepsy is a convulsion of the whole body together with an impairment of the leading functions'. Galen adapted this most influential definition of epilepsy and defined epilepsy 'not only as convulsion of the whole body, but also interruption of the leading functions':[1] According to Galen, epilepsy was either related to congestion of humors in the ventricles of the brain or due to humors arising from other parts of the body. This was the prevailing concept of epilepsy until early Renaissance.

From Antiquity to Renaissance

In medieval times, the Galenic definition of epilepsy continued to prevail and was rarely questioned. The major advance during this period may be the influence of Paracelsus, who now interpreted epilepsy as a physical and chemical condition, with a possible chemical treatment. During Renaissance, the definition of epilepsy was broadened, and Marcus Marci (1595–1667) remarked that epilepsy could present as 'any affection of the body where the victims are disordered in their minds, while the members [of the body], be it all, or some, or only one, are moved against their will'.[9] This was mainly related to the increasing amount of single case reports and the resumption of autopsies that now allowed pathological correlation of clinical conditions, facilitating a better etiological understanding of epilepsy.

The 19th century and John Hughlings Jackson

Due to increasing clinical evidence, the humoral concept by Galen was slowly abandoned in the 19th century, and all epilepsies were thought to arise from the brain. Possible etiologies for epilepsy were either a structural lesion or a functional disturbance of the brain. Epilepsies due to structural lesions were named symptomatic, structural or lesional, or with an underlying pathophysiological approach, partial. Epilepsies without a cerebral lesion were called functional, idiopathic, true, or centrencephalic. In addition to these etiological concepts, John Hughlings Jackson is considered to be the first who introduced a localizing dimension to the understanding of epilepsy by differentiating between generalized and focal epilepsies.[10] Besides an anatomical and pathological subdivision, he also anticipated physiological findings that were later confirmed on EEG. According to Jackson 'Epilepsy is the name for occasional, sudden excessive, rapid and local discharges of grey matter'.[10] This rapid gain of knowledge in epilepsy at the end of the 19th century and the beginning of the 20th century changed our view on epilepsy so profoundly adding multiple facettes to epilepsy, that classifications after Jackson are outlined in a separate paragraph combining multiple classification angles such as localization, seizure type, etiology, age, and other circumstances (see later).

Invention of the EEG

The invention of the EEG by Hans Berger and pioneering work by Gibbs and Gibbs allowed further characterization of EEG patterns in patients with epilepsies. Initial attempts to recognize epilepsies included matching of semiological seizure patterns with typical EEG patterns. One of the major drawbacks of Jackson's theory was the lack of explanation for loss of consciousness during seizures. In 1954, Wilder Penfield and Herbert Jasper at the Neurological Institute in Montreal explained loss of consciousness by interaction of epileptiform discharges between the reticular-thalamic system and the cortex.[11] In the same year, Henry Gastaut published a monograph with an almost similar theory of epileptogenesis.[12] From that point on, epilepsies that were thought to interact with deeper brain structures were called generalized.

ILAE classifications and revisions

Henry Gastaut was also the first to lead the ILEA to a uniform classification of epilepsies.[13,14] This was characterized by an etiological (primary versus secondary) dimension and characterization of the localization (partial versus generalized). Description of benign focal epilepsy of childhood, the first 'partial primary' epilepsy necessitated a revision of this initial proposal, and revised versions in 1985[7] and 1989[15] attempted to classify epilepsies in syndromes according to a strict one-to-one relationship of EEG and clinical seizures. Since then a revised epilepsy scheme and a revised syndromic classification have been discussed.[8,16] Part of the current difficulties may be that there is no such disease as idiopathic epilepsy and generalized epilepsy anymore and this is particularly highlighted by research progress in epilepsy genetics and EEG. Borderlines between focal and generalized epilepsies become less reliable as ultrafast EEG recordings also suggest focal onset even in some generalized forms of epilepsy. Additionally, research in genetics more and more reveals underlying causes for so-called idiopathic epilepsies.

Classification according to clinical epileptic seizure types

The Sakikku ('all diseases') (1067 BC) is believed to be the oldest available written documentation of seizures and seizure semiology. This Babylonian plate deals almost exclusively with the clinical presentation of epilepsy. The translators of this document comment that 'it was evidently the discipline of the times to write down only what was seen.'[5] The main goal of this table appears to be the documentation of observation. In 55 separate entries, this text distinguishes meticulously different clinical features and presentations of seizures. Semiological features described include eye reddening, a warning (the patient that is possessed by a demon recognizes the onset and cries 'it is he again'), eye blinking, cheek twitching, limb extension, laughing, continuous flexion and extension of the limbs, body deviation to one side, paralysis

after a seizure, unilateral body heaviness and prickly feeling, headaches prior to seizures, emotional upset prior to seizures, eye deviation, a feeling of distention in the epigastrium, cloudiness in front of the eyes, hissing in the ears, and constant wiping clean of hands and face and other features. Seizures with and without loss of consciousness are distinguished.[5] Although one might argue that this is not a 'clear-cut' seizure classification, its organization in 55 different entries reveals an underlying structure of information.

The first differentiation of semiological seizure events is found in Hippocrates of Kos' Sacred Disease (400 BC) (Figure 20.1), which also documents the views of 'the others', the magicians, that do not believe that the cause of epilepsy is located in the brain.[17] This magical concept contains an interesting distinction between semiological elements, which are ascribed to different gods. The mother of gods was involved when teeth gnashing movements and right-sided motor seizures occurred. Poseidon induced cries, Ares was associated with salivation and kicking leg movements, and nocturnal events with fear and disorientation were ascribed to Hekate.[17] However, it is not clear whether only epilepsy is included in this classification. Other non-epileptic events and psychiatric conditions may also have been classified according to this scheme.[2]

Aretaeus of Cappadocia (1st century AD) separates premonitory symptoms into symptoms occurring longer before the onset of the event and immediately at the beginning of the seizure. Symptoms occurring longer before the event 'included stupor, vertigo, tension of the members, fullness and swelling of the neck, aversion to food, much vomiting of phlegm, flatulence, high diaphragm.' Symptoms occurring at the onset of the event include 'red or black lights or both together appear in arcs before the eyes, similar to the rainbow. The patients feel their ears ringing, they smell bad odors, are irritable, become angry without reason'.[1]

Although Claudius Galen's (circa 130–210 AD) (Figure 20.2) classification was embedded in Galen's medical theory of humors, it was also based on observation of seizure semiology overlapping with localization. The first type of epilepsy that originated in the brain was related to accumulation of phlegmatic humor in the ventricles causing obstruction.[1] The second type, epilepsy starting from the stomach, was brought on by accumulation of bile in the stomach, leading to evaporations that then also affect the brain.[1] The third type of epilepsy that starts in any other body part was explained by spread of a 'pneumatic substance' throughout the body.[1]

Three other clinical features were highlighted by Caelius Aurelianus (5th century AD) who also distinguished three types of epilepsy: the first type mimicked sleep, the second type presented with convulsion, and the third type manifested convulsion followed by deep sleep.[1] He separated seizures with and without warning.[18] His account of warning symptoms included:

> heaviness and giddiness in the head, an inner noise, which is felt in the occiput, too, tension in the eyes, ringing in the ears … or difficulty in hearing; and together with the vertigo, dimness of the eyesight or something hanging down before the eyes, as it were, either similar to the spots of marble which the Greeks call 'armarygmata' or 'marmary-gas', or similar to spider webs or very thin clouds or to very small flying animals like gnats. The patients also perceive tiny sparks, so to speak, or fiery circles borne around before their eyes. The tongue is not flexible, and at the same time muscles twitch, and they have pains in the back and between the shoulders. There also follow rigor in the throat and a concomitant precordial distention together with yawning, sneezing,

> flow of saliva, and aversion to food or immoderate appetite. … The mind is anxious and troubled, and they are readily roused to anger for no major reason. There is forgetfulness for what has been done shortly beforehand and a ready disposition for things causing gloom.[1]

With or without warning, the epileptic then falls to the ground. At this point, Caelius Aurelianus differs between three semiological seizure parts:

1. manifestation (unresponsiveness and generalized motor features with suffocation)
2. abatement (unconscious discharge of urine, feces, semen, saliva, then end of suffocation)
3. cessation (patient arises with ongoing postictal discomfort).[1]

Cassius Felix (5th century AD), similar to other ancient authors and close to Caelius Aurelianus, distinguishes two types of seizures, presenting either as motor seizure or as sleep.[19]

Theodorus Priscianus (5th century AD) was the first to describe the complete sequence of what today is considered a secondary generalized tonic–clonic seizure with different preceding symptoms, followed by stretching of the body, then by clonic activity, and finally by sleepiness.[1]

Sun Si Miao (682 AD) proposed one of the first seizure classifications in the traditional Chinese literature. This author differentiates between six different semiological seizure types based on the resemblance of the epileptic cry with animal sounds. He differentiated 'goat epilepsy', 'horse epilepsy', 'pig epilepsy', 'cow epilepsy', 'chicken epilepsy', and 'dog epilepsy'.[20]

In the Persian literature, Ibn Sina (Avicenna, 973–1037 AD) semiological seizures based on Galen's humoral pathology were separated into four types: The phlegm type was characterized by paleness, anxiety, fear, unconsciousness, and amnesia. The black-bile type presented with palpitations and chest pressure, obsession, and unrealistic thoughts. The blood type manifested with blood-shot eyes, enlarged neck veins, and cyanosis, and the yellow-bile type became apparent with a yellow face, short attacks, and depression.[21]

St. Hildegard of Bingen (1098–1179 AD) recognized two types of epileptic seizure closely tied to the character of the patient.[22] The first is characterized by 'demoniacal agitation of the irascible' and the second presents with 'pitiful helplessness of the moral weakling'.[22]

Matthaeus Platearius Salernitanus (circa 1150 AD) elaborated on 'major' and 'minor' epileptic seizures based on the galenic epilepsy model. Major seizures presented with distortion of the face, shaking of the neck and body, teeth clenching, and passing of urine, stool, or sperm. Patients with major seizures also continued to froth repeatedly, even if the froth is wiped off. During minor seizures the patient lost consciousness and may or may not fall. Froth did not appear after it has been wiped off the mouth.[19]

Samuel Tissot (1728–1797) is credited with the first semiological description of seizures with loss of consciousness, but nearly no motor features. His description of a 14-year-old girl illustrates his differentiation between grand accés and petits accés.

> … the young patient, in intervals between the great attacks (grands accés), frequently had very short, little (petits) attacks, which were merely marked by an instantaneous loss of consciousness, interrupting her speech, together with a very slight movement of the eyes.[23]

James Cowles Prichard (1786–1848) divided seizures into convulsive epilepsy, tetanic epilepsy, and leipothymia. Convulsive epilepsy presents with loss of consciousness and convulsions. Tetanic epilepsy is characterized by loss of consciousness without convulsions, but tonic activity. Leipothymia presented with sudden onset of loss of consciousness and no motor activity 'sometimes preceded by vertigo, but in other instances without any premonitory symptoms'.[24] Prichard also coined the term 'partial' seizures describing patients with focal motor features or an epigastic aura and no loss of consciousness.[25]

Louis Florentin Calmeil (1798–1895) based his classification in 1824 on severity of seizure semiology and differentiated between three seizure types:[26]

1. 'Grand mal' (generalized tonic–clonic seizure)
2. 'Petit mal, vertiges, étourdissemens parmi les malades'. This type may or may not occur prior to grand mal attacks, and can present with dizziness, head turning, arm extension, or unresponsiveness.
3. 'Absences' are described as short interruptions of consciousness. The patient interrupts his current activity, and even though the senses are aroused, 'ils sont mementanonément fermés aux impressions' – they are for a moment closed off from impressions.[26]

In 1854, Louis Jean Francois Delasiauve's (1804–1893) classified seizures according to severity in four categories: absences, vertiges, accès intermediares, and accès complete. He considered absences with its characteristic symptom loss of consciousness as the most severe form of seizures. This was followed by 'vertige', involving head deviation, ictal speech, and automatisms. Accés intermédiaries involve a variety of clonic, tonic, and myoclonic presentations, and accés complet represent a generalized tonic clonic seizure.[27]

Sir John Russell Reynolds (1828–1896) seizure classification (1861) is also based on the severity of clinical seizure presentation. This concept differentiates between four degrees: loss of consciousness, loss of consciousness with focal motor movements, loss of consciousness with generalized motor features, and focal or generalized motor features without loss of consciousness.[28]

In 1890, Sir John Hughlings Jackson (1834–1911) introduced the anatomical concept of partial versus generalized seizures. Until the 1870s Hughlings Jackson's research was dominated by a physiological research approach to epilepsy. According to this definition of epilepsy as 'occasional, sudden, excessive, rapid and local discharges of grey matter', many epilepsies existed.[6] However, this was not practical for everyday use and therefore he added an empirical semiological classification to his scientific model of epilepsy. He used a comparison between a gardner and a botanist and concluded that both classifications, a utilitarian and a taxonomic, are necessary. Therefore, his 'empirical arrangement of epilepsies and epileptiform convulsions' included: (I) Epilepsy

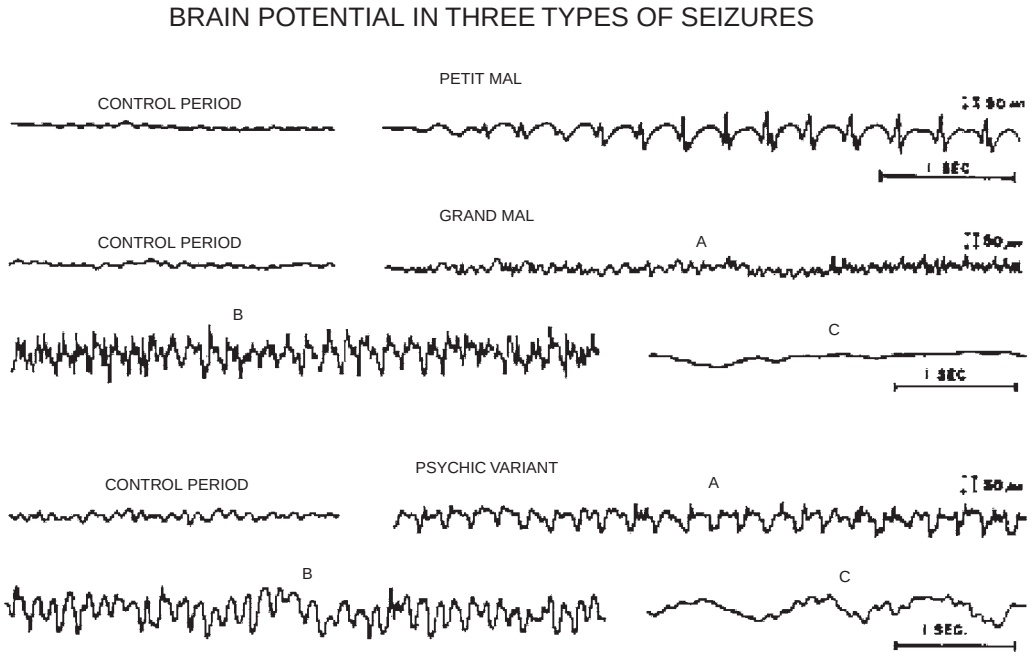

Figure 20.3 EEG classification according to Gibbs and Gibbs (1937), reprinted with permission from ref. 29.

proper: vertigo, petit mal, grand mal and (II) epileptiform and epileptoid convulsions beginning unilaterally, unilateral dysaesthesia (migraine), and epileptiform amaurosis.[25]

The invention of the EEG allowed Frederic Andrews Gibbs and Erna Leonhardt Gibbs (1937) to classify seizures based on their electroclinical presentation.[29] They distinguished three clinical seizure types associated with different EEG patterns (Figure 20.3). Their clinical seizure classification included grand mal as generalized tonic–clonic seizure, psychomotor attacks associated with small motor movements, and petit mal characterized by loss of consciousness.

> The normal frequency of the brain potentials is around 8–20 a second. In grand mal, these waves speed up to 25–30 a second, and appear in our records as sharp spikes. In psychomotor attacks (psychic variants) the rate slows to 3 or 4 a second with a square, flat-top wave predominant. In petit mal quick sharp spikes and slow, round waves at the rate of 3 a second alternate. We can explicitly say, that in grand mal the cortical activity is abnormally fast; in a psychomotor attack, it is abnormally slow; and in petit mal, it alternates between fast and slow.[29]

In 1943, this classification was further elaborated and psychomotor attacks and psychomotor variant were separated recognizing that different EEG features could present with similar clinical features.[30] The prediction of the clinical seizure type based on the EEG pattern was further questioned by Jasper and Kershmann, who only found a correlation between clinical presentation of absence seizures and 3 Hz spike and wave complexes. They subsequently published an EEG classification separate from clinical semiology.[31]

Based on his work with Gibbs and Gibbs, William G. Lennox (1960) outlined a clinical seizure classification in his book *Epilepsy and Related Disorders*.[32] This classification consisted of the petit mal triad including pure petit mal of pyknolepsy, myoclonic and atonic seizures, the convulsive triad including generalized, focal, and Jacksonian (or rolandic) seizures, and the temporal lobe triad including automatic, subjective, and tonic focal seizures.

The first ILAE classification of epileptic seizures was published by Henry Gastaut (1969).[33,34] The major breakthrough of this classification was that it set a common communication standard. The main feature of this classification is the distinction between generalized seizures from the onset and seizures that are focal at the onset and then become secondary generalized. It lists clinical seizure types closely connected with EEG seizure types, interictal EEG, anatomic correlation, etiology, and age. Seizure types include partial seizures with elementary symptomatology (with motor symptoms, with special sensory or somatosensory symptoms, autonomic symptoms, and compound forms), partial seizures with complex symptomatology (such as impaired consciousness only, cognitive symptomatology, affective symptomatology, psychosensory symptoms, psychomotor symptoms or automatisms and compound forms), partial seizures with secondary generalization, and generalized seizures (absences divided into simple and complex absences), myoclonic jerks, infantile spasms, clonic seizures, tonic seizures, tonic–clonic seizures (or 'grand mal'), atonic seizures, and akinetic seizures.[33,34]

In 1981, only 12 years later, an ILAE committee led by Fritz E. Dreifuss revised its clinical and electroencephalographic classification of epileptic seizures.[35] Rapid development and refinement of diagnostic and therapeutic methods, including the advent of simultaneous Video-EEG, and additional antiepileptic drugs and surgical techniques, increased the urge to develop a more precise classification tool for everyday use and research means in order to measure and predict treatment responses.

One of the major changes and most likely its greatest achievement is the inclusion of a glossary of terms to ensure universality of terminology. However, it broke with the previous convention of describing clinical seizure, EEG seizure, interictal EEG, anatomic correlation, etiology and age. Instead it lists clinical seizure type, EEG seizure type, and interictal manifestations. Again, the classification differentiates between partial (or focal, local) seizures, generalized seizures and unclassified epileptic seizures, and describes clinical seizure types in association with their one-to-one EEG presentation. Furthermore simple and complex partial seizures are separated by loss of consciousness. It is also the first classification that accounts for longitudinal seizure evolution of simple partial seizures into complex partial seizures and for evolution from partial into generalized seizures. Partial seizures were divided into simple partial seizures, complex partial seizures (with impairment of consciousness at onset or simple partial onset followed by impairment of consciousness), and partial seizure evolving to generalized tonic–clonic convulsions (preceded either by a simple or complex partial seizure). Generalized seizures were further divided into absence seizures (presenting with a generalized 3 Hz spike and wave pattern), myoclonic seizures, clonic seizures, tonic seizures, tonic–clonic seizures, and atonic seizures. Interestingly, infantile spasms were removed from this part. Unclassified seizure category 'includes all seizures that cannot be classified because of inadequate or incomplete data and some that defy classification …'.[36]

The strict one-to-one relationship of clinical ictal seizure semiology and ictal/interictal EEG manifestations in this classification insufficiently characterized many seizures, and the seizure classification has major limitiations in particular in pediatric patients. Hans O. Lüders and others at Cleveland Clinic pioneered a semiological seizure classification based exclusively on ictal semiology which was published in its preliminary form in 1993[37] and then presented in its finalized form in 1998.[38,39] Rekindled by the advances in video-EEG, this classification reintroduces the easiest and oldest classification of epileptic seizures exclusively based on their clinical presentation. Additionally, it also allows for specification of seizure progression and provides additional lateralizing and somatotopic information. Details of the main categories of this classification including auras, autonomic seizures, dialeptic seizures, motor seizures, and special seizures, are explained elsewhere in this book.

Based on the semiological seizure classification Warren T. Blume, Hans O. Lüders, and others published the *Glossary of Descriptive Terminology for Ictal Semiology* in the name of the ILAE in 2001.[40] This glossary was also included in a recent proposal of a diagnostic scheme by Jerome Engel in 2001.[8]

Classification according to localization in the brain

Trephining of the skull is the oldest known surgical procedure, and has been described in skulls from the Neolithic age around 5000 BC.[41,42] Although the indications for trepanation at that time are unknown due to lack of documentation, epilepsy may have been one of them (Figure 20.4). Perforation of the skull for treatment of epilepsy has later been documented by the founder of the Greek Methodist school of medicine Themison of Laodicea (around 50 BC).[1]

Hippocrates was the first who placed the origin of seizures in the brain. The main pathophysiological mechanism was phlegm located in the brain that has not been purified during the fetal period. The phlegm melts, rushes into the body vessels, obstructs these and produces symptoms (such as leg movements, eye deviation, and others) if it cannot be excreted, e.g. through the bowel by diarrhea or as excretion through the lungs.[1] One of the greatest advances of this pathophysiological theory is the localization in the brain. However, it also acknowledges the fetal development as a crucial and potentially vulnerable period.

The discovery of nerves has been ascribed to Herophilus and Erasistratus (3rd century AD) and this paved the way for Aretaeus, who also localized epilepsy in the brain (or rarely in the stomach) and suggested stimulation of peripheral nerves to explain the spread of symptoms.[1]

Asclepiades of Bithynia (about 124–40 BC) opposed the humoral principles of Hippocrates and explained epilepsy – based on his atomistic view of medicine – as an injury of the meninges, or alternatively due to fear. Soranus of Ephesus (2nd century AD) expanded this concept and added contusion to causes of epilepsy, elaborating on the Hippocratic description that seizures may occur in patients with fractures of the skull.[1,19]

The Roman author Apuleius (125–180 AD), together with Aristotle, is the first who describes further lateralization. Both mention that the disease is more difficult to cure if it affects

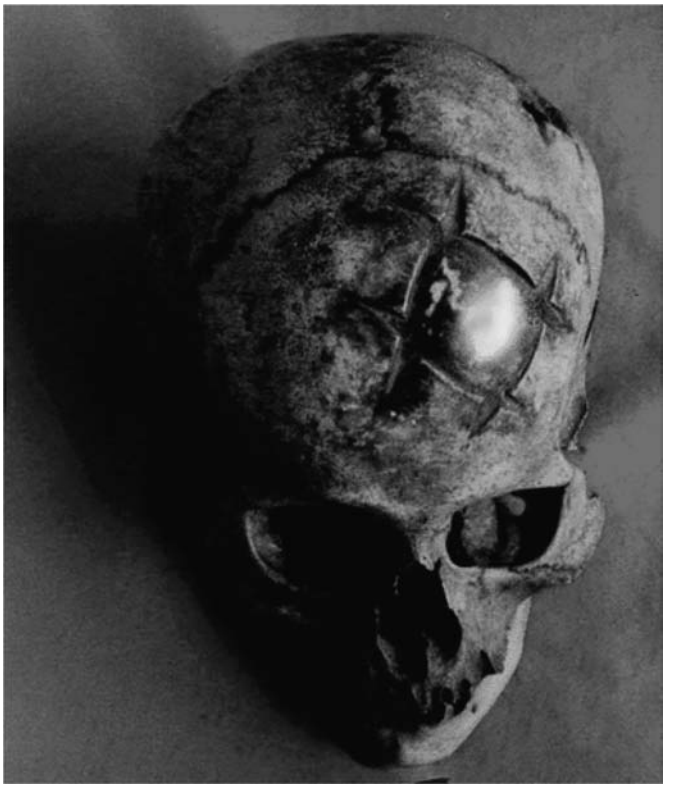

Figure 20.4 Skull demonstrating frontal cranioplasty with a gold plate and evidence of healing. Also note the left parietal craniectomy. Reprinted with permission from ref. 42.

the right side, referring to semiological features affecting the right side of the body.[1]

Claudius Galen (circa 130–210 AD) also localized epilepsy in the ventricles of the brain, in the stomach, or in any other body part.[1] Galen specifically mentions the third and fourth ventricle.[19] Avicenna localizes the origin of epilepsy to the 'anterior ventricle'.[19] This localization to the ventricular system is found throughout medieval times and was only markedly changed in the early 16th century at the beginning of the Renaissance when scientists started to debate and either opposed traditional views or tried to reinterpret authors from antiquity.

In medieval times, each of the three Galenic presentations of the disease was named differently. 'Epilepsy' then referred only to the type that initiated in the brain, whereas the type occurring from the stomach was called 'analepsy', and the type from any other part of the body was referred to as 'catalepsy'.[19]

Another modification of Galen's theory in the medieval times was the distinction between 'true' and 'not true' epilepsy, as documented in writings of Arnold of Villanova (circa 1234–1311 AD) and Gilbertus Anglicus (circa 1180–1250 AD). True or idiopathic epilepsies in their understanding meant epilepsy arising from the brain, whereas not true or sympathetic epilepsies arose from other body parts. This classification is still preserved in Boerhaave's textbook on neurological conditions (Praelectiones de morbis nervorum, 1761), that differentiates 'epilepsia ideopathica' arising from the brain and 'epilepsia deuteropathica' arising from the stomach or other body parts.[43]

However, based on wider clinical experience, the rebirth of case reports and increasing numbers of pathological and anatomical observations, Charles Le Pois (Carolus Piso, 1563–1633)[9] challenged the Galenic concept of origin of sympathetic epilepsies in the respective body parts.[9] Based on observations and rationale, he concluded that epilepsy (and hysterical symptoms) are caused in the brain. These observations of other research necessitated a revision of Galen's distinction between idiopathic and sympathetic epilepsies and paved the way for additional etiological theories.

Antoine Portal (Le Baron Portal, 1772–1832) came to similar conclusions stating that epilepsy was always located in the brain, in particular the medulla. Although he also distinguished idiopathic and sympathetic epilepsy, he concluded that sympathetic epilepsy was caused by irritation of nerves and this was conducted to the brain producing symptoms in respective areas of the body.[44] This was further elaborated by Marshall Hall (1790–1857) who localized centric epilepsy in the medulla oblongata and eccentric epilepsy as part of a reflex arch triggered by a peripheral stimulus.[45,46]

Sir John Hughlings Jackson (1834–1911) (Figure 20.5) distinguished between 'genuine epilepsy of authorities' and 'unilaterally beginning convulsions' in 1863. The genuine epilepsy of authorities presented without warning, consciousness is lost early, and onset of motor manifestations was often bilateral and equal, and the 'march of the spasm' was rapid. The unilaterally beginning convulsions were characterized by warning, consciousness is lost late, motor manifestations are frequently limited, unilateral, unequal and the 'march of the spasm' is slow.[25] This distinction is now considered the first division between generalized and focal epilepsies. In addition to that he added an etiological dimension to his classification by attempting to define the lesion better. This classification and his definition of epilepsy as 'occasional, sudden, excessive, rapid and local discharges of grey matter'[6] set new standards for future classifications.

Later publications also implied a classification of three levels in the nervous system combining clinical seizure types and localization in the brain. The lowest level, including the spinal cord, the medulla, and the pons represent simple movements. The rolandic area and the striatum represent more complex movements and represent the second level. The third level is represented by the prefrontal motor cortex, the highest level of evolution and center of the most complex movements and 'organ of the mind'.[10] Later, he also included 'uncinate fits' in his classification, to include seizures with olfactory and gustatory auras, automatisms, and 'the dreamy state'.[10] Classifications after John Huglings Jackson tend to include combinations of seizure types, localization, etiology, and other levels of classification (see later).

Classification according to etiology

The Sakikku ('all diseases') (1067 BC) is the oldest available documentation of epilepsy. Its 55 entries not always focused merely on semiology, but also provide information on the causing demon or ghost, the prognosis, the diurnal pattern, frequency, and on status epilepticus. According to the translators, these entries have been somewhat grouped and have been retrospectively sorted, considering seizure frequency patterns, single symptom entries, symptoms with prognosis, diurnal features, nocturnal features, features of chronic epilepsy,

Figure 20.5 Sir John Hughlings Jackson (1834), Image courtesy of the American Association of Neurological Surgeons' Cyber Museum of Neurorsurgery.

features preceding seizures, and features following seizures. Additionally, many entries have been ascribed to certain demons and ghosts. Accordingly, different types of epilepsies are differentiated including seizures ascribed to 'miqtu' and 'lilu', ghosts or the hand of ghosts. Additionally causative demons from the river, the 'bennu' demon, the 'e elu' demon and others are differentiated.[5]

In the Gospel according to Mark (9:14–29), we find indications that seizures were related to evil spirits and the devil. In this passage Jesus casts a devil from a young man:

> Teacher, I brought unto thee my son, who hath a dumb spirit; and wheresoever it taketh him, it dasheth him down: and he foameth, and grindeth his teeth, and pineth away: and I spake to thy disciples that they should cast it out; and they were not able (Mark 9;17–18[47]).

Another casting out of an unclean spirit was described in Mark (1; 23) (Figure 20.6).[47] Until the 16th century, many authors considered causes such as demoniac influence, witchcraft, and the devil[48] in addition to other underlying pathologies.

Hippocrates in 'On the sacred disease' indicated a hereditary etiology.[1] This, however, may have been more an argument against magic beliefs than the actual recognition of genetic factors in epilepsy.[1]

Cao Yuan Fang (610 AD) suggests five types of epilepsy based on etiology (and related semiology):[20]

1. Yang epilepsy presents with incontinence. The patient appears 'dead' and subsequently recovers after a short period of time.
2. Yin epilepsy is caused by bathing a child before the umbilical cord wound has healed.
3. Wind epilepsy presents with fixed gaze, limb stiffness, and goat-like crying. This can be caused by exposure to wind or by alcohol or sexual excess.
4. Wet epilepsy presents with frontal headaches and a heavy body feeling, caused by lack of hair drying.
5. Labor epilepsy manifests with upward deviation of the eyes, teeth clenching, and tonic body stiffening.[20]

Sun Si Miao (682 AD), who also provided us with a classification of seizures based on resemblance of the epileptic cry with animal sounds as outlined above, classifies epilepsies according to visceral organs. The diagnosis and classification of epilepsies according to this scheme was embedded in concepts of traditional Chinese medicine, that understands disease as an imbalance of Yin and Yang and an imbalance between five elements that have an organ correlation. Therefore this classification differentiates between heart, liver, spleen, lung, kidney, and intestine epilepsy.[20]

Claudius Galen (circa 130–210 AD) (Figure 20.2) classification was embedded in Galen's medical theory of humors. The first type of epilepsy that originated in the brain was related to accumulation of phlegmatic humor in the ventricles causing obstruction.[1] The second type, epilepsy starting from the stomach, was brought on by accumulation of bile in the stomach, leading to evaporations that then also affect the brain.[1] The third type of epilepsy that starts in any other body part was explained by spread of a 'pneumatic substance'

throughout the body.[1] Based on humoral pathology, he also lists and explains external factors causing seizures including frost, heat, strong winds, baths, repulsive foods, the sight of whirling wheels, sleeplessness, and indigestion among others.[1]

This etiological classification is found throughout medieval times and was only markedly changed in the early 16th century at the beginning of the Renaissance when scientists started to debate and either opposed traditional views or tried to reinterpret authors from antiquity.

Matthaeus Platearius Salernitanus (circa 1150 AD) elaborated on 'major' and 'minor' epileptic seizures based on the galenic epilepsy model. Major epileptic seizures are caused by complete obstruction of the ventricles, whereas minor epileptic seizures represent partial obstruction.[19]

Based on Galen's physiology and Arabic influences John of Gaddesdon (circa 1280–1361 AD) proposed three types of epilepsy: true, truer, and truest epilepsy. The truest epilepsy was induced by obstruction of the ventricles, the truer epilepsy was related to obstruction of the nerves, and true epilepsy was due to obstruction of the arteries.[19]

Paracelsus (Philip Theophrastus Bombastus von Hohenheim, 1493–1541) interpreted all events (and diseases) as reflections of the macrocosm (the world) in the microcosm (the patient). Interpretations were based on the chemical knowledge of his time. He believed in a living spirit in every creature and in a chemical cure for all disease.[45] Epilepsy was thought to be a boiling up of spirits in the patients brain. Based on observations in the macrocosm Paracelsus' distinguished four types of epilepsies deriving from the four elements fire, earth, water, and air and their impression comparing to epilepsy: the thunderstorm (fire), the earthquake (earth), the storm (water), and a milder thunderstorm (air).[49]

Besides Paracelsus' approach, the concept of sympathetic (epilepsies with symptoms that arise in body parts or in the stomach) and idiopathic epilepsies (that arise from the brain itself) continued to prevail until early Renaissance, when more and more case descriptions of multiple diseases causing epilepsy, such as syphilis and ergotism became available.[9]

Charles Le Pois (1563–1636) questioned the concept of sympathetic epilepsy and Galen's humoral pathology attributing all symptoms preceding seizures to a cause in the brain. Additionally, Georg Ernst Stahl (1660–1734 AD) was one of the first who moved the classification of epilepsies away from the severity of its symptoms, the seizures, and distinguished the condition epilepsy from symptomatic convulsive movements related to other medical conditions. This anticipated a change in classifications merely based on the severity or clinical manifestations towards possible etiologies and related conditions.[43] These contributions and additional information from multiple case reports led to several advances in the area of anatomy and pathology that paved the way towards a more etiologically oriented epilepsy classification.

The iatrochemist Franciscus Sylvius (Franz de le Boë) (1614–1672 AD) explained epilepsy by the mixing of a volatile acid spirit with a defective animal spirit that is responsible for movement and sensation. Step by step he lists five causes starting with bile and pancreatic juice as the antecedent cause, followed by an irritative cause (e.g. air or wrong diet), leading to a remote cause (evaporization of the juices). This in turn is the proximate cause (producing the symptoms in the brain) and the conjoint cause (because the symptoms last for the duration of the presence of the vapors).[43]

Samuel Tissot (1728–1797) published his 'Traité de l'épilepsie' in 1770 and distinguished between sympathetic and idiopathic epilepsies (Figure 20.7). Idiopathic epilepsies had its cause in the brain, whereas sympathetic epilepsy was caused by another part of the body. Although this classification reflects the antique epilepsy classification, it now was supported by case reports with some evidence of pathological changes of the brain. For the description of cases in which no definite anatomical cause could be found, Tissot chose the term essential epilepsy.[23] Additionally, Tissot separated between moral and physical provoking factors of epilepsy.[23]

William Cullen (1710–1790) also differentiated symptomatic and idiopathic epilepsies, and divided idiopathic epilepsy further into Epilepsia cerebralis (sudden onset of seizures without known cause), Epilepsia sympathica (preceded by an aura and with known cause), and Epilepsia occasionalis ('arising from manifest irritation, and ceasing when the irritation is removed').[23]

Figure 20.7 Samuel Tissot (1728–1797). Lithography by Jules Hébert (1812–1897) based on a portrait by Angelica Kauffmann (1741–1807). From the 'Album de la Suisse Romande', Vol. 1, Gruaz, Genève, 1843.

James Cowles Prichard (1786–1848) divided epilepsy in 1822 based on its etiology. He related seizures to certain internal organs and differentiated uterine epilepsy, epilepsy related to metastases, epilepsy related to diseases of the intestinal canal and the liver, and last but not least related to cerebral disease.[25]

In 1838, Jean Etienne Dominique Esquirol (1772–1840) separated epilepsy, similar to Galen, into idiopathic (located in the brain), sympathetic (due to a problem at any other place in the body), and sympathetic epilepsy. Idiopathic or essential epilepsy was subdivided into epilepsy caused by an external compression of the brain or skull, into epilepsy related to a structural brain lesion, cranium or meninges, or epilepsy caused by moral causes such as fear or anger. Sympathetic epilepsy could arise from the intestines, from the blood vessels and blood, from the lymphatic system, or from the organs of reproduction. Symptomatic epilepsy was related to the eruption or disappearance of cutaneous rashes, e.g. rubeola or scarlet fever.[25]

Louis Jean Francois Delasiauve's (1804–1893) classification of epilepsy from 1854 is also based on etiology. He distinguishes idiopathic, symptomatic and sympathetic epilepsies. In this classification 'Idiopathic' means absence of anatomical lesion, 'symptomatic' involves a brain lesion, and 'sympathetic' describes epilepsy caused by a condition involving any other part of the body.[25,27]

In 1825, Bouchet and Cazauvieilh classified their experience in a first statistical description of causes of epilepsy.[50] Among 69 patients with epilepsy, they identified fright (21), sorrow (10), masturbation (3), difficult menstruation (3), consequences of childbed (1), critical age (2), dentition (1), vexation (1), head injury (1), artificial insolation (1), and unknown causes (26). Temkin noted that the statistics do not sum up, since the total of these figures would be 70.[51] Similar statistics have later been published by Beau[52] and Leuret.[53]

Sir John Russell Reynolds (1828–1896)[28] developed this concept further and classified four different types of convulsions.

Idiopathic convulsions included epilepsy without a known cause. Secondary (or eccentric or sympathetic) convulsions were caused by diseases in other body parts than the brain leading to seizures. Diathetic (or cachectic convulsions) were related to nutritional causes, intoxications, retained excretions, and others. Symptomatic convulsions arose from diseases of the meninges and the nervous system.[28]

In addition to differentiating between generalized and focal epilepsies Sir John Hughlings Jackson (1834–1911) separated four causes of (unilateral) seizures, including the anatomical 'seat of the internal lesion', the 'functional nature' of the lesion implying the physiological impact of the lesion on the function of the nervous tissue, the 'pathological process' which caused the change in function, and finally 'circumstances which determine the paroxysm' indicating exacerbating factors. Additional etiological classification attempts after Jackson were frequently connected with other features such as localization, etiology, semiology, and age (see later).

Classification according to age

Classifications according to age are rare. In the ancient medical literature, it was recognized that epilepsy was a disease of children and adolescents, as recognized by Caelius Aurelianus.[1] He mentions that seizures occur most frequently during the period of teething.

Hippocrates also mentions that first appearance after the age of twenty years was exceptional.[1] He also related provoking causes such as temperature, season, and wind to the age of the patient and differentiated between children, adults, and elderly.[1]Puberty was considered crucial for the course of epilepsy: epilepsy may stop spontaneously if it occurs prior to puberty. If it occurs after the age of 25 it will last until death. If the disease is not improved by puberty, it will persist and will be difficult to control.[1]

According to Galen, the most frequent form of epilepsy was idiopathic epilepsy arising from the ventricles of the brain, and this form was a disease of early childhood. Rarely, two other forms of sympathetic epilepsy could be seen in older patients.[1]

In the literature on traditional Chinese medicine, Cao Yuan Fang (610 AD) proposes a classification based on age of onset. Patients with seizures under the age of 10 years old suffer from 'Jian' and patients above the age of 10 years old suffer from 'Dian'.

Abu bakr Mohamad ibn Zakariya Razi (Rhazes, 865–925 AD), a Persian physician, classified epilepsies according to the age of onset and distinguishes four types: infants, young children (<7 years), teenagers, and adults.[21]

Berthold of Regensburg (13th century AD) notes that patients suffering from epilepsy for more than 24 years will not be cured.[22] Although several seizure types in children have been described over the following centuries, age as part of epilepsy classifications gained additional importance in the 20th century (see later).

Epilepsy syndrome

The 'lumping' of various semiological and clinical features with possible etiologies is as old as the documentation of epilepsy and seizures itself (as reflected in 3000-year-old Babylonian scriptures).[5] Temkin states that:

> The distinction between symptomatic epilepsy, i.e., a syndrome which might be associated with various diseases, and the possible existence of an 'essential' or 'genuine' disease, epilepsy, is, however, of relatively modern origin and was of little importance in antiquity. The word epilepsy was used to connote both the disease and the single attack.[1]

According to Panayiotopoulos:

> The most important milestone in modern epileptology has been the recognition of epileptic syndromes and diseases, most of which are well-defined and easy to diagnose. The concept of epilepsies as specific syndromes is old (see for example pyknolepsy equals childhood absence epilepsy) [here the author quotes a paper by Adie from 1924][54] and the first attempt to formalize them in an international classification was published in 1970.[55]

Here the author refers to the first ILAE classification in 1970.[14]

Some specific syndromes can be traced back to the middle of the 18th and 19th centuries. One of the earliest publications on syndromes was by West on 26 January 1841 who reported 'on a peculiar form of infantile convulsions' including the case of his own son and several other infants he heard about.[56] Single case reports and clinical descriptions of other conditions similar to Lennox–Gastaut syndrome may also date back to the early 18th century. The invention of the EEG by Hans Berger in 1929 can be marked as the start of further delineation of electroclinical syndromes. Since the late 1930s, pioneers in the field such as Frederic A. Gibbs, Erna L. Gibbs and William G. Lennox supported the view of a one-to-one relationship of clinical presentation and EEG. This view was criticized and questioned by the Montreal School in the early 1950s.

The first attempt to systematically characterize and list epilepsies by the ILAE was published by Gastaut and Merlis in 1970.[14] In this attempt to classify epilepsies, similar criteria were applied to each form of epilepsy, meaning primary generalized, secondary generalized, partial (focal, local), and unclassifiable epilepsies. Subdivisions consisted of four clinical points (seizures, neurological status, age of onset, and etiology) and two electroencephalographic criteria (interical and ictal EEG) in each category. This proposal is very closely oriented on Henry Gastaut's proposal.[13,57] Although this proposal lumps certain types of epilepsies according to different criteria, the concept of epilepsy syndromes has not been mentioned in this proposal nor the actual classification proposal.

Syndromes have been officially introduced in the ILAE epilepsy classification during its revision in 1985.[7] In this classification a syndrome is defined as:

> an epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together. The signs and symptoms may be clinical (e.g. case history, seizure type, modes of seizure recurrence, and neurological and psychological findings) or findings detected by ancillary studies (e.g., EEG, X-ray, CT, and NMR).

> In contradistinction to a disease, a syndrome does not necessarily have a common etiology and prognosis.[7]

The initial strict structure from 1970 that required information on each of these dimensions was abandoned in this revision.

The revision by the ILAE in 1989[15] again defines an epilepsy syndrome as:

> an epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together; these include such items as type of seizure, etiology, anatomy, precipitating factors, age of onset, severity, chronicity, diurnal and circadian cycling, and sometimes prognosis. However, in contradistinction to a disease, a syndrome does not necessarily have a common etiology and prognosis.[15]

A definite distinction between clinical seizure semiology and epilepsy syndrome was only introduced in a recent multiaxial ILAE proposal after publication of the semiological seizure classification. This classification lead to the publication of an ILEA glossary and was one of the decisive publications that lead to a new multi-axial epilepsy classification proposal by Engel in 2001.[8] This ILAE proposal differentiated between epilepsy syndrome, semiological seizure description, pathophysiological seizure type, etiology and impairment in different axes and is described in detail below. A more recent report on the progress of the ILAE core group in 2006 is moving again towards a syndromic classification approach, structuring epilepsy syndromes by age of onset.[16]

Recent concepts and attempts to combine seizures, localization, etiology, age of presentation, and syndrome

In 1954, the Montreal Epilepsy Center led by Penfield and Jasper with its focus on epilepsy surgery is anatomy oriented to identify the seizure onset focus and advanced the classification of different patterns of seizure types, EEG patterns, and imaging findings. They separated three epilepsy types including focal epilepsy, centrencephalic epilepsy, and cerebral seizures associated with different electroclinical presentations. 'Focal epilepsy' presents with psychic, autonomic, sensory features, loss of consciousness or automatisms and has an identifiable cerebral pathological correlate, e.g a tumor or a stroke. 'Centrencephalic' epilepsy is presumed focal, presents with grand mal, petit mal or psychomotor automatism seizures and has no identifiable pathological correlate. 'Petit mal' can either present as petit mal with myoclonus or petit mal with automatisms. 'Cerebral seizures' were not related to an anatomical lesion and not localized, but frequently associated with systemic conditions, such as fever or hypoglycemia.[11] A similar predominantly anatomical concept has also been proposed by McNaughton in 1952.[58]

Symonds (1955) pointed out that clinically similar seizures can present with different EEG patterns. He proposed a separate classification based on clinical, anatomical, physiological (EEG), pathological and therapeutic categories.[59] Masland (1960) also recommended a classification based on etiology, anatomy, physiology and functional impairment.[60] A similar approach has been suggested by Goldensohn (1965) who suggests a classification based on clinical presentation, etiology, and seizure localization. Clinical seizure presentations include generalized major, absence, focal motor, somatosensory, special sensory, automatisms, psychomotor, aphasia, myoclonic, akinetic, spasms, and autonomic. Etiological categories consist of congenital infections, intoxications, trauma, neoplasm, vascular, metabolic, hereditary, and unknown causes. Localizations include frontal, medial and lateral temporal, parietal, occipital and diencephalons. The localization can be more detailed if the affected gyrus is known.[61]

Gastaut's epilepsy classification in 1954 included clinical, EEG, and etiological factors, and it also considered the influence of related medical factors.[12] Gastaut suggested that epilepsy could be divided into partial and generalized epilepsies and then assigned each epilepsy type with different seizure types, EEG findings, etiological factors and related factors. Gastaut used the term partial because the so-called focal seizures not only involve the cortex but – based on EEG – represent an interaction between central gray matter and cortex.

In order to facilitate communication and standardization, the WHO set up a glossary (1967) based on four categories. Terms in this glossary should serve as common building stones in future classifications. The glossary is structured according to: etiology, physiology (clinical and EEG seizure), anatomy, and modifying conditions or circumstance of occurrence including age. This WHO classification was meant to be a framework that allows precise classification of every patient. Etiology includes organic, metabolic, genetic, and unknown causes. EEG and seizure patterns are generalized from the start, partial, erratic with a shifting focus and unilateral seizures. Seizures that are generalized from the start can be divided into typical and atypical seizures with subcategories including absences, generalized tonic clonic seizures, and myoclonic seizures. The anatomical classification is made up of centrencephalic, diffuse and partial epilepsy.[25]

Janz differentiated epilepsy syndromes with age-related petit mal seizures, epilepsies with non-age related petit mal seizures, and epilepsies with grand mal seizures in 'Die Epilepsien'[62] (1969). In the age-related section of his book he separated infantile petit-mal epilepsy, petit-mal epilepsy in school age children, and juvenile petit mal epilepsy. Additionally, he recognized epilepsies not age related including epilepsy with psychomotor seizures, epilepsy with neocortical seizures, and grand mal epilepsy.[62] Each of the three age-related epilepsy types is further described by semiological seizure types, EEG, clinical presentation (including course and prognosis, possible triggers, and etiology), pathological anatomy, pathogenesis, and therapy.

Gastaut revised a classification between 1963 and 1969 based on this glossary and with similarities to the classifications suggested by the Montreal School and McNaughton. In order to gain broader acceptance the glossary was simplified. Main categories include primary generalized epilepsies, secondary generalized epilepsies, undetermined generalized epilepsies, partial epilepsy, and unclassifiable epilepsy. Within these categories, each seizure type was sorted and related

interictal and ictal EEG features, etiology, pathology, and age of manifestation were noted. He differentiated between seizure types that occur in infancy, childhood, or all patients.[34]

This classification provided the basic concept for the first ILAE classification that was shortly thereafter published by Merlis in 1970. Dichotomization of localization of the epilepsies (generalized or partial), etiology (primary without a clear cause) and secondary (related to an organic cause) was also used.

Research advances, such as the wider recognition of benign focal epilepsy of childhood (BFEC) necessitated a revision of this initial classification. Until the description of BFEC, all focal epilepsies were thought to be associated with a certain etiology. Gastaut suggested implementation of primary partial epilepsies, including benign epilepsy with centro-temporal spikes and benign epilepsy with occipital spike-and-wave complexes, into the system. Interestingly, in 1985 Gastaut suggested the characterization of each of these four subcategories (primary versus secondary and generalized versus partial) by age of onset, clinical seizure semiology, ictal EEG, interictal EEG findings, exam, neuroimaging, history of brain injury, family history of epilepsy, response to antiepileptic medications, and prognosis.[63] This proposal was not considered.

In the same year the revised ILAE classification (1985)[7] introduced the concept of epilepsy syndromes. Syndromes were defined as:

> an epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together. The signs and symptoms may be clinical (e.g., case history, seizure type, modes of seizure recurrence, and neurological and psychological findings) or as a result of findings detected by ancillary studies (e.g., EEG, X-ray, CT, and NMR).

Epilepsy syndromes were again dichotomized between the major divisions generalized and 'localization-related' epilepsies. The term 'secondary' was abandoned to avoid confusion with seizure classification ('secondary generalized seizure'). The etiological terminology was changed into idiopathic and symptomatic.

In the 1989 revision of the ILAE classification,[15] the term cryptogenic was added in order to characterize epilepsy syndromes with a presumed but unknown cause.

In 2001, an incomplete revised ILAE classification proposal by Engel[8] including classification axes was published. The huge advance in this proposal was again the differentiation of ictal semiology, etiology and suspected epileptic syndrome. However, this revision again relied heavily on epilepsy syndromes as 'complex of signs and symptoms that define a unique epilepsy condition'. Different axes consist of seizure description (axis 1), seizure type (axis 2), epilepsy syndrome (axis 3), etiology (axis 4), and impairment (axis 5). The first axis relied on seizure characterization according to the ILAE glossary published in the same year and is intended as descriptive seizure characterization.[40] The second axis classified seizure types based on underlying etiology, mechanism, pathophysiology or prognosis. In the third axis, the epilepsy syndrome is characterized. Here syndromes in development and completely characterized syndromes are differentiated. The fourth axis included an incomplete list of possible etiologies and diseases associated with epilepsy. And finally, the fifth axis was incomplete and was intended to outline the degree of impairment due to epilepsy based on a modified scale of the International Classification of Functioning, Disability and Health.

This revised ILAE proposal from 2001 reignited the ongoing debate about a more utilitarian or taxonomic classification of epilepsies, that was first brought up by Reynolds[28] and later by John Hughlings Jackson.[25] In several editorials in the official organ of the ILAE, *Epilepsia*, a taxonomic versus a utilitarian approach to classification was discussed in 2001. In particular, lack of definition criteria and clinical relevance of accepted ILAE syndromes has been questioned.[64] Limitations and shortcomings of this 2001 proposal and redundancy among classification axes have also been demonstrated in several attempts to apply this proposal of a diagnostic scheme to epilepsy patients.[65,66]

A 'report of the ILAE classification core group' in 2006 by Engel returned to a classification of electroclinical seizure types mingling clinical seizure semiology and EEG patterns and to an exclusively syndromic classification of epilepsy. Both the 2001 proposal[8] and the 2006 report[16] by the ILAE neglect that epilepsy syndromes may be less frequent than actually suspected.[65,66] New aspect of the 2006 report – in addition to additional description of syndromes – is the consideration of age of onset in the classification:[16] syndromes during the neonatal period, infancy, childhood, and adolescence from syndromes with less specific age relationship, special epilepsy conditions and conditions with epileptic seizures that do not require a diagnosis of epilepsy were defined.[16]

A possible solution of this dilemma of syndrome arrangements has been suggested by applying a general neurological approach to epilepsy classification rekindling the triple neurological concept of clinical presentation, localization and etiology using an anatomical-dimensional approach.[67] This approach classifies epilepsy according to a general neurological approach into three major categories and adds additional information on seizure frequency and related medical conditions in two more dimensions. The first three dimensions answer the basic neurological questions, namely localization of the lesion, symptomatic presentation and etiology. This is supplemented by dimension four (seizure frequency) and dimension five (related medical conditions). Whereas previous classifications frequently relied on complete information on each case, this diagnostic approach allows progressively detailed classification of each patient as further investigations become available. This classification represents a more practical and patient-oriented approach to each patient.[65] Its orientation towards focal epilepsy is backed by recent studies suggesting underlying focal structural cortical abnormalities in patients with so-called 'generalized' epilepsy[68,69] questioning our current separation of focal and generalized epilepsies.

Future outlook

Our incomplete and limited overview of selected historical and recent classifications of epileptic seizures, etiologies, localizations, age-related categorizations, and epilepsy syndromes revealed a broad spectrum of ways to sort epilepsies through the ages.

Currently, the final revision of the 1989 ILAE epilepsy classification is still pending. It is questionable if the controversy of different classifications for gardeners and botanists can be resolved in one single classification, or if the problem can only be solved by the solution proposed by Jackson – with two classification systems, at least until all details of the disease process are better understood.

Multi-layer and multi-facetted characters of the etiological dimension of epilepsies and further advances in genetics and other clinical and diagnostic techniques may make any classification attempt difficult and always adherent to its time and current knowledge.

This problem has already been recognized by Reynolds in 1861 and will continue to necessitate revisions of epilepsy classifications in the future:

> Perhaps no disease has been treated with more perfect empiricism on the one hand, or more rigid rationalism on the other than has epilepsy. Unfortunately both methods have often and completely failed; the former, as it must do, in a certain proportion of cases; the latter, in a still larger number because the theories upon which it has rested, have often been abundantly wrong.[28]

21 History of electroencephalography as a pre-surgical evaluation tool: the pre-Berger years

WT Blume

Introduction

Inspired by notable advances in peripheral neurophysiology such as the first demonstration of the action potential of nerve by duBois-Reymond in 1984,[1] and first measurement of its velocity by Von Helmholtz in 1950;[2] Richard Caton sought similar activity in the central nervous system of animals but instead discovered persistent fluctuating potentials that he termed 'feeble currents of the brain'.[3] Finding large current oscillations upon exposure to light, Caton speculated that such phenomena would have localizing value within the cortex.

Hans Berger and the Gibbs

Familiar with the pioneering works of Caton and others in animals, Hans Berger in 1924–1929 ultimately succeeded in recording current oscillations from the scalp of humans.[4] Through a series of carefully designed experiments he demonstrated that such currents emanated from cerebral activity and not from the electrocardiogram, blood flow to the scalp, or other artifact.[5]

Berger first demonstrated the lateralizing value of EEG by recording slower waves and 'sudden rises and falls occurring repeatedly over the left central region associated with right-hand myoclonic jerks in a 45-year-old woman'.[6] Berger's Figures 7 and 9 of his seventh report display what now would be termed periodic lateralising epileptiform discharges (PLEDs) and delta activity over the left hemisphere in a patient with epilepsia partialis continua.[7] Subsequently, Gibbs *et al.*[8] also recorded such motor seizures.

By accurately describing several normal and abnormal awake and sleep EEG patterns and their clinical significances, the Gibbs with Davis and Lennox[9] were among those whose works set the stage for a clinical-electroencephalographic partnership in assessing human epilepsies.

Herbert Jasper

As had Wilder Penfield, Herbert Jasper grounded himself thoroughly in those basic sciences relative to his extraordinary accomplishments in electroencephalography and epilepsy. Both Penfield and Jasper trained extensively in Europe as well as in America, enabling each to view their sciences from multiple vantage points. Having confirmed Berger's findings with Leonard Carmichael at Brown University and having found Berger on a 1935 visit to Jena to be 'inspired and inspiring, humble, honest, friendly, distinguished and courageous', Jasper embarked upon a 'whole new field of research' that culminated in many landmark works in electrophysiology relating to epilepsy.[10,11]

Initially Penfield determined the area of cortical excision for epilepsy through scrutiny of the patient's seizure pattern whose features were matched with lesion location and that area whose electrical stimulation reproduced the ictal semiology. A background of many previous cases where seizure semiology and lesion location were related aided each deliberation. When Herbert Jasper brought EEG, then a novel technique of recording brain electrophysiology, to the Montreal Neurological Institute, the scene for Penfield altered significantly in two ways: 1) EEG delineated more precisely the epileptogenic area, and 2) epilepsies not suitable for surgical resective treatment could be identified.[12]

Jasper[12] described normal distinct EEG background patterns of five cerebral regions: 1) temporal-parietal occipital, 2) sensory motor, 3) intermediate frontal, 4) anterior frontal, and 5) hippocampal, insula, and limbic.

He also described aspects of scalp and cortical EEG which aided in localizing epileptogenesis: principally epileptiform discharges (spikes and sharp waves), and abnormal background activity for that region. Jasper found the interictal EEG to 'point to a focus or local area of onset' in over 80% of patients with focal seizures. Thus, he emphasised that the area identified by EEG spikes should also contain abnormal background activity to distinguish a primary spike source from one propagated to normal cortex.[13] These and other EEG and electrocorticographic localising data motivated Penfield to include among his three criteria for epilepsy surgery: 1) an objective abnormality of the brain, 2) clinical and electrophysiological identification of a zone of epileptic discharge within the cortex, and 3) that the identified area is dispensable.[14]

Jasper and Dr. Jack Kershman formed a fruitful electrographic-clinical collaboration culminating in their 1941 article correlating clinical seizure manifestation with interictal EEG abnormalities.[15] These correlations and the clinical associations described by Gibbs and colleagues[8,9] helped to identify those patients whose epilepsies would and would *not* be appropriately treated by resective surgery.

Subdural EEG

Hans Berger, through silver-chlorided needle electrodes placed on human cortex and subjacent white matter, obtained electrical activity only from the cortical gray matter and not from the subjacent white matter.[16] The more precise data so recorded likely instigated development of subdural recordings shortly thereafter. Jasper described a technique for their performance in 1941.[17] However credit is given by Bates[18] to Delgado for development of a technique for chronic implantation, first in monkeys and then in humans.[19,20] Early depth explorations aimed to investigate movement disorders and mental condition. Of some relevance to epilepsy, Gastaut[21] by depth recordings found an occipital response to light in humans that did not appear on surface leads.

From the early 1950s the use of depth recordings focused on the epilepsies.[22] The Mayo Clinic[23] held a symposium on 'intracerebral electrography' that discussed technique, normal rhythms, properties of epileptic foci, stimulation studies, and planning of surgical treatment of focal seizures. Initial advances and applications were made by Bickford[24] among others.

The fabrication and application of stereotactic instruments for precise electrode insertion allowed measurement of cerebral electrical activity in a three-dimensional way, thereby enhancing its accuracy. Initiated by the 'Paris school',[25,26] the Los Angeles group also made substantial gains using this method.[27]

Video-EEG and long-term monitoring

Because seizures occur suddenly, unpredictably, and briefly and because diagnostic and therapeutic decisions may hinge on recording their electrographic correlates (if any); epileptologists have long sought methods to facilitate ictal electrographic recording.

Before technical advances permitted prolonged monitoring, provoking a hopefully representative seizure was the favoured attempt at achieving this correlation. Although hyperventilation, originally used by Berger[28] has long been employed as an activating agent, Pentylenetetrazol (PTZ) (Metrazol) was commonly employed to reliably provoke focal and often secondarily generalised seizures in the 1940s to 1960s.[29] Ajmone Marsan and Ralston recorded PTZ-induced focally-originating seizures using standard scalp EEG, a microphone, and a camera. The resulting clinical-EEG correlations constitute a volume of high value to any epileptologist.[30] Unfortunately, several unwanted PTZ effects led to its abandonment: unpleasant not seizure-related sensations, the 'telescoping' of any focal phase to a few seconds, and the commonly ultimate generalised tonic-clonic seizure. Stepwise antiepileptic drug reduction, hyperventilation and sleep deprivation have replaced PTZ as 'activating agents'.

During the era of analog recording, the technique of long-term monitoring was simply an extension of routine EEG with methods to assure hours-long electrode stability. This led to stacks of paper EEG facing the EEGer every morning. Introduction of FM tape reduced the paper output as limited epochs could be selected, usually ones containing clinical seizures or other attacks.[31]

The advent of digital recording permitted simultaneous EEG and audiovisual recording providing accurate, sequential analysis of clinical-electrographic correlations. Methods of data reduction have enabled the extraction of certain features of interest which would have heretofore been eclipsed among irrelevant or redundant data. However, a knowledgeable decision has to be made concerning data to be jettisoned and in discerning cerebral data from artifact.[32]

In addition to epoch selection, automated detection and analysis of interictal and ictal events have strived to reduce total data and even to assist visual analysis. While distinct progress has been made, the threshold for some commercial systems remains sufficiently low that many 'false positives' are detected.

Nevertheless, digital-based extended monitoring has helped to distinguish seizures of different origins or distributions with common semiologies, e.g., temporal lobe seizures from absence. Such recordings also help to identify pseudoseizures.

Telemetric recordings, developed by Storm van Leeuwen and Kamp[33] and Stevens,[34] would seemingly have provided long-term monitoring while allowing greater freedom of movement. Their value has been limited by artifact and by a limited audiovisual component.[35] Ultimately, their use preceding inpatient epilepsy evaluation may shorten hospital stay and cost.

Integration of data

Principal among the several considerations involved in possible surgical management of the epilepsies are: 1) medical intractability, 2) seizure origin, and 3) dispensability of an epileptogenic area. Initially ictal semiology and obvious lesion location were Penfield's only guides and antiepileptic drug options were few.[10] Since then several other modalities, including electroencephalography, have emerged to assist in decision making. However, these additional components increase the likelihood of incongruent data appearing. Pierre Gloor[36] emerged as one of several wise marshals of such data, particularly the electroencephalographer's role in providing reliable and significant input in decisions such as the utilisation of invasive recordings and taking the option of surgery. Two qualities are requisite for an electroencephalographer to advise on these crucial matters: 1) a thorough knowledge of EEG and, 2) appreciation of EEG's place in the broader fields of basic and clinical neurosciences. Gloor and others like him possess(ed) both attributes.

22 History of neuroimaging in the pre-surgical evaluation

B Diehl and P Ruggieri

The history of modern presurgical evaluation for epilepsy surgery has been shaped by several main influences and approaches in localizing the seizure focus and infer a lesion site: first, clinical observation and seizure semiology; second, the advances in EEG diagnostics; and last, the advances in our ability to image the brain. This chapter aims at illustrating seminal points in the history of brain imaging and highlights its relevance to the presurgical evaluation for patients with intractable focal epilepsy.

Arguably, there is no other technology that compares to modern structural and functional brain imaging in revolutionizing our way of thinking about epilepsy and the presurgical evaluation throughout the last decade of the last century, the decade of the brain. Therefore, reflecting upon the history of neuroimaging in the context of epilepsy surgery and how it shaped the thinking of generations of epileptologists and epilepsy surgeons will likely make us appreciate the huge opportunity we have in the new millennium.

For the longest time in the history of epilepsy surgery, there was no direct way of imaging the brain. In 1896, Sir William Gowers wrote in his famous textbook:

> The nervous system is almost entirely inaccessible to direct examination. The exceptions to this are trifling. The termination of one nerve, the optic, can be seen within the eye. Some of the nerve trunks in the limbs can be felt, as the ulnar, in the normal state; others only when enlarged by disease.[1,2]

Therefore, in the closing decades of the 19th century, evidence about the presence of pathology could only be gained indirectly, and was mainly based on the careful examination and clinical correlation of the deficit and the pathology later analyzed either after surgery or after postmortem pathological examination. Only in 1895, when Roentgen discovered X-rays, were we able to start to look inside the human body *in vivo*, even though with respect to the brain it remained an indirect window by careful analysis of bony changes secondary to intracerebral pathology.

The beginnings of imagery of the brain

For many centuries, the role of the brain was unknown. In ancient Egypt, for example, the heart was considered the essence of life and the brain discarded in the embalming process. Some valuable observations however concerning the brain were documented. In the famous Edwin Smith Surgical Papyrus, tracing its origins back to the third dynasty, approximately 3000 BC, mention is made of various head and brain injuries and how to approach them.[3] Concepts of the use of the brain and its structure and functioning emerging over the following centuries laid the groundwork for a modern understanding of the brain and its diseases.[4]

The brain as the seat of the mind was clearly recognized by an early Greek writer and philosopher-scientist, Alcmaeon of Croton. He detailed in his book around 500 BC the idea that the brain was the organ responsible for sensation and thought. He described that sensory organs were connected to the brain and he excised the eyeball of an animal and observed *poroi* (channels, i.e., the optic nerve) leading from the eye in the direction of the brain. In the years to come this very advanced concept was abandoned and other Greek philosopher physicians such as Hippocrates reverted to more primitive hydraulic theories, postulating that the 'essence' of life, a mysterious substance, was supposed to be carried by the blood. In the book 'on the sacred disease', which is ascribed to Hippocrates' authorship, he recognized however that the brain serves as the controlling center of the body. He also criticized the popular belief that epilepsy was a divine malediction. There is no doubt that Hippocrates recognized that seizures were arising in the head.[5] However, for many centuries to come, people, including Aristotele, ancient Greek's greatest natural philosopher, would continue to believe in the supremacy of the heart compared to the brain.

The history of imagery of the brain dates from antiquity. However, there is no evidence suggesting that these concepts were used to guide treatment.[6] Surgical interventions for the treatment of seizures were often guided by supernatural concepts about the cause of epilepsy. In the hellenistic world trephination was a well established remedy for epilepsy. The procedure was performed to serve as an outlet for pathogenic humors and vapors.[7] For many centuries the concept was that the brain was an organ that functioned as a whole.

Reviewing the history for cerebral localization and the search of the seat of the soul will help to understand the evolution of concepts for imagery and cerebral localization, which are prerequisites for epilepsy surgery.

Around 300 BC, the first human dissections were performed by Herophilus and later Erasistratus in Alexandria (Egypt); they wrote the first detailed account of the structure

of the brain and heart. Herophilus is generally considered the father of anatomy.

The nervous system is discovered and classified into different types of nerves (motor and sensory nerves).

Galen in the 2nd century AD divided the nerves into sensory and motor according to Herophilus and believed they originate in the anterior and posterior brain. He thought that the mental faculties resided in the brain substance. Three primary brain functions were described: sensus communis (the gathering together of all forms of sensory perception to produce imagination), reasoning, and memory. However, he also stated that injury to the ventricles could cause mental damage; this was often interpreted to mean that he placed the locus of cerebral activity in the cerebral ventricles.[8] Nerves as hollow channels were thought to convey the information from the ventricles through the body. Galen made great strides to understand biology and anatomy. His greatest work is considered De usu partium or on the usefulness of the parts of the body. Some time after Galen's death the sensus communis and imagination, reasoning and memory became located in the lateral, third, and fourth ventricles.

During the medieval ages, efforts to understand the human body in health and disease come to a standstill. The pictorial representation of illness in medieval art seen in book paintings in the biblical context offers insights in the symbolism and concepts of a disease characterized by events of sudden alteration of consciousness and unusual behaviors.[9]

Modern medicine began in 1543 with the publication of the first complete textbook of human anatomy, De Humanis Corporis Fabrica by Andreas Vesalius (1514–1564). It includes sections on the brain, and he disputes the prevailing doctrine that higher functions of the brain are situated in the ventricles. Anatomy illustrations became increasingly available for educational purposes, and many illustrate beautifully the new realism in Renaissance. Italian Renaissance artists became anatomists by necessity, as they attempted to refine a more lifelike, sculptural portrayal of the human figure.

Thomas Willis disputed the idea that higher functions were located in the ventricles and wrote in his book 'Cerebri anatome' (1664) that the cerebral hemispheres determine thought and action. He felt though that this was completely separate from the parts of the brain that control motor functions.

In 1791, Franz Josef Gall of Vienna may have been the first to propose that different mental faculties and behavioral functions occupied different anatomical locations in the brain.[6] Gall believed that mental function was localized in discrete areas of the brain and called those organs. He located the organs subserving intellectual function in the cerebral cortex. Although he published these seminal observations, his contributions were overshadowed by his introduction of phrenology, the practice of diagnosis based on palpation of the skull, which evolved increasingly in a pseudoscience. On the other hand, Gall and his disciple Spurzheimer developed a unique system of dissection using alcohol and significantly advanced the knowledge of neuroanatomy.[10]

Not until the mid-19th century did neuroscientists begin to use clinical pathological correlation and faradic stimulation to prove that cerebral gray matter indeed comprised functionally discreet regions.[6] In 1861, Broca published his landmark case, M. Leborgne, who suffered from epilepsy since childhood and had lost his ability to speak. After the patients's death from an unrelated cause, an autopsy showed a chronic progressive softening of the cortex in the third convolution of the frontal lobe. It is considered the turning point that persuaded many learned men to believe in cortical localization of function.[11]

Sir Hughlings Jackson, by many called the father of contemporary epileptology, was a brilliant observer and used the information obtained through analyzing the clinical manifestations of seizures to localize the ictal onset. In 1861 and 1863 he wrote about the unilateral seizures in cerebral syphilis and commented that:

> As autopsies of patients who have died after syphilitic epilepsy appear to show, the cause is obvious organic disease on the side of the brain opposite to the side of the body convulsed, frequently on the surface of the hemisphere.[12]

In 1870, Fritsch and Hitzig finally provided unequivocal experimental confirmation of a 'motor cortex' in the frontal lobes of dogs.[13]

Epilepsy surgery in the strict sense of a neurosurgical intervention at an anatomical site that is defined by the seizure semiology was introduced in the second half of the 20th century and developed from the analytical approach that is closely related to the observations by Jackson. The first epilepsy surgery was performed on 25 May, 1886, by Victor Horsley on a 22-year-old patient with focal motor seizures, due to a scar that had been caused 15 years earlier by a depressed skull fracture.[14] The surgery was planned purely based on clinical semiology, and performed taking into account the *in situ* appearance of the brain tissue. Krause appeared to be the first to utilize intraoperative cortical stimulation to guide surgery[15] particularly to identify central sulcus in cases of Jacksonian epilepsy. However, until the end of the 19th century, it remained impossible to directly or indirectly image the brain before surgery. This changed drastically in 1895.

Radiography and the application of X-rays to skull and brain pathology

The history of neuroimaging arguably starts with a great discovery: On 8 November, 1895, Wilhelm Konrad Roentgen, Professor of Physics at the University of Würzburg, discovered X-rays. Roentgen, an experimental physicist of the old school, had the custom to repeat experiments previously made by others at the beginning of a new experiment. Roentgen was interested in cathode rays and in assessing their range outside of charged tubes. He was repeating Hertz' and Lenard's experiments with cathode rays and used the same experimental armamentarium, then extended his experiments to include a Hittorf-Crookes' vacuum tube. On a Friday evening, 8 November 1895, 'at a late hour when assistants were no longer to be found in the laboratory', he made his groundbreaking observation.[16] Interviews with Roentgen on the discovery revealed the circumstances. One appeared in McClure's

magazine early 1896 written by a reporter, H. J. W. Dam.[17] When asked about the discovery, Roentgen told him:

> I was working with a Crookes' tube covered with a shield of black cardboard. A piece of barium platinocyanide paper lay on the bench there. I had been passing a current through the tube and I noticed a peculiar black line across the paper ... The effect was one which could only be produced, in ordinary parlance, by the passage of light. And when asked: "What did you think?" the answer was: I did not think, I investigated. I assumed that the effect must have come from the tube, since its character indicated that it could come from nowhere else. I tested it. Rays were coming from the tube which had a luminescent effect upon the paper. I tried it successfully at greater and greater distances, even at two metres. It seemed at first a new kind of invisible light.

He plunged into seven weeks of meticulously planned and executed experiments to determine the nature of the rays. He worked in isolation, telling his close friend Boveri simply, 'I have discovered something interesting, but I do not know whether or not my observations are correct'. At the end of December, a brief communication 'on a new kind of rays' was published, the result of seven weeks of systematic studies and well-designed experiments.[18] Roentgen, the great and humble scientist himself gave the newly-discovered phenomenon the name X-rays on account of their unknown character and to distinguish them from other rays. For this discovery he was awarded the first Nobel Price in Physics in 1901 (Figures 22.1–22.3).

With this discovery, the era of radiology was born. Soon after Roentgen's breakthrough, X-rays were applied to examine the neurological system. Arthur Schueller, who graduated in Vienna and was introduced to the study of radiology, performed systematic studies of the skull and is generally considered the father of neuroradiology. He introduced the term Neuro-Roentgenologie.[20] His works on the X-ray examination of the skull are still considered classic,[21] carefully correlating autopsy and clinical findings with bony deformations. In his work on 'Roentgen diagnosis of diseases of the head' published in 1912 he describes a variety of skull X-ray findings in patients with epilepsy: bony defects and signs of underlying encephalomalacia, foreign bodies within the brain, depressed skull fractures, enostosis, and calcifications.[21]

The use of skull X-rays in the diagnosis of epilepsy has been advocated by a German Neurosurgeon, Fedor Krause. In his 'Surgery of the brain and Spinal Cord'[22,23] published in 1910 he remarks:

> Above all other means of diagnosis it furnishes the most useful in tumors with calcareous or bony deposits, as for instance in exostosis and any injury of the skull may bring on epileptic seizures .... whenever possible X-ray examination should be made; it is frequently a great aid in clearing up the diagnosis. Even in other forms of epilepsy, roentgenography is of urgent need.

Up to the 1960s and even the seventies, plain X-rays were recognized as having a place in the evaluation of patients with epilepsy. Bony changes and abnormal calcifications were the main findings in patients with epilepsy. Bony changes are found in a variety of conditions and may occur as a sign of the following conditions (from ref. 24):

Figure 22.1 On a new kind of rays, cover of the first edition reprint and first page of the original manuscript (reprint from ref. 19 with premission from Elsevier).

1. Chronically elevated intracranial pressure with erosive changes of the pituitary fossa, thinning of the inner table of the skull, and if present in childhood widening of the skull sutures from hydrocephalus.
2. Dystrophic calcifictions may possibly occur in the setting of a menigeoma. The differential diagnosis includes calcium deposits from metastasis of prostate or breast cancer.
3. Bony erosions rarely are seen in the setting of epilepsy but could indicate primary hyperparathyroidism, some infectious diseases or pressure from adjacent masses.
4. Cranial hemiatrophy can be seen with there is less development of one hemisphere in the first year of life.
5. Pathological vascular markings can be seen in menigeomas.
6. Congenital cranial abnormalities such as meningoceles or encephaloceles can be detected.

How this information was utilized for the purpose of localizing the epilepsy will be shown in the case presentations below.

Throughout the first half of the last century, roentgenography was explored as a tool to help localize lesions causing

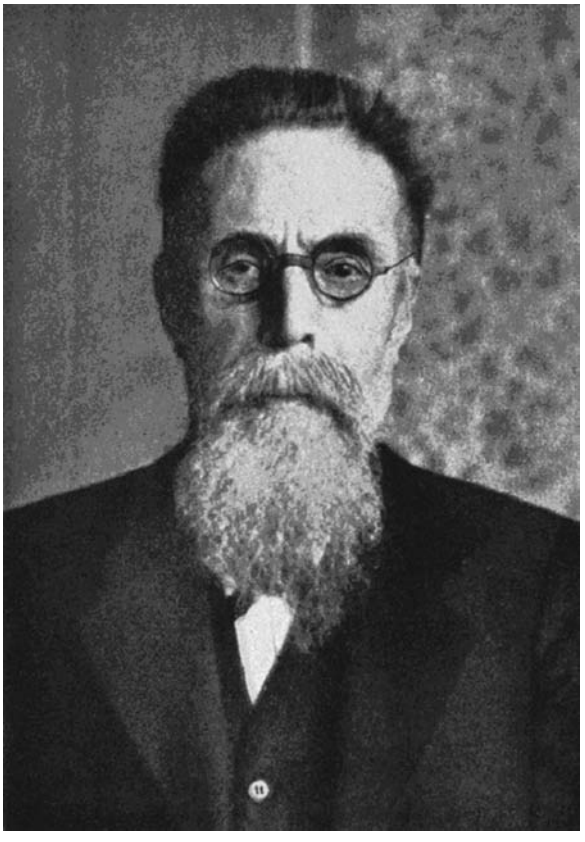

Figure 22.2 Roentgen a few weeks before he died (reprint from ref. 19 with premission from Elsevier).

seizures. In conjunction with pneumencephalography, it remained the main imaging technology for more than 50 years.

The history of pneumencephalography

In 1918, ventriculography using X-rays to explore that contrast between air and fluid was introduced by Walter Dandy.[20,25,26] One or more of the cerebral ventricles can be outlined in the skull X-ray if the ventricular fluid was withdrawn and replaced by an equal amount of air.[26] Dandy attributed the idea of using air as a contrast medium to observations made in roentgenograms of the abdomen and chest, as stomach and intestines were often seen outlined by the contained air.[27] However, earlier reports on spontaneous pneumencephalograms had already appeared and may have also influenced his thinking. In one case, air had entered as a result of head trauma. In another patient, a pneumatocele arose in association with surgery for an orbitoethmoidal osteoma.[28,29] For the first time, effects of intracranial pathology could be visualized without bony changes. The procedure as described by Dandy was mainly performed in the recumbent position, with the head at least 20 degrees higher than the body. 'With each injection, the air will then rush to the brain and a new supply of fluid will fall to the point of the needle.' The cisternae, subarrachnoid space, and sulci become visible. The initial publication included eight patients, five had normal pneumencephalograms, three had pathologies. Patient one showed

Figure 22.3 First Roentgen photograph of Ms. Roentgen's hand (reprint from ref. 19 with premission from Elsevier).

obstructive hydrocephalus at the level of the cisterna pontis due to meningitis, another patient showed a more localized finding of hydrocephalus, and the third patient was diagnosed with a presumed cerebellar tumor based on the pattern of the pneumencephalogram.

From then on pneumencephalography was used to get indirect evidence of brain lesions affecting the subarachnoid space. For example, tumors sitting near the surface of the brain and obliterating the subarachnoid space. Defects in the brain substance, filled with spinal fluid became visible when air was injected.

Brain imaging in the first half of the last century evaluated patients with epilepsy using X-rays and air contrast. The extensive documentation of cases undergoing surgery for intractable epilepsy particularly from the Montreal Neurological Institute illustrates how the new technologies were used to guide the presurgical diagnosis.

The use of skull X-rays and pneumencephalogram in the diagnosis of epilepsy in earlier part of the 20th century

The history of epilepsy surgery in the first half of the last century and in this context also of using imaging techniques to guide epilepsy surgery was dominated by the Montreal Neurological Institute, which opened its doors in 1934. Its founder, Wilder Penfield, had a background shaped by extensive travel and work in various places in Europe and North America. From Foerster, an experienced neurologist who became his own neurosurgeon, Penfield had learned the technique of mapping out the sensory and motor cortical areas by cortical stimulation in order to resect 'menigocerebral scars' safely.[30] Many cases resulted in failure as there were inadequate means to localize the epileptogenic zone.

The number of surgical epilepsy cases continued to increase every year. The thrust came from Penfield's determination to cure seizures by excision of the 'meningocerebral cicatrix'. Through careful catalogization and analysis of seizure type matched with the type of lesion found during surgery, a wealth of well-documented case histories is available from that era.

Etiologies for epilepsies was inferred from lesions visible from X-ray and pneumencephalography. In Wilder Penfield's famous book 'Epilepsy and the Functional Anatomy of the Brain'[31] and a wealth of other books and articles, cases were presented illustrating how indirect roentgenographic evidence was used to infer underlying brain lesions and to guide epilepsy surgery. From the standpoint of diagnosis and treatment, the epilepsies were divided into symptomatic epilepsies and in cryptogenic in the first half of the last century. The etiologies were readily recognized or reasonably assumed in the symptomatic cases and the unknown were classified as cryptogenic ('of obscure origin'). Common etiologies of epilepsies thought to be amenable to epilepsy surgery were grouped into 'expanding lesions' and 'atrophic lesions'.[32] The spectrum of the known etiologies also was remarkably complete for the time.[32,33]

McRae[32] summarized the radiological findings of patients with atrophic lesions operated on by Dr. Penfield and Eriksson between 1937 and 1946. The diagnosis was made based on history, physical signs, electroencephalographic methods, and radiological examination using plain skull films and pneumoencephalography. Often, the presurgical diagnosis was confirmed by the production of a typical seizure on electrical stimulation of an abnormal gyrus during surgery.

For the analysis of the X-rays, 'stereoscopic anteroposterior films', stereoscopic lateral films of the abnormal side and a single postero-anterior film were taken.

Great care was taken that no rotation was present for the frontal films. In order to judge for asymmetry, frontal films were traced on tracing paper and the skull was folded along the mid-sagittal plane and held against the light.[32] Electroencephalograpic studies consisted of six stereoscopic pairs of films.

Atrophy was considered to be secondary to traumatic brain injury and vascular etiologies. The following radiological findings were highlighted in atrophic lesions.[32,34] The most common finding was reduction in volume of the lateral cranial chamber. Other more variable findings were enlargement of the frontal or ethmoidal sinus on the small side, asymmetrical development of the mastoid cells, elevation and smoothness of one petrous ridge. Indirect evidence could be gathered on the timing of the injury. If atrophic lesions were acquired within the first two years of life, a large difference in brain volume between the two hemispheres could be seen; injury between age 2 and puberty may still result in an asymmetry in skull size. Displacement of the calcified pineal gland, calcified choroids plexus or falx these structures towards the side of the lesion is another indirect sign.

Roentgenological abnormalities in the surgical treatment of temporal lobe epilepsy were used as following: small size of the cranial chamber of one side was taken as evidence for an ischemic birth lesion at that side. Pneumencephalography may show enlargement of the inferior horn of the side of the lesion of the temporal lobe. In their series of surgical therapy of temporal lobe seizures, 27 patients were considered to be in the 'success' group and the pneumencephalogram was considered to indicate an abnormality of the temporal lobe, later shown to contain an epileptogenic lesion in 18 cases. In three cases, it pointed to the opposite side and in 6 cases no lateralizing evidence was concluded.[35] The following cases illustrate how indirect evidence form X ray and pneumencephalogram was used for localization to guide surgical intervention in patients with epilepsy.

Case examples

Figure 22.4 (from ref. 31) illustrates the skull X-ray of a 15-year-old boy who at the age of 5 years suffered an accident resulting in unconsciousness for 9 days. Seizures started at the age of 14 years.

The fracture is visible in the 'right frontal bone'. 'Above and posterior fracture line the undersurface of the skull presented such an area of cerebrocranial erosion with evidence of bone absortion and new bone formation'.

The epileptogenic focus was felt to be adjacent to this area delineated on the skull X-ray, the patient underwent surgery and bony erosions were demonstrated.

Another case after head trauma is illustrated in Figure 22.5 (from ref. 36). In 1914 the patient received a shell wound in the right frontal lobe. He suffered no loss of consciousness and immediately had surgery. He started to have seizures four years later characterized by turning of the eyes and head to the left, followed by movements of both the left extremities. Pneumencephalogram shows enlargement of the right lateral ventricle with upward and lateral displacement.

Figure 22.6 illustrates a case with small right hemicranium: 'Brain injury and subdural hematoma at birth, focal seizures from 6 months of age. The case illustrates marked atrophy of

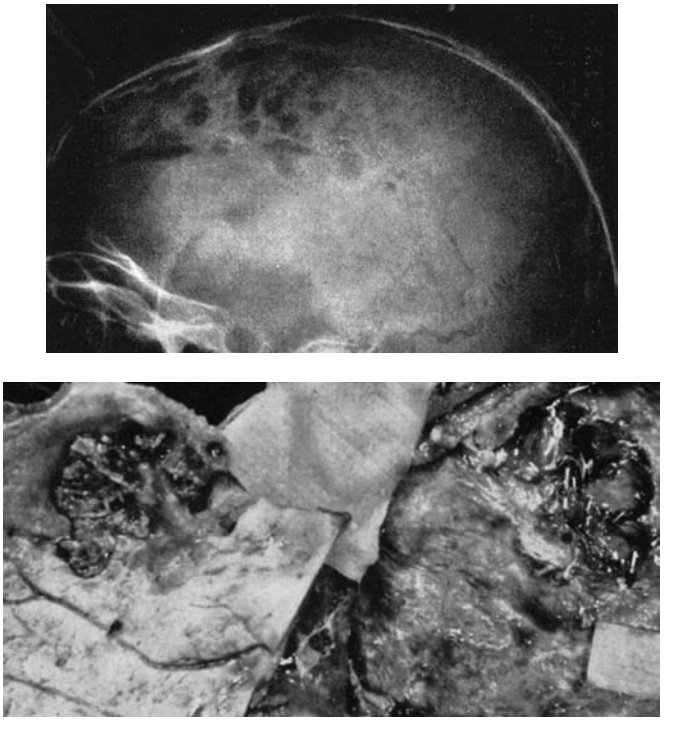

Figure 22.4 Fracture of the right frontal bone 10 years earlier in a 15-year-old boy with epilepsy since the head trauma. Above and posterior to the fracture, craniocerebral erosion is indicated by mottling. The frontoparietal bone flap was turned to show the eroded skull area and the bare brain in its corresponding area (case R.St., from ref. 31).

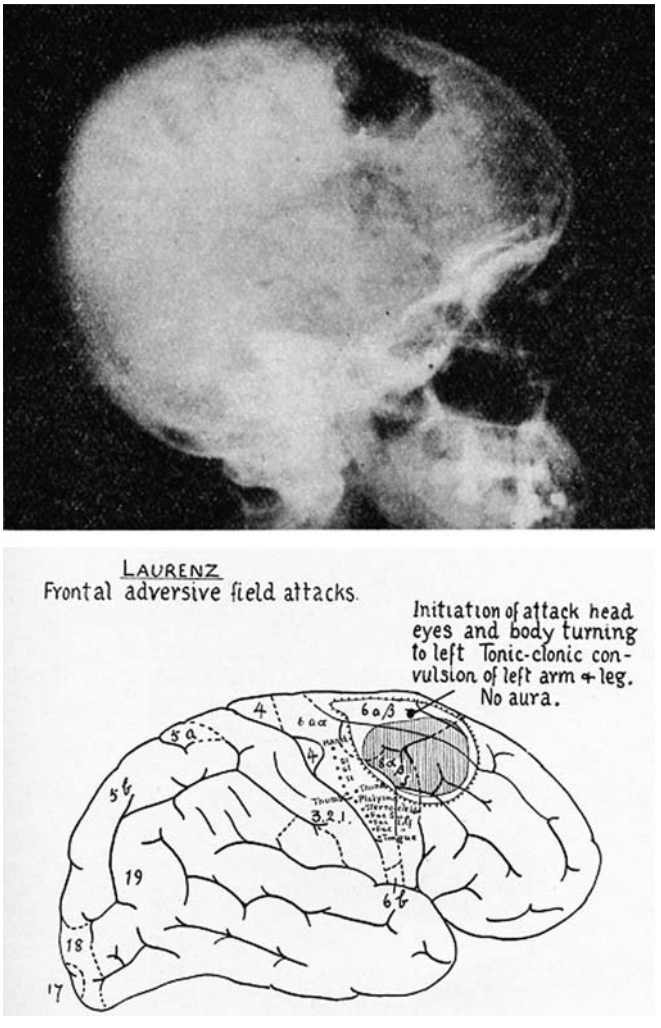

Figure 22.5 Top: Pneumencephalogram (right side of the head) showing cranial defect with enlargement of the anterior horn of the right lateral ventricle and deflection upwards of parts of both anterior horns. Bottom: Lesion as seen at the operation. Motor response to galvanic stimulation is indicated by small dots; the large dot indicates the area a seizure was induced using stimulation. From ref. 36.

the right posterior hemisphere and normal cortex anteriorly' (from ref. 31).

Another case (Figure 22.7) illustrates the use of pneumencephalogram in a patient with 'enlargement of the posterior end of the right lateral ventricle', replacing destroyed brain tissue. Natal or prenatal arterial occlusion produced 'ventricular enlargement without cranial hemiatrophy'.[31]

Figure 22.8 illustrates a case of temporal lobe seizures due to 'birth compression'.

Case J.Mc.[31,37], a 13-year-old girl, was referred for seizures at the age of 9 years, six days after she had the measles. She had a generalized convulsion which was followed by a 6-hour episode of unconsciousness. Seizures are described as 'aura of sensation in abomen and thorax, salivation, swallowing and automatic behavior'. Electrographic localization pointed to the left temporal region. Ventricles were slightly enlarged but symmetrical in size. Simple X-ray films showed the left middle fossa to be smaller than that on the right with an elevated petrous pyramid on the right. EEG showed left temporal sharp waves.

The patient was operated and Penfield comments that 'the first convolution was small and tough. The abnormality extended down into the uncus and hippocampus. Electrical stimulation of this issue reproduced the patient's habitual thoracic aura.' Interestingly, the cause of this abnormality was felt to be 'birth compression'. Histology revealed gliosis.

Penfield and Flanigan presented their results with epilepsy surgery in cases with temporal lobe epilepsy.[38] The epileptogenic zone was determined using the above-described means. Interestingly, the long-term seizure outcomes were not so different from the post MRI era: 52.9% were considered 'cured' with no seizures or only one or more attacks before cessation. 29% were felt to have worth while improvement, and 14% were surgical failures.

In 1991, Rasmussen presented another series on outcomes after temporal lobe surgery for epilepsy: 63% of 100 patients had complete or marked reduction of seizures after 'major hippocampectomy' with medial removal of the amygdala, the pes and half of the hippocampus.[39]

Radionuclide brain scanning

In February 1896, 3 months after Roentgen's discovery, Becquerel described natural radioactivity. The rays were being used for medical treatment. However, another 50 years had to pass before spontaneously emitted rays were used for diagnosis. The discovery was made by George Moore, a young surgeon from Minneapolis. He knew that fluorescein was taken up selectively by tumors of the eye. Prior to surgery for suspected gliomas, he injected a small dose intravenously and was able to detect it in the tissue using ultraviolet light. When the brain was exposed during surgery, he would shine the UV light on the brain and be able to identify the glioma and the edges well. The next step was to tag a radioactive substance to fluorescein; Dr. Moore chose radioactive iodine and used a Geiger counter to detect the radioactive emissions. He was immediately successful and localized 12 of 15 brain tumors.[40,41]

Over the next years this technique was refined and successfully evaluated in the diagnosis of a variety of neurological diseases. The conclusion from a larger study evaluating the utility of the radionuclide brain scan was that it is particularly useful in patients who develop localizing signs, in patents with 'focal fits' (eight of 11 such patients had abnormal scans), in patients with vascular disease and gradual onset of localizing signs and in patients with inflammatory conditions of the central nervous system.[42]

When brain scans were compared to EEG in a patient population with tumors, it was felt that successful localiza-tion using both methods was attained in 90% of all cases. Only in one case was there no congruence between the two methods.[43]

Up until the introduction of CT and later MRI into clinical practice in the late 1970s and 1980s, X-ray, pneumencephalography, and radionuclide brain scanning remained the only means of indirectly localizing a structural lesion in patients with epilepsy.

Carotid arteriography

By the middle of the 1920s, the Portuguese neurologist Egas Moniz investigated to inject radio-opaque material in the arteries. After some animal experiments using sodium iodide

Figure 22.6 X-ray and pneumencephalogram illustrates a case with a small right hemicranium. Frontal sinuses are large on the right (case NP, from ref. 31).

as a contrast agent, he decided to experiment on human cadavers to learn anatomy. After an initial unsuccessful patient experiment when no contrast medium became visible, he concluded it was not injected, and the technique was changed. The next case was done after a surgical cutdown, so that the internal carotid artery was exposed, and the experiment was a success. In 1931, Moniz published his first 90 cases. There were only two deaths in that group, both in patients with artherosclerosis.[27,44]

It remained a valuable tool for epilepsy related to vascular malformations, to determine vascularity, supply extent and site of tumors, obtain indirect evidence to determine the pathology of a mass lesion based on the vascular characteristics.[24] It furthermore gained particular importance to date in pre-surgical investigation, as the development of angiography is a prerequisite for the injection of amobarbital or another barbiturate in order to accomplish language lateralization and assess memory function (intracarotid amobarbital test).

Computerized tomography (CT)

In the late 1960s, efforts were directed to perform measurements of X-ray transmissions from all possible directions through the body. The attenuation of the X-ray is measured from hundreds of different angles and the information is decoded and subdivided in a series of 'slices'. In 1972, Sir Godfrey Hounsfield introduced CT (see Figure 22.9).[45] In Hounsfield's initial experiments using a gamma ray source, it took nine days to acquire the data and 2.5 hours to reconstruct the image on a computer.[46] The second generation of scanners were much faster already: one slice could be acquired in 18 seconds.

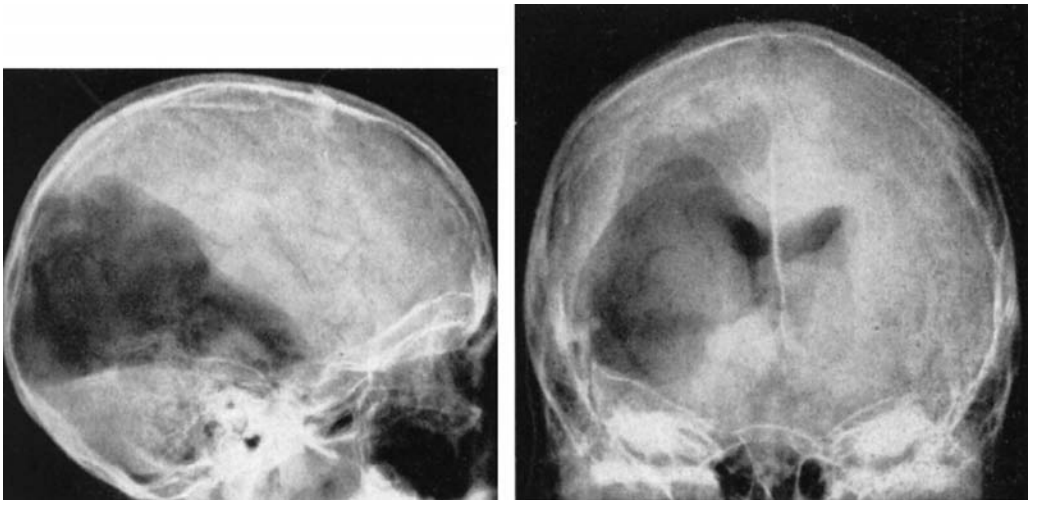

Figure 22.7 Natal or perinatal arterial occlusion producing ventricular enlargement without cranial hemiatrophy. The enlarged ventricle takes the place of the destroyed brain (case HG, from ref. 31).

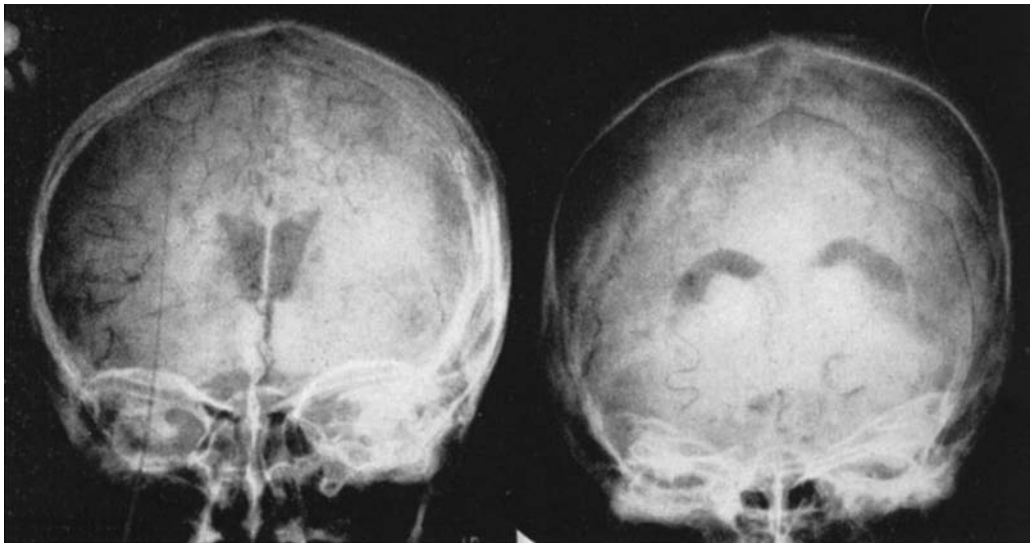

Figure 22.8 Temporal lobe seizures since age 9. Smallness of the middle fossa on the right is indicated by the greater height of the petrous pyramid and floor of middle fossa on that side (case JMc, from ref. 31).

In the 1970s, CT was introduced in clinical practice. Direct imaging of intraparenchymal abnormalities became possible for the first time. In epilepsy, the scanner was used to detect structural lesions and to determine cerebral atrophy. It was quickly shown that CT was superior to radionuclide scanning.[47]

In 1975, at the 21st European Congress of Electroencephalography and Epilepsy, the results of a total of 1702 patients from seven research groups were published. CT abnormalities were found in 46%. The most common abnormality was atrophy. Tumors were found in 10% of cases. It was well recognized that CT is quite sensitive to detect cerebral tumors and lesions like gliomas or various developmental tumors. Other pathologies including cerebrovascular disease, both ischemic and hemorrhagic, vascular malformations, post-traumatic changes and infectious disease could be visualized directly for the first time. It was also possible to demonstrate the structural lesions underlying the epilepsy in epilepsy syndromes such as temporal lobe epilepsy.

The CT scanner therefore replaced plain skull X-rays and pneumencephalography very fast in the 1970s. MRI would soon replace CT in its role to evaluate chronic epilepsy, especially as the sensitivity of CT in patients with epilepsy is no higher than 30% in unselected populations.

Today CT is readily available at all times and remains a valuable tool in many emergency situations and may have added value for the evaluation of intracranial calcifications.[48] If clinical presentation suggests a serious structural lesion, such as an acute intracranial hemorrhage or larger lesions that require immediate surgical intervention, emergent neuroimaging needs to be performed.[49] For the evaluation of a first seizure, CT is still performed if the patient's history and/or focal neurological signs make an acute symptomatic cause likely.

Magnetic resonance imaging (MRI)

In 1946, the first reports on nuclear magnetic resonance were published by Bloch, Hansen and Packard[50] at Stanford and by Purcell, Torrey and Pound[51] at Harvard. The importance of that discovery was recognized and, in 1952, the Nobel Prize for Physics was awarded to Bloch and Purcell.

In the 1980s, MRI was introduced in clinical practice. Since, it has revolutionized the practice of medicine in many areas. The ability to visualize anatomical details and pathologies underlying the focal epilepsy dramatically surpasses previous technologies. The first publications for its usefulness to detect lesions underlying focal epilepsy date to the mid 1980s.[51–54] It was soon demonstrated that MRI was more sensitive than CT to detect structural lesions underlying epilepsy.[54]

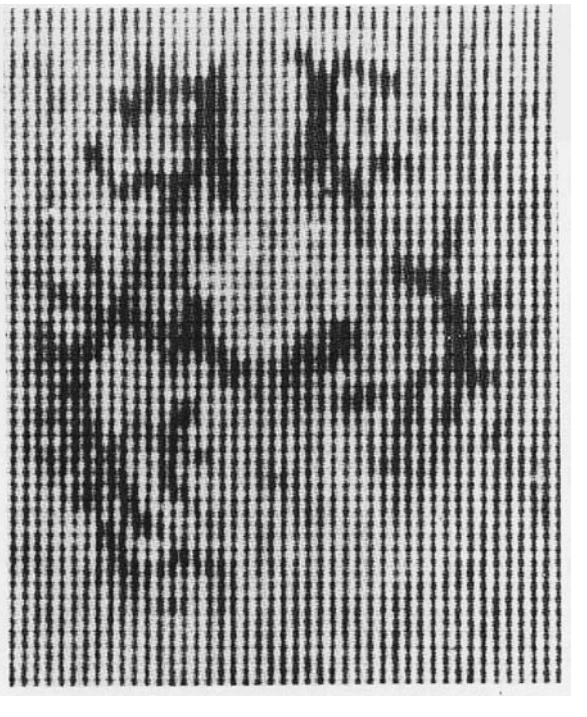

Figure 22.9 Picture of the first brain scanned on the laboratory CT machine. From ref. 46.

Nowadays, approximately 70% of all patients with focal epilepsy referred to a tertiary epilepsy center show structural pathology on MR.[48,55] It became possible to image the temporal lobe and detect hippocampal pathology in a non-invasive way (Figure 22.10). Several groups have found conventional MRI studies to be about 90% sensitive and 85% specific in the diagnosis of hippocampal sclerosis in a series of epilepsy patients undergoing temporal lobectomy.[56–59]

Over the past two decades, significant strides were made to improve the quality of MR-imaging. The introduction of fluid-attenuated inversion recovery sequences (FLAIR)[61] for the diagnosis of hippocampal sclerosis has significantly increased the accuracy of the detection of signal abnormalities in the mesial structures, as CSF is completely suppressed. Assessment of atrophy of the hippocampus can be improved by measuring hippocampal volumes. Visual analysis can detect 85–90% of atrophic hippocampi versus 90–97% detection rate with quantitative volumetry.[62–64] Post-processing methods such as voxel based morphometry and texture analysis have been used to improve the detection rate for cortical dysplasias.[55]

With higher field strength and improved imaging technique, MR images can now provide an unsurpassed anatomical detail[65] (see Figure 22.11).

Positron emission tomography (PET) and other nuclear medicine applications in the definition of the epileptogenic zone

In addition to the structural imaging, functional imaging including PET is an important imaging modality. The evolution of PET began in the early 1960s. Its initial importance as a diagnostic tool to evaluate the brain for structural abnormalities in the 1960s paralleled the widespread use of technetium scanning for the evaluation of brain tumors.[66] This method was fast replaced first by CT, then by MRI. Since then the role of PET has shifted to an evaluation of brain function. The first medical cyclotron installation was at Washington University in St. Louis and methods were developed to produce carbon 11 labeled glucose to evaluate glucose metabolism. Subsequently it was shown that fluorodioxyglucose (FDG) had biological properties similar to C11 labeled glucose and the longer lived fluorine 18 labelling procedure could be used.

PET was soon explored in patients with epilepsy undergoing presurgical evaluation.[67] The first reports of interictal hypometabolism in patients with epilepsy using PET were in the

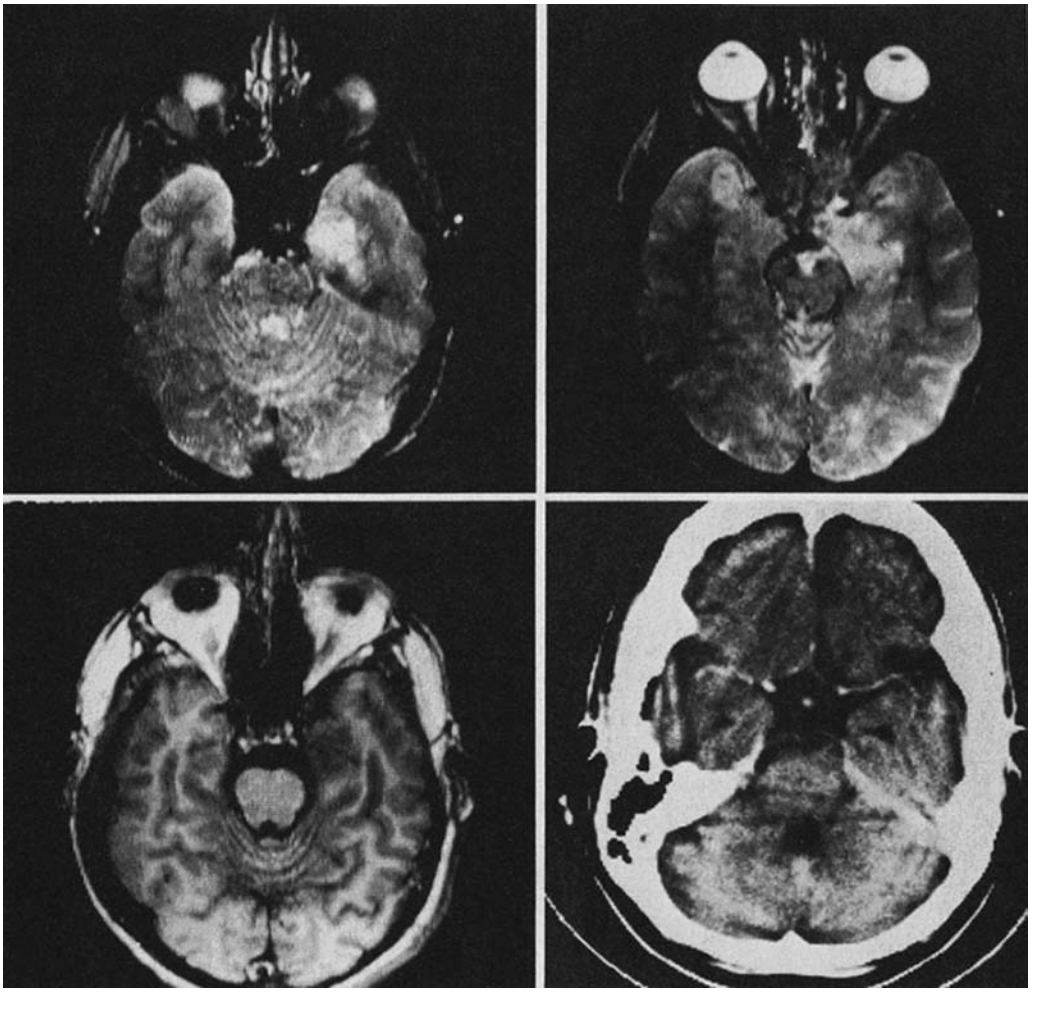

Figure 22.10 Early illustration of left hippocampal sclerosis. Top row: T2 spin echo image showing an rea of signal increase without mass effect in the mesial aspect of the temporal lobe. Bottom left: Inversion recovery image shows area of decreased signal in the same area (from ref. 60, with permission).

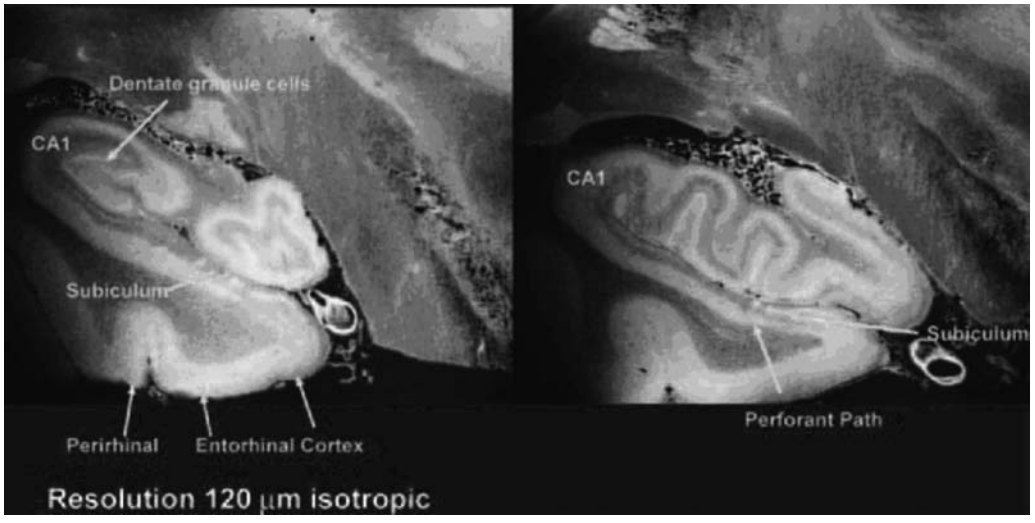

Figure 22.11 High-resolution image of the hippocampus of a human specimen at 7T. Image provided from Larry Wald, Martinos Center for Biomedical Imaging, Massachusetts General Hospital, Charlestown, MA (from ref. 65, with permission).

early 1980s,[68] ictal hypermetabolism was first reported in 1978.[69,70]

In temporal lobe epilepsy, interictal hypometabolism was described in the mesial temporal structures and has been implemented in the presurgical evaluation in patients with temporal lobe epilepsy.[71]

In 1995, the relative contributions of MRI, SPECT, and PET were summarized in a metaanlysis.[72] PET had the highest diagnostic sensitivity in temporal lobe epilepsy (84%) and also has a rather good sensitivity (95%) in mesial temporal sclerosis. In extratemporal lobe epilepsy, the sensitivity for PET is only considered around 33%. In recent years, receptor imaging using PET including imaging of benzodiazepine, glutamate, opiate, serotonine, and acetylcholine receptors has become feasible and will likely allow further insights in the mechanisms of epileptogenicity.[55]

The decade of the brain – what is next

The 1990s, the decade of the brain, saw the introduction of functional MRI. fMRI explores the BOLD (blood oxygenation-level dependent) effect: the magnetic properties of blood are dependent on the oxygenation state of the blood; deoxygenated hemoglobin is paramagnetic, oxyhemoglobin is diamagnetic. In activated brain areas, the relative percentage of deoxygenated hemoglobin is reduced compared to the non-active state, leading to an increase in T2-weighted and T2* weighted signal.

In 1990, the BOLD effect was first described by Sergej Ogawa.[73] In 1992, within one month of each other, S. Ogawa[74] and K. Kwong[75] described the BOLD signal change during visual stimulation in humans. Since, mapping of the cortex

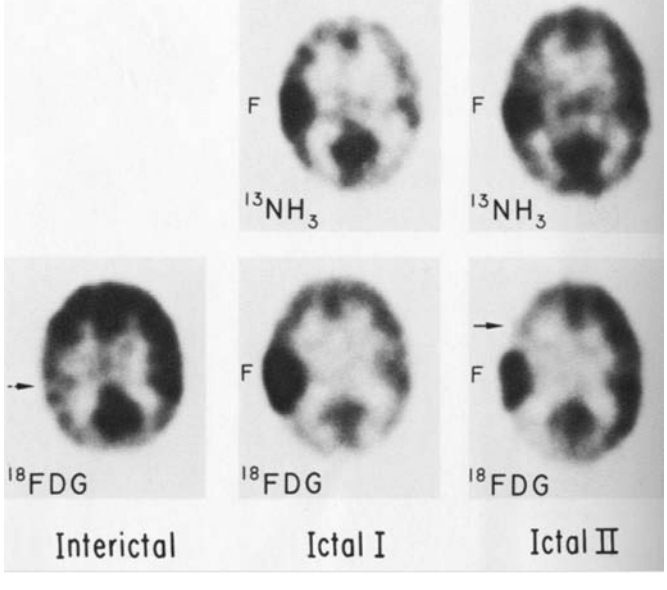

Figure 22.12 Interictal and ictal PET scan of a 5-year-old boy with a 10-month history of right focal motor seizures. The interictal PET (left) shows hypometabolism in the left temporoparietal cortex. At the same site, two ictal studies showed marked focal hypermetabolism (from ref. 70, with permission).

using fMRI has led to numerous publications within the neurosciences. fMRI of memory, language are important applications in intractable epilepsy patients evaluated for epilepsy surgery.[76] Imaging of the interictal activity using combined EEG and fMRI has become possible.

Imaging white matter pathways and connectivity became possible with the introduction of diffusion tensor imaging (DTI). All these new technologies will likely contribute to improving our definition of the epileptogenic zone, its connectivity and the relationship to functional cortex.

Outlook

Over the past century, imaging of the brain has evolved from the indirect window using X-rays and careful analysis of bony changes secondary to intracerebral pathology to the ability to directly visualize the brain structure and function with great anatomical detail.

The next decade will likely see further improvement in our ability to interrogate the brain tissue using new MRI sequences, acquisition and postprocessing techniques with better scanner hardware, higher field strength, and improvements in the signal to noise ratio. The hope is that we will find a structural substrate we can image non-invasively, thus reducing the number of cryptogenic patients with focal epilepsies. As we increase our sensitivity to detect subtle lesions, the number of these lesions will increase and we will need to understand the relation between these imaging abnormalities and the actual epileptogenic process.

The breakthrough may come from a close collaboration between basic science advancing our understanding of the cellular and molecular markers of epileptogenicity and our ability to image these in the future at a cellular level.

23 Epilepsy surgery in literature and film

P Wolf and S Baxendale

Epilepsy surgery is a highly advanced and sophisticated field of modern medicine but, like all medicine, it does not take place in an ideal or abstract world but in the context of real societies. We should therefore be interested in the ways how it is perceived by the general public. Arts are both a reflection of societal perceptions and a vehicle of influencing them. Epilepsy has become a frequent subject of fiction[1–3] and film,[4] and both these artistic genres have also taken sufficient notice of its surgical treatment to make it worth while to consider how it is depicted.

Literature

Since the 19th century, literary accounts of epilepsy are frequent,[1,2] and can be analyzed under many aspects.[3] One aspect is the authors' factual knowledge of the medical aspects, and it has been noted that awareness of the aim of pharmacotherapy being seizure control, and that it can be obtained in many cases is very little spread amongst literary writers.[3] On the other hand, neurosurgical treatment, although it is a relatively young part of our therapeutic armamentarium, has rapidly caught the public's attention. It is therefore not surprising that surgical interventions already have become a subject of literature.

The first example, and related to the first wave of epilepsy surgery which began in the late 19th century[5] is a non-fiction book, *Travel Around My Skull* (1937) by Hungarian journalist and writer Frigyes Kárinthy (1887–1938), an autobiographic account of the author's cerebellar tumor, its symptomatology, diagnosis and operation by Dr. Olivecrona in Stockholm. The writer was married to a neurologist, and in the course of the diagnostic work-up he learns that in contemporary neurology a differentiated view of epilepsy has developed, and that Jacksonian seizures which are correctly defined, are now sometimes treated surgically. He sees a film which shows Dr. Harvey Cushing performing such an operation.

In *The Piano Man's Daughter* (1995) by Timothy Findley (1930–2002) the main character Lily's epilepsy is a central feature of the novel, which is considered under a multitude of aspects.[2] One side character is a Toronto neurosurgeon, Omar Warren, who in a dramatic scene in a small Canadian provincial town in 1907 performs on a kitchen table an emergency operation of a brain tumor. Dr. Warren had 'studied in England with the famous Victor Horsley' whose 'daring experiments and expertise in neurosurgery were legendary'. Horsley's role in epilepsy surgery is not mentioned here, but eleven years later in the story Dr. Warren has become still more renowned and is now 'even claiming he could perform operations in which he could solve the problem of seizures. In time, these came to be called *lobotomies*'. This completes the picture of epilepsy at the time which the author has been careful to depict correctly, but surgery is not discussed as a possible treatment for Lily.

A specific surgical intervention, callosotomy, *is* proposed at a certain stage to Désirée, the leading character in Swedish writer Majgull Axelsson's much praised novel *The April Witch* (1997). Highly intelligent Désirée lives in a nursery home because of severe tetraspasticity caused by a perinatal hemorrhage. She also has intractable epilepsy with a tendency to develop status epilepticus in response to strong emotions. The callosotomy is never seriously considered and seems to fulfil a similar purpose as with Findley's book. Axelsson's interest in epilepsy and related neurosurgery was created by the disturbing experience of her own sister's falling ill with epilepsy caused by a brain tumor.[6]

A similarly distressing autobiographic experience is at the base of another work, belonging to a genre on the fringe of literature, the impressive comic book *Epileptic* (1996–2004) by French cartoonist Daniel B. It is the history of his growing up with an older brother who develops epilepsy at the age of seven. All regular and more alternative cures are tried in vain. Amongst others, the family is:

> referred to Professor T. at the Sainte Anne hospital. Professor T. is a neurosurgeon who specializes in diseases of the brain. His operations are said to be marvels of precision. In 1969, Jean-Christophe is admitted to his care. He is 13 years old. He finds himself in a room with a boy who's been operated on by Professor T. It's his third operation. He got a 105-degree fever and his right side is paralyzed. Professor T. has claimed that the paralysis is temporary. But he's been like this for fifteen days. They examine Jean-Christophe. They perform gaseous encephalograms on him. They shoot gas into his brain to inflate it so they can take photos, in which they hope to find traces of a lesion or a tumor. When my parents tell me about it, I visualize my brother in the clutches of mad scientists. The doctors believe they've found a circumvolution in the brain that's causing my brother's seizures. 'Did it hurt him when he had the encephalograms?' Professor T. never answers. It's always a brusque doctor who answers for him. 'They injected gas into his brain. Of course it hurts!' ... Professor T. sees my parents in his office. He's decided to operate on Jean-Christophe. With the help of slides, he shows us how

he's going to open his skull and take away the 'thing' that, according to him, is causing the epileptic seizures. He goes into a big medical show-and-tell. He explains that this is a very delicate operation, that if his scalpel is off by so much as half a millimetre, my brother will be blind. He lists all the possible outcomes if his knife slips. If he cuts here, my brother loses the use of all his limbs. There, he loses the use of his right arm, there, he will be deaf. My mother faints. Professor T. reassures her: None of this will happen because he is a man of such exceptional skill. The damage will be limited. He'll lose his peripheral vision. 'So he won't be able to see out of the corners of his eyes?' 'Then if he wants to see something off the side he can just turn his head!' And he will be paralyzed for two days after the operation. My parents are shaken by the risks entailed by the operation. The doctor's morgue chills them. Jean-Christophe is the 'case'. He will allow Professor T. to perform a brilliant operation. What do the results matter so long as the surgeon cuts with elegance and precision under the admiring gaze of his assistants?' At this stage, the family reads about George Oshawa, the founder of Zen macrobiotics, and goes to see a Japanese healer, 'Master N.', who uses macrobiotic principles. According to him, the boy's 'root of life is withering. I can treat him. I must see him on a regular basis, and he must not be operated upon'. My parents return to the Sainte-Anne hospital to tell Professor T. and his court that they're refusing the operation. They're not at all happy to see their nice experiment vanish just like that. Jean-Christophe's operation becomes Professor T.'s operation. 'WHAT? You're refusing Professor T.'s operation? Get the hell out! There's nothing for you here! Your son is doomed! It's criminal of you to refuse this operation!' Only the doctor who is in charge of the electroencephalograms approves of my parent's choice, but with many reservations. 'Ultimately, I think that in some way you're not wrong not to want your son to be operated on'.

In fairness it must be said, that with the Japanese healer's treatment the boy becomes seizure free – for some months, then the seizures return.

American author Thom Jones draws much from his own experiences when he writes hard realistic stories from Vietnam and amateur boxing. In the title story of his first collection *The Pugilist at Rest* (1993) the narrator's, a Vietnam veteran's worries express a mixture of the guilt he feels about certain episodes of the war, and increasing numbers of fits of a left temporal lobe epilepsy which is the result of a boxing trauma. When, 'loaded on Depakene, phenobarbital, Tegretol, Dilantin – the whole shit load', he still gets seizures, his sister brings 'a neurosurgeon over to my place around Christmas – not some V.A. butcher but a guy from the university hospital. He was a slick dude in a nine-hundred-dollar suit. He came down on me hard, like a used-car salesman. He wants to cauterize a small spot in a nerve bundle in my brain. "It's not a lobotomy, it's a *cingulotomy*," he said. Reckless, desperate, last-ditch psychosurgery is still pretty much unthinkable in the conservative medical establishment. That's why he made a personal visit to my place. A house call. Drumming up some action to make himself a name. "See that bottle of Thorazine?" he said. "You can throw that poison away," he said. "All that amitriptyline. That's garbage, you can toss that, too." He said, "Tell me something. How can you take all of that shit and still walk?" He said, "You take enough drugs to drop an elephant."

He wants to cut me. He said that the feelings of guilt and worthlessness, and the heaviness of a heart blackened by sin, will go away. "It is *not* a lobotomy," he said. "I don't like the guy. I don't trust him. I'm not convinced, but I can't go on like this." At the end, he is inclined to accept but worries what would happen "if they fuck up the operation"'.

Again, not a flattering image of a neurosurgeon and his ethics, and an unfortunate confusion about epilepsy surgery and psychosurgery.

Concern about the full consequences of a brain operation to treat epilepsy is the subject of *Lying Awake* (2000) by Mark Salzmann. Sister John of the Cross, a Carmelite nun in Los Angeles in 1997 has a great gift for writing about contemplative life. Her collection of essays and poems 'Sparrow on a Roof' is very successful, and this is not only a spiritual joy but also an important contribution to her monastery's economy. The words come to her in a kind of 'ecstasies', accompanied by headaches, which are by a sleep EEG and a CT scan found out to be temporal-lobe seizures. 'Now the good news. The CT scan found what's causing the seizures, and we can do something about it. You have a small menangioma (sic!) – about the size of a raisin – just above your right ear. It's in an excellent position for removal, just under the skull. I've consulted with a surgeon about it, and he said they should be able to peel it right off. It'll be a very clean procedure, very straightforward. If we take care of it now, while the seizures are still localized, your prognosis for complete recovery is excellent.'

But Sister John is very troubled by the diagnosis epilepsy which she has learnt to perceive as a disorder of the soul. Someone applying to be a nun would be automatically rejected if she had to answer yes to the question 'have you ever been treated for mental illness or epilepsy?' 'Epilepsy was particularly feared because of its reputation for producing compelling – but false – visions. Doctors and clergy alike had referred to the disease as "holy madness"' The dilemma she finds herself in is twofold: the tumor should be removed, not the least in view of the future health hazards it carries, but if she loses her seizures, she loses her cherished spiritual experiences. On the other hand, if her ecstasies are not genuine spiritual experiences but spurious, a mere symptom of illness, is it right for her to want to keep them? What is the real worth of her poetry which she was so proud of? What finally decides her is the prioress's describing to her a seizure she had during service, where she wandered around the chapel, staring at the ceiling, humming to herself and threatening at any moment to do some disgrace. The thought of giving offence to her fellow nuns is clearly unacceptable for her.

Like in Daniel B.'s comic, full information about the potential hazards of the operation is given together with an assurance that these are very unlikely to happen because of the surgeon's experience. But Sister John is thoroughly prepared and takes the information calmly without anything like the terror that is provoked in the French family who was completely taken by surprise.

After the operation, she feels empty and depressed and learns from her doctor that this is rather common. 'When they

On lui fait des encéphalographies gazeuses. On envoie du gaz dans son cerveau pour le faire gonfler afin de prendre des photos sur lesquelles on pourra déceler les traces d'une lésion ou d'une tumeur. Quand mes parents m'en parlent, j'imagine mon frère aux prises avec des savants fous.

Les médecins pensent avoir trouvé dans une circonvolution du cerveau la cause des crises de mon frère.

Il explique que c'est une opération très délicate, que si son bistouri taille un demi-millimètre à côté, mon frère sera aveugle.

Il énumère tout ce qui risque d'arriver s'il loupe son coup.
S'il taille là, mon frère perd l'usage de tous ses membres, là il perd l'usage de son bras droit, là de ses jambes, là il sera sourd...
Ma mère s'évanouit.

took this out,' she says, pointing to her bandage, 'my muse went with it.' Her senior tells her that 'God must think you did enough with that gift. Now he wants you to do something else', and the story ends with her being appointed to take care of a novice with a difficult background. 'She'll need a novice mistress with a special understanding of the difficulties we face trying to do God's will.'

In his much-discussed[1] science fiction thriller of 1972, *The Terminal Man*, US writer Michael Crichton foresees a therapeutic intervention which 33 years later is about to become a reality,[7] i.e., treatment by interruption of beginning seizure activity by electric stimulation which is automatically delivered by an electronic device that can detect the activity. The literary connection did not escape a recent commentator.[8] In the novel, the results are dreadful.

The procedure has been developed in the Neuropsychiatric Research Unit of a Los Angeles university hospital. It is called the Stage Three Procedure and after 154 trials in rhesus monkeys used for the first time, on Wednesday 10, March 1971, for the treatment of a human being with temporal lobe or psychomotor epilepsy (both terms are used interchangeably). At neurosurgical grand rounds, surgeon Dr. Ellis explains:

> We know from the work of many researchers that it is possible to abort a seizure by delivering an electrical shock to the correct portion of the brain substance. These seizures begin slowly. There are a few seconds – sometimes as much as half a minute – before the seizure takes effect. A shock at that moment prevents the seizure. We face two problems. First, what is the correct part of the brain to shock? Well, we know roughly that it's in the amygdala, an anterior area of the so-called limbic system. We don't know *exactly* where, but we solve that problem by implanting a number of electrodes in the brain. Mr. Benson will have forty electrodes implanted tomorrow morning. Our second problem is how do we know when an attack is starting? We must know when to deliver our aborting shock. Well, fortunately the same electrodes that we use to deliver the shock can also be used to 'read' the electrical activity of the brain. And there is a characteristic electrical pattern that precedes a seizure. So we have a feedback system – the same electrodes are used to detect a new attack, and to deliver the aborting shock. A computer controls the feedback mechanism. The NPS staff has developed a computer that will monitor electrical activity of the brain, and when it sees an attack starting, will transmit a shock to the correct brain area. This computer is about the size of a postage stamp and weighs a tenth of an ounce. It will be implanted beneath the skin of the patient's neck. We will power the computer with a Handler PP-J plutonium power pack, which will be implanted beneath the skin of the shoulder. This makes the patient completely self-sufficient. The power pack supplies energy continuously and reliably for twenty years.

It is impressive to see all these details imagined by the author who calls them 'a limbic pacing procedure', even as we know that he has graduated from Harvard Medical School and worked briefly in medical research.

A 34-year-old computer scientist Harold Benson has, 2 years earlier, had a car accident with prolonged loss of consciousness. Six months later he developed 'blackouts' which could be provoked by intake of alcohol. They started with the sensation of peculiar, unpleasant odours which lasted several minutes and occurred about once a month. One year after the accident, the blackouts became more frequent and lasted longer; Benson often regained consciousness in unfamiliar surroundings, sometimes with bruises and cuts, suggesting he had been fighting. Again 6 months later, having been arrested with a suspicion he had severely beaten another person, his condition was diagnosed as right temporal lobe epilepsy, and he was started on 'a series of drug trials'. Within three months it was concluded that he showed no improvement to any of three drugs alone or in combination – here the author does not explain how this is possible with a seizure frequency that doesn't very much exceed one per month.

The story is complicated by two features which make it somewhat unfocussed. Benson in his seizures commits rather complex acts of violence for which he has no recall. The writer needs this for his plot to work but describes it as a typical feature of temporal lobe epilepsy: 'Unless you had seen a psychomotor seizure, you could not comprehend the unreasonable, brutal violence of an attack. It was completely beyond any normal life experience. Nothing else was like it, analogous to it, similar to it.'

'We don't know much about the causes of violence,' the chief of the Research Unit explains. 'And there's a lot of crap theory floating around, written by sociologists and paid for by perfectly good taxpayer money. But we do know that one particular illness, psychomotor epilepsy, may lead to violence. ... At the NPS, we think that psychomotor epilepsy may be extremely common among those people who engage in repetitive violent acts – like certain policemen, gangsters, rioters, Hell's Angels. ... We have no exact idea exactly how common psychomotor epilepsy is. But our guess is that as much as one or two percent of the population may suffer from it. That's two to four million Americans.'

Crichton was heavily criticized in the public and media for this denigration of people with TLE, and added a revocation and excuse in the paperback edition of the book.[1]

The other anomaly in the case history is that the patient, a specialist in artificial intelligence, at the time of the operation has developed a paranoid conviction that computers are conspiring against mankind, and actually are about to take over the world. That the operation turns himself into a kind of human-computer hybrid, a living computer terminal (this is what the title refers to) fits well with his delusion, but the author never gets the two disorders, epilepsy and psychosis, and their possible relation neatly sorted out, so that the concepts of seizure control and mind control get rather mixed up – not dissimilar to Thom Jones' *Pugilist*.

After the control unit is in place, stimulations are given to each of the 40 implanted electrodes. Then the author is carried away by his desire to create a sensational plot. As contacts for stimulation he lets the doctors not use ones which can abort a beginning seizure but ones which give the patient pleasant sensations including one which leads to erotic arousal. From here, the tragedy takes its course. The stimulations result in a reinforcing rather than the expected downgrading feedback, and seizure activity and interruptive stimuli increase in frequency to end up in a seizure during which he first has sexual intercourse with a girl friend and then kills her. The following rather conventional man-hunt of a cunning criminal ends with Benson being shot dead in self-defence by his lady psychiatrist who to the last moment wanted to save his life and re-circuit his stimulation device to produce non-dangerous behavior.

The author touches briefly on the important philosophical and ethical implications an intervention of this kind has, but the possible debate this could have initiated did not take place because all attention became focused on his ill-representation of violence as a typical symptom of psychomotor epilepsy.

Although the cinematic adaptation of Michael Crichton's *The Terminal Man* (1974) is generally faithful to the novel, the film rather suffers from the 1970s zeitgeist. The spare, white sets further dehumanize the medics who are cold and aloof whilst operating on Benson who is clearly conscious. Rather bizarrely, traditional surgical greens are dispensed with, in favour of space-age operating suits, with the result that the surgeons resemble an Apollo mission crew. Although clearly capable of monstrous acts, Benson is the only character with whom the audience is invited to connect with. The clinical cinematography and sparse dialogue discourages the audience to make any real connection with the victims. Thus the film strikes a discordant note. It is interesting to note that Crichton produced nine drafts of his book *The Terminal Man* and that it remains his least favorite book. Of the film he says '*I loathed 'The Terminal Man' and make no bones about it. I thought it was wretched and a lost opportunity*'.

Film

Whilst both epilepsy and neurosurgery frequently play a pivotal role in movie plots, epilepsy surgery is a relatively rare feature. Although fast growing, malignant brain tumors are hugely over-represented in the neurological movie population, seizures are very rarely seen in these characters. Other neurological signs (particularly loss of vision and paralysis) generally precipitate the neurosurgical interventions in these movies. The lack of seizures in these characters is curious, since film-makers haven't shied away from depicting seizures in other storylines.[8] Films with characters who experience epileptic seizures can be found in almost every genre, ranging from the classic Disney animation *Snow White* (1937), where Dopey, one of the seven dwarfs appears to experience a nocturnal seizure, when he returns home from a hard day's work in the diamond mine to find Snow White in his house,[9] to obscure cult horror films such as *Vampire Trailer Park* (1991), where the heroine receives helpful advice from her dead grandmother during her complex partial seizures, enabling her to track down a vampire who is running amok in an American trailer park.

Despite the highly imaginative and widespread use of seizures as plot devices, we generally do not see seizures in the very characters in whom they might be expected. One reason may be the continued stigma attached to epilepsy. Movie characters with brain tumors are frequently dignified and heroic and can remain so following the onset of gradual blindness or peripheral numbness. A seizure may well throw the audience off-balance and lead to unpredictable feelings towards the character, upsetting the director's narrative flow. It is interesting to note that the few films that do cover epilepsy surgery can on the whole be divided into two broad categories where this will not be an issue: true life stories and science fiction.

A notable exception is one of the very earliest films to tackle epilepsy surgery. Dr Kildare, the archetypal 'good' young American doctor was created by Frederick Schiller Faust (aka Max Brand) and first appeared in a fiction magazine in 1938. The character rapidly made the transition to the silver screen and appeared in a series of ten very popular feature films between 1939 and 1942. The fifth film in the series, *Dr Kildare's Crisis* (1940), provides a fascinating insight into the medical understanding of epilepsy and public attitudes towards seizures that were prevalent in the 1940s. The dashing young Dr Kildare is engaged to marry one of his pretty nurses, but soon discovers, to his horror, that her brother has epilepsy. This puts the impending marriage in doubt as she is obviously from damaged genetic stock, and his children may inherit epilepsy and as a result become insane. Dr Gillespie, an older and wiser doctor, establishes that the man's seizures are the result of a head injury, dissipating all hereditary concerns. What's more, the seizures can be cured by a simple operation. It is heartening to note that The Medical Society of New York lodged a formal complaint against the film, protesting against

the way that epilepsy was presented. They objected to the claims that epilepsy was automatically inherited, that it led to insanity and, ironically, and that it was curable by surgery.

The Dr Kildare film series ended in 1942, when the lead actor Lew Ayres announced his conscientious objection to the war, and was dropped by the studio. However, the character was revived in the 1960s for a hugely popular TV series with over 190 episodes produced, and is widely thought to have paved the way for Michael Crichton's current medical series *ER*. Although patients with epilepsy did feature, the original epilepsy story line was not repeated in the TV series.

Films based on a true story

The real experiences of epilepsy surgery patients have been the focus of a number of 'made for TV' movies. When Meryl Streep, the star of one of these films (*First Do No Harm,* 1997), was asked why the film was made for TV, she replied:

> There was a lot of talk about making *First Do No Harm* a feature (film), but we all thought that it would be better if it was seen by a lot of people; and you can't count on that in this movie climate. So we took it to TV. It's the populist medium, where we get out what we're trying to say to the most people.

This reply implies that these films are made not just for entertainment, but also have a message to impart. Certainly many of the directors of these films have been attracted to epilepsy surgery as a subject matter as a direct result of their own experiences with loved ones who have epilepsy. However, the messages these films impart regarding epilepsy surgery appear to be very mixed indeed.

In *First Do No Harm* (1997), Meryl Streep plays a mother who discovers the possibilities of the ketogenic diet at the eleventh hour, when neurosurgery appears to be the only option left for her son. Despite meeting considerable resistance and hostility from the medical profession, her son achieves complete seizure freedom by strictly adhering to the diet. The very title of the film implies that surgery equates to harm. The boy is presented as having a narrow escape from a horrific fate, inflicted by medics with closed minds. Many of the events and dialogues within the film were based on the actual experience of the director Jim Abrahams, who apparently withdrew his own child from epilepsy surgery the night before it was scheduled after reading about the possibilities of the ketogenic diet.

Although this boy is presented as having a narrow escape from a horrific fate, the dangers of surgery are largely implicit in *First Do No Harm*, since surgery doesn't actually occur. The harmful effects of epilepsy surgery are far more explicit in *Seizure: The Story of Kathy Morris* (1980); a true story based on the book *Seizure* (1978). Kathy Morris was a young music student who ignored memory difficulties and headaches until she woke up in the emergency department of a hospital having suffered a generalized convulsion. In a departure from his more famous *Star Trek* incarnation as Mr Spock, Leonard Nimoy plays the surgeon who attempts to remove a benign meningioma. Unfortunately, the surgery (which is being filmed for teaching purposes) goes horribly wrong, and the surgeon is forced to cut away normal tissue. Kathy undergoes two further procedures before the tumor is fully resected. Although she is left with profound language difficulties, the film charts her remarkable recovery and ends with Kathy singing again. Cameo performances from actual patients appear in both *First Do No Harm* and *Seizure: The Story of Kathy Morris*, emphasizing the 'real' nature of the portrayals in each film.

The uncertain outcomes associated with epilepsy surgery are also examined in *The Other Half of Me* (2001), which was based on the director/writers real life experience of dating a woman who had undergone a hemispherectomy as a child. Ostensibly a love story, the hero Mikey is on the rebound from a difficult relationship when is set up on a blind date with Morgan who 'only has half of a brain'. Mikey is undaunted by her surgical history and falls for her, despite the reservations of his friends. However, although she is open about her neurosurgical history, Morgan attempts to conceal her ongoing seizures, causing significant difficulties in the relationship. The writer/director Michael Mustizer explained the inspiration for the script.

> Mainly, I wrote of complications that may or may not arise in a girl with half a brain. Seizures. ... one night it happened. Meighan (his girlfriend) had a seizure while sleeping. She was choking. She was screaming. She was scared. When she came out of it, she was in a world all of her own. She was frightened of the cat. She had forgotten the name of her childhood teddy bear. She couldn't count, nor recite the alphabet. I was genuinely scared for the first time in my life ... When I began to film 'The Other Half of Me', I took all of this in. I memorized every aspect of that night. I put it into the script. I put it on screen. Those moments of the film are genuinely scary. And I am proud of that. I truly captured the fear I was going through.

This film is interesting in that the focus is not on the horrors of neurosurgery; the hemisphectomy in the plot is a curiosity, but is accepted, but rather the filmmaker uses the movie to portray the anguish and fear associated with ongoing seizures.

The rare but serious complications associated with early epilepsy surgical practices from the 1950s inspired the celebrated film *Memento* (2000). In *Memento*, the hero Leonard suffers from a dense anterograde amnesia following a severe head injury sustained during an assault during which his wife is killed. Despite his dense amnesia, he attempts to track down the killer and keeps abreast with his investigations with the extensive use of polaroid photographs and even tattoos. The fragmented style of the film echos Leonard's own fragmented memory processes. The film won an Oscar nomination for screenplay, which was directly inspired by the story of H.M., one of the most studied epilepsy surgery patients in the world. H.M., a 28-year-old motor winder underwent a bilateral temporal lobectomy in 1953 and suffered a dense anterograde amnesic syndrome as a result. His case had a significant impact on the history of epilepsy surgery practice and was pivotal in the development of the role of clinical neuropsychology in the presurgical evaluation of epilepsy surgery patients.

These negative and ambivalent attitudes to epilepsy surgery couldn't be further from those portrayed by Patrick Dempsey in *A Fighting Choice* (1986), another made-for-TV movie. Rather than a crude medical intervention, epilepsy surgery is presented as the ultimate goal in this film, as a teenager tormented by frequent generalized convulsions takes his parents to court to allow him to undergo 'split brain' surgery. Although a surgical option is presented in a much more positive light in this film than those reviewed thus far, the uncertain outcomes associated with surgery are again highlighted, with a firm focus on the 'experimental' nature of the treatment sought and the very considerable risks feared by the boy's parents.

Science fiction

Although neurosurgical procedures and devices frequently feature in films from the science fiction genre, most of these attempts at mind/behavior control do not involve seizures, with the notable exceptions of *The Terminal Man* (1974) and *Megaville* (1990). In the latter film, a cop living in the aptly named 'Hemisphere' is sent to neighboring Megaville to investigate the illegal viewing of television and movies. He suffers a series of seizure-like events, and it eventually becomes clear that these have been caused by the malfunctioning of a device implanted in his brain to alter his memories and personality. Although futuristic, these plots have much in common with ancient beliefs that external agents cause seizures. Here 'mad-science' and high tech devices have replaced demonic evocations. However, Megaville is unique in that it is the only film reviewed, where 'seizures' are portrayed as a window into 'real' life and therefore a good thing, rather than the customary temporary opt out from true experience.

Summary

Although epilepsy and neurosurgery frequently appear in movie plots, films featuring epilepsy surgery are relatively rare and generally fall into the 'true life – made for TV' or science fiction genres. The majority of films are characterized by a mistrust of a cavalier and incompetent medical profession. Even when it is presented as a desirable objective, epilepsy surgery is almost always presented as a high-risk, experimental procedure with unpredictable results in the movies. It is particularly interesting to note that the 'new' and 'experimental' qualities of surgery continue to prevail in the movies despite over 50 years of successful epilepsy surgery practise worldwide. As with the literature, sci-fi films that feature epilepsy surgery tend to confuse seizure control with mind control.

It is unrealistic to expect that epilepsy surgery will be treated objectively on the silver screen. Movies are made to entertain and make money, and a story of successful, uncomplicated epilepsy surgery is unlikely to draw big crowds at the box office. It seems probable that the perennially favourite movie themes of the mysteries of the human mind, a fascination with the medical profession and the triumph of the human spirit, will continue to provide ample material for future movie scripts. Whilst this remains the case, epilepsy surgery will remain a prominent target for misrepresentation and distortion but also, and more positively, discussion.

For literature, the situation seems to be slightly different, although there are similarities, and one of the more problematic films is based on an equally problematic book. However, stories and novels written to be read at leisure, some with a clear objective to stimulate the reader's thoughts and reflections, are more likely to present a differentiated view. The question thoughtfully raised in one book, of creativity connected with disease and its possible destruction by successful therapy is an example. But it is unfortunate to see epilepsy surgery in several books getting confounded with psychosurgery. At least three of the seven works discussed here, one novel, one comic book and one autobiography, are based on personal experiences, and the emotions which these experiences created are palpaple in the books. To conclude, like in film, epilepsy surgery does not yet appear in literature as the hopeful therapy which can make a big difference in a life, the way we perceive it in the professional world.

NOTE

In Norwegian writer Edvard Hoem's non-fiction book Mors og Fars Historie (Mother's and Father's Story) of 2005, the father develops epidural hematoma with status epilepticus after a blunt head trauma. The surgeons save his life, and the event becomes a turning point in the parents' relation.

The leading character's post-traumatic epilepsy is a prominent and multifaceted feature in Garth Stein's very recommendable novel of 2005, How Evan Broke His Head and Other Secrets. At one point, epilepsy surgery is proposed to Evan but he rejects it because he fears it will damage his creativity as a musician. The background in real life is Stein's sister's surgically treated epilepsy (see the author's website www.garthstein.com).

24 The future of epilepsy surgery

F Andermann and W Harkness

The ability to generate electrical potentials is a fundamental property of the brain. Vitiation of these potentials can lead to the appearance of epileptic seizures. Long before these properties and mechanisms were recognized, clinical observations showed that brain injuries or lesions could lead to scars and seizures. This prompted attempts to remove these lesions. The work of pioneers like Victor Horsley and Fedor Krause is well recognized. A prolonged hiatus then ensued, until Otfried Foerster in Breslau (now Wroclaw in Poland) began to further advance this approach to treatment. Wilder Penfield, looking for new horizons, spent some months with Foerster and, as one may describe in present terms, was the first epilepsy fellow.

At the Montreal Neurological Institute, which Penfield founded in 1934, he learned of Hans Berger's work in electroencephalography, which promised the ability to recognize epileptic potentials and discharges and to help in localization of epileptic activity. He attracted Herbert Jasper, then working as a psychologist at Brown University in Rhode Island, and their fruitful collaboration provided great impetus to the field of surgical treatment of epilepsy. One of their main advances was the recognition of temporal lobe epilepsy, which later was shown to be the most important cause of intractable epilepsy. The school of Penfield and Jasper attracted numerous disciples from many parts of the world and, after World War II, there was considerable and widespread flowering of interest in the surgical treatment of epilepsy. This enthusiasm however was short lasting, and surgical treatment was widely deemphasized. In some countries, such as Germany or Japan, it was virtually proscribed. When I asked Dr. Theodore Rasmussen why this enthusiasm had waned at that time, he replied, 'It was the wrong surgeons, operating on the wrong patients'.

For years, surgical treatment of epilepsy was confined to very few centers, notably the Montreal Neurological Institute with Theodore Rasmussen, Bill Feindel and their disciples, King's Maudsley in London with Murray Falconer and his school, and the Hopital Ste. Anne in Paris with Jean Bancaud and Jean Talairach. Careful keeping of the score, as Dr. Rasmussen put it, led to recognition of optimal candidates for surgical treatment and the ability to formulate more informed prognosis in the different forms of epilepsy. Interestingly, during that period, the role of structural lesions, such as indolent tumors, was not accepted or well understood. The emphasis was on electrographic localization of the epileptogenic area.

The advent of modern imaging with computed tomography, and even more after the development of magnetic resonance, provided a second and very powerful impetus to surgical treatment of intractable epilepsy. It allowed recognition of the significance of the lesions, and their epileptogenic potential was increasingly emphasized. In the same period in the 1980s and early 1990s, the ability to identify a plethora of lesions previously invisible during life provided an additional stimulus to surgical treatment. A major step was the recognition during life of cortical dysplasia. This had been described by David Taylor from Falconer's group, based on pathological studies of material resected, and of course in those patients the lesion was not visible preoperatively. There was a tremendous explosion of interest in this topic, resulting in an enormous literature, with hundreds of contributions since, addressing the different modalities of investigation and of treatment.

The financial rewards of video telemetry stimulated hospital administrators and neurologists to introduce this investigative approach, which promised to generate important economic benefits. This was not necessarily combined with the development of the required team approach. Many centers had planned to develop surgical treatment without being adequately prepared or willing to provide support for the required multidisciplinary team. They soon dropped out of the field. We have however witnessed the development of a number of centers of excellence in the United States, and in Canada, where this was spearheaded by Penfield's disciples across the country. Comprehensive epilepsy centers with expert investigation and surgical expertise also developed in many parts of Europe, Germany, Italy, France, United Kingdom, and elsewhere.

The recognition of ideal candidates for surgical treatment was further refined and also enabled the development of centers for surgical treatment in the developing world, geared to the treatment of patients with identifiable lesions or unilateral mesial temporal sclerosis. There always remained a temptation to tackle difficult problems, such as for example operating on patients with frontal epilepsy without a lesion that can be demonstrated by imaging, and where the results are considerably inferior to those in well-selected cases.

Surgical treatment of epilepsy has always been complicated by prejudice on the part of neurologists and other physicians, and the amount of prejudice was inversely proportional to the knowledge and expertise of these doctors.

It was recognized early that the search for surgical treatment by patients and families was driving the referrals, much more than the initiative of the treating neurologists and other physicians. Though this type of prejudice seems to be diminishing, it continues to exist. There are also obvious financial incentives in not referring patients for surgical treatment.

There were numerous examples during the recent flowering of trials of new antiepileptic agents of patients going through trial after trial, even though the chances of success were minimal. These patients may have had a much better chance for a more normal life with surgical treatment.

The lack of awareness of the possibilities and advantages of surgical therapy however was probably an even greater factor, and this was coupled in many instances by inadequate interpretation to the patients and their families and of course by their inadequate understanding of the process.

After this lengthy preamble, we turn to the future of surgical treatment. That surgery has been underutilized has been stressed repeatedly by the Commission on Surgical Treatment of the International League Against Epilepsy. Calculated estimates of surgical candidates in the population yielded high figures, but it is not entirely clear whether these figures were always based on discrimination between patients with a very good chance of successful outcome compared to those who, though quite intractable, presented much more difficult problems and a lesser promise of a good result. Furthermore, there are important geographic considerations. In regions or countries where surgical treatment becomes available for the first time, there are a large numbers of patients with eminently treatable forms of epilepsy, such as for instance, people with temporal lobe epilepsy associated with unilateral mesial temporal sclerosis. Initial reports from such areas or centers are able to describe large series with good results obtained in a relatively short period of time. In areas where surgical treatment has been available for some time, and where there is much better awareness of what surgery can accomplish, such patients with optimal prognosis are becoming increasingly rare. I asked the senior surgeon at a major epilepsy center in the Eastern United States how many such ideal surgical candidates he would see in a year and he replied: 'six or seven'. He then proceeded to mention also that since imaging findings are more readily recognized now, such patients are often referred and operated by general neurosurgeons without an abiding interest in the treatment of epilepsy and without the benefit of more complete preoperative investigation. Such a comprehensive study would be likely to lead to even better results in the long run. Similar situations prevail, no doubt, in countries where surgical treatment is introduced for the first time. For example, impressive results were obtained in centers such as the one at Sri Chitra Tirunal in Trivandrum, State of Kerala in South India.

Because of the severity of the epilepsy, and the gradual deterioration of many patients, there is continuing temptation to address problems which are not as likely to lead to very good outcomes. Patients and their families however are generally very grateful even for improvement rather than complete control of their attacks, an often unexpected and gratifying attitude.

There is the hope that increasingly sophisticated technology and refining of functional imaging as well as of electrographic localization may lead to improved understanding of the epileptogenic process and thus to improved outcome. The use of innovative PET ligands, PET activation techniques, various forms of morphometry, magnetoencephalography, spike-driven FMRI, and recording from dense arrays of electrodes are amongst the techniques being developed that hold promise of increasing clinical usefulness.

An example of how new insights develop is provided by gelastic epilepsy related to hypothalamic hamartoma. First the clinical pattern was recognized to be associated with the hypothalamic lesions, and the advent of MRI greatly facilitated identification of these. Attempts of resecting the lesion were initially not encouraging. Identifying epileptogenic areas based on electrographic localization, even with depth electrode studies, led to a number of temporal and at times frontal resections. These were also fruitless. That the lesions themselves could generate epileptic potentials, was then found by Munari and his group using depth electrodes placed in the lesions. This led to a multiplicity of approaches designed to resect or destroy the hypothalamic hamartoma itself. It became clear that some approaches were preferable to others and at the moment a transcallosal approach appears to be optimal, particularly in lesions which are within the lumen of the third ventricle or not very extensive. The completeness of the resection, in so far as it can be determined by imaging and by direct visualization, appears to correlate with the outcome. The role of other approaches such as gamma knife surgery is yet to be confirmed. Despite the proven benefits of resective surgery, there continues to exist considerable reluctance on the part of many neurosurgeons to approach these lesions for fear of disastrous complications. Though some endocrine and other complications may occur with surgical treatment, the benefit, particularly in patients with gelastic seizures and catastrophic secondary generalization, far outweighs these risks.

How do other approaches to the treatment of intractable epilepsy impact on surgical treatment? The new generation of antiepileptic drugs are comparable in their effect to that of the previous generation of agents. It is generally recognized that their main benefit lies in reduction of side effects and that only less than 10% of patients who have intractable epilepsies are fully controllable by any of the new agents. To wait for new agents to be developed is to deprive patients of the benefit of a much better outcome obtainable by surgical treatment. Devices such as vagal nerve stimulation are strongly driven by industrial support and do not require complicated and technically difficult and prolonged investigations. There is also strong support for the utilization of this apparatus by industry sponsored specialized nurses working with the patients. Whether some forms of epilepsy are more likely to respond than others to vagal stimulation is not currently clear. The results appear to be better in children compared to adults. Cerebral stimulation and prostheses designed to arrest seizures at their onset are currently studied and remain experimental.

In reviewing a series of reports on postoperative psychosis arising de novo from Denmark, Finland, and the United Kingdom, it becomes clear that the risk of postoperative psychosis is present mainly in individuals whose seizures have not ceased following surgery. Only a very small number of patients whose seizures have been fully controlled by surgery develop psychosis, probably related more to the preexistent terrain and pathology than to the surgery itself.

One of the criticisms leveled at surgical treatment was that no controlled studies were present. This type of criticism could be leveled also at operations such as appendectomy. However, since some objective evidence seemed required, studies such as the one by Wiebe et al., have confirmed the benefit of surgical treatment in patients with temporal lobe epilepsy compared to

continued medical treatment. Further attempts based on multicenter trials are also planned or underway.

New and as yet unplanned developments in neuroscience may open new perspectives in our understanding of intractable epilepsy and may lead to new approaches, which cannot at present be foreseen.

The possibility that surgery may provide resolution of a person's epileptic problem as far as recurrent seizures are concerned must be kept in mind when seeing or reviewing a patient with epilepsy. It is important not to make value judgments about the severity and dangers of the epilepsy itself. Rather, one should be guided by the person's perception of his or her problem, within reason. Wanting to avoid antiepileptic medication completely is not necessarily a frivolous request. Though this usually cannot be promised, such requests need to be weighed against the possible side effects of a lifetime of possibly heavy antiepileptic medication. Often, the medication can be reduced postoperatively for a period of time and in some patients, eventually discontinued.

The available information at the time of the patient's first review is most often inadequate, and further investigation is required before the options can be presented to the patient and the family. Obsessive trials of every conceivable antiepileptic are not a very fruitful exercise. Above all, the pros and cons, risks, and benefits of surgery need to be explained to the patient's satisfaction, and it is essential to have some idea whether this has actually been understood and carefully considered.

Surgical treatment offers a resolution of the problem of recurrent attacks to many people with epilepsies both in developed and in the developing world, and these patients should not be deprived of this option. Even politicians and governmental agencies have a role to play in enabling patients to benefit from surgical treatment. The situation in Brazil, where this approach is given some priority by the government, is a good example of what can be accomplished in the developing world.

One may conclude that surgical treatment, despite its invasive nature, and often uncertain outcome, will continue to provide a valuable option unless it is surpassed in the unforeseeable future by different, less invasive, but equally effective, approaches.

SECTION 2

Overview

25 Medical intractability in epilepsy

DV Lardizabal

Anticonvulsant drug failure

The mainstay of epilepsy management is drug therapy with anticonvulsant drugs. The appropriate choice of anticonvulsant drugs is mainly determined by the type of epilepsy (generalized or partial) and the seizure type. The clinical goal of anticonvulsant therapy is to make patients seizure-free with minimal or no side effects. The anticonvulsant dose in controlling seizures is also very individualized. It is very important that during the anticonvulsant drug titration, the *lowest dose* that controls seizures should be first achieved. During the titration phase, there are three possible outcomes. First, the patient's seizures are controlled with no undesirable side effects – the therapeutic end point. Second, the patient may develop intolerable side effects or idiosyncratic drug reactions and the drug is discontinued during the first few days of drug titration. Third, the patient continues to have seizures when the drug is within the recommended dosage. At this point, the compliance of the patient should be investigated. Serum drug levels and pill counts are important in determining compliance. Assuming good drug compliance, the clinician's next step is to determine the maximum tolerable dose (MTD). The maximum tolerable dose is individualized and is determined by the patient's clinical side effects. The anticonvulsant should be titrated up slowly. If the patient has undesirable side effects at a specific dose, the clinician should *lower the dose* that will produce the least side effects (subtoxic). The maximum tolerable dose is the highest dose *before* reaching clinical toxicity. Hence, it is impossible to know that maximum tolerable dose until the patient reports significant neurotoxicity. It is important to note that the maximum tolerable dose is *not* based on the drug levels.[1] Sometimes, the patient may not experience clinical toxicity despite being above the 'therapeutic range'. Moreover, clinical toxicity may even develop within the 'therapeutic range'. The maximum tolerable dose may or may not control the seizures. An adequate anticonvulsant drug trial also takes into consideration the duration of therapy.[1] The appropriate length of time during which a drug should be tried will vary mainly as a function of the baseline seizure frequency. Reasonable drug trial duration for a given drug would be about 5 to 10 times the average seizure interval at baseline before the drug was introduced. This time frame may not apply to very high and very low seizure frequencies, such as more than two seizures per week or less than one seizure per month.[1] *Therefore, a drug failure is usually considered if the patient has uncontrolled seizures despite reaching the maximum tolerable dose and after an adequate treatment duration.* When there is a drug failure, there are usually two options: switch to another anticonvulsant or add another anticonvulsant with the first. In both situations, the lowest dose that can control seizures without side effects should be determined again. When necessary, the maximum tolerable dose must be sought if the seizures persist.

Definition and epidemiology of medical intractability

The usual criterion for drug remission is at least *one year* of the intake of anticonvulsant medication. The initial response to anticonvulsant drug therapy is highly predictive of long-term outcome. Almost two-thirds of patients respond to anticonvulsant therapy. Approximately 47% respond on one drug alone; about 13% respond to two drugs and 4% respond to three drugs or more.[2] Generally, it has been observed that the chance of achieving seizure control beyond three drugs is 5 to 10%.[3–5] Medical intractability is also known as *multidrug resistant* (MDR) *or pharmacoresistant* epilepsy. There is no general consensus on the definition of medical intractability. In recently published studies, the *minimum* number of anticonvulsant drug failures to qualify for medical intractability is two or three.[6–10] There are also other components in medical intractability. The seizure frequency and duration of drug refractoriness are important components in medical intractability.[6] The *stringent criteria*[6] for medical intractability as defined by Berg *et al.* are: (a) failure of two appropriate anticonvulsants, (b) the occurrence of an average of one seizure per month for at least 18 months, and (c) no more than 3 months of seizure-free hiatus during those 18 months. However, patients having very frequent seizures, multiple times per day or per week, have a greater impact than those patients with seizures occurring once a month. Hence, catastrophic epilepsy patients will require a shorter duration of observation in qualifying for medical intractability. The observation of drug refractoriness ranges from 6 months to 2 years. Another consideration in the defining medical intractability is the presence of a structural brain abnormality.[2] In patients with a known epileptogenic structural abnormality that is surgically accessible, a failure of at least two drugs may be all that is needed to classify pharmacoresistant epilepsy.

If the minimum two-drug criteria is use to classify medical intractability, the percentage meeting this criteria ranges from 31 to 37.5%.[7] Following the stringent criteria by Berg *et al.*, only 10% fulfilled medically intractability.[9] In a prospective study,[11] 13.8% and 23.2% of epilepsy children fulfilled the stringent criteria and two-drug failure criteria, respectively.

Hence, the two-drug failure criterion is sensitive for identifying refractory epilepsy. However, for surgical purposes, stringent criteria may be useful in identifying surgical candidates. Poor prognostic factors associated with medical intractability are early age at seizure onset, multiple seizure types, structural brain abnormalities (cortical dysplasia, hippocampal sclerosis), and high frequency of seizures before drug therapy, and persistence of seizures despite multiple drug trials.[2] The highest risks for medical intractability are the catastrophic epilepsy syndromes that occur frequently in children. Idiopathic (genetic) epilepsy has the least risk of drug resistance. Partial epilepsy has moderate risk of developing intractability. Using the two-drug failure criteria, the percentage of medical intractability are: focal epilepsy, 24%; idiopathic epilepsy, 9.3%; and catastrophic epilepsy, 66.7%. Using Berg's stringent criteria, 13.3% of focal epilepsy, 3.9% of idiopathic epilepsy, and 52.2% of catastrophic epilepsy are pharmacoresistant.[11]

In partial epilepsy, the duration of the epilepsy before becoming intractable is an average of 9 years (12). Younger patients (< 5 years old at onset of epilepsy) had a longer median latency time (15 years) before becoming intractable. In contrast, older patients (> 30 years old at onset of epilepsy) had a shorter *median* latency time of 1 to 2 years and an *average* of 3.2 to 3.6 years to become intractable. Among patients whose epilepsy onset was between 10 and 19 years old, the median latency and average duration to become intractable was 3 to 5.5 years and 7.2 to 8.6 years, respectively. In patients with partial epilepsy with *no* history of febrile seizures, the median latency was 5 years (9 years median latency with febrile seizure). Patients with hippocampal atrophy also had a longer median latency (8 years versus 3 years). Interestingly, about 47.5% of epilepsy patients whose seizure onset was at less than 5 years old reported a period of at least 1 year remission before they became medically intractable. There is a trend that epilepsy onset above 5 years or older had a smaller percentage of having a history of 1 year remission during drug therapy (7–28%).

Hypothesis of medical intractability

The factors leading to multidrug resistance are unknown. Drug resistance can be seen early in the course of the disease or up to several years after good drug response. There are two main hypotheses probably responsible for multidrug resistance. The first is the *Drug Transporter* hypothesis and the second, the *Drug Target* hypothesis.

Drug transporter hypothesis

Multidrug resistance transporter protein-1

There are a multiple drug transporters in the central nervous system that may be responsible for multidrug resistance.[13–16] The most studied efflux drug transporter is MDR1 or P-glycoprotein. It is commonly expressed in the brain, liver, intestine, and kidneys.[13] In the brain, MDR1 is found in astrocytes and in the endothelial lining of the blood brain barrier. It is a transmembrane 170 kD drug efflux transporter protein that belongs to the ATP-binding cassette (ABC) family (chromosome 7q21.1). Interest in MDR1 began with the discovery of MDR1 in cancer tissue resistant to chemotherapeutic medications. Drug resistance in cancer cells is secondary to the subtherapeutic *in situ* concentration of chemotherapy drugs. MDR1 has a broad substrate for the efflux transport of medications. These include antibiotics, steroids, lipid lowering drugs, calcium channel blockers, cardiac medications, HIV protease inhibitors, immunosuppresants, antiemetics, and antihistamines.[17–19]

Tishler *et al.* in 1995[20] were the first to report MDR1 protein expression in brain tissue of drug-resistant epilepsy patients. Out of the 19 cases studied, 10 had more than a tenfold increased expression of the MDR1 protein. Thirteen of the specimens were from patients with temporal lobe epilepsy secondary to hippocampal sclerosis. Five of these 13 also showed increased expression of MDR1. Similar results were obtained in studies on five patients with temporal lobe epilepsy,[21] and eight cases of cortical malformation.[22] Sisodiya *et al.*[21,22,23,24] reported evidence of MDR1 expression in the capillaries and perivascular glial tissue in 30 patients with cortical malformations and drug resistant epilepsy. Lazarowski *et al.*[25] reported one case of MDR1 expression in an epilepsy patient with tuberous sclerosis. Other epileptogenic brain tissue with increased MDR1 expression were found in eight patients with dysembryoplastic neuroepithelial tumor,[22] five patients with Rasmussen encephalitis,[26] and one case of fatal human status epilepticus.[27]

It is possible that frequent seizures can induce the overexpression of MDR1. This hypothesis is supported by animal studies that show that seizures can influence the expression of MDR1.[28–34] Rizzi *et al.*[28] studied the mRNA expression of MDR1 in the mouse after kainic acid-induced seizures and showed that MDR1 is increased by 85% 3–24 hours after seizure induction. Moreover, status epilepticus induction caused a 180% increase of MDR1 expression in the mouse hippocampus and a 500% increase in the entorihinal cortex. Seegers *et al.*[30] reported that amygdala-kindled rats showed an overexpression of MDR1 1–2 weeks after kindling. In rats genetically prone to epilepsy,[31] a single audiogenic-induced seizure caused a gradual increase of MDR1 in 4 hours to 7 days.

Functionally, the presence of MDR1 transporter proteins may lead to an efflux of antiepileptic drugs from epileptogenic brain parenchyma to blood vessel lumens. The effect of MDR1 on antiepileptic drugs has been shown in animal studies. Rizzi *et al.*[28] showed that extracelluar fluid (ECF) levels of phenytoin decreased by 30% after seizure induction. Potschka *et al.*[35,36] studied the effect of MDR1 and multidrug-related protein (MRP) inhibition of carbamazepine and phenytoin in the rat brain. Using microdialysis methods, inhibition of MDR1 and MRP caused a 40% increase of carbamazepine in the rat brain extracellular fluid. In 2002,[37] the study was extended to see the effect of MDR1 inhibition on the brain ECF concentrations of felbamate, phenobarbital, and lamotrigine. Using verapamil as an MDR1 inhibitor, AED concentrations increased in ECF by 52%, 95%, and 107%, respectively. In another experiement, chronic epileptic rats showed an increased responsiveness with phenytoin when treated with a selective MDR1 inhibitor, Tariquidar.[38] Only one study has demonstrated brain anticonvulsant levels in epilepsy patients using microdialysis techniques. Twenty-two pharmacoresistant epilepsy patients had intraoperative microdialysis measurements of brain anticonvulsants levels (extracelluar space) compared with cerebrospinal fluid (CSF). Brain concentration of anticonvulsants was significantly lower than CSF. However, there was no concomitant measurement from nonepileptogenic region.[39]

Aside from the over-expression of MDR1, it has been shown that the gene polymorphisms encoding for MDR1 protein also confer anticonvulsant drug resistance.[40–42] It has been found that patients with drug-resistant epilepsy were more likely to have the CC genotype at ABCB1 3435 than the TT genotype.[40] However, other studies have found no association of MDR1 polymorphisms with anticonvulsant drug resistance.[43,44]

Other drug transporters

The other efflux drug transporters are multidrug-resistance-related proteins (MRP1, MRP2, MRP5), Major Vault Proteins, and RLIP76.[15,21,45,46] The RLIP76 is not related to MDR1 or MRP. This transporter is expressed in the luminal surface of endothelial cell membranes of the blood brain barrier of excised pharmacoresistant epileptic brain tissue. Saturable, energy-dependent, antigradient transport of both phenytoin and carbamazepine were demonstrated using recombinant RLIP76 reconstituted into artificial membrane liposomes. Immunotitration studies showed that RLIP76 is dominant transporter for carbamazepine and phenytoin using crude membrane vesicles prepared from whole-brain tissue endothelium. In the RLIP76-/- knockout mice study, it exhibited dramatic toxicity upon phenytoin administration due to decreased drug extrusion mechanisms at the blood brain barrier.[46]

Drug resistance may also be related to a dysfunction of glutamate transporters of glial and neuronal cells of epileptogenic tissue.[47,48] Pharamacoresistant epilepsy brain slices showed that glutamate transporters in the glia (EAAT1 and EAAT2) and neurons (EAAT3) are downregulated in specific areas of the hippocampus.[47] It is probable that poor reuptake of glutamate cause increase levels of glutamate and worsen the epileptogenicity of the brain.

Drug target hypothesis

The hypothesis is that there is an intrinsic or acquired loss of brain target sensitivity to anticonvulsants.[14] The drug target hypothesis was recently described by Remy *et al.* in 2003. This study was based on studies with carbamazepine on voltage-gated sodium channels in hippocampal neurons. The primary mechanism of carbamazepine (CBZ) is well established, and it is thought to be related to its action on voltage-gated sodium channels that are integral to the generation of seizure discharges. Vreughdenhil *et al.*[49] first reported that the modulation of sodium current inactivation by CBZ in hippocampal CA1 neuron from patients with temporal lobe epilepsy (TLE) and mesial temporal lobe sclerosis was only half of that measured in neocortical neurons from the same patients and in CA1 neurons from patients without mesial temporal lobe sclerosis. These data was substantiated by Remy *et al.*[50] It showed that use-dependent block of voltage-dependent sodium channels of dentate granule cells by CBZ is completely lost in patients with CBZ-resistant temporal lobe epilepsy. A loss of drug–target sensitivity was also noted in rat models of TLE.[51] The study showed that use-dependent block of sodium channels of dentate granule cells by CBZ is absent in the pilocarpine rat model of TLE. It also demonstrated that the effect of phenytoin on the fast recovery from inactivation in hippocampal granule neurons was significantly reduced in the pilocarpine model, though not as much with the carbamazepine.[51]

Summary

In published literature, the consensus of medical intractability is usually a two to three anticonvulsant drug failure. Catastrophic epilepsy and partial epilepsy syndromes have the tendency to develop pharmacoresistance early. The mechanisms of multidrug resistance may be multifactorial. The current hypothesis of drug intractability is probably due to low drug penetration in the blood brain barrier, drug target insensitivity, or impaired reuptake of glutamate in epileptogenic brain tissue.

26 Epidemiology of the intractable generalized epilepsies

AT Berg

Introduction

Gowers is often quoted as having said about epilepsy that, 'The tendency of the disease is toward self-perpetuation; each attack facilitates the occurrence of another by increasing the instability of the nerve elements... The spontaneous cessation of the disease is an event too rare to be reasonably anticipated'.[1] The first population-based epidemiological study to examine prognosis published in 1979 provided a very different assessment of the nature and outcome of epilepsy. This study demonstrated that most individuals with epilepsy entered lasting long-term remission.[2] Gowers' characterization of epilepsy, and that derived from the epidemiological studies, both reflect important truths. Most people with epilepsy do have seizures that are well-controlled and may ultimately remit. Those who have the worst seizures and who are cared for in specialized referral centers often have inexorably progressive, nonremitting disorders. While this latter group reflects a relatively small minority of all individuals who ever have epilepsy, these are the patients who occupy the majority of the epilepsy specialist's endeavors and are the intense focus of research aimed at prevention and improved treatment of this disabling disorders.

To a large extent, the prognosis of epilepsy is determined by the type of epilepsy. The International League Against Epilepsy (ILAE) has made concerted efforts to identify distinctive forms of epilepsy and to arrange them into a practical classification of the epilepsies. Thoughtful and scholarly treatments of these efforts are available.[3–5] Although imperfect and as yet incomplete, the ILAE classification provides a useful framework for thinking about epilepsy[6,7] (Table 26.1). In children the most aggressively intractable forms of epilepsy arise from certain clusters of syndromes, some generalized, some localization-related, and some with combinations of features.

The emphasis in this chapter is on the intractable generalized epilepsies. This presents a few issues in definition and terminology that must first be addressed.

Generalized

While the term appears self-explanatory, in fact the apparently neat dichotomy between generalized versus focal really represents a continuum. Although the classification and terminology used to describe the epilepsies is under revision, at this point in time, it would be fair to consider, in the context of intractable generalized epilepsies, the epilepsies currently listed under the heading 'undetermined with both focal and generalized features'. These forms of epilepsies are complex but do have some distinctive generalized features and thus merit consideration here.

Intractable

There is no single operationalized definition for the concept of intractable or pharmaco-resistant epilepsy.[8] As it turns out, this is likely to be more of a problem for refractory partial epilepsies where the course of the epilepsy may be such that patients are seizure free for prolonged periods, and it is difficult to decide exactly when they are clearly intractable. Regardless, for the purposes of classifying a case of epilepsy as intractable, some minimum number of appropriate pharmacological treatments must be demonstrated ineffective, and a minimum criterion for seizure occurrence must be specified. Finally, knowledge of the natural history of the disorder is required as some forms of epilepsy, even those clearly refractory to medication, may go through relatively quiescent periods.

'Epileptic encephalopathy' and 'catastrophic epilepsies'

These terms have often been used in reference to many of these forms of severe epilepsy, localization-related as well as generalized and with both generalized and focal features. The concept of epileptic encephalopathy implies that the epileptic discharges associated with these disorders, which occur virtually exclusively in infants and young children, are thought to cause irreparable changes in brain development and function and result in lasting alterations in brain function. Children with these disorders may appear perfectly normal before onset but, with time, are frequently retarded or have pronounced cognitive deficits, are autistic, or both. The term 'catastrophic' epilepsy is restricted by some authors, to refer primarily to West, Lennox-Gastaut syndromes, and progressive myoclonic epilepsies.[9,10] Others consider catastrophic to be more expansive and use it to refer both to epileptic encephalopathies and to progressive encephalopathic conditions associated with epilepsy.[4] For the purposes of this discussion, the term catastrophic epilepsies will be used with the understanding that there is some variation in its use.

Intractable generalized epilepsies

Cryptogenic or symptomatic generalized epilepsies

These syndromes may or may not be preceded by a recognized symptomatic cause. The most common and best known of

Table 26.1 Outline of the classification of the epilepsies, 1989 report.[6]

Localization-related (partial, focal)
Idiopathic
Symptomatic
Cryptogenic
Generalized
Idiopathic
*Cryptogenic or symptomatic
*Symptomatic
Undetermined
*With both focal and generalized features
Without unequivocal focal or generalized features
Special situations

*Defined as catastrophic epilepsies for the purposes of this discussion.

these syndromes are West and Lennox-Gastaut. Myoclonic-Astatic Epilepsy (MAE or Doose syndrome) presents some difficulties in terms of classification. It was originally considered a form of idiopathic generalized epilepsy. In the 1989 classification, it was placed among the cryptogenic/symptomatic generalized epilepsies. This syndrome has been considered one of the epileptic encephalopathies.[11] More recently, it has been reintegrated into the idiopathic generalized epilepsies.[4,12] This reorganization in its classification does not indicate that MAE should be considered a benign disorder. In fact, fairly distinct subtypes with markedly different outcomes are described, suggesting that there is some complexity to this disorder that is not captured in the current approach to its classification.[13]

Symptomatic generalized epilepsies

This heading includes some well-recognized, although not necessarily entirely distinct, syndromes such as early infantile epileptic encephalopathy with suppression bursts (EIEE) or Ohtohara syndrome and early myoclonic encephalopathy (EME). Although typically associated with a specific symptomatic cause, occasional 'cryptogenic' cases are found.[14] In addition, there are epilepsies that result from very specific diseases in which the epilepsies tend to be characterized according to the disease rather than as a syndrome. As a group, these are often referred to as the progressive myoclonic epilepsies (PME). The better known among these include myoclonic epilepsy with ragged red fiber or MERRF, Lafora, and Unverricht Lundborg.[10,15,16] The report for the ILAE Task Force on Classification provides a current complete list.[7] In these disorders, the encephalopathic aspect of the disorder is a function of the underlying disease and not of the epileptic abnormality per se. Any one of these epilepsy diseases is exceedingly uncommon.

Undetermined with both focal and generalized features

Finally, well-recognized syndromes within the undetermined group should be considered in the context of catastrophic generalized epilepsy because they have generalized features and because it is important to differentiate them from other forms of intractable generalized epilepsy.

With the mounting evidence concerning its genetic basis, it seems increasingly apparent that that Dravet syndrome may represent the severe end of the spectrum of idiopathic epilepsy.[17,18] Dravet has also been linked to the familial clustering of epilepsies commonly known as GEFS+ (generalized epilepsy with febrile seizures plus). The finding of some cases of temporal lobe epilepsy with GEFS+ has resulted in the suggestion that the cluster be renamed autosomal dominant epilepsy with febrile seizures plus or simply FS+ (febrile seizures plus).[19] MAE has also been associated with the FS+ cluster and may well be part of this spectrum of idiopathic channelopathy epilepsies.[20,21] Landau-Kleffner syndrome and epilepsy with continuous spike wave in sleep (ESES) have a more localization-related presentation and may, in some cases, also represent the severe end of the localization-related idiopathic epilepsies. The two are not entirely distinct and some authors have suggested that they are manifestations of the same underlying process in different areas of the cortex.[22,23]

Basic epidemiology of epilepsy in the population

Overall incidence

For all epilepsy in the population, the estimates of the annual incidence range from a low of 24[24] to high of 64.1[25] per 100,000. The best overall population estimate from the US is based on the Rochester Epilepsy project and is 61/100,000 per year.[26]

Age at onset

From the population-based, epidemiological perspective, one of the most dramatic determinates of epilepsy is age (Figure 26.1).[26,27] In populations, the incidence of epilepsy is extremely high during the first year of life. It drops but remains relatively high throughout childhood and adolescence finally leveling off at a nadir in the third decade. It remains low into the sixth decade and then precipitously climbs in the elderly. The very elderly (>80 years) have

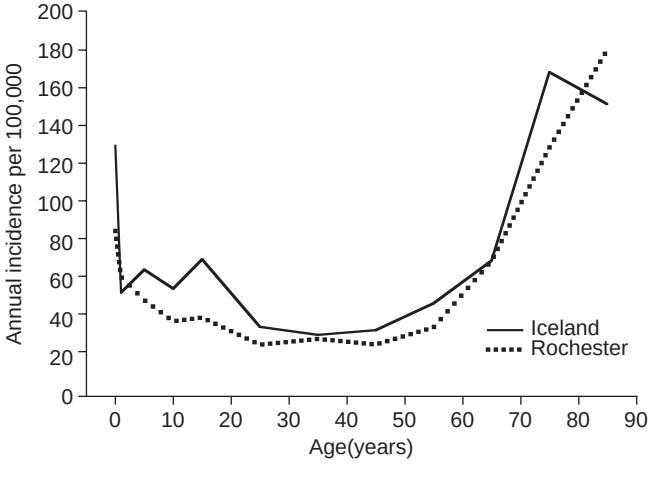

Figure 26.1 Incidence of epilepsy by age in Rochester, MN, US and Iceland. Data adapted from the original articles.[26, 27]

incident rates considerably higher than those seen in infants.[25–28]

Age and type of epilepsy

Part of the age-related pattern for the incidence of epilepsy is due to the occurrence of generalized seizures and epilepsies, many specific forms of which occur almost exclusively in infants, children, and young adolescents. This can be clearly seen in the Icelandic study where, for generalized seizures other than generalized tonic-clonic, the incidence is very high in infancy and drops precipitously in childhood, practically to disappear in adults.[27] The CAROLE study from France provides some of the most stable estimates of the relative occurrence of syndromes throughout the age span.[29] New onset generalized epilepsies of any kind account for little of epilepsy beginning in adults but are quite common in children and intermediate in adolescents and young adults.

Incidence of the catastrophic epilepsies

The Icelandic data provide incident rates by age and overall category of epilepsy.[27] The category for cryptogenic and symptomatic generalized epilepsy (dominated by West and Lennox-Gastaut syndromes) has an overall incidence of 0.7/100,000 per year in the general population; however, all cases observed in that population occurred in infants, and among infants (<1 year of age) the annual incidence rate was 43.4/100,000. For all the catastrophic epilepsies together, the population incidence rate was 1.7/100,000. The Icelandic study is a true prospective, population-based study. Because of the size of the population, the actual number of cases included in the study is fairly small (about 200 with newly diagnosed epilepsy and another 200 with first ever unprovoked seizures). The estimates for catastrophic disorders provided above were based on a total of 15 cases with such conditions.

Population-based estimates of the incidence or prevalence of some of the more common specific forms of catastrophic epilepsy are available from studies from a variety of countries. West syndrome is fairly consistently found to occur in 3 to 4 per 10,000 live births.[30–33] One study from Finland estimated the incidence of Lennox-Gastaut at 2/100,000 per year in the overall population.[34] A separate estimate more specific to children found the incidence to be 0.28/1000 live births.[35] Prevalence studies have provided fairly consistent estimates of the syndrome as being present in about 0.2 to 0.3 per 1000 children by age 10–15.[36,37]

Because this disorder often develops after West syndrome, incidence figures for Lennox-Gastaut must be made and interpreted with a little caution. Children who begin with one then evolve to the other cannot be counted twice in overall incidence estimates. For example, in separate reports from the US and Finland, about 25–40% of the children with Lennox-Gastaut first presented with West.[35,36,38] Up to half of children with symptomatic West syndrome may undergo an evolution to Lennox-Gastaut.[39]

One population-based estimate for Dravet syndrome comes from the United States. Based on the National Collaborative Perinatal Project, Hurst estimated that Dravet affects 1/40,000 children.[40]

Relative frequency of catastrophic epilepsies

The incidence figures provide a rough idea of how often some of the more common catastrophic epilepsies occur in the population. For understanding how common they are in the epilepsy clinic, other sources of information are more revealing.

The CAROLE study as well as other community- and population-based studies provide the distribution of types of epilepsy at initial diagnosis (incident cases) as well as in cross-section (prevalent samples). While these are not always strictly speaking 'population-based studies' and therefore precise incidence estimates cannot be obtained from them, the studies are representative of patients seen in the populations from which they come and can be reasonably used to estimate relative frequencies of different forms of epilepsy. In children, the encephalopathic disorders as a whole represent between 10 and 21% of epilepsies [29,41–43] although the highest estimate was based on the most clinic-based (referral center) of the reports.[43]

Syndromes such as West, Lennox-Gastaut, and MAE account for the majority of the children who have catastrophic epilepsies. Individually, each may account for 1–5% of pediatric epilepsy cases. Estimates from the rare syndromes are harder to come by. In a US study, Dravet was found in 0.5% of children recruited at the initial diagnosis of epilepsy. [38] Another study from Israel reported that syndromes such as Ohtahara and Landau-Kleffner accounted for 0.2% each of pediatric epilepsy.[44] Generally, such estimates are based on one or a few cases out of several hundred.

In all, what is apparent is that those forms of generalized epilepsies most likely to be intractable occur relatively rarely in absolute terms and represent a relatively small proportion of all individuals with epilepsy in the population although they represent an important minority of children.

Descriptive epidemiology of the catastrophic epilepsies

Available information is often based on case series from specialized treatment centers. Such cases may not entirely represent the disorder as it occurs in the population. On the other hand, true population-based estimates are difficult to obtain.

Age at onset

The catastrophic epilepsies tend to occur very early in life; however, each has a typical age at initial appearance. EME and Ohtahara have the earliest onset occurring during the neonatal period although they may first present later up through the first 3 months of life. West and Dravet syndromes generally occur within the first year with a peak around five months. Lennox-Gastaut, Myoclonic-Astatic Epilepsy, Landau-Kleffner, and Continuous Spike Wave in Sleep all occur mostly after the first year through about 7 to 8 years of age although CSWS may have its onset after the first decade.

Gender

For epilepsy overall, there does not seem to be much difference between boys and girls.[41,42] This lack of a gender difference overall, however, belies some rather distinct differences within in specific forms of epilepsy. For example, one of the most common forms of idiopathic generalized epilepsy, childhood absence, occur about twice as frequently in girls compared with boys.[4]

For the catastrophic epilepsies, there is some tendency for studies to report a predominance of boys relative to girls for several of the syndromes. For example, for West syndrome, 10/13 cases reported in Iceland [30] and 38/57 cases reported in Sweden (Sidenvall) were boys.[31] Lennox-Gastaut has also been associated with a predominance of boys[36] as have Dravet syndrome,[45] Landau-Kleffner syndrome,[4] and MAE[13] Ohtahara syndrome is very rare. To the extent it has been studied, there does not appear to be a tendency for boys or girls to be more susceptible than the other.[14]

Many of these encephalopathic conditions are secondary to known insults or other conditions each of which has its own epidemiology. Each of these symptomatic causes may tend to affect preferentially people of one gender or another. On the other hand, syndromes such as Dravet, Landau-Kleffner and MAE typically, if not always, occur in children who were previously neurologically and developmentally normal and in whom evaluations fail to reveal any explanation for their disorders.

Etiology

Many of the catastrophic epilepsies are often associated with and secondary to identified etiological factors. Because these are disorders that occur in infancy and early childhood, genetic as well as pre- and perinatal causes are particularly prevalent. Etiologic factors include a variety of brain malformations. These are often cortical; however not exclusively. Neurocutaneous syndromes (especially tuberous sclerosis), pre- and perinatal hypoxia and hemorrhage, and a variety of chromosomal disorders and genetic syndromes a common antecendants. Postnatal causes, particularly infections, are other potential causes but considerably less common, at least in developed countries. The specific findings vary between syndromes.

West syndrome

This disorder may be cryptogenic in about a fifth to a third of cases. In the Swedish series of 57 cases of West syndrome, 43 (75%) of the cases had recognizable symptomatic causes including four with neurocutaneous disorders, eight with various types of malformations of cortical development, and five with chromosomal disorders.[31] Pre- or perinatal asphyxia with or without evidence of intraventricular hemorrhage is another cause of West syndrome. Tuberous sclerosis receives considerable attention as a cause of West syndrome both because the possibility for surgical intervention and because of some evidence that West syndrome in this selected setting may be best treated with vigabatrin, a drug not available in the US but which has been approved in many other countries.

Lennox-Gastaut

This syndrome often develops in children who have had West syndrome and is associated with similar etiological factors.[35,36,38,39] As with West syndrome, however, a quarter to a third of the cases of Lennox-Gastaut are considered cryptogenic. That is there is no identified underlying cause and the infant or child was apparently 'normal' prior to the onset of seizures.

Myoclonic-astatic epilepsy

MAE is typically not associated with an identifiable symptomatic cause.[13] In part for this reason as well as the high proportion with family history of epilepsy, it has been grouped with the idiopathic epilepsies in the past and now again in the proposed update to the classification of the epilepsies.[7] In some cases, it may be part of the GEFS+ spectrum.[46]

Dravet syndrome

This disorder always occurs in infants who were previously considered neurologically and developmentally normal. It has increasingly become a prime example of a channelopathy, with many cases demonstrating severe functional mutations in the SCN1A gene coding for the alpha1 subunit of the sodium channel.[17,18,20] Other findings have implicated SCN1B as well.[47] This syndrome has also been considered part of the GEFS+ spectrum.[48]

Landau-Kleffner and CSWS

Landau-Kleffner syndrome occurs in children who were previously neurologically and developmentally normal. Some have speculated regarding the apparent continuum between this disorder and benign rolandic epilepsy with centro-temporal spikes.[22,23] The related phenonmenon, CSWS, is sometimes seen in association with pre- or perinatal insults, particularly certain types of cortical malformations as well as vascular lesions.[49,50]

Prognosis

In general, the prognosis of these disorders is extremely poor with respect to seizure outcomes, intellectual development, and mortality.

Seizure and intellectual outcomes

The catastrophic epilepsies, although accounting for only 10–15% of childhood onset epilepsy, account for half or more of all children with intractable epilepsy.[51] The absolute risk of becoming intractable depends on the definition of intractability. In a preliminary report from one prospective study, the risk was approximately 70% when failure of two appropriate antiepileptic drugs was considered and only somewhat less when more stringent criteria were applied.[52] Even within the catastrophic epilepsies, the risk of developing intractable seizures and the likelihood of entering a later remission depend on the specific type of epilepsy and, when applicable, whether there is an underlying symptomatic cause.

West Syndrome

The cryptogenic form of West syndrome is generally more likely to respond well to treatment with a complete cessation of seizures. Whether because of that or because there are no obvious structural abnormalities or other insults to the brain, these children also have the greatest likelihood of enjoying a

relatively normal development.[30,31,33,39] When associated with a symptomatic cause, the outcomes are very poor, with lasting seizure intractability and moderate to severe mental retardation being the rule. West syndrome with its characteristic epileptic spasms may remit for a period and then reoccur.[53] More typically, West syndrome evolves into Lennox-Gastaut syndrome or a focal epilepsy.

Whether the intellectual deficits are a result of the epilepsy or are an indication of the severity of the underlying insult is not entirely clear. A recent practice parameter from the American Academy of Neurology concluded that there was insufficient evidence to conclude that successful suppression of seizures resulted in substantially better cognitive and developmental outcomes.[54] The recent report from the UKISS study, a UK-wide randomized trial for treatment of infantile spasms and published since the practice parameter, found evidence suggesting the control of seizure was not necessarily all that was needed to secure better developmental outcomes. In that study, children with cryptogenic West syndrome responded equally well in terms of seizure control to ACTH and vigabatrin. Developmental outcomes were significantly better, however, in children who received ACTH.[55]

Lennox-Gastaut

Although this syndrome is often cryptogenic, it has an even more sinister outlook than West syndrome. Regardless of the presence or absence of a symptomatic cause, children with this syndrome rarely experience complete, lasting seizure remission, although it is not uncommon for the seizure occurrence to fluctuate. Developmental and intellectual outcomes in Lennox-Gastaut may be initially normal but are rarely so after several years.[56,57]

Myoclonic-astatic epilepsy

When considering the outcomes associated with MAE, it becomes less clear that this is a single entity.[13] Two groups distinguish themselves. In one form, seizures remit after a few years and development is fairly, if not completely normal. In the other, seizures are intractable and development and cognition are moderately to severely impaired.

Ohtahara and EME

These have extremely poor outcomes on all counts often because of the nature of the underlying cause of the epilepsy. Remission let alone normal intellectual outcomes are virtually never described. Dravet syndrome is similarly described as nonremitting and associated with severe intellectual disorders .

Landau-Kleffner and CSWS

Seizures tend to occur infrequently and generally remit. They are not the predominate concern. The language and other cognitive disturbances that develop after the onset of these disorders can be minimal but tends to be significant.[59–61]

Mortality

Almost all the excess mortality risk observed in children with epilepsy occurs in children with one of the catastrophic epilepsies or with severe neurological involvement, regardless of the type of epilepsy. In almost all cases, the death is due to the underlying cause of the seizures. Deaths due to seizures themselves are exceeding rare. In a US study, 13 deaths were observed in a cohort of 613 children. Eleven of the deaths occurred in children with catastrophic epilepsies.[62] Ten of the deaths were due to the underlying cause of the epilepsy and one was a sudden unexpected death (SUDEP) in a child with Dravet syndrome. In three population- or community-based studies (including the US study mentioned above), a total of 48 deaths were observed in 1777 children followed for a total of more than 15,000 person-years.[62–64] Only three deaths in this combined series were due to the occurrence of seizures, and 32 (67%) of the deaths occurred in the 10–15% of children with either catastrophic epilepsies or severe neurological impairment secondary to a symptomatic cause.

Table 26.2 provides a summary of some of the key epidemiological features of the syndromes discussed above.

Treatment options

By definition, many children with catastrophic epilepsies do not respond well to standard pharmacological therapies. Relatively small studies, some randomized, have provided a basis for selection or avoidance of specific drugs for specific syndromes. For example, lamotrigine may exacerbate seizures in Dravet syndrome[65] while being reasonably effective for Lennox-Gastaut.[66,67] West syndrome associated with tuberous sclerosis may respond better to vigabatrin than to ACTH, the generally preferred first line treatment for this condition.[54]

Surgical therapies, including stimulation devices, have been used in selective cases. In general, epilepsies with cryptogenic (possibly idiopathic) etiologies such as Dravet and MAE or that are due to progressive degenerative encephalopathic diseases are inappropriate for resective surgery. The greatest experience has been in the context of children whose epilepsy is secondary to identifiable and resectable lesions. Many of these catastrophic epilepsies are secondary to diffuse or multifocal lesions; however, they often limit the use of surgery in such cases. Callosotomies have been, and in places continue to be, used for Lennox-Gastaut syndrome.[68]

Vagal nerve stimulation has been used with guarded success in individuals with the Lennox-Gastaut and occasionally other severe generalized epilepsies.[69–71]

Summary

The catastrophic epilepsies occur at a very low frequency in the population overall and account for a small minority of cases of epilepsy. Their initial onset is concentrated in infants and young children and represent about 10–15% of childhood onset epilepsy. They account for half or more of all intractable epilepsy in children and about two-thirds of deaths occurring in association with epilepsy in children. Some of these epilepsies can occur in the absence of an identifiable preceding insult or conditions, and some may possibly represent the severe end of the spectrum of idiopathic epilepsies. Effective treatments for these conditions are largely lacking although, in selected cases, certain pharmacologic therapies as well as surgery may prove relatively beneficial. This is a group of epilepsies for which effective intervention could provide tremendous benefits by preventing life-long seizures, disability, and dependence.

Table 26.2 Summary of key epidemiological features of the more common and better known forms of catastrophic generalized epilepsy

	Proportion of pediatric epilepsy*	Typical age at onset	Gender	Etiology	Seizure outcome	Intellectual outcome
Ohtahara	<0.5% pediatric epilepsy	Neonatal – 2–3 months	No clear gender difference	Almost always symptomatic	Uniformly poor	Uniformly poor
EME	<0.5%	Neonatal – 2–3 months	No clear gender difference	Almost always symptomatic	Uniformly poor	Uniformly poor
West	2–3%	3–12 months	Boys usually more often than girls (studies vary)	1/4–1/3 cryptogenic	Variable – cryptogenic: can be good; symptomatic: uniformly poor	Tends to parallel seizure outcome
Dravet	<0.5%	<1 year	Boys maybe more often than girls	Channelopathy in most cases	Uniformly poor	Uniformly poor
MAE	1–2%	1–6 years	Boys more often than girls	Typically cryptogenic/idiopathic	Varies – either excellent or intractable	Intellectual outcome tends to parallel seizure outcome
Lennox-Gastaut	1–3%	1–7 years	Boys slightly more often than girls	1/3 cryptogenic	Uniformly poor	Uniformly poor
Landau-Kleffner	<0.5%	2–8 years	Boys more often than girls	Typically cryptogenic	Good, seizures usually remit	Variable, mild to significant impairments persist
CSWS	<0.5%	2 months –12 years	Boys more often than girls	Cryptogenic or symptomatic	Good, seizures usually remit	Variable, mild to significant impairments persist

* Estimates are based on citations throughout the literature. They should be interpreted with caution because the basis of these figures is not always sufficient for precise estimation of such rare disorders.

27 Genetic factors contributing to medically intractable epilepsy

JF Bautista

Summary

- Medically intractable epilepsy may have genetic causes, mediated by pharmacogenetics or disease-related genetic effects.
- Two possible pharmacogenetic effects include overexpression of drug transporters and altered drug targets.
- Certain genetic epilepsy syndromes are characterized by medical intractability, although the relationship between phenotype and genotype is often complex.

Introduction

There is growing evidence that genetic effects contribute to medical intractability in epilepsy. Genetics can play a role in altering the pharmacology of an antiepileptic medication, and pharmacogenetics is the study of how genetic variation can influence individual drug response. In addition, genetics can play a role in the disease process itself. In some genetic forms of epilepsy, medical intractability is an inherent feature of the phenotype. To simplify the subsequent discussion, biological mechanisms of drug resistance will be grouped into two broad categories: drug-related (tolerance, ineffective mechanism, ineffective delivery, altered drug targets) and disease-related (etiology, progression/severity, altered neuronal networks).

Pharmacogenetics

Pharmacokinetics encompasses drug absorption, distribution, target interaction, metabolism, and excretion. At each step genetic variation has the potential to alter drug responsiveness. Drug resistance may result from decreased absorption or distribution, altered drug–target interactions, or increased metabolism and excretion. Medically intractable epilepsy patients are typically unresponsive to multiple antiepileptic drugs regardless of the drug's mechanism of action, suggesting that drug resistance is nonspecific, or at least not restricted to a single mechanism of action.

Altered metabolism and clearance

Historically, the metabolism of most drugs, including many antiepileptic drugs (AEDs), is classified into two pathways. Phase I reactions involve the additional of a functional group, through oxidation, reduction, and hydrolysis, which can be used as a site of conjugation in phase II reactions, involving acetylation, glucuronidation, sulfation, and methylation. In fact, phase II reactions can occur before or without phase I reactions. The P450 enzymes, a superfamily of microsomal drug-metabolizing enzymes, catalyze phase I reactions. Phenytoin is primarily metabolized by the polymorphic P450 CYP2C9 isoform with a minor contribution from CYP2C19. DNA variations in the genes coding for these enzymes can influence drug response by affecting metabolism. For instance, polymorphic variants that result in high enzymatic activity can lead to treatment failure due to increased drug metabolism and inadequate drug levels.

DNA variations (alleles or polymorphisms) have been associated with altered metabolism of several common antiepileptic medications. The CYP2C9*2 and CYP2C9*3 allelic variants show significantly reduced activity compared to the wild-type (normal) CYP2C9*1 allele.[1,2] The presence of an allelic variant correlates with the required maintenance dose of antiepileptic medication, in that, for equal serum levels, individuals with at least one mutant CYP2C9 allele require 30% less phenytoin than those individuals homozygous for the wild-type allele.[3] This pharmacogenetic effect on metabolism is not likely to be a significant contributor to medically intractable epilepsy, as AED dose would be adjusted to compensate for inadequate serum levels, in clinical practice.

Impaired central nervous system penetration

Overexpression of drug transport proteins

Medical intractability may also result from inadequate delivery of drug to the brain. There is mounting evidence for the upregulation of drug transport molecules in human epilepsy. This upregulation may be acquired (e.g., a consequence of repeated seizures) or inherited (e.g., functional variants of genes encoding drug transport proteins). Several genes have been identified that encode drug efflux pump proteins, including multidrug resistance genes MDR1 and MDR2, and the multidrug resistance-associated protein family, MRP1-7. The most well-studied example is the MDR1 gene product, P-glycoprotein, also known as the ATP-binding cassette subfamily B member 1 (ABCB1) transporter. Both MDR1 and several MRPs are expressed at the blood–brain barrier and act as pumps to export molecules to the vascular space away from neurons. Several AEDs are transported by MDR1 or MRPs.[4] Drug transporters are upregulated in human epilepsy, and this upregulation is associated with medical intractability.[5,6]

Interestingly, this overexpression of drug transporters appears to be localized to the seizure focus.[7] While appropriate brain tissue is difficult to obtain for human controls (drug-responsive epilepsy patients do not typically present for epilepsy surgery), experiments in a rat model of temporal lobe epilepsy (TLE) suggest that P-glycoprotein expression is increased in animals that are drug-resistant compared to those that are drug-responsive.[8] It is proposed that overexpression of drug transport proteins leads to lower brain tissue drug concentrations, and this is supported by indirect evidence that in culture, cells expressing MDR1 have lower intracellular phenytoin concentrations than cells not expressing MDR1.[5]

Role of MDR1 gene polymorphisms

A polymorphism in exon 26 of the MDR1 gene (C3435T) has been associated with a functional change in intestinal expression and activity of P-glycoprotein in normal Caucasian volunteers; specifically the TT genotype produces lower levels of expression compared to the CC genotype.[9] This finding does not appear to hold for other ethnic populations.[10] In any event, over the last several years there has been a great effort to correlate the C3435T polymorphism with disease, but the results have been conflicting for epilepsy. An initial study found an association between the CC genotype and medically intractable epilepsy in a British population from London ($N = 315$).[11] A similar finding was reported in a study from Austria ($N = 210$) restricted to TLE patients using three different categories of drug-resistance,[12] as well as in a Taiwanese study ($N = 331$) using definitions closer to the original study.[13] However, the original study's finding could not be confirmed in an Australian cohort of nearly twice the size and identical inclusion criteria as the original study ($N = 609$).[14] Additional attempts to confirm the original study in a Scottish cohort ($N = 400$),[15] and a Korean epilepsy patient population ($N = 171$)[16] have been unsuccessful.

The C3435T polymorphism occurs in a noncoding, nonpromoter region of the gene and is therefore unlikely to be causative itself, but thought to be linked to the causative allele. Conflicting reports are common in case-control association studies of this kind and may be due to differences in study design, case definition, and population ethnicity and genetic background. In addition, multiple testing, ascertainment bias, and small sample sizes lacking statistical power often play a role. While overexpression of MDR1 appears to play a role in medically intractable epilepsy, the role of MDR1 polymorphisms in producing this overexpression is unclear. It is not clear if the functional effect of the C3435T polymorphism on duodenal MDR1 expression is also true of MDR1 expression at the blood–brain barrier. Further, it seems counterintuitive that a genetic polymorphism, presumably present in all cells, could explain the finding that MDR1 overexpression is localized to the epileptic focus.

Role of other drug transport proteins

Other drug transporter proteins that may play a role in medically refractory epilepsy include MRP1,[17–19] MRP2,[17,19,20] breast cancer resistance protein (BCRP),[21,22] and major vault protein (MVP).[17,23] Increased expression of P-glycoprotein, MRP1, MRP2, and MVP was observed in surgical specimens of TLE patients with hippocampal sclerosis (HS), compared to TLE patients without HS and normal autopsy controls.[17] In another study, P-glycoprotein, BCRP, and MVP were found to colocalize on vascular endothelium in epileptogenic brain tissue.[21] This coexistent overexpression of several multidrug transporter proteins in epileptic brain tissue raises the question of whether these proteins are actually increased in response to seizures, as opposed to being the cause of drug resistance. Regional overexpression of drug transporters may serve as a protective mechanism in response to transient blood–brain barrier opening during seizures, for instance. Experimentally-induced seizures can produce overexpression of P-glycoprotein in animal models,[24,25] indicating that upregulation can be acquired as well as inherited. Clearly, much work needs to be done to clarify the role of drug transporter genes in medically intractable epilepsy.

Altered drug targets

Another possible mechanism for medical intractability is altered targets of AED action. AED targets can be divided into three broad categories: 1) voltage-gated ion channels, 2) proteins involved in synaptic inhibition (e.g., enhancing GABA neurotransmission), and 3) proteins involved in synaptic excitation (e.g., inhibiting glutamate receptors).[26] Clearly, a particular AED can have more than one target, and there are likely to be other targets that do not fall into the above categories.

Polymorphisms in genes encoding AED targets may affect drug response by altering target function, a pharmacodynamic effect. In one study the effect of carbamazepine was enhanced in mutated neuronal nicotinic acetylcholine receptor subunits (a mutation observed in autosomal dominant nocturnal frontal lobe epilepsy, which is typically responsive to carbamazepine) compared to wild-type subunits.[27] In another study, the sensitivity to phenytoin was reduced in neurons expressing a mutant voltage-sensitive sodium channel (VSSC) beta-1 subunit (a mutation associated with generalized epilepsy with febrile seizures plus (GEFS+)) compared to those expressing normal beta-1 subunits.[28] Similarly, a splice-donor site polymorphism in the VSCC alpha-1 subunit (SCN1A) was associated with maximally tolerated doses of phenytoin and carbamazepine.[29] These results await replication in larger, independent cohorts, but they provide preliminary evidence that altered drug targets can contribute to medical intractability.

In addition to gene mutations, AED drug targets can develop 'acquired' alterations, perhaps as a result of seizures. For example, there is reduced carbamazepine (CBZ) sensitivity in hippocampal CA1 neurons compared to neocortical neurons, in patients with TLE and HS.[30] Further work suggests a loss of effect of carbamazepine on VSSCs in ten patients with CBZ-resistant epilepsy compared to two patients with CBZ-responsive epilepsy.[31] Additional evidence suggests that changes in the distribution and density of sodium channels is related to epileptogenicity.[32] In addition to changes in voltage-sensitive ion channels, there is evidence that GABA-A receptors are altered in human TLE and post-status epilepticus animal models of TLE, and that these changes are associated with receptor pharmacology and drug resistance.[33,34] Genetic polymorphisms in the promoter regions of these genes play a potential role in seizure-induced receptor changes through effects on transcriptional regulation.

While there is some evidence for a role of altered drug targets in medically intractable epilepsy, the overall importance of

this mechanism is unclear. It is interesting that many of the genes identified as epilepsy-causing genes are also the targets of antiepileptic medications. Although not a major contributor, variants of SCN1A have been associated with increased risk for development of idiopathic generalized epilepsy.[35] This suggests that mutations in a single gene can increase the risk for development of both epilepsy and drug-resistance in epilepsy.

Gene–gene interactions

The pharmacogenetics of medically intractable epilepsy are clearly complex and likely involve multiple genes and gene–gene interactions. For example, drug transporter genes are regulated by other genes, as well as the environment.[36] In particular, transcription of MDR1 is regulated by a ligand-activated nuclear receptor, the pregnane X receptor (PXR), which is activated by many commonly prescribed medications.[37] It is unclear whether this upregulation is neuroprotective or whether it contributes to epileptogenesis, drug resistance, or both. The above proposed pharmacogenetic mechanisms are not mutually exclusive, nor are they the only possible pharmacogenetic explanations for drug resistance in epilepsy. As more and more candidate genes are identified, attempts to tease apart the specific contribution of each gene would benefit from prospective data collection of drug dose, concomitant medications, serum levels, efficacy, and adverse effects.

Disease genetics

Certain epilepsy syndromes are characterized by medical intractability, the prime examples being the progressive myoclonic epilepsies, the malformations of cortical development, and the epileptic encephalopathies (e.g., Lennox-Gastaut Syndrome, Othara Syndrome, West Syndrome). Many of these disorders are now known to be caused by genetic defects. In many cases it is not clear how the genetic defect leads to epilepsy or medical intractability, but it is clear that there are many genetic pathways to the common final phenotype of medically intractable epilepsy.

Progressive myoclonic epilepsies

The progressive myoclonic epilepsies (PMEs) are characterized by intractability, inherent in their progressive nature. Five disorders are typically included in this group: Unverricht-Lundborg disease, Lafora body disease, neuronal ceroid lipofuscinoses, sialidosis, and myoclonic epilepsy with ragged red fibers. Many of the genetic defects underlying these disorders have been identified, although the details of their relationship to epilepsy pathogenesis remain unclear.

Unverricht-Lundborg disease is an autosomal recessive disorder characterized by stimulus-sensitive myoclonic and generalized tonic-clonic seizures, as well as progressive ataxia, tremor, dysarthria, and cognitive decline. The disease is due to mutations in EPMI on chromosome 21q22, which encodes the protein cystatin B (CSTB), a protease inhibitor.[38] The most common mutation contains an unstable GC-rich dodecamer repeat in the promotor region, leading to reduced amounts of cystatin B. Wild-type alleles contain 2–3 tandem copies of this dodecamer repeat, while individuals with Unverricht-Lundborg disease have 30–150 copies. There is no clear correlation between the number of repeats and the severity of disease or age of onset. Cystatin B is thought to play a neuroprotective role, inhibiting neuronal apoptosis.

Lafora body disease is an autosomal recessive disorder with similar clinical features to Unverricht-Lundborg disease, onset between 6 and 22 years of age of myoclonic and generalized tonic-clonic seizures and progressive cognitive decline. It is characterized by the formation of Lafora bodies in brain, skin, liver, cardiac, and skeletal muscle. Two genes have been identified to date, EPM2A which encodes the protein laforin,[39] and EPM2B which encodes a protein called malin.[40] Laforin is thought to prevent accumulation of polyglucosans.

The neuronal ceroid lipofuscinoses (NCL) are a group of autosomal recessive lysosomal storage disorders, although adult-onset NCL (also known as Kufs disease) in some families shows an autosomal dominant pattern of inheritance. NCL is characterized by myoclonic seizures, visual loss, progressive cognitive decline, and motor abnormalities. To date, eight different forms have been identified, CLN1 to CLN8. Genes have been identified for nearly all the different forms, and most are lysosomal proteins of unknown function.

Sialidosis, also known as 'cherry-red spot myoclonus syndrome' is another autosomal recessive lysosomal storage disorder. Sialidosis types I and II are caused by a mutation in the gene encoding neuramidase (NEU1). Over 30 mutations have been described in the sialidase gene with clinical severity roughly correlating with genotype. Those with frameshift mutations or mutations resulting in premature truncation of protein generally have a severe form of sialidosis.[41]

Myoclonic epilepsy with ragged red fibers (MERRF) has variable clinical presentations but is typically characterized by myoclonic and generalized tonic-clonic seizures, ataxia, deafness, optic atrophy, and ragged red fibers on muscle biopsy. Mutations in multiple genes have been associated with this syndrome, but the most common defect is in mitochondrial DNA, in the gene encoding transfer RNA for lysine (MTTK).[42,43] These mutations cause a global defect in mitochondrial protein synthesis and subsequently a wide range of respiratory chain abnormalities.

It is striking that such varied molecular defects, from glycogen storage to energy production, can each result in myoclonic seizures. In general terms, these genetic defects produce irreversible or progressive neuronal damage which in turn produces multiple clinical manifestations, one of which is epilepsy. They differ in this respect from 'idiopathic' epilepsies with myoclonic seizures, such as juvenile myoclonic epilepsy, which are typically drug responsive and not associated with neurological deficits. While many consider the idiopathic epilepsies to also be genetic, an important difference may lie in the severity of the genetic defects. The idiopathic epilepsies are considered to be polygenic, due to multiple 'small' defects in several genes (each alone insufficient to produce disease), as opposed to the PMEs which are often the result of 'major' mutations in single genes (each alone sufficient to produce disease).

Malformations of cortical development

Malformations of cortical development (MCDs) are a frequent cause of medically intractable epilepsy in both adults and children. There is evidence that overexpression of drug transporters plays a role in focal cortical dysplasia.[7,44] In addition,

a number of genes have been described associated with malformations of cortical development, involving neuronal proliferation and/or survival, neuronal migration, and cortical organization.[45,46] The list of genes associated with MCDs is ever growing, as evidenced by a recent report of a group of Amish children with cortical dysplasia and intractable focal epilepsy in which mutations in the gene encoding contactin-associated protein-like 2 (CASPR2) were discovered, although the precise of role of CASPR2 in human cortex is unknown.[47] Active research in this area provides insight into mechanisms of epileptogenesis as well as the genetics of brain development.[45,46]

GEFS+/SMEI familial syndromes (SCN1A mutations)

Neuronal voltage-sensitive sodium channels play an important role in several human genetic epilepsy syndromes. Mutations in the alpha-1 subunit have been associated with a spectrum of disorders thought to form a continuum, from the relatively benign generalized epilepsy with febrile seizures plus (GEFS+) to the intractable severe myoclonic epilepsy of infancy (SMEI). Many of the mutations associated with SMEI produce nonfunctional channels (nonsense or frameshift mutations), as opposed to the predominantly missense mutations seen in GEFS+. This suggests that the ultimate functional consequence of these mutations is a loss of sodium channel function. These disorders demonstrate an overall correlation between severity of phenotype and genotype in that the most severely affected individuals appear to have the most severe genetic defects. Within families, however, genotype–phenotype correlations are complicated by incomplete penetrance and variable expressivity.[48] Approximately 5% of SMEI patients with identified mutations have inherited SCN1A missense mutations, and their family members typically have mild GEFS+ phenotypes.[49]

Conclusion

Drug resistance in epilepsy is clearly a complex phenomenon that likely involves multiple mechanisms, both genetic and non-genetic. Among pharmacogenetic mechanisms there is evidence for a role of multidrug transporter proteins, but the full extent of their involvement is not clear. Other mechanisms are likely to be important, such as altered drug targets. Intractability due to 'disease genetics,' as in the progressive myoclonic epilepsies and malformations of cortical development, may result from 'altered neuronal networks' as is hypothesized in TLE with HS, ultimately a very difficult hypothesis to prove. Regardless of the mechanism, medical intractability in epilepsy is clearly associated with significant morbidity and mortality and as such, is an important area of research. Identifying genetic mechanisms for medically intractable epilepsy may provide improved methods of diagnosis and prognosis, as well as new targets for pharmacological treatment.

28 Informed consent

FL Vale and S Benbadis

Introduction

'Every human being of adult years and sound mind has the right to determine what shall be done with his own body; and a surgeon who performs an operation without the patient's consent commits assault'.[1] Since 1914, the legal system established the principle of informed consent between physicians and patients in the medical practice.

Informed consent is a legal document that defines the patient–physician relationship in a legal and ethical (personal) way. Critical to the medical system as physicians are, informed consent is a necessary document that testifies for a process of communication and understanding. A basic understanding of this process is necessary for any treating physician.

Epilepsy is a chronic disease with specific and significant clinical and cultural connotations that require special understanding and evaluation. In particular, uncontrollable epilepsy can cause severe social limitations, decline in cognitive function and even the potential for sudden death. This disease can be as devastating as uncontrolled hypertension and diabetes for any individual, but unfortunately is less well understood in our society. Specifics to this process will be discussed in this chapter to allow a better understanding of the disease process and need for adequate communication during informed consent.

Basic process

The pinnacle of the patient–physician relationship is not better exemplified than by obtaining a thorough and clear informed consent. Physicians are medical and technical experts, while patients are concerned with their own personal values and life goals. Obtaining consent requires an effective exchange of ideas with the patient and (usually) with their closest family members. This requires good rapport, communication, and empathy. Trust has to be developed for a successful long-term relationship.

The basic element of informed consent takes into consideration the need to disclose and understand the medical plan and alternatives. Obtaining an informed consent assumes that the patient and/or surrogate has full capacity to make medical decisions, free from coercion and persuasions that will interfere from full authorization to perform the proposed treatment.[2]

Decision making has to take into consideration the patient's right and self-determination. Active participation in health care decisions is expected in the current situation. Education through an exchange of ideas is the only way to achieve success. The process of education involves direct communication and understanding of the social and family dynamics. Mutual respect, collaboration, and negotiation have to occur for a successful interaction.

The key point in this interaction requires a clear understanding of the procedure to be performed. Informed consent is a process of education that involves discussing the following:

(a) options and alternatives to the procedure
(b) details of the procedure
(c) risks and benefits of the procedure
(d) results, including 'quality of life' issues.

Not only do physicians have to discuss what surgical procedure is going to be performed, but it is ethically necessary to educate the patient about possible alternatives to the surgical recommendation. It is also necessary to discuss success rates and complications as well as the consequences of declining or delaying the recommended procedure. Failure to cover these aspects could potentially be viewed as misinformation and result in a strain of the patient–physician relationship, with possible legal consequences. After a reasonable discussion, details of the selected procedure should be covered. Visual clues such as diagrams, physical models, and even physical description should be used for the sake of simplicity and clarity. All possible complications should be discussed in detail, including potentially life-threatening situations and rare events. Short- and long-term results should be discussed in a clear and concise manner. There should not be a bias in the information given to the patient. Finally, clear documentation is necessary for adequate social and legal understanding.

From the patient's point of view consent means the following:

(a) patient's capacity to make a voluntary decision
(b) acknowledgement of understanding relevant information.

Failure to understand the illness and consequences of the intervention are common causes for misunderstanding and stress to the patient and family. In our experience, patients' personal expectations are critical and can cause a tremendous amount of concern and stress if not discussed prior to the intervention.

Decision-making should promote active patient participation. Through a thoughtful dialogue between patient and physician, patients and families can receive an education about their illnesses and options, which will result in a better understanding and comprehension of the procedure to be performed.

Why epilepsy surgery?

Epilepsy is a chronic disease with clear social and medical connotations. It is no different than treating severe hypertension or diabetes. It may be controlled with medical management and behavioral modifications (avoid lack of sleep and alcohol abuse, etc.), but by definition the risk of seizures is always present and potentially dangerous, especially in cases of intractable epilepsy. In the medical community, surgery to treat a chronic medical disease is not common, and as a result not well established outside a small group of experts, which may explained the delay in referral to comprehensive epilepsy centers.[3] Brain surgery is sometimes viewed as an aggressive, usually life-saving procedure for diseases such as brain tumors, ruptured brain aneurysms, etc. It should not be forgotten that uncontrollable seizures can be potentially life threatening and more commonly can be devastating for the individual personal and social development. Epilepsy surgery performed by an experienced and well-trained neurosurgeon is a safe and successful intervention to control seizures. Unfortunately, it continues to be misunderstood in the medical community. Ethically, a neurologist should offer and discuss all potential alternatives to the affected individual. Currently, by the time a patient is sent to a center for evaluation, many years of uncontrolled seizures will have taken a toll on the functional abilities of this individual, medically and socially. The patient may or may not accept the clinical situation, but the chronic nature of the disease has most likely changed the overall performance of this person with a resultant decrease in quality of life issues.

Despite physical and social limitations caused by severe and intractable epilepsy, most patients have no major structural abnormalities on magnetic resonance imaging (MRI) and no physical stigmata to separate this individual from any other member of society. Thus, brain surgery to control epilepsy is viewed sometimes as a drastic maneuver and involves major decision making from the part of the patient and/or family. Psychosocial issues and lack of social support can also adversely affect patient–physician relationship. So, why offer epilepsy surgery?

To understand surgery, the patient must understand the current treatment and medical limitations from drug therapy. Surgical intervention should be offered when benefits outweighs the risks. Surgery should be offered in the context of medical failure such lack of seizure control and/or limiting side effect. Surgery may or may not result in complete medical (drug) withdrawal, but most likely offer seizure control with possible gain in independence in their role in society. Options should be discussed by the epileptologist prior to referral to a neurosurgeon. The surgeon should continue to educate the patient and their family without any bias toward the surgery. Understanding each individual psychosocial issue will help to establish good rapport and communication. A fair and clear conversation with open-ended questions will help develop trust in the relationship.

Surgery for epilepsy is an elective procedure. 'Elective' means that the patient can decide when this procedure can be performed. The local environment, family situation, and support play a key role in the decision-making process. Achieving seizure control is the goal. It is ethically necessary to discuss and offer this option to the patient that suffers from intractable epilepsy. If a patient has not responded well to medical therapy, it is the duty of the neurologist to discuss alternatives of treatment, such as surgery. In that case, referral to an epilepsy center by the local physician should be performed.

For example, sudden death in epilepsy is a known entity in intractable epilepsy and represents a much higher risk for the poorly controlled patient than the risk of surgical intervention. In fact there are more risks associated with intractable seizures than with epilepsy surgery. Temporal lobe epilepsy is a typical example of surgery for epilepsy. This represents a clear situation where benefits outweigh risks. In the case of mesial temporal lobe sclerosis, the success rate is as high as 80% for seizure control, which means that it offers better clinical outcome than any kind of medical intervention after initial drug failure. If drug failure is well documented, the chances of seizure control are less than 20% for polypharmacy,[4] and surgery may become the most effective approach. It is ethically correct in this situation to discuss this alternative early in the treatment plan for this group of affected individuals.

When mental capacity is in doubt

For specific clinical situations where mental (cognitive) capacity is limited, this will require a different approach to the problem. Mental retardation, severe psychiatric problems (severe depression, etc.), dementia, legally underage, etc, are conditions that require the appointment of a legal guardian to serve in the best interests of the patient. Nevertheless, the clear lack of decisional capacity is not an excuse to alienate the affected person from involvement in the decision-making process. Although the patient is not capable of giving a full and valid informed consent to surgery, he or she is able to give assent or dissent to the treatment being offered. The surrogate (usually the closest family member) should have a clear understanding of the patient's healthcare preferences, goals, and values, as well as the courage to uphold the decision despite any potential problems or misgivings.[5]

In situations where the patient lacks decisional capacity and yet is able to participate in the decision process at limited level, physicians should engage the individual in the process of decision-making. Physicians' efforts to educate, to determine understanding, and to solicit values, preferences, and goals should be targeted at the family and patient together as 'one voice'.

Epilepsy surgery in this situation is a valuable alternative for patients with intractable epilepsy, even in the case where total seizure control is not expected. Even though 'cure' might not be a feasible option, the potential for decrease in seizure frequency and, as a result, better quality of life should be considered by the surrogate as a reasonable alternative. In any case, surgery is an option that should be discussed when medical treatment offers a limited response.

Conclusions

Epilepsy surgery is a well-established alternative for the control of epilepsy, but unfortunately is underutilized and misunderstood in society as well as the medical community. The cognitive limitations that may accompany a severe and

intractable seizure disorder may interfere with the necessary skills for social development and understanding of the disease process. Extensive education and communication is required for decision-making. Involvement of the family in the education process is sometimes necessary for adequate communication. This process involves mutual trust and understanding. From the ethical perspective, disclosure and education are a requisite for the exercise of patients' independence in decision-making prior to any surgical intervention.

Surgery, despite the invasiveness of the procedure, is a clear alternative for patients that suffer from medically intractable epilepsy. Ethically it is necessary to educate and inform the patient and family members of the potentially hazardous alternatives and options regarding this disease. In summary, informed consent is a frank and open dialogue, permitting the physician to give the patient and/or family enough detailed information to make a decision regarding a specific treatment and alternatives.

29 Epilepsy surgery: access, costs, and quality of life

MG Campos and S Wiebe

Introduction

Epilepsy is a common, serious, chronic neurological condition with high prevalence worldwide, but particularly in developing countries. Data suggest that 85% of the 50 million people with epilepsy worldwide live in the developing world.[1–3] The chronicity of epilepsy results in significant economic costs, especially in cases of medically refractory epilepsy, which requires continued symptomatic treatment. In addition, people's ability to work and develop vocationally can be affected, contributing to a significant social and psychological burden.[4,5] The advent of economic and cost analyses has resulted in a plethora of publications in this regard. However, there has been substantial variability in methodology. For example, the definition of cost can take on many different meanings, including that of a fee or tariff. Additionally, costs can be considered from many different perspectives, such as a third-party payer, society, the individual, or the healthcare system. From a purely economic viewpoint, costs should be defined as 'opportunity cost', i.e., the value of time or any other element in its highest value used in a cost of illness study. For the purpose of studies comparing different therapeutic alternatives, opportunity cost refers to the benefits lost because the next best alternative was not selected.

Confusion in terminology and variability in methods have fostered the creation of recommendations for adopting a 'reference case' type of analysis in economic evaluations, in which a standard set of principles is applied to the analyses, allowing for meaningful comparisons across studies.[4,6] These recommendations stipulate that costs should be expressed as a value of the goods, services, and other resources that are consumed in the provision of an intervention or dealing with other current and future consequences linked to it. These costs are often expressed in monetary terms. Even if a 'reference case' is not adopted in cost analyses, all studies should clearly describe the definition and perspective of the costs considered. Throughout this chapter we will use the term cost to refer to the fees related to epilepsy surgery, which is the most commonly reported metric, and not necessarily to the opportunity cost.

Because economic factors play an important role in healthcare worldwide,[7] it is important to analyze the main factors that influence costs of and access to epilepsy surgery, and some of the reasons behind differences in costs in various countries.

Determining the cost of epilepsy surgery

Although the effectiveness and safety of epilepsy surgery has a long tradition and has been established through various avenues, it remains underutilized. Several reasons underlie this phenomenon, including physicians' and patients' perceptions of its invasiveness and irreversibility, therefore making it a last-resort therapy.[8] In many parts of the world, the determining factor is a lack of physical resources and of expertise for the management of complex cases requiring presurgical evaluation with intracranial EEG.

The importance of defining the perspective from which costs are calculated is illustrated by the existing studies on the cost of epilepsy surgery. In many developed countries, patients rarely pay directly for treatments and instead receive healthcare that is paid for by national insurance schemes. From the patients' perspective, healthcare services cost little or nothing at the point of delivery, other than any user-charges or copayments that are made for drugs or hospital services. Consequently, economic analyses in North America and in most European countries often confine their analyses to the perspective of the major health insurer.[9–14] This contrasts with the organization of health services in most developing countries, where patients often pay for most or all of their epilepsy treatment at the point of delivery.[15,16] In these countries, it may be appropriate to consider a broader perspective that includes patient payments. From any perspective used, costs and savings are categorized in terms of their relationship to treatment. The most widely used classification of costs distinguishes between direct costs, indirect costs (productivity costs), and intangible costs.[17]

Direct costs

Direct costs and savings are those that arise in direct relation to an illness and its treatment. These include medical costs such as outpatient appointments, antiepileptic drugs (AEDs), hospital admissions, laboratory investigations, diagnostic procedures, surgical treatment, etc. Direct non-medical costs include payments required when patients receive treatment, such as transportation or childcare. Patients may also incur substantial expenditure traveling to clinics when services are concentrated in major cities, which is the typical pattern in the developing world. Other non-medical direct costs in epilepsy

patients include rehabilitation, vocational training, social services, volunteer services, etc. Direct costs and savings are easily understood in terms of their monetary value. Economic evaluations use the prices and charges made for these goods and services when calculating the overall cost of a treatment or program. In the USA, patients with uncontrolled epilepsy incurred direct costs of nearly $10,000 a year, while similar costs in patients with controlled epilepsy reached only about $2,000 a year.[18] These figures did not include direct non-medical costs, which in some countries can be substantial.

Indirect costs ('productivity costs')

Epilepsy can reduce productivity if patients perform less well at their jobs, take time off work, or become unemployed. Premature mortality can also be considered in terms of its effects on the workforce, as is the effect on productivity of caring for family members with epilepsy. These types of costs are typically referred to as indirect costs – a term that can create some confusion because of its different connotation in accounting, where it refers to overhead costs.

In most economic evaluations, productivity costs are estimated in terms of the average value of the work time missed. This process has its basis in the human capital method, which values a person's life in terms of future earnings.[19] This method has also been used to evaluate the effects of temporary illnesses on individuals' ability to do their job. For example, the cost of missing 10 days of work because of epilepsy would be valued as the equivalent of the loss of 10 days of average earnings for that individual worker.

Time is more difficult to value for the unemployed. For example, housework and childcare are important to the individuals concerned and also to the general economy, but such work is rarely paid for in a financial transaction. In the developing world, large numbers of people live in isolated and rural areas where work may also be unwaged. In these cases, either an arbitrary value is assigned, or 'shadow' pay rates are used – based on the prices charged for hiring workers to perform similar jobs.[3,20]

The human capital approach presents some problems. For example, older people typically have low indirect costs due to a shorter life expectancy, lower earnings, and lower expectancy of employment. Similarly, children's time is valued at a lower level for this reason. Nonetheless, the approach is practical, broadly used, and can be used if one acknowledges its limitations. Candidates for epilepsy surgery are most often school-age children or young adults, and the latter are often eligible to join the workforce. In the USA, the projected lifetime cost of epilepsy for an estimated 181,000 people with onset of epilepsy in 1995 is $11.1 billion, and the annual estimated cost for the approximately 2.3 million prevalent cases is $12.5 billion. Indirect costs account for 85% of the total costs and are highest in people with intractable epilepsy.[18]

Intangible costs

Intangible savings and costs pertain to the well-being associated with improved or worsening health, and their measurement is not straightforward. In chronic, socially stigmatized conditions such as epilepsy, intangible costs are likely to be significant. Unfortunately, no method of assessing the financial value of improved health and well-being in epilepsy has been agreed upon. Contingent valuation methods such as willingness to pay for a treatment or outcome can be used to estimate such costs from the patients' perspectives, but these techniques have not been widely used in healthcare.[3,21]

People with well-controlled epilepsy after surgery are more likely to be able to work and contribute to their personal and their society's wealth, thereby producing 'indirect' savings. Economic benefits may also accrue from the 'intangible' benefits of good health.

Cost in epilepsy surgery

Because the costs of presurgical evaluation and epilepsy surgery are highest at the outset, it is important to understand the time-course of costs incurred with various treatment modalities. Also, an assessment of direct, indirect, and intangible costs provides the necessary framework for assessing the costs of epilepsy surgery. The cost of intractable epilepsy is eight times higher than that of well-controlled epilepsy.[22,23] Twenty-five percent of patients comprising the more resistant epilepsy cases account for 79% of the total cost of incident cases.[18] Several studies have compared the costs of epilepsy surgery with those of medical treatment.[22,24–27] These studies demonstrate that, despite the high initial cost of presurgical evaluation and surgery, the benefits achieved in terms of clinical improvements and reduced requirements for medications and medical services outweigh the costs of surgery in the long term. A description of studies exploring the cost of epilepsy surgery follows.

A recent cost effectiveness study from France compared surgical and medical therapies in a 14-center prospective cohort of intractable patients with epilepsy who were candidates for resective surgery.[28] The mean cost of presurgical evaluation was €8,364 ($9,957) (25th, 75th percentiles = €3,286, €12,027). The mean cost of presurgical evaluation and surgery was €20,772 ($24,729) (25th, 75th percentile = €15,000, $25,310). An analysis of projected costs over several years concluded that epilepsy surgery became cost-effective within 9 years after surgery, i.e., surgery became a cheaper alternative to medical therapy. These results were based on direct costs only and on an assumption of seizure-free rates of 77% of patients at 2 years. Interestingly, these authors replicated the findings of an earlier Canadian study which found that, although the costs of epilepsy surgery were higher up front (during the first year), surgery became cheaper than medical therapy after 8.5 years because of averted costs of medical care due to the high rate of seizure-free patients with surgery.[24] In the USA, the estimated payback time for epilepsy surgery is approximately 6 years.[29] Whereas the Canadian study[24] comprised both intracranial and noninvasive presurgical evaluations, the USA figures apply particularly to noninvasive and uncomplicated temporal lobe resections. This figure is still germane because it is estimated that approximately 60% of all epilepsy surgeries needed in developing countries at this point require no intracranial or complex evaluation. Therefore, these data provide a strong support for establishing and expanding epilepsy surgery programs in developing countries. The cost difference in presurgical evaluation involving intracranial EEG versus that involving scalp recording is substantial.

A recent communication from the USA showed that the cost of patients requiring intracranial recordings ($72,032)

Table 29.1 Proportion of seizure-free patients treated with new AED and with surgery.

AED	Seizure-free*
VGB	5%
LTG	2–4%
TPM	10%
LEV	8%
PGB	5–17%
Surgery	58%

*Based on data from multicentre, placebo-controlled, add-on, randomized trials of new AEDs in pharmaco-resistant epilepsy (follow-up: 12 weeks), and one randomized trial of temporal lobe epilepsy surgery (follow-up:1 year).[54]

was almost twice that of those requiring only scalp recordings ($40,912) ($p < 0.01$).[29,30] In this study, seizure freedom was associated with a significant reduction in total healthcare costs from year one. By year two after evaluation, the total cost in seizure-free patients had declined to roughly half that of patients who continued to have seizures. This decline was due to a reduction in the number of inpatient admissions and AEDs prescribed, particularly the newer, more expensive medications (Table 29.1).[30] A few reports have compared the cost of epilepsy surgery between developed and developing countries. One such study compared the direct costs of epilepsy surgery programs in Colombia and Switzerland,[31] and showed that the average epilepsy surgery cost per patient in Colombia was a mere 5.5% of that in Switzerland. Thus, epilepsy surgery can be a relatively inexpensive and efficient treatment option for patients with epilepsy in developing countries.

Although empirical data are not available, it would appear that, in developing countries, epilepsy surgery may even be considered as an earlier therapeutic alternative for patients who cannot afford the lifetime costs of medical therapy. Some studies show that the costs (or fees) of epilepsy surgery vary by a factor of up to ten between developing and developed countries. For example, in the public healthcare system, epilepsy surgery without invasive investigations costs between $5,000 and $6,000 in Chile or Brazil,[32,33] and it may be even cheaper in Colombia or India.[7,31,34] The same surgical procedure can be 8–10 times more costly in the USA, and 6–8 times more costly in Germany.[35] The pertinent question at this point is, what explains such wide between-country variability in costs.

Why are costs different among countries?

To answer this question, we need to consider several variables that play a role in this discrepancy.

(a) *Price of instruments*: The cost (price) of instruments such as magnetic resonance imaging (MRI) and video-EEG equipment, before taxes, is similar at the place of origin (FOB price). However, the price of equipment at the place of destination varies due to a number of factors, such as transportation, insurance, or national taxes. However, these elements play a small role in the overall between-country price variation and do not fully explain it. On the other hand, the price of an examination using these technologies varies tremendously by country and within countries. For instance, the cost of an MRI in Chile is $350, whereas in Miami it is $3,438, i.e., ten times more costly. This difference could be explained because the examination in Miami incurs high overhead, salary, research, maintenance, or renewal expenses, and, no less important, the requirement of high profitability.

(b) *Drug prices*: These vary if we consider brand-name or generic drugs.[36] A comparison of the annual costs of brand name AEDs in Germany and Chile shows that almost all AEDs cost twice as much in Germany, but original valproic acid is more expensive in Chile, where it is also considered a first-line drug.[32] The reason is the different industry politics in merchandise between different continents.

(c) *Medical supplies and technology*: This is clearly the main factor underpinning the vast cost differences in epilepsy surgery between developed and developing countries. It reflects the elevated cost of high-end technologies, which are the gold standard in developed countries, but only exceptionally used in the average epilepsy surgery centers in developing countries.

(d) *Professional salaries*: In general, the salaries of physicians in university and publicly-funded hospitals are low in developing countries. This stands in stark contrast to the situation of their peers in developed countries. As a result, most doctors in developing countries need to complement their meager salaries by working in private practice settings. This has important implications in the analyses of the cost of epilepsy surgery. First, the cost disparities between surgical procedures performed in public versus private settings is apparent. Second, the large number of graduating physicians and specialists can drive the demand–supply curve in directions that may affect the cost and provision of medical and surgical services. Finally, a crisis in the demand–supply of medical services would necessitate the creation and implementation by regulatory bodies of epilepsy surgery guidelines to avoid the potential problem of surgery performed with suboptimal expertise, for questionable or inappropriate indications, or without sufficient investigations to allow adequate patient selection.

(e) *Malpractice insurance*: This is another important aspect contributing to the differences in surgical costs between developed and developing countries. For example, in the USA, an average neurosurgeon requires malpractice insurance that costs about $84,151 a year, a sum many times higher than that required by their peers in developing countries.

(f) *Administration costs*: The administration costs are difficult to assess, but in general they are considered to be low.

Are surgical results different in developing countries and developed countries?

The general answer is 'no'. Analysis of the evidence shows that surgical results in Europe, USA, Latin America, or Asia are practically the same. A recent systematic review found no difference in surgical results for common procedures among large world regions.[37] The simplest explanation is that surgeons' skills are similar worldwide. An exception to this generic statement could apply to surgeons specializing in rare pathologies, special surgical techniques, or in those dealing

with exceptional epilepsy cases (e.g., hypothalamic hamartomas, insular epilepsy, etc.).

On the other hand, an important challenge facing clinicians in developed countries is globalization. Conceivably, the surgical management of epilepsy patients in the future will see private health insurance companies paying for patients to travel to selected centers in developing countries for epilepsy surgery.

Access to epilepsy surgery

The problems surrounding increasing costs of treating epilepsy are magnified in developing countries, where healthcare resources are scarcer. Excellent neurology and neurosurgery services exist throughout Asia and South and Central America, but they tend to be concentrated in major cities. Public health insurance systems are not as prevalent or sufficient in developing countries as compared with Europe and North America, and many patients who could benefit from treatment cannot receive it. This 'treatment' gap is due in part to economic factors such as the relatively low average income of much of the population,[3,5,7,36] although political, social, and organizational factors are also highly relevant.

Twenty years ago, only ten countries had epilepsy surgical programs; in contrast, 26 countries had such programs in the year 2000,[38] the majority of which were in developed countries. However, epilepsy surgery remains underutilized even in developed countries. For example, it is estimated that only 1,500 of the nearly 100,000 eligible patients in the USA undergo such surgical procedures each year.[39] Also, clinical investigations for epilepsy surgery are often delayed, ranging from 8 to 20 years.[24,27] This inappropriately long waiting time and underutilization stands in stark contrast to the proven benefits of epilepsy surgery[40,41] and to the poorer quality of life and increased risk of death during the waiting period.

The macro-economic viewpoint

In Latin America, the average family member earns $2 a day ($60/month or $740/year), whereas in the USA, income under $17,500/year is considered 'poverty'. This is equivalent to less than half of the per-capita gross domestic product (GDP), which is $36,056 in the USA (http://www.who.int/en/). The GDP is defined as the per-capita market value of the total final output of goods and services produced in a country over a specific period. The international dollar (ID) is a common currency unit that takes into account differences in the relative purchasing power of various currencies. Figures expressed in ID are calculated using purchasing power parities (PPP), which are rates of currency conversion constructed to account for differences in price levels between countries. For example, the Chilean annual domestic gross was approximately $7,200 in 2002, but the corresponding amount in ID was $11,086 (Table 29.2).

Table 29.2 Per-capita gross domestic product (GDP) in international dollars (ID), total expenditure on health as a percentage of GDP, and per-capita total expenditure on health in ID (2002), in representative countries of each continent

Country	GDP ($ID)	% of GDP spent on health	$ID per capita for health
United States of America	36,056	14.6	5,274
Luxemburg	49,228	6.2	3,066
Germany	25,842	10.9	2,817
France	28,094	9.7	2,736
Australia	28,277	9.5	2,699
Japan	26,860	7.9	2,133
Israel	20,780	9.1	1,890
Republic of Korea	19,523	5.0	982
Lebanon	6,081	11.5	697
South Africa	7,935	8.7	689
Russian federation	8,588	6.2	535
Mexico	8,979	6.1	379
China	4,460	5.8	261
Chile	11,086	5.8	246
Brazil	7,762	7.9	206
Egypt	3,891	4.9	192
Cambodia	1,607	12.0	192
Philippines	5,231	2.9	153
Equatorial Guinea	7,645	1.8	139
Georgia	3,260	3.8	123
India	1,568	6.1	96
Peru	5,101	4.4	93
Senegal	1,202	5.1	62
Sudan	1,171	4.9	58
Nigeria	984	4.7	43
Haiti	1,093	7.6	29
Democratic Republic of the Congo	352	4.0	14
Liberia	520	2.1	11

- Total health expenditure per capita is the sum of public and private expenditure on health.
- Quelle: Website of the World Health Organization (WHO) (http://www.who.int/en/)

Nations differ in the percentage of their GDP they invest in healthcare. For example, the USA invests 14.6%, Georgia invests 3.8%, and Africa Equatorial Guinea invests only 1.8% (Table 29.2). This translates into a total per-capita expenditure on healthcare of $5,274 in the USA and only $11 in Liberia in 2002 (Table 29.2) (http://www.who.int/en/). However, 17% of the USA population has no health insurance, nor access to epilepsy surgery programs. This means that in many countries health expenditures are almost entirely out-of-pocket at the point of service delivery. Out-of-pocket spending is defined as the direct outlay of households, including gratuities and payments in kind made to health practitioners and suppliers of pharmaceuticals, therapeutic appliances, and other goods and services whose primary intent is to contribute to the restoration or to the enhancement of the health status of individuals or population groups. It includes household payments for public services, and to nonprofit institutions or nongovernmental organizations. It excludes payments made by enterprises that deliver medical and paramedical benefits, mandated by law or not, to their employees.

In summary, resources are scarce, particularly in developing countries, which makes it essential to obtain robust data on economic evaluations of epilepsy surgery. This would ensure that limited resources are efficiently and appropriately allocated, and that they are used in a rational manner. The main differences in the costs of epilepsy surgery between developing and developed countries arise from a low GDP in developing countries and a low expenditure on healthcare in relation to their GDP.

Quality of life (QOL)

Epilepsy presents multiple complex problems to everyday life.[3,42-44] The primary goal of surgical treatment is to control seizures, but the treatment must also be targeted to overcome the broad spectrum of physical, psychological, cognitive, and social effects of the disorder. Health-related QOL is a comprehensive multidimensional construct, and in epilepsy patients many factors affect it negatively. These include seizures themselves, drug adverse effects, psychosocial consequences, social stigma, etc.[45]

Although there is no standard definition for QOL, an operational definition includes:

> a state of well-being that is a composite of two components: (1) the ability to perform everyday activities that reflect physical, psychological, and social wellbeing, and (2) patient satisfaction with levels of functioning and control of disease and/or treatment-related symptoms. [46]

In assessing these constructs, one must take into account that QOL deals largely with the individual's (subjective) perceptions and experiences of health and disease. In addition, instruments used to measure QOL must satisfy the general measurement (psychometric) properties of validity, reliability, reproducibility, responsiveness to change, and ability to detect small but clinically important differences. Several analyses have assessed the specific properties of QOL instruments, such as validity of generic (non-targeted) instruments to be used in epilepsy,[47] as well as the minimum clinically important change[48] for specific instruments, and the minimum change that instruments can detect reliably in epilepsy.[49] These important parameters can help clinicians assess whether observed changes in QOL are clinically meaningful and statistically reliable in individual patients. QOL instruments can be classified as generic (non-targeted), targeted (epilepsy-specific), and as utility instruments (those measuring health state preferences).

Over the last decade, numerous instruments have been developed to assess QOL in epilepsy, as well as specific aspects of QOL. For example, different epilepsy-specific scales have been validated for children, adolescents, and adults, to assess AED adverse effects, severity of epilepsy, effects of surgery, impact of epilepsy, and other domains. For a catalogue of epilepsy-specific QOL instruments, see Cramer *et al.*[47]

Epilepsy surgery and QOL

Adults

Studies of QOL in adults after epilepsy surgery have shown improvements in QOL, e.g., employment, functional status, role activities, social functioning, emotional status, cognition, health perceptions, and general life satisfaction.[50–53]

The only randomized trial comparing medical and surgical therapy demonstrated statistically significant superiority of QOL after surgery ($P<0.001$), occurring as early as 3 to 6 months after surgery, and improving over time ($P<0.003$).[54] Although more patients in the surgical than in the medical group were employed or attending school at 1 year (56.4% vs. 38.5%), this difference did not achieve statistical significance ($P=0.11$).[54] Recent cohort studies have reported similar findings, with regard to early improvements in QOL after surgery, but without control comparisons.[55]

Postoperative QOL is clearly related to seizure improvement,[56] as well as to reduction of the stigma and handicaps associated with epilepsy.[51] Patients who are not seizure-free after epilepsy surgery generally have little regret about undergoing surgery, but are less likely to be satisfied and have a poorer psychosocial profiles.[57] Other important determinants of QOL postoperatively include mood, anxiety, and AED adverse effects.

Psychiatric function is an important predictor of QOL after surgery. A study compared seizure-free patients with temporal lobe epilepsy and extratemporal patients. Temporal patients reported significantly higher levels of depression (26%), anxiety (42%), and psychosocial adjustment difficulties (64%) at the 1-month review than did extratemporal patients. Mood disturbance was significantly associated with adjustment difficulties in both groups, but was not related to seizure outcome at any review period. A general increase in mood disturbance was evident after surgery, particularly in temporal resection patients at the 1-month review. Site of surgery and psychosocial adjustment showed significant associations with postoperative mood disturbance, supporting the role of both neurobiological and psychosocial factors in mood outcome.[58]

There is substantial variation in outcome definition, methodology, and interventions among the many reports on postoperative cognitive outcomes. Psychosocial benefit is substantial after surgery, but so is memory loss incurred with dominant temporal lobe resection. The only controlled study in this regard, from the University of Bonn, involved adults

with temporal lobe resections. After a mean follow-up of 5 years, memory decline occurred in 50% of patients in the medical group and 60% of patients in the surgical group, and it was worse in those undergoing left temporal lobe resections.[59] However, there was no change in intelligence.

A recent Australian study of psychosocial outcomes following epilepsy surgery ($N=89$) reported good outcomes in 58% of patients by 24 months post-surgery, characterized by improved family dynamics, enhanced vocational and social functioning, and driving. Associated prognostic variables included early postoperative adjustment difficulties. In contrast, 31% of patients perceived their outcomes as poor, reporting affective disturbance at 12 months and difficulties discarding sick role behaviors. Early anxiety served as a marker of poor outcomes, while resolution of early anxiety and vocational change at 12 months were indicators of good outcomes at 24 months. The remaining 11% of patients reported minimal adjustment features. This means that, for most patients, seizure surgery results in a process of postoperative adjustment that leads to distinct outcome trajectories.[60]

No differences have been found in the satisfaction of patients with epilepsy of different countries (developed vs. developing), based on their aspirations and needs. For example, a controlled study in a Middle Eastern population (Beirut, Lebanon) showed improvements 1 year after epilepsy surgery, similar to those reported in Western populations after a similar period. Patients had marked improvements in overall QOL, health perception, well being, and cognitive functioning. They had less remarkable improvements in social functioning and role limitations.[61] The results were similar for Turkish epilepsy patients, but independence seemed to be the most important concern and gain.[62]

In summary, compared with medical management, epilepsy surgery has a significant positive impact on QOL and psychosocial outcomes in terms of employment, independent living, driving, and financial independence in patients who are refractory to AEDs. Additionally, patients who are not entirely seizure-free still achieve beneficial psychosocial outcomes if their seizures are significantly improved.[63] Moreover, QOL improvements early after epilepsy surgery are both statistically and clinically significant.[64]

Children

There is a long-held view that epilepsy surgery during childhood results in sustained improved psychosocial function and QOL. There is little data on long-term outcomes, but a recent Canadian communication showed that early surgery results in better QOL in young adulthood for those who are seizure-free,[65] confirming the results of previous studies.[66] The studies also point out the importance of the number of AEDs and psychological functioning in determining QOL. In children and adolescents, epilepsy surgery sets the stage for improved QOL and for social integration. It appears that most of the QOL improvement occurs in the first 6 months after surgery.[67] However, against the classical results of better QOL after epilepsy surgery, a prospective study was performed in children with intractable epilepsy who underwent epilepsy surgery ($N=51$) for evaluation of cognitive, psychosocial and family function. The results showed that 1 year after surgery, 57% of the surgical group was seizure-free. Seizure status after surgery did not predict change over time in any of the areas measured. Cognitive and psychosocial status did not change over time in either group, and the strongest predictor of individual change in psychosocial status in the surgical group was baseline level of function. Within the surgical group, a trend toward an increase in independence was noted in the family, but the children's satisfaction with the family declined. These findings challenge the assumption that elimination of seizures will result in improved cognitive, psychosocial, and family functioning, at least within the first year after surgery.[68]

Conclusion

Epilepsy surgery must be considered as soon as drug resistance is reached: 'surgery does not need to be a last resort',[8] because it is the most effective treatment in cost/effectiveness for refractory epilepsy, i.e., in temporal lobe epilepsy. In addition, the improvement of QOL after surgery is clearly established in adults.

30 Epilepsy surgery: patient selection

H Morris, I Najm, and P Kahane

Introduction

In this chapter, we will outline how adult patients with medically refractory epilepsy are selected for resective epilepsy surgery. Due to specific management,[1] primarily pediatric epilepsy surgery topics that include hemispherectomy and corpus callosotomy will not be covered. We will deal only with resective (supposed to be curative) surgery, so palliative procedures such as subpial transection procedures and vagus nerve stimulation will also not be covered.

Identification of surgical candidates

Eligibility criteria for resective surgery are far from being clearly defined, since they depend on many individual factors (type of epilepsy, presence or absence of an epileptogenic lesion, age, comorbidities, etc.), as well as on the exams that are considered mandatory for deciding whether an epileptic patient is a good epilepsy surgery candidate. Yet, there is only one randomized study that has demonstrated the superiority of (temporal lobe) surgery versus medical treatment,[2] so that it appears difficult to give evidence-based recommendations on who are the ideal candidates for surgery in general. Therefore, if there exists a relatively large consensus on the effectiveness of temporal lobe surgery, especially in the so-called mesiotemporal lobe epilepsy syndrome,[3] whether epilepsy surgery is really effective in other focal epilepsy types remains a debatable issue.[4] Many nonrandomized studies, however, strongly suggested that epilepsy surgery may lead to seizure-freedom in a substantial number of extratemporal and/or cryptogenic cases, and this has long been confirmed by daily practice.

Therefore, it seems legitimate to consider epilepsy surgery as a therapeutic option, whatever the type of *partial* epilepsy, provided that it is *drug-resistant* and *disabling*, and provided that the *benefit/risk ratio* for surgery *is* a priori acceptable.

Focal seizures

Up-to-date, resective surgery is exclusively considered when seizures are focal, i.e., when they arise from a limited portion of one hemisphere, and when they represent unequivocally the electroclinical expression of a nonidiopathic partial epilepsy syndrome. The minimum required for answering to these issues includes a good description of seizure semiology, interictal EEG data, and a good MRI scan. There exist, however, some situations where the distinction between partial epilepsy and generalized epilepsy is not so easy. For instance, asymmetric or focal interictal EEG abnormalities, as well as clinical signs suggesting a focal onset of the seizures, can be observed in generalized epilepsy syndromes.[5–7] Also, partial epilepsies, especially frontal, can manifest with bilateral interictal EEG discharges and with seizures that mimic absence seizures, or generalized tonic or tonic-clonic seizures.[8–10] In any case, when there exists a doubt, these patients should be referred to a specialized center for long-term video-EEG monitoring.

Drug-resistance

There is a general agreement to consider a patient medically refractory (or pharmacoresistant) if two or three appropriately selected and managed AEDs failed to control the seizures. This is in accordance with the prospective study of Kwan and Brodie,[11] who showed that a patient with focal epilepsy had only a 47% chance of achieving full seizure control with the first anticonvulsant taken, a 9% chance with the second anticonvulsant, and a dismal 4% chance with a third or multiple anticonvulsants. This clearly means that it is not necessary or reasonable to try all the 'older' and 'new' anticonvulsants either in monotherapy or polytherapy before considering surgery. However, the number of AED trials, as well as the minimum duration of the epilepsy (1 year, 2 years, more?) that are required before considering surgery depend on many factors, among which the type of epilepsy and the likelihood of rendering the patient seizure free after surgery are of particular importance. For instance, it seems legitimate to consider surgery very early in patients suffering from temporal lobe seizures associated with hippocampal sclerosis, since seizures are very often refractory,[12] and because surgery proved particularly effective,[13–15] especially when the delay between epilepsy onset and surgery is short.[16] Also, patients suffering from 'lesional' epilepsies should be considered quickly for surgery, mainly when the lesion is relatively well-limited in space, and/or when it appears to be of tumoral origin.[17]

Disability

Seizure frequency and severity are the most commonly used factors to account for epilepsy disability. Undoubtedly, they greatly participate to the assessment of the handicap, and they

have a major impact on the quality of life. However, this does not necessarily mean that a patient having frequent and devastating seizures is a good epilepsy surgery candidate. For instance, surgery for frontal lobe epileptic 'drop attacks' is often disappointing or not feasible, especially in cryptogenic cases, so that the decision to begin or not a presurgical evaluation must take into account this low likelihood of seizure alleviation. By opposition, a patient may suffer from relatively low frequent seizures which do not appear disabling for the physician (e.g., automotor seizures once a month), but this condition may have a major professional impact due to driving prohibition of, so that surgery should be considered rapidly. Thus, it is clear that many factors must be taken into account, including not only the frequency and severity of the seizures, but also the underlying pathology, the associated neurological or neuropsychological deficits, the AEDs toxicity and, above all, the socioprofessional and familial impact of the disease, as well as its psychological consequences.

Benefit/risk ratio

As a rule, mortality and morbidity of epilepsy surgery are small. No surgical mortality was reported in the Class I randomized controlled trial of Wiebe *et al.*[2] In the recent report of Engel *et al.*,[4] two out of 556 patients (0.4%) from seven centers died within a month after surgery, but deaths were unrelated to the surgical procedure. True, epilepsy surgery carries risks but, in actuality, the risk of surgical death following anterior temporal lobectomy is <1%.[18] As compared to this surgical risk, patients with uncontrolled seizures have a significant risk of death by injuries, drowning, suicide, and especially sudden unexpected death of epilepsy (SUDEP). The risk of SUDEP in medically refractory patients has been estimated as high as 0.5 to 1.5% per year and the risk is cumulative[19]. Sperling *et al.*[20] recently reported that following successful epilepsy surgery the risk of death was 0.85 per 1,000 person-years which is approximately the same as the general population while patients with unsuccessful epilepsy surgery had a mortality rate of 11.4 per 1,000 person-years. Surgical complications, as assessed in the report of Engel *et al.*,[4] were found to occur in 11% of 556 patients from seven centers, 3% experiencing permanent neurological deficits. In this report, postoperative cognitive and behavioral disturbances were described in 6% of patients of three series, and were permanent in 3%. Obviously, the risk and morbidity of epilepsy surgery depend on the specifics of the particular surgery planned for each patient.

For example, the risk of significant memory decline following removal of an atrophic, sclerotic, nondominant hippocampus is low compared to the significantly higher risk of removing a normal, dominant hippocampus. The risk of visual field deficit is high with removal of an epileptic occipital lobe and essentially nonexistent with a frontal lobe resection. In any cases, however, risks cannot be realistically estimated until the seizure semiology, EEG/video monitoring, and MRI findings, neuropsychological and/or functional MRI results are known. Patients and many non-neuroscience physicians have considerable misinformation about epilepsy surgery. As an example, multiple medically refractory persons with epilepsy have told one of the authors (HHM) they were informed by medical professionals that they should not consider having a dominant temporal resection because of the high risk of 'being unable to speak' following surgery.

Other factors

Role of age

Patients older than 45 years may benefit from epilepsy surgery, at least for temporal lobe seizures.[21–23] Postoperative results, however, are poorer than in younger patients in terms of seizure control and quality of life.[21,23,24] Overall, the risk of postoperative cognitive deficit does not seem higher than for younger patients.[23] A greater age at surgery, however, seems predictive of a stronger decline in verbal memory for surgery of the dominant hemisphere for langage.[25] Also, the risks of major complication of surgery might be higher in patients older than 35 years.[26]

Psychiatric problems

The cumulative incidence of mental problems in drug-resistant partial epilepsy patients referred to epilepsy surgery centers is especially high, ranging from 50% to 80% (for a review, see ref. 27). Such mental problems, however, do not seem to have any influence on the postoperative seizure outcome,[28] and it is much more common to observe their stabilization or improvement after surgery, than their aggravation.[29,30] Patients with personality disorders, however, might be at higher risk of suffering from severe postoperative psychiatric complications.[31] Overall, postoperative psychiatric problems are found in up to 50% of temporal lobe cases.[32] They consisted the most often in transient anxiodepressive states, especially in patients undergoing right hemispheric surgery and who had a high presurgical depression-related morbidity.[33] Nevertheless, the occurrence of such problems is lower in those patients who become totally seizure free after surgery.[34] Therefore, and based on our actual knowledge, it would certainly be unwise to reject a patient simply on the grounds of psychiatric problems.

Other associated diseases

Epilepsy is a common disease, and the coexistence with other pathological conditions, either neurological or non-neurological, is not so rare. Whether the comorbidity may interfere with presurgical evaluation and surgery may be an important issue, for instance when the patient is suffering from a disease (or takes medication) which makes impossible (or at least very difficult) any surgical act (e.g., hematologic problems). Also, some pathological conditions may aggravate the seizures (e.g., sleep apnea syndrome), so that the treatment of the associated disease may be necessary before considering surgery. As a rule, caution is required before considering surgery whenever the patient's health suggests that epilepsy is an epiphenomenon.

Presurgical evaluation: general principles

Once the history of disabling medically refractory focal seizures is clearly established, the principal requirement for resective epilepsy surgery is the identification and accurate localization of the epileptogenic zone,[35] the removal (disconnection, irridiation, or coagulation) of which will not create a new unacceptable handicap. To answer these issues, many examinations are available, the use of which is usually

complementary and will define various cortical zones: symptomatogenic zone, irritative zone, ictal onset zone, eloquent cortex, functional deficit zone, and the epileptogenic lesion.[35] All examinations are not utilized systematically, and the presurgical evaluation process must be conducted step by step, according to the individual anatomo-electro-clinical features of each patient (Figure 30.1).

Basically, epilepsy surgery candidates must have at least the following evaluation

(1) A *detailed history and neurological examination* are the obvious starting place and guide which studies will be required. Historical details regarding aura and seizure semiology and the sequence of events during a seizure should be sought (from both the patient and family members) and later compared, when performed, with the videotaped seizures recorded during EEG/video monitoring. Questions regarding birth history, febrile convulsions, head injuries, CNS infections, and other possible causes of seizures should be asked. Medication trials and their side effects should be reviewed. A detailed family history should be taken with particular reference to seizures and other neurological illness(es).

(2) A *high-resolution MRI scan* that includes at least volume acquisition T1-weighted and FLAIR sequences to document the presence of hippocampal sclerosis or other potentially epileptogenic brain lesion(s) should be performed. Neuroradiologists active in epilepsy surgery programs have a higher detection rate than do neuroradiologists in nonepilepsy surgery centers.[36] In most instances, gadolinium is not necessary unless a tumor or mass lesion is found. While a lesion seen on MRI is very helpful in the epilepsy surgery evaluation and may correlate with a good surgical outcome, a normal MRI does not by itself exclude a patient from epilepsy surgery; it does, however, make the presurgical evaluation significantly more complicated and expensive.

(3) *Repeated interictal EEGs* are very helpful to grossly evaluate from where seizures are expected to arise. Particular attention must be paid to the constant or variable location of interictal spikes, the possibility that their topography has evolved with time, and their unilateral, bilateral (asynchronous or not) or multifocal origin. Also, the type of interictal abnormalities, especially in the so-called cryptogenic cases, may be particularly informative when they strongly suggest the possibility of an underlying brain lesion (e.g., well-localized fast rhythms or repetitive fast spikes in focal cortical dysplasias).

(4) *Neuropsychological evaluation* must be done to determine the patient's baseline cognitive function and to help estimate the risk to those functions if a surgical resection were to be done. Neuropsychological results by themselves are not reliable enough to localize the epileptogenic zone. (The reader is referred to these topics in this book for more detailed discussions.)

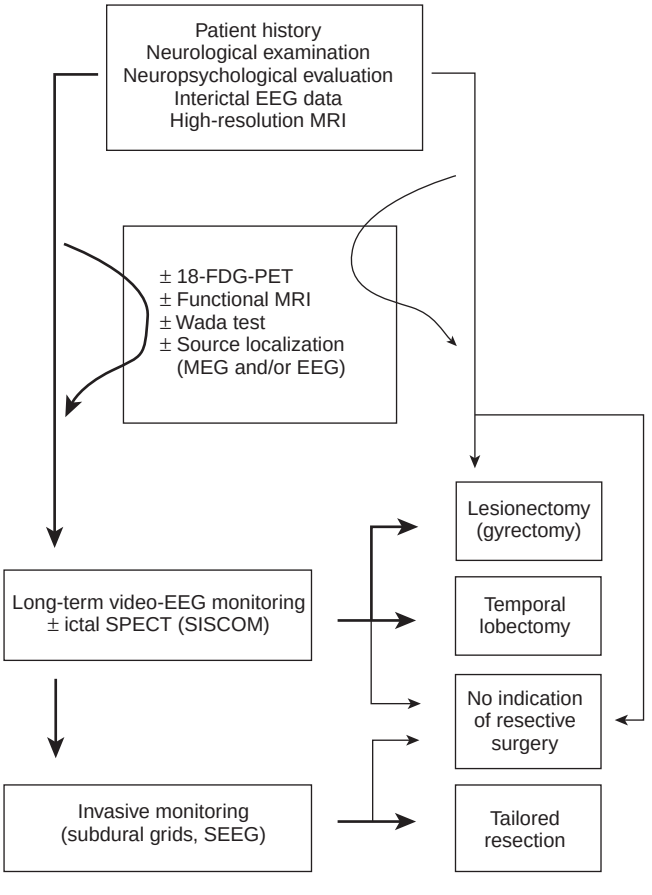

Figure 30.1 Strategies for presurgical evaluation.

In a few lesional cases, these data proved sufficient enough to decide whether surgery can be performed, even without additional EEG/video monitoring. This should concern only those patients with a recent history of drug-resistant seizures associated with a well-limited brain lesion (e.g., dysembryoplastic neuroepithelial tumor, cavernoma, etc.), providing that a good concordance exists between the localization of the lesion, the clinical semiology of the seizures as reported by the patient and/or his/her family, and the interictal scalp-EEG abnormalities. Also, brain imaging study, interictal EEG, and ictal clinical findings may sometimes be sufficient to exclude the patient from surgery. For instance, surgical possibilities are very low in a patient without neurological deficit who experiences simple motor clonic seizures of the right arm, whose interictal EEG shows well-localized left central spikes, and whose MRI does not demonstrate any lesion. Caution is required, however, to ascertain whether a patient is a good epilepsy surgery candidate, without having previously recorded seizures during EEG/video.

In general, noninvasive scalp EEG/video monitoring should be done in a majority of cases

EEG/video monitoring allows the localization of interictal epileptiform discharges (the irritative zone) and, above all, localizing the seizure onset zone and documenting the seizure type(s). It is helpful to the physicians working in the EEG/video monitoring unit to have the MRI scan before the monitoring is done. The information from the history, neurological examination, and MRI scan are helpful in planning the monitoring. For example, a patient with an olfactory aura, automotor (complex partial) seizures, and right hippocampal atrophy on MRI probably should have closely spaced bitemporal electrodes (International 10/10 System) applied with the standard International 10/20 scalp electrodes and sphenoidal

electrodes inserted at the beginning of EEG/video monitoring. In this patient, only a small number of seizures (one or two) would need to be recorded if they were of right temporal origin. A second patient with a sensory aura of the left hand and right hippocampal atrophy on MRI scan should have 10/10 electrodes placed over the right posterior frontal/anterior parietal region in addition to the temporal and sphenoidal electrodes (because of the distinct possibility of an extratemporal epileptogenic zone). A third patient with bihippocampal atrophy on MRI scan and bitemporal spikes would have electrodes placed the same as the first patient, but multiple seizures would be recorded (because of the higher risk of bitemporal independent seizures). At Cleveland Clinic Epilepsy Center most patients with suspected temporal lobe epilepsy undergo monitoring, employing closely spaced scalp electrodes placed bitemporally (10/10 international system) and with sphenoidal electrodes. Hopefully, there will be concordance between the seizure semiology, MRI, and EEG findings; if so, the patient's evaluation will involve fewer days in the hospital, less testing, and significantly less cost.

Selected candidates for epilepsy surgery may also have the following studies depending on the particular issues at hand

(1) *Fluorodeoxy glucose positron emission tomographic scans* (FDG-PET) and *intracarotid sodium amobarbital/methohexital tests* (WADA tests) are considered 'routine' in many epilepsy centers but are no longer done on every patient at Cleveland Clinic Epilepsy Center. For example, in a right-handed patient with right hippocampal sclerosis and agreement of semiology and EEG, the patient would most likely proceed to surgery without a PET scan or a WADA test. However, a PET scan may be of substantial interest to look for a localized hypometabolism in cryptogenic cases, and/or to help to define what the preferential spread pattern of seizures can be when invasive recordings are planned.

(2) A subtraction *ictal SPECT scan co-registered with MRI* (SISCOM or related technique) image may be most helpful in those patients who suffer from focal epilepsy but with normal MRI and in those with extensive focal cortical dysplasia.[37,38]

(3) Some centers employ *magnetoencephalography* (MEG) and/or *EEG dipole source localization* of interictal discharges in an attempt to further localize the irritative zone (area of interictal spiking). These studies are not required on all patients but may be helpful when the location of the epileptogenic zone is in doubt after the routine studies. As yet the exact role of MEG in evaluation of patients for epilepsy surgery is undetermined. MEG is used principally for the localization of interictal epileptiform activity as the chance of recording a seizure during MEG is very small unless the patient is having frequent daily seizures.

(4) *Functional MRI* (fMRI) may help localize some functional areas of the brain and their relationship to a suspected epileptogenic zone. Functional MRI may replace the WADA test in the future for determination of side of language dominance and may possibly be useful for memory assessment. A potential advantage of speech fMRI over WADA is its ability not only to lateralize speech but to anatomically localize cortical speech regions (both anterior and posterior speech areas). fMRI is also a promising technique for cortical localization of interictal epileptiform activity, but EEG recordings with time-locked functional MR imaging are technically challenging and the significance of interictal spiking in ictal onset zone localization is not entirely clear.

Invasive recordings may be needed when noninvasive data remain insufficiently concordant, discordant, or inconclusive, and when they suggest an early involvement of highly eloquent areas

In the 1980s, before high-quality MRI was available, many epilepsy centers performed invasive EEG studies in almost all patients. Some centers favored subdural grid and/or strip evaluations, while others favored depth electrode evaluations. Currently, most centers reserve invasive recordings for those patients in whom the location or extent of the epileptogenic zone is not well defined or those who require localization of eloquent cortex by electrical stimulation of the cortex.

While surgical techniques and the invasive electrode technology have improved, invasive electrodes do carry additional risks of infection, hemorrhage, and sometimes mass effect. Risk of the invasive study increases with the number of electrodes, length of time they are in or on the brain. It markedly increases if another craniotomy is done to move the electrodes. The task at hand then is to use the smallest number of electrodes for the shortest period of time (typical length of invasive electrode monitoring at Cleveland Clinic Epilepsy Center is 2 weeks, but some electrodes were left in for up to 4 weeks).

Most major epilepsy centers in North America employ grids, strips, and depth electrodes, or a combination of them depending on the task at hand. Invasive recordings with subdural grids are extremely helpful in the accurate localization of epileptogenic regions located on the cortical surface but are inaccurate in the definition of EcoG patterns arising from deeper generators such as the insula (that is not well covered by subdural electrodes because of anatomo-technical reasons), and the amygdalo-hippocampal complex (see appropriate chapters in this book). The hippocampus poses major problems, as recording of epileptic activities from an electrode covering the parahippocampal gyrus may point to an epileptogenic neocortex or hippocampus. Alternatively, some epileptic activities arising from the hippocampus may not be detected on subdural electrodes (author's personal observation, IN). The limitations of the subdural/cortical surface electrode mapping in the definition of deep epileptic foci are at least in part addressed in the technique of intracerebral depth electrodes (stereoencephalography, SEEG) that was introduced by Bancaud and Talairach and later was extensively used in many European epilepsy surgery centers (see appropriate chapters in this book). The advantages of SEEG include its ability to sample deep areas of the brain and anatomically distant regions and both hemispheres.

There are no set criteria that can be systematically used to decide whether or not invasive recordings should be performed. Nevertheless, some factors, such as the type of epilepsy (temporal vs. extratemporal), or the presence/absence of a lesion (lesional vs. cryptogenic), may influence to various

degrees the need of invasive recordings (see Chapters 28 and 29). In any case, such recordings must be planned on the one condition that the questions derived from the noninvasive protocol are clear, that the positioning of the electrodes will be able to answer to these questions, and that the patient is likely to benefit from surgery. In other words, since the precise site of the epileptogenic zone is usually uncertain, considerable thinking and planning should be done before the electrodes are placed. Placement of the invasive electrodes requires a hypothesis about where the epileptogenic zone is likely to be.

Temporal lobe epilepsy

Temporal (TLE) is the most common surgical epilepsy diagnosis. Although various pathologies (including cortical dysplasia, tumors, vascular malformations, etc.) may underlie TLE, hippocampal sclerosis remains the most common pathological diagnosis.

Typical cases

The best surgical outcomes are obtained when the localization by seizure semiology, the EEG interictal focus, the EEG seizure onset zone, and an MRI lesion are all functionally and anatomically concordant. An example would be a right-handed patient with an aura of *déjà vu*, followed by an automotor seizure (complex partial with automatisms) during which the patient demonstrates ictal speech, left hand dystonic posturing, that are followed by head version to the left and secondary generalization. A high-resolution MRI in this hypothetical patient reveals right hippocampal atrophy on T1-weighted images and the FLAIR sequence shows increased signal in the right hippocampus. A right anterior temporal lobectomy (with resection of the mesial structures) in this patient would carry low risk for language and memory dysfunction with a likelihood of seizure freedom of approximately 75% at 1 year and 55% 10 years later.[39] The likelihood of seizure freedom following surgery is high because the principal determinants of seizure localization are all in agreement. The ictal semiology suggests the right hemisphere because of the left hand dystonic posturing, ictal version to the left, and ictal speech in a right-handed patient. Both the interictal and ictal EEG findings point to the right temporal lobe and the MRI lesion is right mesial temporal. The surgical risk is low because the patient is almost certainly left-hemisphere dominant for language (because he is right-handed and exhibits ictal speech, suggesting left-hemisphere language dominance) and removal of a nondominant anterior temporal lobe with MRI evidence of hippocampal sclerosis is unlikely to result in clinically significant post operative memory impairment.

Cryptogenic cases

Contrast the above patient with another hypothetical case identical to the first, but whose high-resolution MRI scan is normal. This second patient would also be a surgical candidate but would be somewhat less likely to be seizure free because of the absence of a MRI abnormality and would have a higher risk of postoperative memory decline because the right temporal lobe did not have evidence of hippocampal atrophy; i.e., the resection would include a 'normal' hippocampus by MRI evaluation. This second patient probably should have a PET scan and a SISCOM study to obtain neuroimaging confirmation of the location of the ictal onset zone. More than likely, this patient would require invasive electrode studies and the EEG, PET, and SISCOM findings would help guide the placement of invasive electrodes. The reader should note that in this worst-case scenario, epilepsy surgery is *not* contraindicated, but there is a need for invasive monitoring in most patients (depth electrodes, subdural grids, and/or stereotactically placed depth EEG electrodes). Seizure outcome analyses in patients who underwent invasive evaluation suggest that the chances of seizure freedom after temporal lobe resection is lower (48% seizure free) than in those patients who did not undergo surgical evaluation (65% seizure free).[39] We feel strongly that issues such as these must be discussed with the patient before surgery, and the final decision for or against surgery should be a joint one made by an informed patient and a knowledgeable multidisciplinary team of physician experts.

Dual pathology

Dual pathology usually implies the presence of a neocortical lesion (most commonly a low-grade tumor or focal cortical dysplasia involving temporal or extratemporal (often occipital) neocortex and hippocampal sclerosis. If both lesions are not surgically addressed, the chance of seizure freedom is low. Invasive study may be required, depending on location of the associated lesion. The questions to be answered are: (1) where is the seizure beginning, and (2) to where does it spread?

Pitfalls

In patients suspected to have TLE, the following possibilities should be investigated and answered: (1) temporal versus 'pseudotemporal' epilepsy, (2) unilateral versus bitemporal lobe epilepsy, (3) mesial versus 'neocortical' lateral temporal lobe epilepsy, and (4) temporal versus 'temporal plus' epilepsy.

(1) *Temporal versus 'pseudo-temporal' lobe epilepsy*. This possibility is raised when a patient is suffering from pharmacoresistant epilepsy with EEG and semiological features pointing to the anterior temporal/fronto-temporal regions, but whose MRI scan is normal, and whose memory function is not deficient. As the epileptogenic zone in these cases may be in one of following regions: the temporal lobe, the orbito-frontal region, the temporo-occipital junction, or the mesial parietal/posterior cingulate/posterior interhemispheric areas, there is a need for invasive evaluation with a combination of grids and depths. As it is extremely difficult to lateralize the side of the epileptogenic zone in mesial/interhemisphere epilepsy, hypothesis generation in these cases should be aided by neurophysiologic cues such as the presence of bilateral independent interictal and/or ictal temporal epileptic patterns, and by additional studies that may include an ictal SPECT (with SISCOM).
(2) *Unilateral versus bilateral temporal lobe epilepsy*. Bilateral interictal temporal spikes are present in up to 40% of patients with unilateral hippocampal sclerosis.[40] The findings of typical MRI features of unilateral hippocampal

sclerosis with hypometabolism on ictal FDG-PET with concordant ipsilateral ictal EEG patterns help in making the diagnosis of unilateral mesial temporal lobe epilepsy. If the ictal patterns are bilateral anterior temporal, and the MRI is within normal limits, there will be a need for a confirmation of the seizure lateralization through the use of bilateral depth electrodes to be implanted in amygdalo-hippocampal regions bilaterally. If seizures recorded on surface EEG arise independently from left and right temporal lobes, the patient still may be a surgical candidate, but will require bitemporal depth electrodes for invasive recordings and chance of seizure freedom will be lower still if invasive studies proved bitemporal independent seizure onsets.

(3) *Mesial versus neocortical lateral temporal lobe epilepsy*. This is illustrated by a case that we recently reported:[41] a 42-year-old right-handed male who presented with recurrent daily seizures that were resistant to antiepileptic drugs. Multiple noninvasive (scalp) video-EEG evaluations revealed focal epilepsy arising from the left fronto-temporal region. Multiple high-resolution MRIs failed to show any abnormality. PET scan showed extensive left antero-mesial temporal hypometabolism and ictal SPECT showed increased perfusion in the left insula in addition to the left mesial and anterior temporal pole. Neuropsychological and Wada testing revealed excellent memory to the left dominant side. A two-stage invasive evaluation with subdural grid electrodes followed by depth electrode recordings allowed the localization of the epileptogenic region to the temporal pole. A selective resection of the left temporal pole (that spared the hippocampal formation) resulted in seizure-free outcome (>2 year follow-up) with no significant consequences on the memory function. The management of this case shows that targeted invasive recording techniques should be used for the accurate localization and delineation of the extent of the epileptogenic zone in cases of suspected nonlesional dominant hemisphere temporal lobe epilepsy with preserved memory function. The use of the staged invasive approach may increase the chances for memory (function) sparing through tailored temporal resection.

(4) *Temporal versus temporal 'plus' epilepsy*. Temporal 'plus' seizures are characterized by seizures involving a complex epileptogenic network including the temporal lobe and the closed neighbored structures such as the orbito-frontal cortex, the insula, the frontal and parietal operculum, and the temporo-parieto-occipital junction.[42] There are only a few data on this topic,[43–45] thus making the identification of this form of seizures largely ignored. Thus, some patients submitted to temporal lobe surgery who continue to experience seizures postoperatively might suffer from temporal 'plus' seizures and identifying those patients by means of invasive recordings, might lead to performing a more extensive and effective cortectomy, according to surgical possibilities and limits.[45] Recently, Barba *et al.*[46] have found that when compared to 'pure' temporal lobe patients, patients suffering from temporal 'plus' seizures more frequently had gustatory hallucinations, rotatory vertigo, and auditory illusions at seizure onset; they exhibited more frequently contraversive manifestations of the eyes and/or head, piloerection and ipsilateral tonic motor signs, and they were more often dysphoric in the postictal phase; also, they had more frequently bilateral or precentral interictal scalp-EEG abnormalities, and ictal scalp-EEG more frequently pointed over the anterior frontal, temporo-parietal and precentral regions.

Extratemporal epilepsy

In general, patients with extratemporal epilepsy surgery are less likely to be seizure free following epilepsy surgery, as compared to those who have temporal lobe resections. As a rule, the delineation of extratemporal epileptogenic network is much more difficult than that of temporal lobe seizure origin, so that many patients suffering from extratemporal lobe epilepsy have to undergo invasive EEG recordings. Indeed, there are no clear extra-temporal lobe epilepsy 'syndromes', no equivalent of hippocampal sclerosis on MRI, scalp EEG is often mislocalizing and even mislateralizing, and there are no standardized resection techniques.

Lesional cases

The complete removal of a well-limited lesion (and at least its surrounding neocortex) can prove effective against extratemporal lobe seizures, providing that there is a good concordance between the site of the lesion, the clinical semiology of the seizures, and the scalp EEG data, and subject to the one condition that it can be done without significant neurological deficit. Partial lesionectomy is significantly less likely to result in postoperative seizure freedom, notably in patients suffering from dysembryoplastic neuroepithelial tumors.[47] Invasive recordings may be necessary when the relationships between the lesion itself and the region of seizure generation remain unclear, and/or when there is a need to clarify the relationships with eloquent cortical areas. This is especially true for focal malformations due to abnormal cortical development, as the epileptogenic area is frequently larger than the visually-identified lesion, and as a large proportion of patients with such lesions have the diagnosis of focal epilepsy arising from the frontal or perirolandic regions. In any cases, the decision to perform or not invasive recordings in lesional cases must be based on 'anatomo-electro-clinical grounds', and the goals from the invasive evaluation, if decided, should be clear (mapping of epileptogenicity and function) with the understanding of the limitations and risks of the evaluation.

As an example of a straightforward case, a patient, left hemisphere dominant for language, has a small lesion (cortical dysplasia or low-grade congenital tumor) on a MRI scan located in the posterior aspect of the left inferior frontal gyrus. His seizures begin with a slight muscle twitch of the right lip. It is obvious that the lesion is related to the seizures. The questions to be answered are: How extensive is the epileptogenic zone, and exactly where is it located. Does the epileptogenic zone involve Broca's area or the motor strip? Depth electrodes would not be very helpful in this patient. A subdural grid could be used to cover the lesion, the motor strip, and Broca's area in order to record seizures and interictal epileptiform activity. In addition, subdural grids evaluation would enable functional cortical mapping with trigeminal/median nerves,

somatosensory evoked potentials, and physiologic localization of Broca's area and the primary somatosensory cortex by electrical cortical stimulation. As an alternative, fMRI might assist with localization of the eloquent cortex, but it would not localize the epileptogenic zone. Craniotomy under local anesthesia with electrocorticography and localization of the primary motor cortex by cortical stimulation in the operating room would be another alternative. However, this approach may be limited by the lack of ictal recordings (as the significance of some interictal patterns, besides the continuous rhythmic discharges remains unknown), and at times the technical difficulties associated with cortical mapping in the operating room. Surgical management recommendations should be made after a thorough discussion in a multidisciplinary patient management conference with the active participation of epileptologists, epilepsy surgeons, neuroimagers, neuropsychologists, psychologists/psychiatrists, and clinical nurses. The final decision should be made with active input from the patient after a long discussion of the multidisciplinary group's recommendations.

Cryptogenic cases

As with the temporal lobe surgical cases, the likelihood of seizure freedom with extratemporal resection is somewhat lower if the MRI scan is normal.[48,49] In such cases, the use of intracranial recordings remains essential, as illustrated in the following example of a left hemisphere language dominant patient with a left frontal interictal and ictal focus on EEG and with seizure semiology suggesting a left frontal epileptogenic zone. His MRI is normal, as is his interictal PET scan. His ictal SPECT scan is nonlocalizing. Because no lesion is found on neuroimaging, his chance of seizure freedom with surgery is lower. These cases present a challenge for both ictal onset cortical seizure localization and mapping of the functional regions that may be overlapping with the seizure onset zone. The electrode placement in these types of cases is typically guided by ictal semiology and EEG interictal and ictal patterns. In this patient, in addition to subdural grid electrode recordings from the mesial fronto-central region, the lateral convexity, and the inferior orbito-frontal region, multiple depth electrodes could be used to sample the mesial posterior orbital frontal cortex and medial frontal lobe.

Conclusions

The risks of the evaluation and surgery, and the likelihood of seizure freedom should be discussed with the patient. Risk-aversive patients may decline to proceed, while others may be more adventuresome. These complicated decisions are not black or white. A patient management multispecialty conference is very helpful in decision making concerning which patients are good epilepsy surgical candidates, which require additional noninvasive study, which require the use of invasive recordings and the type of electrodes and where they should be placed. At Cleveland Clinic, all epilepsy surgery candidates are discussed at a patient management conference before epilepsy surgery or invasive recordings. The epileptologists, epilepsy neurosurgeon, neuroradiologists, nuclear medicine physician, neuropsychologists, and epilepsy nurses are all in attendance. In addition to providing a group discussion with a variety of inputs before a decision is made, a benefit is that the conference plays an important educational role for epilepsy fellows and staff.

31 Exclusion criteria

EMT Yacubian

Introduction

Surgery is an alternative for some patients whose seizures cannot be controlled by medication. It has been used for more than a century, but its use dramatically increased in the 1980s and 1990s, reflecting its effectiveness as an alternative to seizure medicines. Recent advances in epilepsy surgery can be traced to many factors, including progress in video-EEG monitoring and neuroimaging, advances in surgical techniques, and a better understanding of brain biology, including that of pediatric patients. Results from pediatric surgical series suggest that children should be referred for surgical evaluation at whatever age they manifest severe intractable focal epilepsy, even in infancy. Also, substantial experience in neuropsychological preoperative evaluation limiting any unwanted impact of surgery on normal brain function, development of a wide array of pharmacological agents that can be useful to manage psychiatric symptoms and comprehension of the social consequences of disabling seizures have contributed to the expansion of this treatment modality. It is now clear that specialized centers with extensive epilepsy surgery experience and the availability of progressively more accurate diagnostic techniques and safer surgical procedures resulted in a progressive shrinking of exclusion criteria for surgery.

Who is a surgical candidate?

Not every patient is amenable to surgical treatment. Patients, both adults and children, must fulfill the following criteria:

1. Recurrent seizures that continue despite adequate trials of antiepileptic medication. Medical intractability is one of the absolute indications in considering epilepsy surgery, although there are no widely accepted or uniformly applied definitions of 'refractory epilepsy' and the criteria used to determine medical intractability are either quite heterogeneous or rather vague.
2. Disabling seizures which must be a significant detriment to the patient life.
3. Anatomic localizability, meaning that the epileptogenic zone must reside in a specific area of the brain that can be removed safely.
4. No identifiable, resectable, single epileptogenic zone and very poor prognoses when a palliative surgical intervention is conceivable and might help the patient and caregivers. Any patient with medically refractory disabling epileptic seizures should be referred to an epilepsy center since epilepsy specialists are the best qualified to conclude that surgical treatment is not a treatment option.

Who is not a surgical candidate?

Not only must the patient fulfill the above criteria, but there are also some contraindications to surgery that must be assessed. Absolute and relative contraindications for epilepsy surgery must be considered as listed in Table 31.1.

Absolute

Idiopathic age-related epileptic conditions

This group comprehends focal and generalized epileptic syndromes. Among the first, Benign Childhood Epilepsy with Centrotemporal Spikes (BECTS) is the most common idiopathic partial epilepsy syndrome of childhood. Typically presenting between the ages of 3 and 13 years, it is characterized by a well-recognized seizure pattern related to sleep (brief, simple, partial, hemifacial motor seizures, frequently having somatosensory symptoms) arising in a normal child with blunt high-voltage centrotemporal spikes, often followed by slow waves that are activated by sleep and tend to spread or shift from side to side.[1] In the second-most prevalent type of idiopathic focal epilepsies, Idiopathic Childhood Occipital Epilepsy, occipito-temporal discharges present the same electrographic characteristics. Seizure control is usually, but not always, easily achieved, and prognosis is believed to be uniformly good. Some authors have suggested that individuals fitting these parameters need not undergo neuroimaging. However, symptomatic partial epilepsies may mimic this electroclinical phenotype configuring the 'pseudo-BECTS' or 'BECTS-like electroclinical type.'

Table 31.1 Epilepsy surgery contraindications

Absolute
Idiopathic age-related epilepsies
Diseases underlying epilepsy
Incapability to comprehend and cooperate with the procedure
Relative
Unrealistic expectations
Psychopathology
Mental retardation
Involvement of eloquent cortex
Bilateral, independent interictal and/or ictal EEG
Progressive underlying neurological diseases

BECTS and lesions, pseudo-BECTS or BECTS-like electroclinical picture

Occasionally, BECTS 'phenotype' has been associated with nonevolutive cerebral lesions not located in the rolandic area,[2] unilateral opercular migration disorder,[3] low-grade astrocytoma and cavernous angioma[4] and a malignant rolandic-sylvian epilepsy characterized by sensoriomotor seizures, medical refractoriness, normal MRI and cognitive problems.[5] Variable atypical features were present in most of these rare case reports. In such cases, epilepsy may or may not be ascribed to the lesions.[6,7] As in BECTS, symptomatic occipital epilepsy such as cortical malformations, mitochondrial disorders, Lafora disease, and celiac disease often imitates Gastaut type-Idiopathic Childhood Occipital Epilepsy.[8] Unusual bilateral occipitofrontal sharp waves, increasing in frequency and distribution during sleep suggestive of benign focal epileptiform discharges of childhood were reported in two children with refractory mesial temporal epilepsy related to hippocampal sclerosis.[9] The postoperative freedom from seizures in each case confirmed that hippocampal sclerosis was the primary epileptogenic process and that benign focal epileptiform discharges were incidental or an atypical secondary manifestation. Therefore, since children with lesions can be dismissed as candidates for epilepsy surgery because of the EEG pattern, caution is necessary in the interpretation of the criteria of absolute contraindication of epilepsy surgery in patients whose electroclinical data are initially suggestive of benign focal childhood epilepsies.

Coexistence of idiopathic generalized and symptomatic focal epilepsies

Idiopathic generalized epilepsies are an absolute contraindication to surgery. However, idiopathic generalized epilepsies may also coexist with focal epilepsies, although this is certainly an uncommon event. Out of 350 consecutive patients who had temporal resections, Koutroumanidis *et al.*,[10] described two cases with clear electroclinical evidence of coexisting temporal lobe epilepsy related to mesial temporal sclerosis cured by resective surgery and idiopathic generalized epilepsies. In one, spontaneous and photically induced generalized spike-wave discharges preceded temporal lobectomy by 5 years. In this patient, clusters of bilateral and arrhythmic clonic jerks of the limbs, mainly on awakening, suggestive of juvenile myoclonic epilepsy, started shortly after the surgical resolution of complex partial seizures. In the second, temporal lobe epilepsy and juvenile absence epilepsy occurred together for almost 7 years. In two other case reports, juvenile myoclonic epilepsy only appeared after successful anterior temporal lobectomy for complex partial seizures.[11,12] Coexistent idiopathic generalized epilepsies should not affect decision for epilepsy surgery.

Diseases underlying epilepsy

Progressive degenerative, neurometabolic and systemic diseases that may underlie the seizures are contraindications to epilepsy surgery.

Incapability to comprehend and cooperate with the procedure

Candidates for surgery need to be able to fully comprehend the procedure and to cooperate with a prolonged hospitalization for monitoring; for many, there will be further tests that require cooperation, such as MRI scanning, angiogram, invasive monitoring and even awake craniotomy with cortical localization studies.[13] Participation and involvement in decisions, even when being made on their behalf, to provide informed consent for preoperative investigations and surgery is highly desirable. After surgery, acceptance and involvement in the rehabilitation program aiming at psychosocial integration is also necessary.

Relative

Unrealistic expectations

Expectation that surgery will correct all the losses associated with chronic epilepsy that are unyielding, despite repeated attempts to correctly inform the patient of the risk-to-expected-benefit ratio of surgery, represent a relative contraindication.[14]

Psychopathology

The importance of this topic is highlighted by the fact that preoperative behavioral problems occur in approximately 67% of candidates for anterior temporal lobectomy, depression, anxiety, and/or suicidal tendencies in 20%, and psychosis in 16%.[15] Disputes have continued over whether presurgical evaluation may adversely influence the psychiatric disorder, whether psychiatric symptoms may be aggravated postsurgically, and whether these patients would benefit from surgery with respect to quality of life.[16] The NIH Consensus Statement suggested that severe psychiatric disorders should be included for consideration in recommendation of epilepsy surgery.[17] However, recent reports have indicated that the psychiatric status is little influenced by surgery and preexisting psychiatric problems may improve in half of the patients and could even disappear in about one third.[16] In the beginning of the 1990s, Fenwick[18] already noted a decrease in the number of patients with postoperative psychopathology, presumably because of rejection of patients with preoperative psychiatric disorders or presurgical identification of patients who were vulnerable psychiatrically. There are few definitive psychiatric contraindications to elective epilepsy surgery. Surgery is contraindicated in patients with severe psychiatric illness refractory to psychopharmacological treatment that cannot be managed safely on a nonpsychiatric award. Also, when there is a significant danger for suicide and aggressiveness during presurgical evaluation given the risk of self-injury, injury to personnel and other patients. Untreated psychopathology, including depression and psychosis, which is not always resistant to psychiatric treatment, may also preclude evaluation because of the patient's inability to cooperate and the difficulty in postoperative rehabilitation. Proper risk management warrants delay of the surgery until these risks have been abated.[19,20]

Psychosis

Chronic psychosis has been considered a contraindication to surgical treatment in the past. Whereas many centers prefer not to accept patients with fixed psychosis as surgical candidates because the psychosis remains even when the patient becomes seizure free, episodic psychoses that are seizure

related, usually as postictal phenomena, often disappear.[19] Actually, postictal psychosis has been considered a factor favoring rather than opposing surgical treatment of refractory epilepsy.[16,20] Another concern is exacerbation of psychosis with seizure remission after surgery, analogous to 'forced normalization'. Although aggravation may occur in a few cases, patients with chronic psychosis may benefit if they become free from seizures after operation, even though psychosis persists. Reutens *et al.*[21] reported that chronic psychotic patients might be able to provide informed consent, cooperate during preoperative investigation, have an uneventful course after surgery, and achieve an improved quality of life. Therefore, it would be unwise to make a decision on whether to reject a patient for surgery on the grounds of psychosis, and a detailed psychiatric evaluation should be performed for each individual case.[19]

Depression

The greatest predictor for postoperative depression is preoperative depression, and a third of patients with baseline depression will still be depressed after surgery. However, depression, as postictal psychosis, as mentioned above, improves in the majority of patients who become seizure free after surgery.[22] Therefore, preoperative depression is not a reason to withhold surgical treatment. Since untreated depression will produce lasting effects on a person's quality of life and postsurgical outcome, identification and treatment of depression should be an integral aspect of presurgical care to stabilize patients optimally before epilepsy surgery.

Substance abuse

Substance abuse represents a relative contraindication to epilepsy surgery. If it contributes to poor seizure control preoperatively and the patient is unmotivated to achieve abstinence, it may well contribute to poor seizure control postoperatively.[14]

Additional psychogenic seizures

Patients with epilepsy who have additional psychogenic seizures represent a particular diagnostic and therapeutic challenge and have been excluded from some epilepsy surgery programs. Epilepsy surgery should be offered only to patients predominantly disabled by epileptic rather than psychogenic seizures. In a series of 13 patients with both types of events who had epilepsy surgery, 11 had a relevant improvement and seven became free of both epileptic and psychogenic seizures. However, there was no definite link between the postoperative prognosis in terms of epileptic and psychogenic seizures.[23] Although a diagnosis of additional psychogenic seizures should not be considered an absolute contraindication to epilepsy surgery, patients should undergo careful preoperative psychiatric evaluation in which a diagnosis should be formulated, a psychological intervention programmed and a prognosis recorded.

Mental retardation

The NIH Consensus Statement suggested that profound mental retardation should be included for consideration in indication of epilepsy surgery.[17] In adults, mental retardation has been considered a poor prognostic sign for localized cortical resection because of the assumption of more diffuse brain damage and the likelihood of multiple epileptogenic regions as well as being considered a poor prognostic indicator. Additionally, the ability to compensate for surgically induced deficits is supposed to depend on the integrity of brain regions beyond the epileptogenic zone and these patients would be at risk with respect to their postoperative outcome. Different series have shown that the rate of success, although not as high as usually reported in patients with IQ >70, appears sufficiently high to justify the treatment. On the other hand, no deterioration of cognitive functioning or of psychosocial adjustment postoperatively has been observed.[24,25,26]

Involvement of primary language, motor, or sensory cortex in the epileptogenic zone

Participation of eloquent cortex in the epileptogenic zone has been considered a contraindication to surgical resection, since removal of these cortical areas can result in permanent neurological deficits. There are exceptions, however. When permanent deficits already exist, surgery introduces no additional risk; for instance, hemispherectomy is commonly performed in individuals who have a hemiparesis and a useless hand. Small areas of the lower sensoriomotor cortex can actually be removed at any age without inducing significant motor deficits, even in the dominant hemisphere.[27] Surgical resections that involve primary language cortex in infants and small children up to about the age of seven do not result in appreciable aphasia because contralateral cortex takes over this function. The nonablative technique of subpial transection of the primary cortex has been reported to have a beneficial effect on habitual seizures without inducing neurological deficits.[28]

Bilateral, independent EEG spikes and/or electrographic ictal onsets

In patients with mesial temporal sclerosis, interictal EEG findings include unilateral or bilaterally independent mesial temporal spikes. Initially, the latter would seem a contraindication to surgery. However, the majority of the authors concluded that, although associated with less favorable outcome (50–77% seizure freedom) compared to patients with pure unilateral discharges, the presence of bilateral independent interictal discharges is not necessarily a sign of bilateral epileptogenesis.[29] Some centers contraindicate surgery for bitemporal epilepsy, defined as clinical seizures arising independently from both temporal lobes on scalp EEG. Nevertheless, invasive monitoring reveals unilateral or preponderant (≥80%) ictal onsets in a significant proportion of cases with very satisfactory surgical results, with ≥75% of the patients becoming seizure free. Identification of lateralizing factors during the noninvasive phase of evaluation is crucial to the indication of invasive recordings in this group of patients. They are represented by at least one of the following factors concordant with the side of surgery: ≥75% preponderance of interictal scalp EEG discharges to one temporal lobe, unilateral temporal lesion on MRI, or lateralizing verbal or visual reproduction memory deficits on neuropsychological tests. Other methods of noninvasive assessment such as lateralizing factors on positron emission tomography, single-photon emission tomography, or magnetic resonance spectroscopy could be as useful as the factors mentioned above.[30]

A series of temporal lobe indolent tumors have also shown that contralateral interictal discharges are dependent on the epileptogenic side.[31] On the other hand, patients who experience a variety of clinical ictal onsets may still have seizures originating in one area of the brain with multiple spread patterns.

Progressive underlying neurological diseases

Although a clearly progressive underlying disease process is usually a contraindication to surgical intervention, early hemispherectomies can be an effective treatment for instance in Rasmussen's encephalitis and Sturge Weber syndrome. Yet, caution is again necessary. Bilateral involvement, mainly seen in children with unusually early onset and in adolescents and adults, has been reported in a few cases of Rasmussen syndrome.[32] Progressive features in other neurological conditions that reflect secondary epileptogenesis, drug effects, or psychosocial factors, should not exclude patients from surgery.

Additional special issues in children

In children other issues, as timing, widespread EEG abnormalities, psychopathology and mental retardation need special consideration.

Timing

Precocious onset of intractable epilepsy within the first 24 months of life is a significant risk factor for mental retardation independent of etiology.[33] Despite the recognition that the earlier the surgery is performed in the subgroup of infants with frequent and severe seizures, the better the long-term outcome relative to cognition and behavior taking advantage of neuroplasticity, surgical indications in extremely young children are still debated. Timing of surgery is a critical decision facing technical challenges at this age for an 'elective' procedure. The most serious risk of epilepsy surgery is perioperative mortality. The risk may be higher in infants, because of their tendency to require extensive surgery in the face of small blood volume. For each patient, the timing of surgery must carefully be considered based on a full assessment of the relative risks and benefits, derived from a detailed presurgical evaluation.[34]

Bilateral, independent EEG spikes and/or electrographic ictal onsets

Widespread pathology as well as electrographical interictal and ictal findings are very common in presurgical evaluation of children. Still it has been demonstrated that selected individuals with drug resistant epilepsy may benefit from epilepsy surgery. Despite multiple structural abnormalities on MRI and multifocal EEG abnormalities, stereotyped seizures may arise from a single tuber in patients with tuberous sclerosis. The same is seen in hemimegalencephaly, where hemispherectomy may improve a significant percentage of cases in spite of bilateral interictal discharges and ictal onset in more than half of them.[35,36] Even secondary generalized epileptic syndromes do not represent a formal contraindication for epilepsy surgery, since corpus callosum section may improve drop attacks in patients with Lennox-Gastaut syndrome and localized resections may benefit infants with infantile spasms.[37]

Psychopathology

Children's psychopathology differs from that of adults. Higher rates of psychopathology (83%) with over-representation of autistic spectrum disorders and unusual disruptive behavior disorders have been described in children who had undergone temporal lobe resection for temporal lobe epilepsy.[38] In adults, improvements in mental health problems are directly related to good seizure control postoperatively. On the contrary, epilepsy surgery in children may have a variable effect on psychopathology since preoperative psychiatric disorders may improve, deteriorate, or remain unchanged, independent of seizure freedom. This unpredictability reinforces the importance of a careful counseling to parents and children about the range of mental health outcomes after surgery.

Mental retardation

Substantial global mental delay is common in young children treated with surgery and about 80% of patients present moderate or severe mental retardation.[39,40] In a series of 50 consecutive preschool children, surgical prognosis was related to mental development since 80% of those with IQ ≥70 became seizure free. However, the same was observed in almost half of the severely retarded children. Therefore, profound mental retardation should not be an exclusion criterion for epilepsy surgery selection in small children. Postoperatively, gains in IQ have been related to seizure outcome being observed in seizure-free children and in those with shorter duration of epilepsy.[40]

Conclusion

There are contraindications to epilepsy surgery and a reference center has to provide a full range of established presurgical assessment, surgical treatment, and rehabilitation program. In children and especially in infants, it is critically important that epilepsy surgery be reserved only for patients with severe epilepsy, and performed at specialized pediatric centers.

SECTION 3

Epilepsies remediable by epilepsy surgery

32 Classification of epileptic seizures and epilepsies

HO Lüders

Introduction

Already Hippocrates in his descriptions of the 'Sacred Disease' discussed several types of epileptic seizures. The majority of the descriptions of epilepsy since Hippocrates also includes detailed classifications of the epileptic seizures.[1] In most of these cases the seizures are simply classified by their main ictal symptomatology. Until relatively recently, however, no clear attempts were made to differentiate between epileptic seizures and epilepsies, i.e., the epilepsies were similarly subdivided according to the ictal symptomatology the patient was suffering from. The 1969-proposals by Gastaut[2,3] was the first attempt to clearly differentiate between the classification of seizures and the classification of epilepsies. The initial proposals by Gastaut in 1969[2,3] and the international classifications which essentially were modeled following Gastaut's philosophy were all adhering to the following principles:

a. Epileptic seizures are paroxysmal events defined by the ictal symptomatology and by a characteristic interictal and ictal EEG.
b. Epilepsies, on the other hand, are defined by a cluster of signs and symptoms (*syndromes*) which usually include one or more types of epileptic seizures, associated neurological deficits, a certain age of seizure onset, and a typical prognosis regarding frequency of seizure recurrence and persistence of seizures with age.

In most cases, however, the seizure type (seizure semiology and EEG) was the main factor which characterized a certain 'epilepsy syndrome'. Therefore, the distinction between epileptic seizures and epilepsy syndrome was frequently unclear. In most cases also, there was a one-to-one mapping from seizure type to epilepsy syndrome. Typical examples are absence seizures and absence epilepsy or infantile spasms and 'West syndrome'. Besides, over the years researchers described a progressively larger number of epilepsy syndromes which they felt tended to occur in clusters. This culminated with the recent 'diagnostic scheme' for the classification of epileptic seizures and epilepsies,[4] which again includes so many different syndromes that even neurologists subspecialized in epilepsy would have difficulties in applying it in everyday practice. This is also most probably the reason this 'diagnostic scheme,' even if approved by the ILAE, has never been implemented.

It is clear that the international classifications of epileptic seizures or epileptic syndromes played a major role in the development of clinical epileptology and have been extremely useful in everyday clinical practice. However, recent diagnostic advances in the epilepsies (including particularly neuroimaging and genetics) point to the need of a completely different approach regarding classification of the 'epilepsies.' Epileptic seizures can now be understood as a *neurological symptom* that occurs in association with an infinite type of insults to the human cortex. We now also know that all epileptic seizures are produced by *multiple etiologies* which converge in producing a particular type of epileptic seizures.[5] In this sense, epilepsy as a symptom is not too different to for example spasticity. Both can be produced by multiple lesions in different parts of the nervous system, both can be the consequence of multiple etiologies, and both respond to medications that are somewhat independent from the location of the lesion or the etiology of the symptom.

These observations lead us to propose a 5-tier 'classification' system.[6] Two of these five tiers (semiological characteristics of the seizures and seizure frequency) define the *symptom*, namely the epileptic seizures. The other three tiers (etiology, associated neurologic deficits, location of the epilepsy) define *what is producing the epilepsy* and the *location* of the brain abnormality.

It is also very important to clarify the terminology as it applies to epileptic seizures and epilepsies. As will become clear below, in the classification system proposed here, epileptic seizures are defined exclusively by ictal semiological features. Therefore, all the modifiers of the term 'seizures' refer to ictal semiology and anatomical modifiers (left, right, etc.) refer to the location of these semiological characteristics. For example, in the expression 'left hand clonic seizures', left refers to location where the clonus occurs. On the other hand, anatomical modifiers of the expression 'epilepsy' refer to the location of the epileptogenic zone, i.e. generalized epilepsy implies that the whole brain is epileptogenic, whereas left paracentral epilepsy implies that the epilepsy originates from the left paracentral region of the brain.

We will now give a short summary of the five-tier classification system. Detailed description of this system can be found elsewhere.[5–16]

Tier 1: Epilepsy

This tier defines the location of the epileptogenic zone. The precision with which we can define the location of the

epileptogenic zone varies depending on the number and type of diagnostic procedures we perform (interictal EEG, ictal EEG, MRI, PET, SPECT, invasive EEG studies, etc.). The following subdivisions can be defined:

1. Focal: epileptogenic zone located within one cortical lobe
   a. Frontal
   b. Perirolandic
   c. Temporal
      i. Neocortical temporal
      ii. Mesial temporal
   d. Parietal
   e. Occipital
   f. Other
2. Multilobar: epileptogenic zone affects more than one brain lobe
   a. Bilobar homotopic: epileptogenic zone affects two homotopic brain lobes (bitemporal, bifrontal, etc.)
   b. Other
3. Generalized: epileptogenic zone is bilateral, diffusely distributed affecting most or all of the brain cortex.

Classical 'epilepsy syndromes', which are a shortcut for a constellation of clinical features, almost invariably refer to generalized epilepsies. Most, if not all epilepsy syndromes, are clearly defined by listing the characteristics of the five tiers that are outlined her. However, for many experienced epileptologist the 'syndromic expression' is a useful shortcut expression. Therefore, we felt it would be useful to list the epilepsy syndrome in parenthesis after specifying the epileptogenic zone. For example; *Epilepsy: Generalized (Lennox-Gastaut Syndrome)*

Tier 2: Semiological seizure classification

The ictal semiology is, by definition, the clinical expression of a patient with epilepsy. Until the discovery of the EEG in 1930, epileptic seizures were defined exclusively by clinical semiology.[17] However, with the discovery that the EEG could localize the origin of the seizures investigators felt that the combination of the EEG findings and the seizure semiology could add significant precision to an 'epilepsy classification'. This was the first step towards an 'epilepsy syndrome' classification. Later, additional factors like MRI findings, associated neurological deficits, etiology, etc. were added leading to our modern definition of epileptic syndromes. At the same time, as mentioned above, in many instances in which the epilepsy syndrome was defined almost exclusively by the semiology/EEG findings, there was no distinction between semiology/EEG 'syndrome' and 'epilepsy syndrome'.

In the five-tier epilepsy classification shown here, the second tier classifies the epileptic seizures exclusively by clincial semiology, *independent of the results of any other tests* (interictal EEG, ictal EEG, MRI, PET, SPECT, neurological and neuropsychological examination, etc.). This leads to a clear distinction between epileptic seizures (*refers to the ictal semiology*) and epilepsy (*refers to the epileptogenic zone*). The tests used to define the epileptic seizures is exclusively *clinical observation* by the physician (video recordings) or by the patient itself or other direct observers (anamnesis). On the other hand, to define the location of the epileptogenic zone (epilepsy) we use the results of all available tests.

Details of the semiological seizure classification can be found in previous publications.[8,10,11,13,15,18–21] The main categories included in the semiological seizure classification are listed below.

Semiological seizure classification

1. Auras
   a. Somatosensory auras
   b. Visual auras
   c. Auditory auras
   d. Gustatory auras
   e. Olfactory auras
   f. Autonomic auras
   g. Abdominal auras
   h. Psychic auras
2. Autonomic Seizures
3. Dialeptic Seizures
4. Motor Seizures
   a. Simple Motor Seizures
      i. Myoclonic seizures
      ii. Clonic Seizures
      iii. Tonic Seizures
      iv. Versive Seizures
      v. Tonic-Clonic Seizures
      vi. Epiletic Spasms
   b. Complex Motor Seizures
      i. Automotor seizures
      ii. Hypermotor seizures
      iii. Gelastic Seizures
5. Special Seizures
   a. Atonic seizures
   b. Akinetic seizures
   c. Astatic seizures
   d. Negative myoclonic seizures
   e. Hypomotor seizures
   f. Aphasic seizures

Each seizure type listed above is considered a seizure component. Each seizure component can be modified by somatotopic modifiers, for example, *generalized tonic-clonic seizures* or *left visual auras*. In this case the somatotopic modifier always refers to the clinic semiology. The evolution of a seizure is expressed by linking two to four seizure components by arrows. Alterations of consciousness during a seizure is indicating by inserting (*AOC*) after the seizure component during which the patient had a clear alteration of consciousness. Besides, lateralizing signs not specified by listing the seizure evolution can be added. Example: *Left visual aura → left hand clonic seizure* (*AOC*) → *generalized tonic-clonic seizure. Lateralizing sign: postictal aphasia.*

Tier 3: Etiology

It is becoming more and more clear now that epilepsies are always produced by multiple etiologies. In some cases one of

the etiological factors might play a clearly dominant role (for example, seizures secondary to a tumor) whereas in other instances it is almost impossible to isolate a single etiology that is responsible for the epileptic seizures (for example, patients with 'genetic' epilepsy in which multiple genes contribute to the generation of epileptic seizures). However, there are always multiple contributing etiologies even if there is a single clearly dominant etiological factor. For example, the studies of Andermann and Metrakos[5,22,23] show that the incidence of seizures, epilepsy, and EEG abnormalities is significantly higher in close relatives of patients with surgically treated epilepsy than in the general population. This indicates that even in patients who were treated surgically for epilepsy, genetic factors still play a significant role in the etiology of focal, symptomatic epilepsy.

To facilitate entering the seizure/epilepsy classification into a database, Lodeenkemper et al. suggested the following classification of seizure/epilepsy etiologies.[6]

1. Hippocampal sclerosis
2. Tumor
   a. Glioma
   b. Dysembrioplastic neuroepithelial tumor
   c. Ganglioglioma
   d. Other
3. Malformations of cortical development (MCD)
   a. Focal MCD
   b. Hemimegalencephaly
   c. MCD with epidermal nevi
   d. Heterotopic grey matter
   e. Hypothalamic hamartoma
   f. Hypomelanosis of Ito
   g. Other
4. Malformations of vascular development
   a. Cavernous angioma
   b. Arteriovenous malformation
   c. Sturge–Weber syndrome
   d. Other
5. Central nervous system infections
   a. Meningitis
   b. Encephalitis
   c. Abscess
   d. Other
6. Central nervous system inflammation
   a. Rasmussen encephalitis
   b. Vasculitis
   c. Other
7. Hypoxic-isquemic brain injury
   a. Focal ischemic infarction
   b. Diffuse hypoxic-ischemic injury
   c. Periventricular leukomalacia
   d. Hemorrhagic infarction
   e. Venous sinus thrombosis
   f. Other
8. Head trauma
   a. Head trauma with intracranial hemorrhage
   b. Penetrating head injury
   c. Closed head injury
   d. Other
9. Inheritable conditions
   a. Presumed genetic cause
   b. Tuberous sclerosis
   c. Progressive myoclonic epilepsy
   d. Metabolic syndrome
   e. Channelopathy
   f. Mitochondrial disorder
   g. Chromosomal aberration
   h. Other
10. Structural brain abnormality of unknown cause
11. Other
12. Unknown etiology

Tier 4: Seizure frequency

The management of a patient with epilepsy is primarily focused on reducing the frequency and intensity of epileptic seizures. Therefore, at each office visit the health-care provider needs precise information about the type of seizures the patient is actually suffering from (given by the semiological seizure classification) and the number of seizures the patient had since the last visit (given by seizure frequency). In the seizure classification we can just list the average seizure frequency since the last visit or use broad categories which we also defined in previous publications.[6]

1. Daily seizures
   One or more seizures per day
2. Persistent seizures
   Less than one seizure per day but at least one seizure/6 months
3. Rare or no seizures
   Fewer than one seizure every 6 months
4. Undefined
   Seizure frequency can not be specified because of unknown seizure frequency, recent onset of epilepsy or recent surgery of epilepsy

Tier 5: Related medical conditions

Here we provide additional information (free text) about major non-etiological medical conditions the patient may be suffering from. Example: mental retardation, hemianopia, depression, previous surgical procedures, etc.

Examples of classifications

Case 1

Epilepsy: Left mesial temporal
Seizures: Psychic aura → automotor seizure (AOC) → Right face clonic seizure
Lateralizing sign: postictal aphasia
Etiology: Left mesial temporal sclerosis
Seizure frequency: Persistent
Related medical condition: Depression, poor verbal memory

Case 2

Epilepsy: Right frontal
Seizures: Left hand clonic seizures → generalized tonic-clonic seizure
Etiology: Right frontal malformation of cortical development
Seizure frequency: Undefined
Related medical conditions: Postsurgical left hand paralysis, right frontal lobectomy (January, 2008)

Case 3

Epilepsy: Generalized (Lennox-Gastaut syndrome)
Seizures: Generalized astatic seizures
Dialeptic seizures
Generalized tonic seizures
Generalized tonic-clonic seizures
Etiology: Diffuse hypoxic-ischemic injury
Seizure frequency: Daily
Related medical conditions: Severe mental retardation, left hemiparesis

33 Mesial temporal sclerosis

HO Lüders

Already in the late nineteenth century, investigators realized that in patients with epilepsy, mesial temporal sclerosis was frequently found.[1] However, it was the development of modern neurodiagnostic techniques and the growing interest in surgery of epilepsy (particularly for patients suffering from mesial temporal sclerosis) that has greatly advanced our understanding of mesial temporal sclerosis. In spite of all these advances, there still are many unanswered questions.

Mesial temporal sclerosis is defined by its anatomical characteristics, namely gliosis and loss of neurons in the hippocampus, subiculum, parahippocampal gyrus, and inferomedial temporal cortex. Consistently the main change is seen in CA1, CA3, and hilus with relative sparing of CA2 and the granular cells of the dentate gyrus.[2] These changes are associated with typical sprouting of the dentate granular cells,[3] as well as of neuropeptide Y, substance P, and somastatin fibers.[4] Many authors consider these cellular reorganizations as an indispensable feature in the neuropathological diagnosis of mesial temporal sclerosis.

From an epileptological point of view, mesial temporal sclerosis is of special interest because of its high prevalence and its association with a relatively uniform clinical syndrome of high epileptogenicity. The high epileptogenicity of mesial temporal sclerosis is most probably related to the relatively selective loss of mossy cells in the hilus, essential for an inhibitory feedback to the main hippocampal input pathway, namely the dentate gyrus granular cells,[5] and the sprouting of the granular cells, which essentially establishes an excitatory feedback to the dentate gyrus granular cells.[3] Direct neurophysiological studies of resected tissue have actually confirmed the hyperexcitability of the granule cells as also the loss of inhibition.[6]

The characteristic clinical syndrome is mainly an expression of the fact that mesial temporal sclerosis is a highly epileptogenic lesion that affects selectively a constant region of the brain, namely the hippocampus and the immediately adjacent cortex. There certainly are other focal epilepsies also characterized by a constant pathological substrate (cortical dysplasias, heterotopias, etc.), but none of the other entities affects consistently the same anatomical region. Most of the characteristics of focal (regional) epileptic syndromes, namely semiology of the seizures and interictal and ictal EEG abnormalities, are defined by the location of the epileptogenic zone.

The abdominal aura, one of the most characteristic initial clinical semiology of seizures arising from the hippocampus, is most probably determined by spreading of the epileptogenic discharge to the closely adjacent insular cortex. In other words, as for most focal epileptogenic lesions, the epileptogenic zone and the symptomatogenic zone does not overlap. Depth recordings have shown that in patients with mesial temporal sclerosis, most of the seizures arise from the hippocampus. However, electrical stimulation suggests that the symptomatogenic area, for most of the symptoms associated with mesial temporal lobe seizures, was due to spread of the epileptiform activity to adjacent structures. Fear, the other typical aura, is most probably produced by activation of the amygdala. Other of the typical auras observed in patients with mesial temporal sclerosis are also most probably an expression of epileptogenic activation of paramesio-temporal regions (basal temporal region for psychic auras, amygdala for olfactory auras, etc). Most of the ictal as well as postictal symptoms observed in patients with mesial temporal sclerosis can also be attributed to a typical spreading pattern of seizures arising from the mesial temporal region (automatisms possibly produced by activation of the cingulate gyrus, postictal aphasia due to 'Todd paralysis' of the basal temporal and/or Wernicke's area, etc.). Certainly all the lateralizing signs seen with seizures arising from the mesial temporal region are also an expression of seizure spread with involvement of adjacent brain regions (basal ganglia for the contralateral dystonia, language areas for the postictal aphasia, ipsilateral motor strip for the contralateral version and clonic seizures, etc.).

Patients with mesial temporal sclerosis also have a typical interictal and ictal EEG, which again is just an expression of the constant localization of the epileptogenic zone to the mesial temporal region. Surface recordings show spikes and sharp waves localized primarily to sphenoidal and nasopharyngeal electrodes or in the anterior temporal–inferior frontal region (F7-F8). These surface spikes are most probably an expression of epileptiform activity in the parahippocampal cortex as opposed to hippocampal spikes itself. Spikes limited to the hippocampus, which is a closed field, are usually 'invisible' to surface electrodes. With depth electrodes, however, the main spiking is detected in the hippocampi. Ictal EEGs, when recorded with surface electrodes, tend to lateralize the seizure onset but only infrequently show localized seizure onset to the anterior temporal–inferior frontal electrodes (Sp1, Sp2, F7, F8). This is an expression of the surface electrodes' inability to detect hippocampal spikes and the relatively rapid spread of the ictal discharge once a seizure has been initiated. On the other hand, depth electrodes and electrodes placed directly on the hippocampal gyrus (foramen ovale and subdural electrodes) usually demonstrate extremely localized seizure onsets at a time when no alterations are evident when recording simultaneously with surface electrodes.

Originally published in Chapter 16, pp. 121–124, *The Epilepsies: Etiologies and Prevention*, Hans O. Lüders, The Academic Press, USA, 1999.

There are, in addition, functional alterations typical of patients with mesial temporal sclerosis that are also due to the typical location and neuropathological characteristics of the lesion in these patients, namely a relatively selective loss of neurons usually affecting, to different degrees, both hippocampi. Neuropsychological testing of patients with mesial temporal sclerosis (including particularly pre- and posttemporal lobectomy studies) has greatly contributed to our understanding of the function of the hippocampus. The results of these studies have been complemented by the Wada test and also correlation studies between neuropsychological tests and MRI or neuropathological findings. The results of all these studies show that the dominant (usually left) hippocampus is essential for anterograde verbal memory, whereas the right hippocampus is most probably related to anterograde nonverbal memory. These conclusions come from studies that observed verbal memory deficits in patients with left mesial temporal sclerosis and the degree of deficit was a function of the degree of hippocampal volume loss on MRI studies[7–9] or neuronal loss on pathological studies.[8,10] This also explains why the postsurgical deficit is most marked in those patients that had the least hippocampal atrophy presurgically, namely patients with (1) intact memory function presurgically[11–15]; (2) relatively limited atrophy of the hippocampus on MRI[16–18]; (3) limited histopathological neuronal loss,[19–22] and (4) relatively preserved memory of the temporal lobe to be resected on Wada test.[23, 24] All these studies also showed that one hippocampus can compensate for most of the functions of the contralateral hippocampus. This is the reason that resection of one hippocampus, if the other hippocampus is relatively intact, leads only to mild to moderate memory deficits. On the other hand, it is well known that bilateral lesions of the hippocampus (e.g., herpes encephalitis) consistently produces devastating anterograde memory deficits.[25–27]

It is clear from this discussion that mesial temporal sclerosis is a focal epileptic syndrome that presents an unusually stereotyped clinical picture because the underlying pathology is extremely constant and it consistently affects the same neurological substrate (hippocampus and immediately adjacent cortex). However, it is unlikely that mesial temporal sclerosis is the consequence of a single etiology, the indispensable criterion to classify it as a disease. There is extensive evidence in the literature that the hippocampi are easily damaged by a variety of noxious stimuli. Patients with mesial temporal tumors or hamartomas usually have a mild degree of mesial temporal neuronal loss attributed to the excitotoxic effect of hippocampal seizures. This conclusion is supported by evidence that generalized, or focal status, in adults may induce swelling and eventually may lead to mesial temporal sclerosis.[28,29] It has also been shown that patients with mesial temporal sclerosis (shown on pathological studies or by MRI) have a significant higher incidence of febrile convulsions[30–34] and that mesial temporal sclerosis occurs more frequently in patients who had suffered febrile convulsions.[35,36] This evidence again suggests that the febrile convulsions itself could have led to damage of the hippocampus, perhaps by a mechanism of excitotoxicity. However, we should not forget that mesial temporal sclerosis occurs in a high percentage of patients (close to 70%) with no evidence of febrile convulsions. This again suggests that mesial temporal sclerosis is just the 'final pathological pathway' to a number of different hippocampal insults.

The hypothesis that mesial temporal sclerosis is not a unique disease with a single etiological factor is further supported by the observation that meningitis can frequently lead to mesial temporal sclerosis in children. These studies also suggest that the hippocampus is particularly susceptible to the excitotoxic effects of seizures in children of less than 5 years of age,[37–39] corresponding with, a period during which the hippocampus grows rapidly and, there-fore, may be particularly vulnerable. This special susceptibility of the immature brain to damage has also been proven experimentally by Wasterlain and Plum[40] and Hattori and Wasterlain.[41]

Summarizing, focal epileptic syndromes are currently classified according to the location of the epileptogenic zone. However, patients with an epileptogenic zone in a similar brain structure frequently present with very dissimilar epileptic syndromes because many etiologies can produce epileptogenic zones in a similar or identical brain region. Mesial temporal sclerosis, however, not only affects a clearly defined set of neurons but is associated with an extremely uniform pathological picture. Growing evidence in the literature suggests that mesial temporal sclerosis is the result of excitoxicity to hippocampal neurons at a relatively young age (less than 4–5 years). This explains why these patients frequently have a history of febrile convulsions or another illness associated with convulsions at a young age, followed then by a 'silent period' of 5 to 10 years before the actual seizures emerge. A better understanding of the pathogenesis of mesial temporal sclerosis will be essential to eventually prevent the occurrence of such a frequent and devastating disease.

34 Neocortical temporal lobe epilepsy

A Ebner

Introduction

Temporal lobe epilepsy is usually divided into two different forms, depending on from which part of the temporal lobe the seizures actually originate. The division into mesial temporal lobe epilepsy (MTLE) and neocortical temporal lobe epilepsy (NTLE) is especially important since each of these epilepsies requires a distinct surgical strategy.

Compared to MTLE in which the seizure origin is rather circumscribed and essentially confined to the mesial structures, seizures in NTLE may arise from many different foci. Therefore, NTLE resembles other neocortical extratemporal focal epilepsies.

Historically, the concept of a distinct syndrome of NTLE has developed over recent decades, essentially based on the increasing interest in surgical treatment of intractable focal epilepsies of temporal lobe origin. The distinction between mesial and lateral temporal lobe epilepsies has been made possible through the availability of detailed analyses of seizure symptoms stored on video, together with surface and invasive EEG recordings, as well as the increasingly higher resolution of structural imaging techniques. The most convincing proof of the existence of lateral temporal lobe epilepsy is the successful resection of a neocortical temporal focus leading to seizure freedom.

Anatomy of the temporal neocortex

Figure 34.1 shows the distribution of various types of cortices found in the medial and lateral part of the temporal lobes adapted from Engel.[1]

The medial temporal lobe comprises several neural structures, such as the amygdala; the hippocampus together with the adjacent entorhinal and perirhinal cortex; and the parahippocampal cortex, also called the paralimbic areas, including the temporopolar cortex (area 38 from Brodman). Bordering the paralimbic areas are the inferior temporal gyrus containing Brodman area 20 in its anterior and middle part, and area 37 lying in the temporo-occipital junction. Areas 20 and 37 belong to modality-specific association areas. Between the entorhinal area and the inferior temporal gyrus, a strip of high-order association cortex (Brodman area 36) is located.

The medial temporal gyrus with Brodman area 21 also represents modality-specific association cortex. A second strip of high-order association cortex (Brodman area 36) is located between the middle and the superior temporal gyrus. The superior temporal gyrus contains the primary auditory cortex (Heschl area) with the medial transverse temporal area (Brodman area 41) and the lateral transverse temporal area (Brodman area 42). The other part represents a modality specific association area (Brodman area 22).

Functional anatomy

The main functions ascribed to different regions of both temporal lobes are depicted in Figures 34.2 and 34.3 (adapted from refs 2 and 3). These functions comprise verbal and nonverbal memory, emotional behavior, smell, and hearing.

Semiology of seizures arising from temporal neocortex

Aura

The content of auras in NTLE is produced by ictal activation of functional cortex in which the seizure originates. An auditory aura, for example, is the consequence of ictal activation of the primary or secondary auditory cortex and may indicate that seizure onset is in the Heschl area. However, it is also possible that the seizure origin is in a silent cortical area and spreads from there to the auditory cortex where it produces the first clinical symptom. Thus, the presence of an auditory (or any other sensory) aura always has to be interpreted cautiously in terms of localizing the seizure onset zone. In addition, it is important to be aware of the possibility that seizure activity, especially with neocortical origin, may spread very rapidly, leading to almost simultaneous co-activation of more widespread areas including mesial temporal structures. Thus experiential phenomena, as they were called by Penfield and Jasper, may not be specific for the lateral temporal neocortex. Rather, as was proposed by Gloor,[4] reciprocal connections between the limbic structures and the temporal isocortex have to be activated in order to obtain these phenomena. This has also been proposed by Blume *et al.*,[5] who concluded that ictal experiential phenomena represent simultaneous epileptic discharges of the temporal neocortex and the limbic system.

Types of auras reported in NTLE

Auras described in NTLE depend on the functional areas being activated at seizure onset or early during a seizure. According to the functional anatomy shown in Figures 34.2 and 34.3, several types of experiential or psychical auras[6] may occur due to activation of the memory system and, the auditory system, or the visual system.

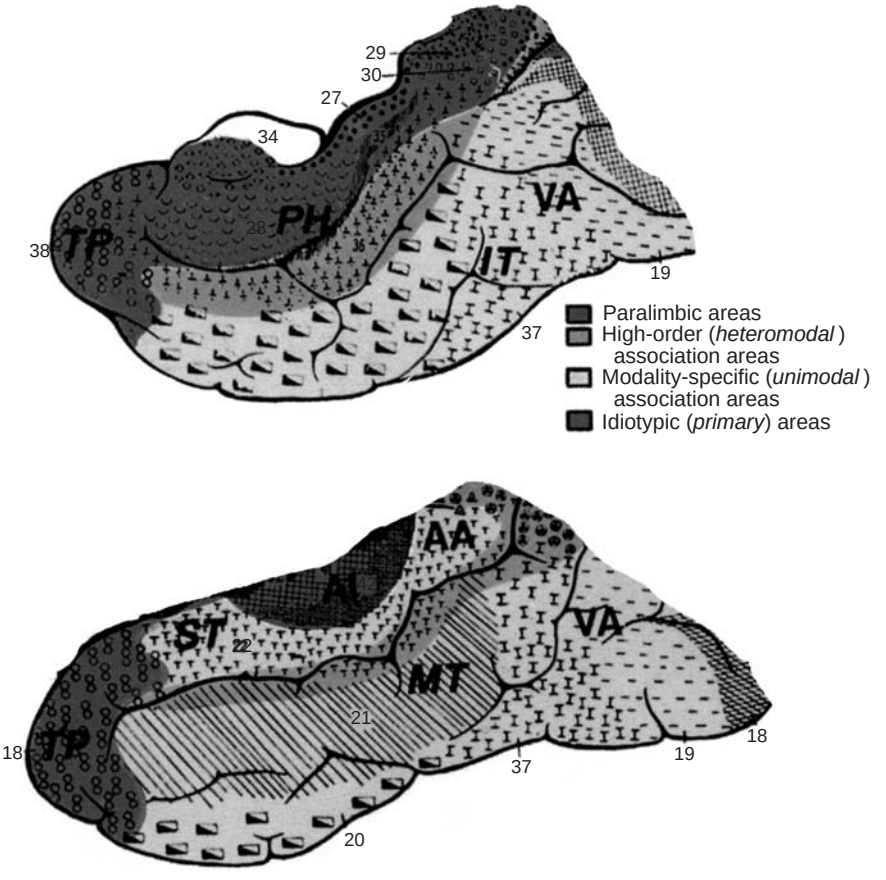

Figure 34.1 Medial (top) and lateral aspect of temporal lobes showing the supposed distribution of paralimbic (green), high-order (pink), modality-specific (yellow), and idiotypic or primary (blue) areas. This information is mainly based on experimental results in animals. AI: primary auditory cortex, AA: auditory association cortex, IT: inferior temporal gyrus, MT: medial temporal gyrus, ST: superior temporal gyrus, TP: temporopolar cortex, PH: parahippocampal area, VA: visual association cortex. The numbers indicate cytoarchitectonic areas following Brodman's map of the human brain (from Engel 1989, with permission). (See Color plates.)

These consist of memory illusions (*déjà vu, jamais vu, déjà entendu, jamais entendu*, feeling of strangeness) and memory hallucinations (memory flashbacks, dreams of past). Auditory auras can occur as unformed hallucinations (ringing, buzzing, chirping, machine-like) or as more elaborate sounds (voices, music). Auditory illusions can be perceived as advancing or receding, louder or softer, clearer or fainter sounds. Visual hallucinations originating in the posterior temporal association cortex consist of the perception of scenes, objects or faces. Illusions may occur as macropsia, micropsia, seeing objects nearer or farther, clearer or blurred.

Several reports support the assumption that patients with NTLE have different types of auras when compared with patients with MTLE. Maillard *et al.*[7] investigated 187 stereoencephalography-recorded seizures of 55 patients who were classified into three groups according to their electrophysiologic findings. There were 24 patients whose seizure onset was in the mesial temporal structures, 13 in the lateral temporal cortex, and 18 patients in both medial and lateral temporal areas. Auditory and other sensory hallucinations or illusions occurred significantly more often in the lateral group and viscerosensory and emotional auras in the medial group. However, with the exception of fear and dreamy states, which were not seen in the lateral group, all other auras also occurred in all three groups.

Gil-Nagel and Risinger[8] compared a group of 16 patients with hippocampal seizure onset (proven by seizure freedom after surgery) with a group of 19 patients with extrahippocampal temporal seizure onset. In the first group, 13 patients reported one of the following auras: five reported epigastric auras, three fear, two smell, two somatic, and one gustatory. In the NTLE group 11 patients reported auras mostly of the psychical type, none reported epigastric or emotional auras. Pfander *et al.*,[9] on the contrary, found a relatively high number (33%) of epigastric auras in a group of 36 patients with NTLE.

O'Brian *et al.*[10] found no statistically significant differences in the incidence or nature of auras in a group of 31 patients with MTLE compared to 15 patients with NTLE.

The difference might be explained by different patient populations studied. Psychical auras are more common in patients suffering from NTLE but they are in no way specific to NTLE. In our series of 14 patients with circumscribed lesions affecting the temporal neocortex as revealed by MRI (neocortical temporal lobe epilepsy group: nTLE, Figure 34.4a, b), significant differences were found in auditory/visual auras and epigastric auras: auditory/visual auras were more frequent in the nTLE and epigastric auras more frequent in the mTLE group consisting of 18 patients who were seizure free after temporal lobectomy (Figure 34.5). There was no difference between the two groups regarding other auras (memory illusions, fear, gustatory or none).[11]

Seizure semiology

Epileptic auras occur isolated, i.e., stop before other seizure symptoms follow, or progress to seizure signs that can be observed and analyzed when recorded on video. Many ictal motor manifestations have been described, such as version, clonic and tonic activity, unilateral epileptic spasms, dystonic posturing and unilateral automatisms, automatisms with preserved responsiveness, ictal spitting and vomiting, emotional facial asymmetry, unilateral eye blinking, ictal nystagmus, and akinesia. Furthermore, loss of consciousness, ictal language manifestations and postictal features, such as Todd's palsy, postictal aphasia, postictal nosewiping, postictal memory dysfunction, as well as peri-ictal water drinking, peri-ictal headache, and ipsilateral tongue biting have been analyzed.[12]

Several studies addressed the question whether seizures arising from temporal neocortex exhibit ictal signs that can help to differentiate them from seizures originating in other regions of the brain, most specifically the mesial temporal region.

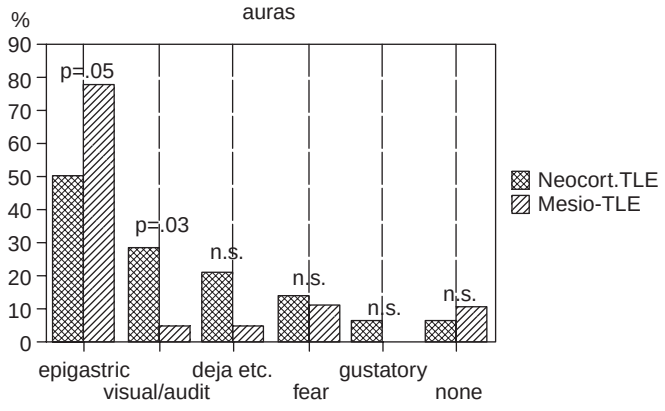

Figure 34.5 Comparison of the frequency of auras reported in the mesial and neocortical TLE group. Only epigastric and visual/auditory auras showed a significant difference (Fisher's exact test).[11]

In the study of Maillard *et al.*[7] only initial loss of contact, shorter duration, and more frequent generalizations were associated with neocortical temporal lobe seizures, whereas other investigated signs (oro-alimentary automatisms, vocalizations, verbal automatisms, upper limb automatisms, upper-limb tonic posturing, head and/or eye deviations) when occurring early or late during the seizures were either observed significantly more frequently in seizures of mesial temporal origin or did not show any difference between NTLE or MTLE.

Gil-Nagel and Risinger[8] found that early oral automatisms were significantly more frequent in MTLE than NTLE, whereas early motor involvement of the contralateral upper extremity without oral automatisms occurred significantly more often in NTLE. No difference between NTLE and MTLE was found in arrest reaction, vocalization, speech, facial grimace, postictal cough, late oral automatisms, and late motor involvement of the contralateral arm and hand.

Pacia *et al.*[13] found a motionless stare at ictal onset the most common behavioral manifestation in NTLE.

Pfander *et al.*[9] observed early clonic activity following automatisms significantly more frequently in NTLE.

Holl *et al.*[14] investigated 80 seizures (51 MTLE and 29 NTLE) of 30 patients (20 MTLE and 10 NTLE) with regard to dystonic posturing of the upper limb. Ictal dystonia was subdivided into different subtypes according to distinct clinical features. Their frequency and latency from the clinical onset of seizure were assessed. Frequencies of all subtypes were similar in MTLE and NTLE. Concerning the latencies, contralateral dystonic posturing characterized by sustained muscle contractions with flexion of the wrist and fist closure occurred significantly earlier in NTLE than in MTLE seizures.

Dupont *et al.*[15] reviewed the videotapes of 60 patients with well-defined MTLE, NTLE, or both to assess the presence and the localizing value of unilateral dystonic posturing associated with motor automatisms. Twenty-eight of the 60 patients exhibited unilateral dystonic posturing. This sign was observed in patients with MTLE and NTLE. It was mostly contralateral to the seizure focus in patients with MTLE and exclusively ipsilateral in patients with NTLE. Unilateral motor automatisms occurred in 26 of the 60 patients with MTLE or NTLE. It was predominantly ipsilateral to the seizure focus in patients with MTLE and exclusively contralateral in patients with NTLE. The association of ipsilateral motor automatisms and contralateral dystonic posturing was found in 14 patients with MTLE but in none of the patients with NTLE. Two patients who had medial and neocortical seizure onset also exhibited this clinical feature. The authors concluded that the association of ipsilateral motor automatisms and contralateral dystonic posturing may help to differentiate MTLE from NTLE with a reliable lateralizing value.

Contralateral motor automatisms were described by Mirsattari *et al.*[16] in a patient with right temporal neocortical seizures. The authors concluded that early onset unilateral motor automatisms without dystonic posturing can localize the seizure origin to the contralateral temporal lobe neocortex.

In our own study,[11] there was no difference in clinical ictal symptoms when patients with NTLE were compared to patients with MTLE (Figure 34.6).

The literature about clinical semiology in neocortical temporal lobe seizures shows heterogeneous results, sometimes with contradictory findings. Most studies compared seizures arising from the temporal neocortex with seizures of mesial temporal origin due to hippocampal sclerosis or other mesially located etiologies. At best, what can be concluded from the above cited publications is that experiential auras with auditory and visual content, early behavioral arrest, and rapid generalization may speak in favour of a neocortical seizure origin although this is, by far, not a common finding in all studies reviewed. Ictal symptoms of seizures arising in the mesial temporal structures exhibit a rather uniform pattern, especially when the sequence of symptoms and signs is regarded.[17]

Theoretically, neocortical temporal lobe seizures may arise from numerous foci with clinical symptoms and signs reflecting the functional properties of the activated area(s) as well as the different possibilities of spread that are predetermined by the cortico-cortical and cortico-subcortical connections.

Etiology of neocortical TLE

In the Epilepsy Surgery Program Bethel 910 patients received resective surgery between 1991 to April 2002. Among those, 610 patients (67%) had temporal lobe resections of which 60% had pure mesial temporal lobe surgery due to hippocampal

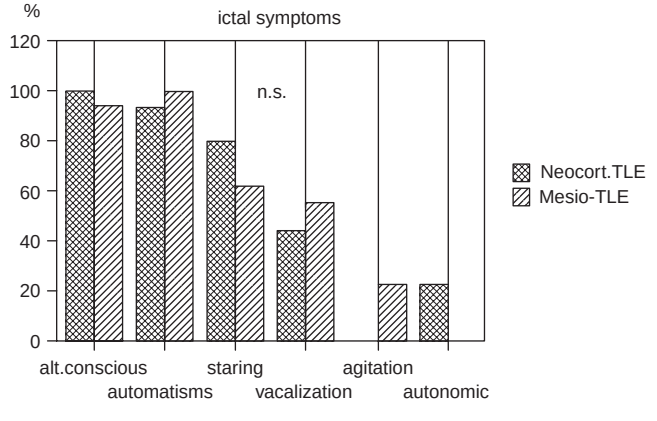

Figure 34.6 Comparison of the frequency of ictal symptoms observed in the mesial and neocortical TLE group. There is no significant difference between the two groups (Fisher's exact test).[11]

sclerosis and another 122 (20%) had other mesially located etiologies. There were 122 patients (20%) who had neocortical temporal resection without mesial structures (unpublished data).

Tumors of benign dignity such as gangliogliomas, dysembryoplastic neuroepithelial tumors or neurocytomas, vascular malformations (mostly cavernomas), and malformations of cortical development are among the most frequent chronic structural abnormalities found in neocortical temporal lobe resections.[18]

Figures 34.7 (a–f) show examples of different lesions in the MRI scans. Other etiologies encompass posttraumatic and postinflammatory defects.

Extrahippocampal temporal lesions may coexist with hippocampal sclerosis, a finding which is called dual pathology. It is not clear whether hippocampal sclerosis is the consequence of ongoing epileptic activity originating from a neocortical focus or a coincidental concurrence. Whenever this constellation is found in a patient it creates diagnostic problems when surgery is regarded. The following case should demonstrate this.

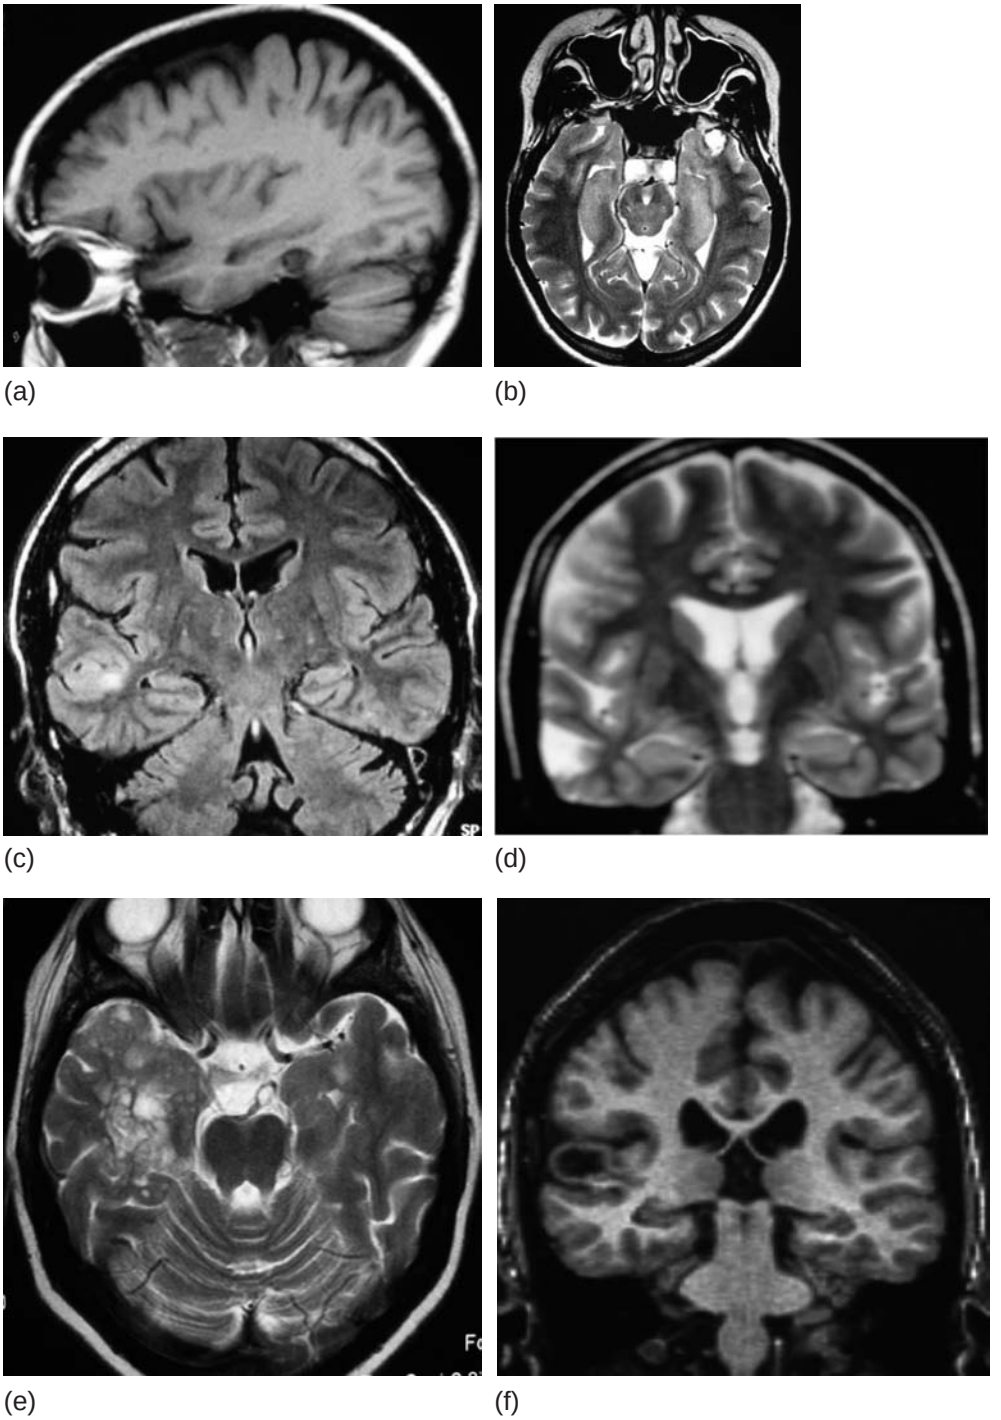

Figure 34.7 Examples of various histologically proven lesions found in patients with neocortical TLE located in different regions of the temporal lobes: (a) cavernoma in the right inferior temporal gyrus; (b) cavernoma in the left temporal pole; (c) focal cortical dysplasia in the right medial temporal gyrus; (d) post-traumatic defect in the right middle temporal gyrus; (e) dysembryoplastic neuroepithelial tumor affecting mainly the right inferior temporal gyrus; (f) gangliocytoma in the right superior temporal gyrus.

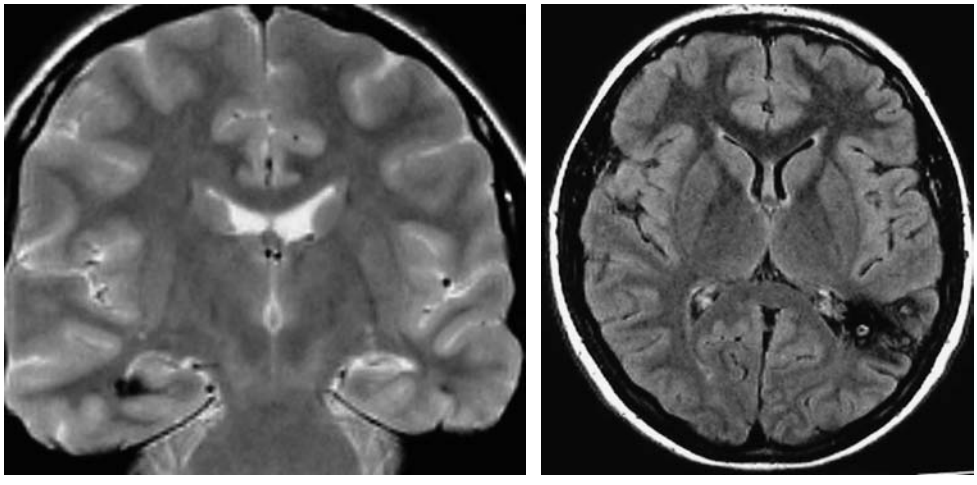

Figure 34.8 Coronal (left) proton density MRI showing the right subhippocampal cavernoma and the left sided hippocampal sclerosis, and axial FLAIR image showing a large left posterior temporal cavernoma.

Case report

A 19-year-old girl suffered from epilepsy since she was 6 months old. Until the age of 15 she occasionally complained about epigastric sensations before seizures, accompanied by loss of consciousness, heavy breathing, and stiffening of the right leg. She had an average of four seizures a month and she failed three first line AEDs before preoperative evaluation was carried out. The neurological examination was normal; her intellectual functions were above average. Her MRI revealed three lesions (Figure 34.8), the largest a cavernoma at the left posterior temporal area, the second a left-sided hippocampal sclerosis, and the third a cavernoma located immediately under the right hippocampus, which was otherwise normal.

During intensive EEG Video Monitoring over 5 days, three of the habitual seizures were recorded. Interictal EEG showed sharp waves over the left temporal region with a phase reversal either at the left sphenoidal electrode (Figure 34.9a) or at electrode T7 (Figure 34.9b) indicating that the maximum negativity of the interictal discharges occurred at the mesiobasal or the temporal lateral region.

Ictal EEG consistently started with low voltage fast activity over the left hemisphere maximal at the posterior electrodes (Figure 34.10a) then evolved into a rhythmic 4–5Hz theta pattern over the left temporal region (Figure 34.10b).

Intracarotid amobarbital test and fMRI for language revealed that the right hemisphere was dominant for speech and memory (Figure 34.11).

Mainly based on the ictal EEG showing a seizure pattern unusual for mesial TLE but in favor of a neocortical left temporal origin an extended lesionectomy of the left posterior vascular malformation guided by intraoperative electrocorticography was carried out.

The patient has been seizure free for 2 1/2 years despite bitemporally located lesions (see Figure 34.12 corresponding to preoperative MRI and Figure 34.12 showing the postoperative MRI scans).

Electrophysiology of neocortical TLE

As was shown in the case report, surface EEG can provide essential information regarding the seizure origin in some patients. Although there is certainly an overlap in interictal and ictal EEG findings in patients suffering from MTLE and NTLE, interictal epileptiform activity in MTLE usually shows a predominance of discharges at the anterior temporal or sphenoidal electrodes and less often at the mid-temporal or posterior temporal electrodes. Pfander *et al.*,[9] and O'Brien *et al.*[10] investigated electroclinical differences in patients with NTLE and MTLE. Regarding the EEG findings, they found no difference in the interictal EEG. There was an increased frequency of fast rhythmic sharp waves (>4 Hz) in the ictal-EEG of MTS patients (mean 81% vs 60%, $P = 0.05$). The patients with NTLE developed bilateral ictal EEG changes more often (mean 55% vs 26%, $P < 0.05$) and more rapidly (mean 23s vs 74s, $P < 0.005$). The onset of ictal EEG seizure activity was bilateral more often in patients with NTLE (20% vs 4%, $P < 0.005$). There were no significant differences between the two groups for any of the video-EEG features, in terms of whether or not the feature occurred at least once in an individual patient. They concluded that there are a number of clinico-electrical differences between patients with mesial MTLE and patients with NTLE, but that none of these are sufficient to allow a distinction to be made in an individual patient. Foldvary *et al.*[20] found a lower mean frequency of lateralized rhythmic activity (LRA) in NTLE ictal EEG recordings that frequently had a hemispheric distribution, whereas LRA in MTLE seizures was maximal over the ipsilateral temporal region. They concluded that it may be possible to differentiate lesional NTLE from MTLE on the basis of historical features, seizure symptomatology, and ictal surface EEG recordings.

In summary, interictal and ictal surface EEG are important to prove (or disprove) the epileptogenicity of a structural abnormality in the temporal neocortex in patients with epilepsy. Some EEG features are more in favor of a neocortical

seizure origin and it might help to place invasive electrodes in patients without an MRI-visible lesion in order to clarify the situation.

Prognosis

The postoperative outcome in patients with NTLE due to MRI visible lesions is as good as in patients with MTLE. Patients with clearly identified nonlesional NTLE who were operated on and became seizurefree postoperatively are probably rare and nonexistent in the Bethel series comprising more than 1500 operated cases.

Two recent studies have investigated prognostic factors in NTLE. In the study of Janszky *et al.*,[19] more than two-thirds of the patients with NTLE became seizure-free postoperatively. Lateralized/localized EEG seizure pattern and tumors on the MRI were associated with postoperative seizure-freedom, while focal cortical dysplasias (FCD) were associated with a poor outcome. The 6-month postoperative outcome was a reliable predictor for the long-term outcome. Yun *et al.*[31] found that the presence of a focal lesion on MRI, correct localized hypometabolism on FDG-PET, or localized ictal rhythms on EEG are predictors of a seizure-free outcome.

35 Premotor and central lobe epilepsy

S Bauer, HM Hamer, and F Rosenow

Anatomy

Structural anatomy

Premotor cortex is part of the lateral frontal lobe, which extends from the central sulcus to the frontal pole. Its upper and lower limits are the fissura longitudinalis and the sulcus lateralis, respectively. The surface is formed by the gyrus precentralis between central and precentral sulcus and the superior, medial and inferior gyrus frontalis, which are divided by the superior and inferior frontal sulcus. The inferior frontal gyrus again is subdivided into the triangular, orbital, and opercular part.

The lateral surface of the *central lobe* consists of gyrus precentralis and postcentralis, which are located between sulcus precentralis and postcentralis and divided by the sulcus centralis. The mesial part of the central lobe consists of the lobulus paracentralis between the precentral sulcus and the ramus marginalis of the cingulate sulcus.

Microanatomically, the frontal lobe cortex is part of the neocortex. Therefore, its cortex consists of six neuronal layers. Brodmann subdivided and numerated 52 areas of different cytoarchitectural patterns.[1] Considerable variability has been found in the extent of cytoarchitectonic areas in relation to macroanatomical landmarks, especially in the premotor region.[2–4] Cytoarchitectonic findings and their relationship to gyri and sulci connect the structural anatomy to localization of cortical functions as described below.

Functional anatomy

The *central lobe* contains the somatotopically organized primary *motor and sensory cortex* (Brodmann area 4 and 3, respectively). Historically, the sulcus centralis was thought to be the border between motor and sensory areas,[5] but more recent studies suggested both motor (tonic or clonic and 'negative motor', i.e., motor arrest) and sensory responses after electrical stimulation of the gyrus precentralis as well as in gyrus postcentralis.[6]

In primates, central lobe neurons receive their main input from thalamus and secondary motor and sensory regions, while their efferences form a considerable part of the pyramidal tract: 30–50% of the pyramidal tract fibers arise from primary motor and around 25% from primary sensory cortex. These neurons control kinematic and dynamic parameters of movement rather than single muscles.[4]

The *lateral frontal cortex* is usually subdivided in *premotor* and *prefrontal* cortex.[7]

The *premotor cortex* contains the secondary motor area (Brodmann area 6 in the posterior parts of the frontal gyri), the frontal eye field (Brodmann area 8 at the intersection of sulcus precentralis and superior frontal sulcus) and Broca's language region (Brodmann areas 44 and 45 at the opercular and triangular parts of the inferior frontal gyrus in the dominant hemisphere).

In primates, the secondary motor area is organized roughly somatotopically, receives input from thalamus, primary motor cortex and parietal lobe and sends projections to the spinal cord, the superior colliculus, and the reticular formation. It is involved in planning and controlling movements in response to somatosensory and visual information.[4]

The frontal eye field (Brodmann area 8) is located at the intersection of sulcus precentralis and superior frontal sulcus.[8] Its main function is the control of intentional saccades. Therefore, it receives input from occipital and parietal lobe.

Broca's language area (Brodmann areas 44 and 45) is located at the opercular and triangular parts of the inferior frontal gyrus in the dominant hemisphere.[2] Connections with Wernicke's temporal speech area and primary motor cortex are necessary for its function in speech production.

The supplementary sensorimotor are a (SSMA) also belongs to the premotor cortex and is located in the mesial frontal lobe.

The lateral frontal lobe surface between premotor cortex and frontal pole is sometimes referred to as *prefrontal cortex*. Its function is only vaguely defined and covers executive control, monitoring in working memory, learning, temporal structuring of behavior and control of behavior by context.[9] Few specific regions were identified which were recruited by different demands indicating a prefrontal network involved in solution of diverse cognitive problems.

Epidemiology

Data on incidence and prevalence of frontal lobe epilepsy (FLE) differ widely between general population, patients referred to epilepsy centers, and surgical series. Additionally, various criteria of estimating the location of the epileptogenic zone are used which hampers comparison of study results.

Population-based studies

In 594 patients with newly diagnosed epilepsy, 42% were found to suffer from partial epilepsy.[10,11] In this patient group, the *symptomatogenic zone* was localized as follows:

- primary motor cortex 12%
- primary sensory cortex 4%

- overlapping (motor and sensory) central regions 8%
- one or more frontal regions anterior to the primary motor cortex 14%
- frontotemporal 4%
- (together: 42%).

However, EEG and CT results revealed a strong variance with the seizure semiology in 20% of the patients. This shows the limited value of seizure semiology as single feature for localization of the epileptogenic zone. Reasons for overestimation of frontal lobe epilepsies defined by seizure semiology might be the large extension of eloquent cortex in the frontal and central lobe and the impressive presentation of motor signs in the course of seizures compared to more subtle symptoms of seizures that start in other cortical areas.

Another population-based prospective study[12] used seizure semiology, EEG, and imaging results for classification of epilepsy syndromes according to ILAE criteria.[13] Of 1,016 patients with newly diagnosed epilepsy, 43% suffered from either symptomatic or cryptogenic partial epilepsy. Of those, 26% had frontal lobe epilepsy and 5% parietal lobe epilepsy which included the postcentral part of the central lobe.

In general, the frontal or central lobe appear to be involved in 30–40% of all newly diagnosed partial epilepsies.

Hospital-based studies

Patients with extratemporal epilepsies might be referred less frequently to presurgical video-EEG monitoring compared to temporal lobe epilepsies due to unclear results in seizure semiology and interictal EEG and MRI findings that make eligibility for surgery difficult. Frontal lobe epilepsy was found in 10–27% of adult patients[14–17] and in 18–21% of children[18–20] who were referred to epilepsy centers.

Using a newly-proposed five-dimensional epilepsy classification [21] instead of the ILAE classification, the epileptogenic zone was found to be localized in the frontal lobe in 4% and in the perirolandic area in 3% of 94 randomly selected adult patients of a tertiary epilepsy center; in 7% of 91 children the epileptogenic zone could be localized to the perirolandic area and no child with frontal lobe epilepsy was identified.[22] The differences with previous evaluations may reflect the influence of various classification systems on assessing the diagnosis.

Surgical series

Underrepresentation of frontal lobe epilepsy in surgical series might occur due to the same reasons as stated for presurgical monitoring. A serial of 2177 patients who had undergone epilepsy surgery stated central lobe epilepsy in 7% and epilepsy of (remaining) frontal lobe in 18%.[23] Another study included 124 consecutive patients and found frontal lobe epilepsy in 15% of the patients.[24]

Etiology

Brain tumors

Of all patients with brain tumors, 25–75% develop seizures.[25,26] Infiltrating well-differentiated tumors localized in the forebrain have the highest risk to be accompanied by seizures.[25] Frontal lobe involvement was accompanied by a high epilepsy risk of 40–45%. Patients with tumors involving both frontal and parietal lobe (therefore including central lobe) showed seizures in 58% of the cases.

Presurgical and surgical series of patients with extratemporal neocortical[27] or frontal lobe[23,28–31] epilepsy reveal an incidence of brain tumors of 13–35%. In particular, astrocytoma was found in 10% (with higher incidence of low grade tumors), ganglioglioma in 5–10%, oligodendroglioma in 3–10%, and dysembryoplastic neuroepithelial tumor (DNET) in 1–5% of all frontal lobe epilepsy patients. In other surgical series, 15–30% of DNET were found to be located in the frontal lobe.[32,33]

Focal cortical dysplasia (FCD)

FCD are cortical lesions that contain architectural abnormalities like dyslamination, immature or giant neurons, balloon cells of neuronal or glial origin, and/or dysmorphic neurons. In frontal lobe epilepsy, cortical malformations were found in 20–84%[18,28–31,34,35] and are associated with positive family history of seizures, lower IQ, neurological deficits, multiple seizure types of early onset, and frequent status epilepticus.[36] A series of 14 consecutive children <7 years with frontal lobe epilepsy revealed FCD in all cases.[37] These data were consistent with earlier seizure onset in patients with FCD compared to other etiologies.[28]

FCDs can be divided into two subclasses: type 1 without dysmorphic neurons or balloon cells, and type 2 containing dysmorphic neurons and/or balloon cells ('Taylor-type FCD').[38] Type 1 FCDs were found to be located frequently in the temporal lobe while type 2 tends to occur more often extratemporally, especially in frontal and central lobes.[39] Patients with FCD type 2 have a higher seizure frequency.[40]

Vascular malformations (VM)

Vascular malformations include arteriovenous malformations (AVM), cavernomas, teleangiectasias, and venous malformations and occurred in 7–15% of patients with frontal lobe epilepsy.[30,31,41]

Arteriovenous malformations (AVM) were detected in 6% of frontal lobe epilepsies.[28]

About 20–40% of all supratentorial cavernomas are located in the frontal lobe.[42–44] 25–80% of cavernoma patients develop seizures[42,43,45]; accordingly, in 9% of FLE patients cavernomas were found.[28] Frontal lobe cavernomas presented less frequently with seizures than temporal lobe cavernomas did (45% vs. 70%).[44] Compared to other locations, frontal lobe cavernomas might have a higher probability of causing generalized seizures.[43]

Venous malformations and dural AVM do no seem to cause seizures.[45]

Genetic causes

There are two types of idiopathic focal epilepsies related to frontal or central lobe: Benign epilepsy with centro-temporal spikes (BECTS) and autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE).

ADNFLE is genetically heterogeneous and can be caused by mutations of genes coding for subunits of the neuronal nicotinic acetylcholine receptor.[46] BECTS has been classified as idiopathic (and therefore with a presumed genetic etiology) by the ILAE[13]; however, the lack of concordance in twin studies makes the classification doubtful.[47]

Other etiologies

Other etiologies include gliosis, e.g., due to head trauma (11–28% [23,28–30]), postinflammatory scars (up to 10%[23]), and birth trauma (up to 8%[23]). Frontal lobe arachnoid cysts were detected in 4 of 867 epilepsy patients (0.5%), but only 1 of the cysts was located near the irritative or seizure onset zone[48] which makes their relationship with epilepsy unlikely.

In up to 20% of frontal lobe epilepsy cases, no underlying pathology can be found.[23,29]

Diagnostic evaluation

Determination of the symptomatogenic zone–Seizure semiology

Most clinical studies concerning seizure semiology in frontal lobe epilepsies estimate location of the epileptogenic zone by defining the symptomatogenic, irritative, or seizure onset zone as well as epileptogenic lesion and may therefore include patients with epileptogenic zones outside frontal or central lobe, whereas studies of patients who became seizure free after frontal lobe resection are not representative for the group of patients who can be treated nonsurgically.[35] Moreover, many studies do not distinguish between certain regions of frontal lobe.

According to functional anatomy described above, *central lobe* seizures may be accompanied by focal somatosensory auras and focal motor signs:[49,50]

- *Focal somatosensory auras* are specific for involvement of central lobe. On the other hand, nonspecific auras occur in the majority of patients with frontal lobe epilepsy.[29,51]
- *Focal motor signs* contain *tonic, dystonic, clonic* and *complex motor* symptoms. Asymmetric tonic limb posturing occurs more frequently during seizures with temporal onset than in frontal lobe seizures.[7] Using EMG and subdural EEG electrodes, it has been shown that clonic seizures are preceded by a tonic phase which is sometimes too short to be recognized clinically.[52] Repetitive EEG spiking in primary motor areas during the initial tonic phase is followed by spike wave complexes and synchronous clonic contraction of both agonistic and antagonistic contralateral muscles. EEG spiking matches muscle contractions whereas relaxation occurs synchronized with EEG slow waves.

Seizures involving the lateral *premotor cortex* may present with the following symptoms:[49,50]

- *Contralateral version* that precedes secondary generalization in half of the seizures.[53,54]
- Version has to be distinguished from the rarer nonforced *head-turning* of unknown pathophysiology without any clonic or pronounced tonic component which frequently appears at seizure onset.[53] Both forms can appear successively in the same seizure.
- *Aphasia, dysphasia or vocalization* may occur if Broca's language area is involved. Pure vocalization other than those caused by cloni or apnea sound was seen in 40%.[55] Another study of 26 FLE patients reported articulate vocalization with uttering of words or swearing in 31%, while 42% of the patients produced other sounds.[56] Surprisingly, prolonged postictal dysphasia occurred in less than 10% of 118 complex partial frontal lobe seizures of 24 patients.[57] The dysphasia was of short duration even if the seizure onset zone was located in the dominant hemisphere; on the other hand, seizures starting in the frontal lobe of the dominant side and spreading to the ipsilateral temporal lobe caused long-lasting postictal dysphasia in >90%. Low distance between seizure onset zone and anatomical location of Broca's speech area (determined by electrical cortical mapping) did not correlate with appearance of postictal language disturbances. This finding suggests a disruption of temporal speech networks rather than direct influence on cortical speech areas as the cause for dysphasia.

  Seizures involving *prefrontal cortex* can present with *complex motor seizures* including automotor, hypermotor and gelastic seizures.[58]
- *Hypermotor seizures* (complex movements involving trunk and proximal limb segments, e.g., bicycling movements, as well as screaming, jumping, running around, or aggressive sexual automatisms), which are considered to be specific for frontal lobe epilepsy with special relation to lesions of frontopolar and orbitofrontal cortex,[49] occur frequently at night and tend to cluster.[29] It can be difficult to distinguish hypermotor seizures from psychogenic seizures. Behavioral symptoms like mood change, unexpected quietness, subtle change of awareness or awakening are other features of prefrontal seizures.[59] Unlike seizures involving primary motor or sensory areas, the complex semiology of prefrontal seizures may be caused rather by disruption of neuronal synchrony between different brain regions than by excitation of single cortex areas (Table 35.1).[60]

Cluster analysis of seizure evolution

Because the described seizure semiology usually does not occur isolated, the analysis of characteristic clusters has be performed.[49] Three seizure patterns have been found to be of localizing value in lateral frontal or central lobe epilepsy:

- Somatosensory aura with or without Jacksonian march, often followed by tonic posturing and head version or clonic seizures (*Video*). Automatisms and vocalization are rare in this seizure pattern. As expected, there is a strong association with central lobe lesions.
- Focal (tonic-)clonic seizures with Jacksonian march without secondary generalization, usually accompanied by ipsilateral head version and followed by postictal paresis. This seizure pattern is also associated with central lobe lesions.
- Version or posturing occurring early during the seizure evolution, frequently followed by other motor manifestations like simple automatisms. This seizure sequence is associated with lesions of the premotor cortex.

Table 35.1 Frequency and lateralizing value of some seizures symptoms and signs in lateral frontal lobe epilepsy

Symptom	Frequency in patients with lateral FLE	Lateralizing value (positive predictive value)	Literature
Postictal headache	41–53%	None (in contrast to temporal lobe epilepsy)	61,62
Unilateral tonic posturing	37–48%	Contralateral (67–100%)	50,54–56,63
Vocalization	37–77%	Probably none (contradictory data)	54,55
Postictal paresis	27–37%	Contralateral (100%)	29,54
Unilateral clonic seizure	23–37%	Contralateral (83–100%)	29,50,54,64
Head-version	22–60%	Contralateral (66–100%)	29,50,53,54,56,64
Complete loss of consciousness	19%	Nondominant	24
Focal somato-sensory auras	16–31%	Contralateral (100%)	31,50,54
Unilateral automatisms	16%	Ipsilateral (67%)	54
Hypermotor seizures	11–38%	None	29,31,50,54,55
Nonforced head-turning	11–31%	None	50,53,54
Postictal nose rubbing	10–37%	None	50,65
Unilateral dystonic posturing	0–21%	Contralateral (100%)	50,54,56

General features of frontal and central lobe seizures

Seizure frequency varies within a wide range. At least in surgical series, high frequency of several seizures per day is not rare in FLE,[29] but in patients with newly diagnosed epilepsy no significant differences in average seizure frequency were found between various partial epilepsies.[10]

Frontal lobe seizures tend to *cluster especially at night times*. More than half of the patients experience *status epilepticus* in their history which may even appear periodically in some patients.[29]

The *duration* of partial seizures arising from the frontal lobe is reported to be significantly shorter than the duration of temporal lobe seizures and does usually not exceed 1 minute.[29,51] Another study[49] did not confirm these results concerning the average seizure duration, but noted also that extremely short seizures (<10 s) were more likely to occur in frontal lobe epilepsies.

Secondary generalization occurs in up to 70% of the patients during lifetime.[29] However, the hypothesis that secondary generalization was more frequent in frontal lobe epilepsy than in other epilepsies could not be confirmed in more recent studies.[51]

Frontal lobe seizures were found to occur more frequently during non-REM-*sleep* than temporal lobe seizures.[66] However, this feature is of little clinical value to distinguish both syndromes in individual patients, because patients who develop seizures during sleep are seen in both epilepsy syndromes.[29,66,67]

Postictal headache (migraine-type, tension-type or unclassified) occurred in 41–53% after frontal lobe seizures.[61,62] The more posteriorly the seizures start, the more frequent is the migraine-type postictal headache (occipital lobe 20%, temporal lobe 10%, frontal lobe 5%).[61] In contrast to temporal lobe epilepsy in which the side of the headache was found to be ipsilateral to the seizure onset zone in 90%, there seems to be no lateralizing value of postictal headache in frontal and central lobe epilepsy.[62]

In *children* with FLE, the immature cortex architecture might influence seizure semiology; the lack of automatisms and secondary generalization has been attributed to this feature.[37]

Determination of the irritative zone

Interictal EEG

Interictal spikes or sharp waves appear in 60–80% of frontal lobe epilepsies (Figure 35.1); they are considered to be of less localizing value than in temporal lobe epilepsy because they can be bilateral, multilobar, or even generalized.[26,35,68–70] However, as far as the lateral frontal lobe is involved both interictal and ictal EEG findings are of higher localizing value.[71] Concordance of the epileptogenic zone with the irritative zone was found in 72% of the patients with lateral FLE compared to 33% with mesial FLE.[72] Possible reasons for this difference are the smaller distance between lateral cortex areas and scalp electrodes and the fact that tangential dipoles in mesial FLE cannot be detected by EEG.

The use of closely spaced surface electrodes other than those of the 10–20-system may improve localization if the irritative zone but did neither increase EEG sensitivity in 23 patients with frontal or central lobe epilepsy nor did it help in lateralizing the irritative zone in those patients who had bilateral epileptic discharges in conventional EEG.[73]

The sensitivity of interictal EEG is higher in intracranial subdural than in scalp recordings. Due to the closer distance to cortex, subdural electrodes may reveal a smaller extent of the irritative zone in some patients than surface electrodes do. However, a sampling bias remains in invasive monitorings.[69]

Pre-excision epileptiform activity during intraoperative electrocorticography recorded from >2 lateral frontal lobe gyri and central lobe predicts a poorer surgical outcome while postresection absence of spikes or sharp waves other than those at resection borders strongly correlates with a favourable surgical result.[74,75]

Magnetoencephalography (MEG)

Registration and localization of interictal discharges using magnetoencephalography (MEG) and magnetic source imaging (MSI; MEG co-registered with MRI) has been shown to be of predictive value for surgical outcome in some FLE patients.[76] Of 21 FLE patients who were considered for invasive monitoring, nine had no epileptic EEG discharges.[77]

In three of these patients, MEG showed interictal epileptic discharges. Especially patients with lateral neocortical localization of the irritative zone and patients whose epilepsy was caused by focal cortical dysplasia seemed to benefit from MEG investigation. Hence, combination of MEG with EEG can be helpful for tailoring the placement of invasive electrodes.

Determination of the seizure onset zone

Ictal EEG

Short seizure duration, fast cortical spreading and frequent muscle artifact in seizures with early motor signs as well as the large portion of frontal lobe cortex that is 'hidden' to scalp electrodes due to its far distance and vertical orientation restrict the value of ictal EEG recordings in frontal lobe epilepsy.[78] Again, this restriction applies more to mesial than to lateral frontal lobe epilepsy: seizures originating in the mesial frontal lobe were found to propagate faster than dorsolateral frontal seizures.[79] Ictal scalp EEG in 127 seizures of 15 patients with lateral frontal lobe epilepsy showed correct localization of the epileptogenic zone in 65% of the patients, while 26% of the seizures started with generalized EEG activity and 3% were mislateralized in the EEG analysis.[80] Only 1.5% of the seizures were obscured by artifacts or did not show EEG changes at all. The most frequent EEG patterns at seizure onset were repetitive epileptiform activity (36%) (Figure 35.2), rhythmic delta (26%) and EEG suppression (14%). Rhythmic theta activity, the most frequent seizure pattern in temporal lobe epilepsy, was seen in only 9%. A smaller study of nine patients also comparing medial and lateral frontal lobe epilepsy found that absence of focal electrographic seizure activity excluded the possibility of dorsolateral frontal lobe seizures with a negative predictive value of 93%.[71]

Although scalp electrodes showed widespread seizure onset and MRI was read as normal or nonlocalizing, the use of subdural grid electrodes that covered extensively frontal areas were reported to localize the seizure onset zone in >90% by several authors.[79,81]

Ictal single photon emission computed tomography (SPECT)

An early report about exploration of the seizure onset zone in 22 children with frontal lobe epilepsy using ictal 99Tc-HMPAO-SPECT showed hyperperfusion in 91% and correct localization in 95% of the cases.[82] However, newer data on adults did not confirm these promising results. Localization of seizure onset was found in only 33–43% of frontal lobe epilepsy patients.[83–85]

Subtraction ictal SPECT co-registered to MRI (SISCOM) as well as the combination of ictal SPECT with near-infrared spectrospcopy (NIRS) has increased diagnostic sensitivity,[86–88] but sufficient data on frontal lobe seizures are not yet available.

Determination of the epileptogenic lesion

Magnetic resonance imaging (MRI)

Surgical series showed MRI-lesions in 46–97% of the patients[28,29,31,68,89–91] (Figure 35.3). In 38 children, the rate of lesions detected by MRI were found to be only 32% compared to 97% in 17 children with mesial temporal lobe epilepsy.[20] Presence of an MR lesion strongly correlates with a good surgical outcome: 25–41% of patients without MRI lesions became seizure free or had only nondisabling seizures after surgery as compared to 67–72% of MR-positive patients.[70,89,90] According to the frequent etiologies of frontal lobe epilepsies, inclusion of FLAIR and proton weighted series for detection of dysplasias and blood products is recommended.[51,92,93]

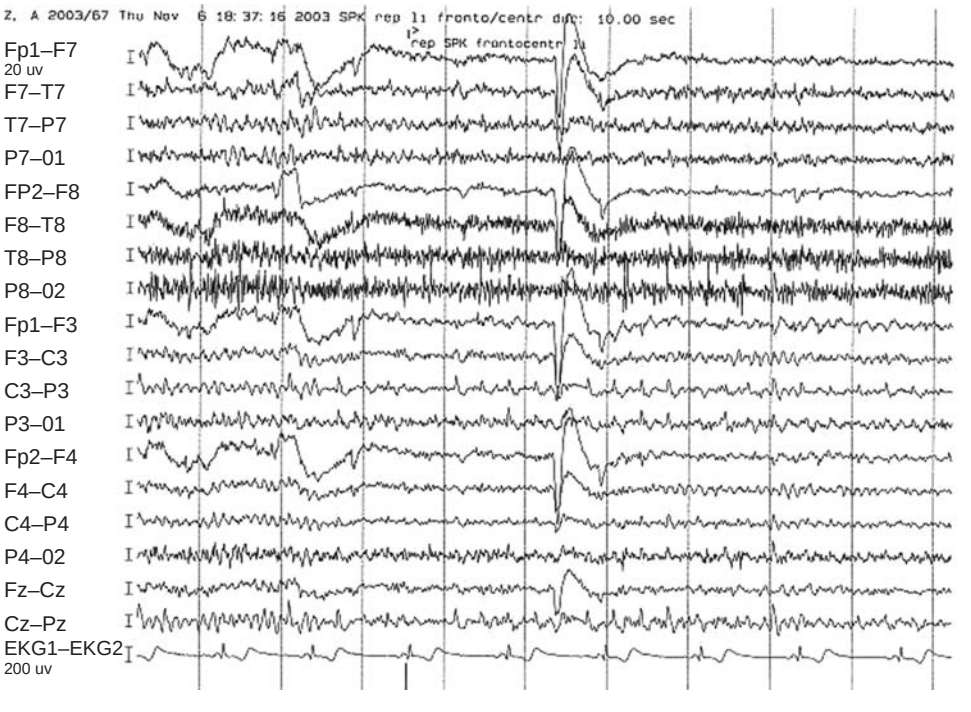

Figure 35.1 Interictal EEG recording of a 35-year-old man with lateral frontal lobe epilepsy caused by a left frontal cavernoma. The EEG shows repetitive spikes left frontocentral (F3 = C3 > P3, 5Fp1).

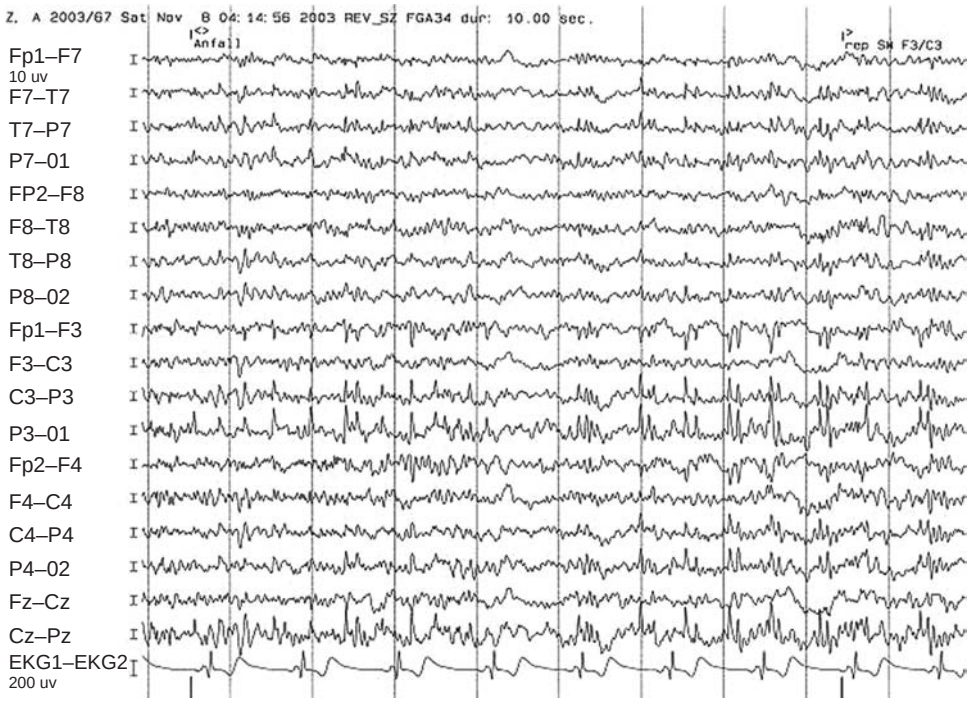
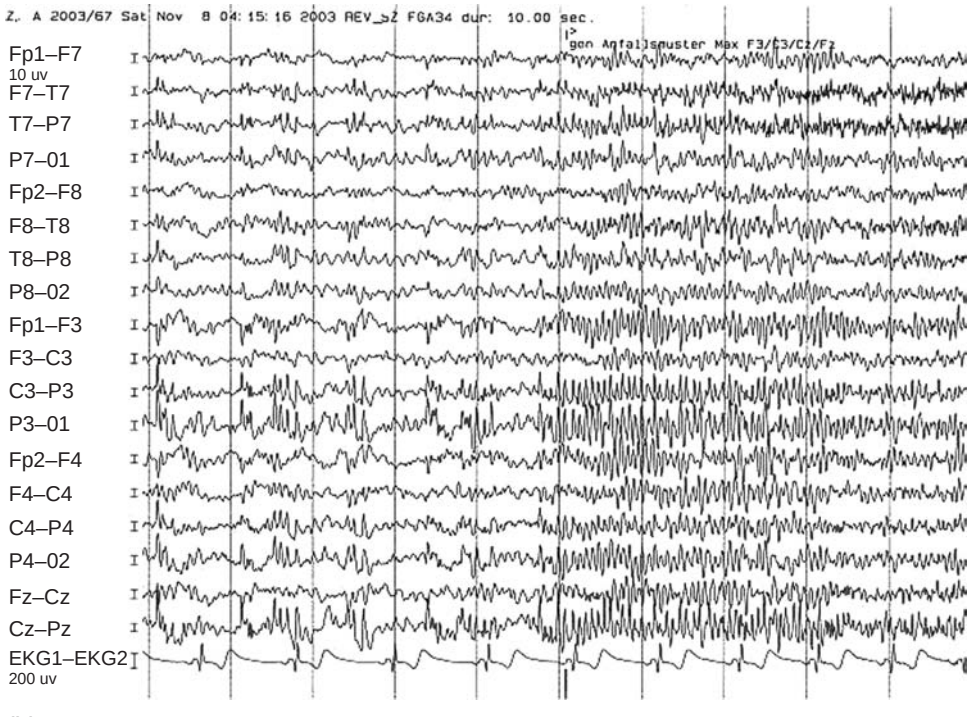


(a)



(b)

Figure 35.2 (a,b) Ictal EEG recording of the same patient as in Figure 35.1. The seizure starts with repetitive spikes, regional left frontocentral (F3,C3) and propagates toward a generalized beta-activity with left frontocentral (F3,C3,Fz,Cz) maximum.

MRI review by experienced neuroradiologists can remarkably improve its sensitivity.[94]

Additional and experimental methods

Despite its low spatial resolution, *MR spectroscopy* can help to lateralize and even localize epileptogenic frontal and central lobe lesions by detection of reduced N-acetylaspartate levels.[95,96] The area of decreased N-acetylaspartate concentration frequently exceeds the epileptogenic lesion as seen in MRI.[97]

Diffusion tensor imaging may be helpful for detection of the epileptogenic lesion in patients without structural changes on conventional MRI, especially in patients with focal cortical dysplasia.[98–100] Furthermore, multiplanar reconstruction and curvilinear reformatting were shown to improve the localization of focal cortical dysplasias in the frontal lobe.[101]

Unlike in mesial temporal lobe epilepsy, postictal *diffusion weighted MRI* may be helpful in detection of the seizure onset zone in selected patients with FLE.[102]

Determination of the functional deficit zone

Interictal single photon emission computed tomography (SPECT)

Interictal 99Tc-HMPAO-SPECT is of little value in neocortical epilepsy: areas of hypoperfusion have been found in only 24% of patients without MR-abnormalities, and these areas did not match the epileptogenic or seizure onset zone.[103] In 22 children with frontal lobe epilepsy, only two had interictal localized hypoperfusion that was concordant with clinical, EEG, MRI, and pathological findings.[82] Therefore, performance of interictal SPECT seems to be reasonable only together with ictal SPECT.

Positron emission tomography (PET)

The overall sensitivity of ^{18}F-fluorodeoxyglucose-PET (FDG-PET) scans in frontal lobe epilepsy was reported to be 46–96%.[104] There is a correlation between MRI lesions and pathologic results in FDG-PET: hypometabolism was found in about 75% of patients with unilateral frontal lobe epilepsy and MR abnormalities.[14,105] However, only in 29–45% of patients without MR-detectable lesion but electroclinical features of unilateral frontal lobe epilepsy localizing hypometabolism were seen in FDG-PET.[14,83,105] In a prospective study PET revealed pathological findings in no patient with bifrontal epilepsy and normal MRI.[14] Flumazenil-PET for detection of low benzodiazepine receptor density showed only a slightly higher sensitivity to lateralize cryptogenic unilateral frontal lobe epilepsy. The method did not contribute significantly to localization of the epileptogenic zone.

The sensitivity for ^{18}F-fluorodeoxyglucose-PET was found to be 92% in children with frontal lobe epilepsy while the specifity for frontal lobe lesions was only 62% and additional hypometabolism outside frontal regions could be detected frequently.[106] Hence, the value of ^{18}F-Fluorodeoxyglucose- and flumazenil-PET seems to be restricted in frontal lobe epilepsy compared to temporal lobe epilepsy,[14] although sensitivity can be slightly increased by use of statistical parametrical mapping.[107] The role of alpha-[^{11}C]methyl-L-tryptophan-PET remains to be determined because only small case series have been published.[108]

Neuropsychological examination

The published studies on neuropsychological deficits in frontal lobe epilepsy do not differentiate between certain cortical areas. Impaired motor programming and coordination together with reduced response inhibition can be found in about two-thirds of frontal lobe epilepsy patients and may contribute to differentiate them from patients suffering from temporal lobe epilepsy, while speed, attention, and memory span does not differ between the epilepsy syndromes.[109] An exception might be the patients with right-sided frontal lobe epilepsy and early seizure onset (<6 years) in whom motor skills were found to be less impaired than in patients with frontal lobe epilepsies of the left side or later onset.[110]

Estimation of the epileptogenic zone

Ictal EEG, seizure semiology, and MRI are most important for estimation of the localization and extent of the epileptogenic zone. If seizure semiology, MRI, PET, and SPECT results are pointing to a certain frontal lobe region, intracranial EEG may be abdicable.[111] In MR-positive cases, pure lesionectomy without further attempt of locating the epileptogenic zone led to at least 95% seizure reduction in 13 of 14 patients with central lobe epilepsy.[112]

Difficulties arise especially

- if non-invasive investigations reveal equivocal results;
- in patients without MRI-detectable lesion;
- in patients with close relation of the epileptogenic zone with eloquent cortex; and
- in patients with focal cortical dysplasia because of the ill-defined lesion margins.

In those patients, invasive EEG monitoring is frequently required.[17,113,114]

Determination of the eloquent cortical areas

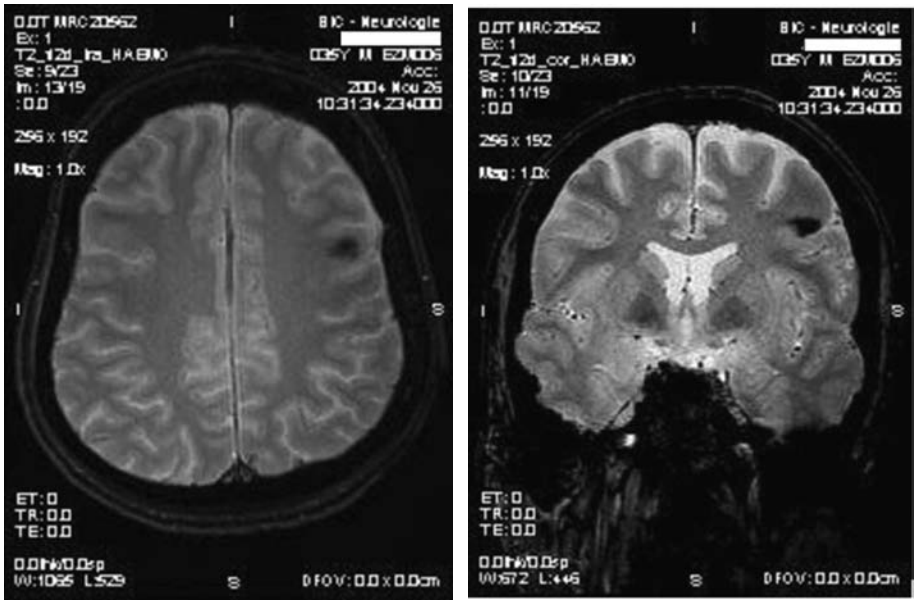
The detection of eloquent cortical areas is crucial prior to and during resection of central lobe cortex due to the motor representation in this area.

Pre-and intraoperative localization of the central sulcus by use of SEP is possible in >90% of the cases; however, the method may fail in patients with tumor etiology in which the anatomical cortex structure is deranged.[41,69,115] Magnetoencephalographic responses evoked by electrical stimulation of the median nerve can also help to locate the central sulcus.[116] Electrical cortical stimulation via implanted grid or strip electrodes has the highest validity for cortical mapping. Reproducibility of seizure symptoms during cortical stimulation is associated with good outcome in extratemporal epilepsy, if these areas were included in the resection.[81]

Therapy and outcome

Medical therapy

In general, medical therapy leads to seizure freedom in about two-thirds of patients with newly diagnosed focal or generalized epilepsy.[117] There are few data on medical therapy of frontal lobe seizures. Medical therapy led to seizure freedom in 37% of 200 patients with difficult-to-treat frontal lobe epilepsy who were referred to a tertial epilepsy centre.[15] In one open-labeled nonrandomized study, a combination of valproate and lamotrigine was used in 21 patients, of whom 48% were seizure free after 1 year of treatment and another 29% experienced seizure reduction of at least 50%.[118] However, the use of additional antiepileptic drugs was allowed. A similar seizure freedom rate of 50% was



(a) (b)

Figure 35.3 (a,b) 3T-MRI scans of the patient whose EEG is shown in figures 35.1 and 35.2(a,b). The gradient echo sequences show the cavernoma as a hypointense left frontolateral lesion. (Courtesy of Dr. S. Knake, Marburg and Dr. K. Krakow, Brain Imaging Center, Frankfurt).

seen in 22 retrospectively observed children with frontal lobe epilepsy.[119]

Surgical therapy

Resective surgery: seizure outcome and prognostic factors

In older series, 13–55% of patients with frontal lobe epilepsy had a favorable outcome after surgery;[23,28,35] a meta-analysis showed an overall seizure freedom rate of 27%.[120] However, since diagnostic capabilities (especially neuroimaging) improved, seizure freedom, or an outcome with nondisabling or very rare seizure was reported in up to 60–70%.[28,29,68,121–123] In patients without MRI-detectable lesions, Engel class I outcome was achieved in 43% of 35 FLE patients.[83]

Acute seizures within the first week after resection occurred in around 25% of patients after frontal lobe epilepsy surgery, particularly in patients who develop intracerebral hematomas; an association with long-term outcome could not be proven.[124] During five postoperative years, seizure outcome improved in 15% and deteriorated in 5% of frontal lobe epilepsy patients.[125]

Neuropsychological benefits (e.g., improvement of short term memory) may occur in patients who become seizure free after frontal lobe resection.[126]

The following factors have been found to be associated with good postoperative outcome in patients with frontal lobe epilepsy by several authors:[30,70,122,123,127–132]

- Tumor or post-traumatic etiology;
- Focal MRI lesion;
- Focal lesion or normal result in FDG-PET;
- Focal ictal β-activity in EEG at seizure onset;
- Slow spreading of EEG seizure pattern;
- Localization of the resection in lateral frontal lobe;
- Seizure control within first year after resection.

On the other hand, the following factors seem to be associated with poor outcome:[30,31,70,114,123,127]

- Autonomic seizure symptoms;
- Etiology of focal cortical dysplasia;
- Contralateral head version;
- Eye deviation (any direction);
- Incomplete resection;
- Generalized slowing or generalized interictal epileptiform discharges (IED) in presurgical EEG;
- Postsurgical IED in scalp EEG;
- Additional extrafrontal lesions;
- Localization of the resection in medial frontal lobe;
- Childhood febrile seizures.

Some factors could not be shown to correlate with the outcome:[30,31,83,122,123,127,129]

- Age at operation;
- Age at onset;
- Epilepsy duration;
- Seizure frequency;
- Seizure duration.

However, it has to be pointed out that the prognostic value of several above mentioned features was not corroborated by other authors. For example, most studies revealed a strong correlation between presence of MRI-detectable lesions and favorable seizure outcome,[30,122,127] while other data showed no correlation[123,132] or even better results in patients with normal MRI.[29]

Complications

Neurological deficits after lesionectomy (paresis, hypesthesia, dysphasia, abulia, incontinence) appeared in 15–40% after frontal lobe resection, but only 1–3% of the deficits persisted.[28,35,123]

Resection of primary hand and arm motor cortex leads to contralateral paresis. Functional recovery starts within 1–3 weeks, but fine motor skills do not recover completely.[133] Due to crossing fibers leading to bilateral representation, resection of axial, face, and tongue motor areas usually recovers completely, and so does sensory function after removal of postcentral cortex.[133,134]

Vagus nerve stimulation

Vagus nerve stimulation reduces seizure frequency by at least 50% in 30–40% of patients, whereas efficacy increases over time.[135] No specific data on premotor or central lobe epilepsy are available.

Other and experimental methods

If resective surgery is impossible due to overlap of the epileptogenic zone and eloquent cortex, multiple subpial transsections (MST) and callosotomy remain as further surgical approaches.

Three months after MST in the frontal lobe, 30% of the patients were seizure free in one study.[126] However, the long-term seizure freedom rate is probably far lower.[120]

In patients without localizing diagnostic results, callosotomy is a palliative option.[136] Freedom of most disabling astatic seizures can be achieved by this procedure in 35%.[120]

Other methods like deep brain or cortical stimulation or focal cortical cooling are still experimental.

36 Mesial frontal epilepsy

A Bleasel and D Dinner

Introduction

The unusual semiology of seizures arising in the frontal lobes; frenetic asynchronous movements, bilateral posturing and partial awareness often presents diagnostic challenges to physicians. Epilepsy surgery assessments are beset by the brevity of the seizures, the speed of seizure propagation within and beyond the frontal lobe and the limitations to resection imposed by sensorimotor and language cortex. Seizure foci within the mesial frontal lobe add to the challenge by their remoteness to scalp EEG electrodes, propensity to transcallosal spread and bilateral hemisphere involvement and difficult surgical access.

A clinical syndrome of mesial frontal lobe epilepsy is not easy to define because of the anatomical complexity and interconnectivity of the mesial frontal lobe, the non-specific seizure semiology and the diverse pathologies of symptomatic frontal lobe epilepsy. The mesial frontal lobe contains primary motor cortex for the lower limb, the supplementary sensorimotor area, and the anterior cingulate motor area. Each of these motor areas is interconnected, within and between hemispheres, and receives input from subcortical nuclei and the parietal lobe. There are non-eloquent anterior cortical regions that give no clue to seizure onset before propagation within and beyond the mesial frontal lobe. Despite the potential pitfalls a knowledge of the anatomy of the mesial frontal lobe and its connections, typical seizure semiology, scalp EEG patterns and surgical experience can guide the assessment of patients with intractable partial seizures suggesting mesial frontal lobe involvement or identified mesial frontal lobe pathology.

Anatomy of mesial frontal lobe

Cortical surface

The mesial frontal lobe contains portions of each of the major divisions of the frontal lobe; primary motor cortex, premotor cortex and prefrontal cortex. Conventional MRI scans in sagittal and axial views can identify critical boundaries between primary motor and premotor cortex (Figure 36.1 and 36.2). The cingulate gyrus can be identified above the corpus callosum and curves around the genu of the corpus callosum anteriorly (Figure 36.1). The cingulate sulcus is easily identified above the gyrus. It may be divided anteriorly with the two sulci running roughly parallel around the genu of the corpus callosum.[1] Posteriorly the cingulate sulcus ceases to run parallel to the corpus callosum and travels superiorly as the marginal ramus to the parasagittal surface of the brain. The marginal ramus is the posterior boundary of the frontal lobe mesially and divides the primary sensorimotor cortex of the paracentral lobule from the precuneus (mesial parietal lobe). The most rostral aspect of the central sulcus can be identified immediately anterior to the marginal ramus in sagittal MRI views.[2] The central sulcus usually does not enter the interhemispheric fissure[3] and sagittal planes just lateral to the midline are best used to locate it in relation to the marginal sulcus. The superior frontal gyrus occupies much of the mesial surface of the frontal lobe anterior to the paracentral lobule. It is divided from the paracentral lobule by the paracentral sulcus, in continuity with the cingulate sulcus, and passes forward to form the frontal pole. Inferior to the anterior portion of the superior frontal gyrus a number of gyri run obliquely toward subcallosal region becoming parallel with the gyrus rectus of the orbitofrontal cortex. The anterior inferior aspect of the mesial frontal lobe is contiguous with the orbitofrontal cortex. The superior frontal gyrus and central sulcus are also seen well in axial MRI views of the brain (Figure 36.2). The superior frontal sulcus, the lateral boundary of the superior frontal gyrus, ends posteriorly in the precentral sulcus, an interrupted sulcus when traced laterally. The uninterrupted central sulcus can be followed laterally in successive caudal axial images and a characteristic '**Ω**' shaped bend in the central sulcus identified.[4] This feature of the precentral gyrus has proven to be a reliable cortical landmark for the hand region of the motor cortex based upon cortical stimulation and evoked potential studies.[4,5]

Functional anatomy

Classical functional divisions of the frontal lobe motor areas into primary, premotor and supplementary motor regions do not adequately convey the complex reciprocal connectivity of mesial frontal motor areas with lateral frontal regions, striatum, thalamic nuclei and the parietal lobe.[6] The mesial surface of the frontal lobe includes primary sensory and motor cortex for the lower limb, the supplementary motor area, the anterior cingulate motor areas, anterior cingulate cortex and the prefrontal cortex.[7] Because of the coincidence of motor and sensory responses with cortical stimulation of the supplementary motor area, the term supplementary sensorimotor area has been proposed.[8] Specific subregions of these cortical areas can be distinguished based upon the inputs and projections between these mesial frontal areas and subcortical nuclei, the parietal lobe and lateral frontal motor areas.

The supplementary sensorimotor area (SSMA) is found in the mesial portion of the superior frontal gyrus anterior to the

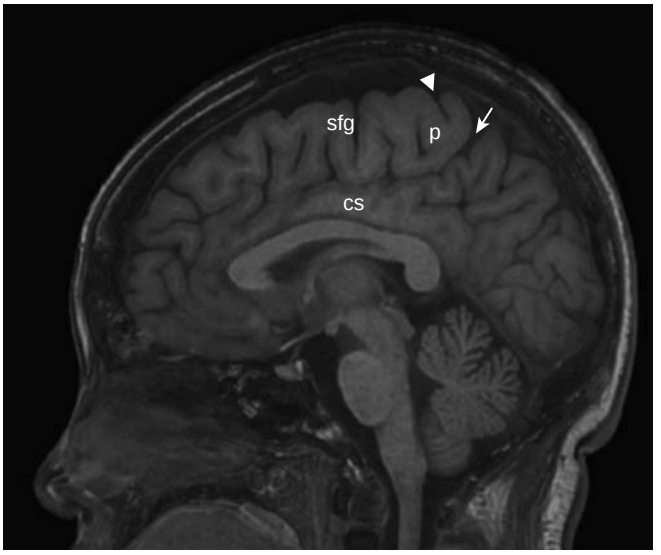

Figure 36.1 The midline sagittal plane of a 3D reconstruction of an MRI of the brain showing the mesial surface of the hemisphere. The paracentral lobule (p), the mesial surface of the superior frontal gyrus (sfg) and the cingulate sulcus (cs) are labelled. The central sulcus, indicated by the arrow head, lies immediately anterior to the marginal ramus (arrow) of the cingulate sulcus. The supplementary sensorimotor area is found on the mesial surface of the superior frontal gyrus anterior to the paracentral lobule.

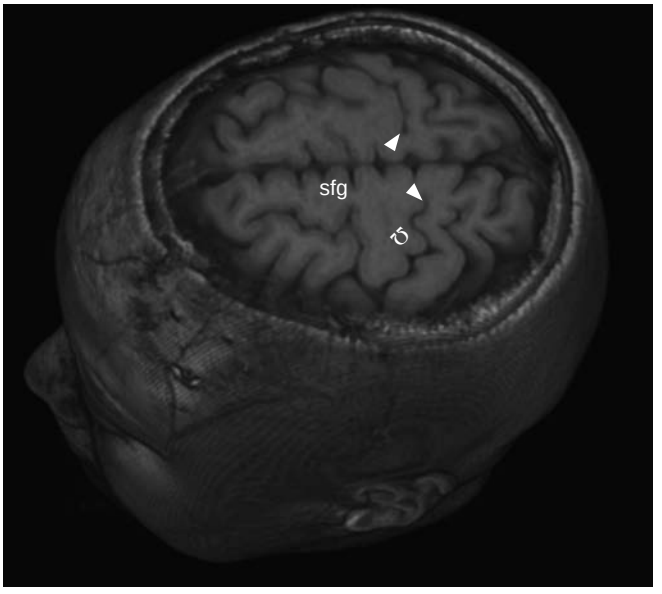

Figure 36.2 Axial cut of a 3D reconstruction of an MRI of the brain showing frontal and parietal lobes. The rostral end of the central sulci are indicted (small arrow heads) in the right and left hemispheres. The superior frontal gyrus (sfg) occupies the parasagittal region. The characteristic Ω shaped bend in the central sulcus is seen in the left hemisphere, the Ω symbol lies over the precentral gyrus at this point. This portion of the precentral gyrus is a reliable anatomical landmark for the hand motor cortex.

primary motor area for the lower limb extending to approximately the level of the genu of the corpus callosum. The inferior border is formed by the cingulate sulcus but the superior border has no clear cortical landmark. Cortical stimulation studies have suggested the SSMA extends onto the dorsolateral aspect of the superior frontal gyrus[8–11] although Talairach and Bancaud[12] concluded that the SSMA was only found on the mesial surface. The precentral sulcus may be a more reliable landmark defining the border between the primary motor foot area and the SSMA than the paracentral sulcus as the primary motor cortex may not occupy a great portion of the paracentral lobule.[2,13,14]

Motor responses to electrical stimulation of the SSMA are characterised by the simultaneous activation of axial, proximal and distal muscle groups. Tonic muscle contraction with posturing of the trunk and limbs is usually seen rather than focal clonic activity.[8,11,15–17] Simultaneous activation of more than one extremity is common and bilateral movements of the limbs occur.[8,11,16] Arrest or slowing of voluntary motor activity occurs[11,18] and these negative motor responses result from the anterior portion of the SSMA.[8] Sensory responses to cortical stimulation can be obtained from the mesial frontal cortex and parietal cortex inferior and posterior to the paracentral lobule.[11,18] These 'supplementary sensory' responses are not as precisely localised by the patient as those occurring in response to stimulation of the primary sensory cortex in the postcentral gyrus. Motor responses have also been obtained posterior to the paracentral lobule.[8]

The SSMA is located in the mesial portion of area 6 of Brodmann's cytoarchitectonic map of the brain corresponding to the Vogts' areas 6aα and 6aβ.[18,19] Immunohistochemical and microstimulation studies in primates and functional imaging studies in humans have shown that the anatomical SSMA is not a single functional region.[6,19] There is an anterior ('pre-supplementary motor area') region, interconnected with the prefrontal cortex and anterior cingulate motor areas, involved in motor processing of other parietofrontal circuits. Detailed cytoarchitectural studies in human brains has shown this region corresponds to the mesial portion of area 6aβ and a more posterior 'supplementary motor area-proper' is formed by the mesial portion of area 6aα.[14] In the primate the supplementary motor area-proper has significant connections with the primary motor cortex and spinal cord and important reciprocal connectivity with the mesial parietal regions.[20] The SSMA is a non-primary motor area involved in preparing voluntary movements with the primary motor area responsible for the execution of the movement.[19] The supplementary motor area-proper seems more important for postural control and movement execution while the rostral pre- supplementary motor area has more 'supramotor' programming function.[20]

Human cortical stimulation studies have found a topographic representation of the body within the SSMA. Motor responses are more concentrated within the posterior portion of the classically defined supplementary motor area,[12] and within this region eye movements responses lie most anteriorly followed by upper limb and then lower limb movements as one moves posteriorly. Negative motor responses are located anterior to positive motor responses.[8] Support for this somatotopic organisation of the SSMA can be found in functional neuroimaging studies of cerebral blood flow

with motor activation[21] and recording of movement-related cortical potentials.[22]

The anterior cingulate cortex lies inferior, rostral and superior to the corpus callosum and accounts for a significant portion of the mesial frontal cortex. It is made up of Brodmann areas 32, 24, 25 and 33. In addition to the premotor functions of the anterior cingulate motor areas, lying deep within the cingulate sulcus, the anterior cingulate cortex is involved in the regulation of autonomic and endocrine function, affect, emotional vocalisation, pain perception and cognitive processing for response selection.[1] The anterior cingulate cortex receives input from multiple thalamic nuclei. Its projections reach the skeletomotor system via the spinal cord, red nucleus and pons, the striatum, the limbic system via amygdala and the midbrain periaqueductal grey, and the autonomic system via the solitary tract and dorsal motor nucleus of the vagus.[1] It is not surprising that electrical stimulation of the human anterior cingulate region has produced an enormous variety of autonomic, emotional and complex motor responses. Cingulate stimulation may produce changes in heart rate, blood pressure, facial flushing, pupillary dilation and may induce nausea, salivation, bladder or bowel evacuation.[1,23,24] Emotional responses such as fear, agitation, pleasure and euphoria and repetitive simple and complex motor actions may occur.[1,23,24] The prefrontal cortex anterior to the SSMA and cingulate motor cortex is relatively silent when subject to cortical stimulation although reciprocally connected to the pre-supplementary motor area.

Vascular anatomy

The anterior cerebral artery is the major arterial supply of the mesial frontal lobe with only a small contribution from distal branches of the superior division of the middle cerebral artery to the lateral aspect of the superior frontal gyrus. The anterior cerebral artery courses from the circle of Willis to the parieto-occiptial area and shows great anatomical variation between individuals.[25–27] The orbitofrontal cortex, the mesial anterior frontal lobe, the superior frontal gyrus, cingulate gyri, paracentral lobule and anterior corpus callosum are all supplied by branches of the anterior cerebral artery.[25,26] The proximal anterior cerebral arteries may be very asymmetric with dominance of left or right, and branches of the callosomarginal or pericallosal may cross the midline to supply the contralateral mesial frontal lobe.[26] Thus the occlusion of one anterior cerebral artery may lead to bilateral mesial hemispheric infarction and is a potential complication of surgery in the mesial frontal regions.

A 'C' shaped inferior portion of the mesial frontal surface surrounding the corpus callosum, including cingulate gyrus and inferior aspect of the superior frontal gyrus, drains in to the deep cerebral venous system to the straight sinus. The more rostral and anterior arc of mesial frontal cortex and the parasagittal lateral convexity drains via the superficial cortical veins to the superior sagittal sinus. The superior anastomotic vein of Trolard travels between the superficial middle cerebral vein in the sylvian fissure and the superior sagittal sinus. It can be identified on lateral venous phase angiograms and the surface of the cerebral convexity at craniotomy. It runs parallel and adjacent to the central sulcus. The superficial venous system is very important in planning the placement of subdural electrode arrays and cortical resections in the mesial frontal region. The passage of proximal superficial cortical veins to the sagittal sinus anchors the parasagittal convexity to the dura at several points and may indeed limit what can be introduced in to the interhemispheric fissure. These large but distensible veins are exposed to any subdural electrode arrays and may be compressed and thrombose especially if patients are not kept well hydrated postoperatively.[13]

Seizure semiology

The seizures associated with mesial frontal lobe epilepsy share the common features of frontal lobe seizures; abrupt onset, short duration and clusters of multiple daily seizures. The bilateral asymmetric tonic seizure[28] is most often linked to the mesial frontal lobe. These seizures have attracted different labels over the years; 'postural seizures',[29] 'supplementary motor seizures',[30] or asymmetric tonic motor seizures.[31,32] This seizure semiology is not specific for mesial frontal lobe onset and other distinct semiologies may also be seen with mesial frontal lobe onset. These include the uncommon 'frontal lobe absence seizures'[33] with motionless staring, 'frontal lobe complex partial seizures'[34–36] with hyperkinetic motor automatisms, repetitive vocalisations and agitation, focal clonic seizures of the lower limb and negative myoclonus. Focal clonic seizures involving the face and upper limb, or versive seizures are not typical of a mesial frontal onset. Complex partial seizures with oral and manual automatisms (psychomotor seizures typical of mesial temporal lobe onset[37] are not typical but may be seen with seizure onset within the cingulate gyri.[1]

Bilateral asymmetric tonic seizures

Bilateral asymmetric tonic seizures are characterised by an abrupt onset of tonic posturing, maintained for 10-40s and not followed by any postictal stupor or confusion.[38–40] Typically the tonic posturing appear to be bilateral from the onset but careful analysis has revealed it may begin in one part of the body and move rapidly to the other limbs.[41] Less often posturing may be unilateral or restricted to a single limb but proximal limb and axial muscle involvement is always prominent.[39] Most often all 4 limbs are involved with abduction of the upper limbs and asymmetric flexion of the elbows. The lower limbs are abducted at the hips with the knees extended or semi-flexed.[39] Penfield described 'the arm being raised and the head and eyes turned as though to look at the hand' and this has been referred to as the 'fencing posture'.[18a] Clinical series show the assumption of a true fencing posture is uncommon.[34, 38, 42]

The patient's posture may change during the seizure if the distribution and intensity of muscle contraction changes. Patients may also attempt to change their position during the seizure and show coarse incoordinate movements of their tonically postured limbs. They may cry out (perhaps cursing) or moan loudly at the onset.[43] Patients are unresponsive during the tonic phase of the seizure but do not lose consciousness during brief bilateral asymmetric tonic seizures and words or

instructions given during a seizure can be recalled. Longer seizures, as may be seen with antiepileptic medication withdrawal during prolonged video/EEG studies, may be associated with some ictal amnesia and postictal confusion.[44] Focal clonic activity may occur due to involvement of the primary motor cortex[34,42] and may appear late with seizure spread or precede the tonic phase if the epileptogenic zone includes the primary motor cortex.

A somatosensory aura may immediately precede the tonic seizure. This may be a feeling of tension, pulling or heaviness in a limb or the sense of the limb 'being about to move'[18,39,45] or more simply a 'tingling' feeling. The symptoms may arise from the sensory representation within the supplementary sensorimotor area[8,16] or may be the awareness of tension developing in muscle groups involved in the tonic contraction. The sensation may be relatively focal involving a portion of a limb, lateralised with both upper and lower limbs involved simultaneously or a less well defined bilateral sensation in the head or body.[18,39,45]

Although evidence exists to support ictal involvement of the supplementary sensorimotor area in producing bilateral tonic posturing, the seizure onset may be outside the mesial frontal region or outside the frontal lobe itself. Subdural and depth electrode monitoring has shown the seizure onset zone and epileptogenic zone commonly extends beyond the supplementary sensorimotor area to primary motor cortex, the dorsolateral premotor cortex, the cingulate gyrus, the mesial prefrontal cortex and the mesial parietal lobe.[34,35,38,46] Patients with seizures arising exclusively from the SSMA are rare[34,35,38] and the seizure semiology of such patients can not be distinguished from that occurring in patients with ictal onset's that included adjacent cortical areas.[34,38] Surgical series have shown the typical bilateral asymmetric tonic postural seizures described above may occur in patients with ictal onset, confirmed by surgical outcome, in lateral frontal, parietal or occipital lobes.[40,47–52] Similar observations have been made in a clinical series comparing seizure semiology to clinical localisation based upon lesion location.[53] Detailed analysis of the evolution of seizure semiology in patients with bilateral tonic seizures can provide some features to distinguish between focal onset within frontal and parieto-occipital regions[54] but one must consider an extra-frontal onset in all cases of non-lesional epilepsy.

These observations suggest that the epileptogenic zone in patients with bilateral asymmetric tonic seizures may be outside the mesial frontal lobe with this seizure semiology arising by propagation of ictal discharges to the one or both SSMA in the mesial frontal lobe. This concept is well supported by the primate anatomical studies of fronto-parietal connectivity.[6] Evidence for such propagation has been limited in human studies[45,55] as invasive electrode placement will always be concentrated in the proposed area of resection and there will be limited sampling regions of seizure onset and propagation.[56] More recently Ikeda *et al*[52] found good evidence of seizure propagation to the SSMA from epileptogenic regions outside the mesial frontal region to coincide with the asymmetric tonic semiology. Dorsolateral frontal regions and mesial parietal cortex gave rise to seizures which immediately spread to electrodes implanted over the SSMA.

A more challenging question is whether ictal involvement of cortical (dorsolateral premotor areas and cingulum) and subcortical motor regions (basal ganglia) other than the SSMA may be capable of producing the bilateral asymmetric tonic seizure semiology.[34,57,58] Apparently isolated ictal involvement of either the lateral premotor area or the primary motor area can produce tonic motor activity.[34] The tonic motor activity was manifest as unilateral posturing of a limb or limbs (contralateral to the ictal activity) and usually associated with clonic motor activity. Unilateral tonic limb posturing without clonic activity was seen in 2/13 seizures in the patients with ictal discharges limited to the primary motor area.[34] Cortical stimulation of frontal convexity premotor areas in primates can produce contralateral tonic motor activity in proximal muscle groups but not bilateral or ipsilateral motor responses.[59-61] Intraoperative[62,63] and extraoperative[64,65] cortical stimulation studies in humans have not revealed convexity premotor (Broddman area 6, or Vogt and Vogt area 6a alpha) responses distinct from primary (area 4) motor responses but the convexity premotor motor responses are not bilateral. At present there seems to be good evidence for a central role for the SSMA as the symptomatogenic zone for bilateral asymmetric tonic seizures with preserved awareness but questions remain regarding the participation of other cortical motor areas and subcortical systems.

Hypermotor seizures

Complex partial seizures characterised by vigorous sometimes bizarre motor automatisms, vocalisation and relatively minor postictal confusion are often seen in frontal lobe epilepsy and have been distinguished from those associated with mesial temporal lobe seizure onset.[35,66,67] The complex movements resulting in repeated changes in posture and asynchronous perseverative proximal limb movements, have been termed 'hypermotor seizures' in the semiological seizure classification proposed by Lüders *et al*.[68] Patients may have wild repetitive movements of the outstretched hands, kicking or pedalling of legs, hopping, pelvic thrusting or genital mani pulation.[69,70] Vocalisation is common and may be loud and intrusive and socially disabling.[66,70,71] The vocalisation is often primitive consisting of grunting or barking sounds but can consist of intelligible phrases repeated over and over. Patients may be partially responsive during the episodes, occasionally have some recall of the events and often have minimal postictal disorientation. Because of the bizarre character of the episodes and the rapid recovery these seizures may be mistaken for pseudoseizures or behavioural outbursts.[70,72] However, the stereotyped nature of the events and the loss of awareness should point an experienced physician toward epilepsy. There may be an overlap between the hypermotor and the bilateral asymmetric tonic postural seizure semiology as axial tonic activity may be present whilst the patient struggles and attempts to change position.[58] Both hypermotor and tonic postural seizure types may be brief lasting less than 30-40s, may be predominantly nocturnal, and have minimal or no postictal confusion although completely preserved awareness is not as common with the hypermotor semiology.

This seizure semiology is not well localised within the frontal lobe and has been described with orbitofrontal seizure onset[73–76] and lateral frontal seizure onset.[42,77] While seizure onset in a number of frontal regions may produce this seizure semiology the anterior cingulate region has most often

been discussed as the cortical region responsible for the clinical signs and symptoms.[78] Seizures with onset in the anterior cingulate gyrus are characterised by these vigorous automatisms and vocalisations[78] and stimulation induced complex motor behaviours are similar to these automatisms when the anterior cingulate region has been explored with invasive electrodes.[1,23] Ictal single photon emission computerised tomographic scans (SPECT) studies have demonstrated hyperperfusion of the frontopolar regions in children with complex gestural automatisms, vocalisation and hyperventilation.[76,79] The hypermotor seizure has been though to have some specificity for a frontal lobe onset[35] but more recently seizure onset within temporal neocortex[80] or insular cortex[81,82] has been shown to also produce the typical hypermotor seizure semiology.

Frontal lobe absences

Motionless staring with amnesia may occur in seizures arising from the mesial frontal cortex, so called 'frontal absences'.[33,83] Bancaud and Talairach described seizures characterised by impairment of consciousness, speech and movement arrest, simple gestural automatisms and immediate recovery of consciousness.[33] The duration varies, they may be as brief as 10s and are usually between 15-45s. Compared with the absences of childhood absence epilepsy frontal lobe absences may have subtle repetitive vocalisation, rocking movements, small degrees of head and eye turning and some brief postictal confusion.[1,33,84,85] The patient may report awareness of a motor arrest without loss of consciousness.[86] The staring may evolve into a secondarily generalised tonic clonic seizure via version of the head and eyes, focal tonic posturing of an upper limb or bilateral tonic posturing.[33] Episodes of status epilepticus are characterised by subtle alteration in responsiveness or mood, and variable degrees of stupor may occur.[86–88] Patients with absence seizures in frontal lobe epilepsy seem to have a more anterior epileptogenic zone than those with bilateral asymmetric tonic seizures.[33] The clinical semiology has been ascribed to bilateral cingulate gyrus involvement in the seizure[1,89] via the callosal route.[90] However, the common association of bilateral synchronous frontal interictal discharges and the coincidence of clinical and scalp EEG seizure onset suggest a rapid entrainment of both frontal lobes in the ictus possibly via thalamocortical pathways involved in the production of idiopathic generalised absence seizures.[33]

Negative myoclonus

Epileptic negative myoclonus is characterised by brief lapses of postural tone usually with dropping of an outstretched limb. The muscles need to be activated for the clinical manifestation and it is not seen when muscles are at rest. Frontocentral epileptiform discharges immediately precede the atonia. Most commonly focal negative myoclonus occurs in association with a central seizure onset in cases of idiopathic focal epilepsy of childhood.[91] In symptomatic partial epilepsy foci have been demonstrated in primary sensorimotor cortex[92] and dorsolateral premotor areas.[93] The association focal negative myoclonus and asymmetric tonic seizures has been noted with mesial frontal seizure onset.[94] The electromyographic correlate of negative myoclonus is a brief (<500ms) silent period not preceded by any electromyographic evidence of myoclonus.[95] It has been reported with direct cortical stimulation via subdural electrodes the primary sensorimotor cortex could produce a silent period but not the SSMA.[96] Rubboli *et al.*[95] performed cortical stimulation via depth electrodes of premotor cortex, primary motor cortex, primary somatosensory cortex and the supplementary sensorimotor area at low frequency. They found a motor evoked potentials most often preceded the silent period for primary motor and premotor cortex, low but not high intensity stimulation produced an isolated silent period from primary sensory cortex but the SSMA consistently produced only a silent period.[95]

Lateralising and localising signs

It is true that all of the frontal lobe seizure semiologies discussed with this chapter have limited localising value for subdivisions of the frontal lobe.[58] It is most important to be aware the distinctive semiology of the bilateral asymmetric tonic seizures does not have localising value for an onset within or adjacent to the SSMA.[52,97] Lateralising signs have not been well studied in frontal lobe epilepsy. Consistently unilateral sensory symptoms are usually contralateral to the hemisphere of onset. Focal clonic activity reliably lateralises seizure onset to the contralateral hemisphere[34,42] and focal tonic posturing has a similar lateralising value.[58,98,99] Unilateral tonic posturing is not as common as bilateral asymmetric tonic posturing. The position of the arms, elbow extension vs flexion, is not a reliable guide to lateralisation of seizure onset. Head turning as part of a bilateral asymmetric tonic seizure is not a reliable lateralising sign.[58] Head turning occurring early in the seizure may be contralateral[18,34] or ipsilateral[44,100] to hemisphere of seizure onset. Head version, with clonic movement, occurring immediately prior to secondary generalisation to a generalised tonic clonic seizure is more reliable lateralising sign.[101] Unifocal or unilateral somatosensory aura is a reliable sign appearing contralateral to the hemisphere of onset.[58]

Interictal and ictal EEG

Several factors often combine to reduce the localising value of interictal and ictal scalp EEG in frontal lobe epilepsy; the inaccessibility of mesial frontal and orbitofrontal cortex to scalp EEG electrodes, the rapid propagation of seizure discharges within and between frontal lobes and movement artefactc.[35,56,102,103] The interictal EEG in patients with mesial frontal lobe epilepsy most commonly shows an abundance of nonlateralised epileptiform activity or none at all.[38,70,85,89,104–108] Quesney and colleagues from the Montreal Neurological Institute[109] have examined interictal epileptiform activity in 34 patients seizure free after selective frontal lobe excisions and compared parasagittal resections with anterofrontal and fronto-opercular resections. None of the parasagittal group (10 patients) had focal discharges, 5 had exclusively bilateral or generalised discharges, 4 had regional frontocentral discharges and one had no discharges. Localised epileptiform activity appears to be more common in lateral frontal lobe foci.[108,109] Quesney *et al.*[109] found only two of 18 anterior resections and none of 6 fronto-opercular resections had exclusively bilateral or diffuse discharges. In another series scalp EEG revealed no interictal epileptiform discharges

in 7/9 patients with mesial frontal lobe epilepsy confirmed by intracranial EEG.[107] An absence of interictal discharges has not been reported in the lateral frontal lobe resections.[108,109]

Focal interictal spikes and sharp waves at or adjacent to the midline have been reported in other series of patients with tonic postural seizures.[39,45] In a group of 16 patients with bilateral asymmetric tonic seizures, scalp EEG's recorded during long-term video/EEG monitoring showed midline frontocentral interictal epileptiform discharges in 50% of the patients.[45] Blume *et al.*[106] found a similar incidence of midline (Fz, Cz) (5 patients) or frontal (F4, F3) (2 patients) spike foci in a group of 13 patients with 'supplementary motor area epilepsy'. Examination of the EEG with montages using the midline electrodes, Fz, Cz and Pz, is essential as discharges maximal at these electrodes may have a very limited field.[39,105,110] Midline discharges present only during sleep can be difficult to distinguish from vertex sharp waves of sleep. Polyspikes and spikes with a prominent aftergoing slow wave will suggest epileptiform activity rather than sleep transients.[105] Normal sleep transients have a broad symmetric field and the addition of parasagittal 10-10 system electrodes may be helpful in documenting a persistent asymmetry of the electrical field of midline epileptiform discharges.[39,105] Identification of the same midline sharp waves or spikes during wakefulness will of course distinguish them from sleep transients.

Bilateral synchronous discharges are characteristic of but not specific to mesial frontal epilepsy[85,111] having been reported in orbitofrontal, lateral frontal foci and extrafrontal parietal lobe epilepsy.[74,76,112,113] Subtle lateralisation may be present in patients with bilaterally synchronous frontal discharges and recording during sleep is important if lateralising information is not to be missed.[106,111,114,115] Such lateralisation may be misleading, Blume and Oliver found interictal discharges maximal contralateral to the hemisphere of seizures origin in 2/8 patients with mesial frontal lobe epilepsy and secondary bilateral synchrony. Subtraction techniques may reveal consistent lateralisation in bi-frontal discharges not obvious when examined in bipolar montages.[116] Epileptiform discharges and regional slowing may also be present in frontopolar, parietal and occipital regions. This may be an indicator of seizure onset in extrafrontal regions[106] but it has also been reported as a misleading finding.[108]

The interictal EEG may show only non-epileptiform slowing in mesial frontal lobe epilepsy.[39] Intermittent rhythmic midline frontocentral slowing is seen in patients with bilateral asymmetric tonic seizures[38] and in patients with midline parasagittal epileptic discharges.[105] Ciganek[117] described a similar activity in patients with temporal lobe epilepsy although an association between this pattern and epilepsy was not confirmed in a large series of routine EEG studies.[118]

Muscle activity is prominent from the onset of bilateral asymmetric tonic seizures and the EEG is frequently contaminated with considerable electromyographic (EMG) and movement artefact. Electroencephalographic seizure patterns may still be evident at the vertex where EMG activity is least and transverse montages will usually demonstrate this best. Characteristic findings include an initial high amplitude slow wave transient or midline sharp wave followed by bilateral frontocentral low voltage fast activity or electrodecrement.[38,39,105,111,115,119] Electrodecrement will usually evolve into low voltage fast activity and then bilateral frontocentral or generalised rhythmic theta slowing.[38] The low voltage fast activity and the rhythmic slow activity may either be localised to the vertex or be more diffuse. Subtle lateralisation of these rhythms may occur but in general the lateralising information from ictal EEG is minimal.[106–108] This was the case in an excellent study looking at the localising and lateralising value of ictal scalp EEG recording in well defined focal temporal and extratemporal epilepsy.[120] Seizures from mesial frontal lobe foci most commonly showed paroxysmal fast activity (33%) or electrodecrement (29%) as the initial ictal pattern whereas seizures of lateral frontal lobe epilepsy showed repetitive epileptiform discharges (36%) or rhythmic delta at onset (26%). Foldvary and colleagues found only 25% of mesial frontal lobe epilepsy seizures correctly localised or lateralised and 75% had nonlateralised patterns.[120] Lateral frontal lobe epilepsy showed 65% of seizures to be correctly localised with an additional 6% correctly lateralised. Bautista *et al.*[108] found seizures originating in the dorsolateral region had focal ictal EEG patterns correctly localising to the region of seizure onset[108] but none of their 5 patients with mesial frontal lobe seizure onset had focal ictal EEG patterns.[108] An absence of any ictal or immediate postictal EEG slowing has been reported in patients in mesial frontal lobe epilepsy.[39,108] In Foldvary's study just over 50% of the seizures examined were obscured or showed no EEG change in the mesial frontal lobe group, an uncommon occurrence in the other focal epilepsy subsets.[120] The demonstration of an EEG seizure pattern may require examination of multiple recorded seizures to detect a subtle but reproducible pattern.

Aetiology of mesial frontal epilepsy

In symptomatic focal epilepsy arising from mesial frontal lobe the surgical specimens have the range of pathologies associated with all extratemporal surgical series. No unique pathologies exist for the mesial frontal lobe. Encephalomalacia, developmental tumours and malformations of cortical development predominate. There are seizure free surgical cases with non-specific findings presenting a cryptogenic category and raising the possibility of sporadic cases of autosomal dominant nocturnal frontal lobe epilepsy appearing in the refractory series.

Early surgical series excluding tumours have identified 'meningocerebral cicatrix' or gliosis as the commonest pathology related to a past history of head trauma, postinfectious scarring or birth injury.[121] Talairach *et al*[122] reviewed the aetiology in 100 patients with frontal lobe epilepsy undergoing surgery and also found a large percentage of patients with birth injury (18%), encephalitis (15%), and postnatal head injury (15%). Tumours were present in 10 patients in the Paris series.[122] A variety of neoplasms have been associated with intractable partial seizures in frontal lobe epilepsy including gangliogliomas, gliomas (low grade gliomas, astrocytoma, oligodendrogliomas) and hamartomas.[70,77] An aetiology could be identified in 15/18 patients with refractory tonic postural seizures undergoing surgery at the Cleveland Clinic Foundation;[43] 7 had tumours including ganglioglioma and astrocytoma, 5 had regional cortical dysplasia and 3 had encephalomalacia related to remote infarction, previous

cerebral abscess and head injury. In another series of 5 patients with mesial frontal lobe onset seizures; 3 had cortical dysplasia, 1 oligodendroglioma and 1 gliosis with a normal MRI.[108] Other pathologies include vascular malformations (cavernoma, thrombosed arteriovenous malformation)[123] and tuberous sclerosis.[124]

The literature on FLE is dominated by patients seen in comprehensive epilepsy centres with intractable seizures being assessed for epilepsy surgery. There are more benign frontal lobe epilepsies with tonic postural and hypermotor seizure semiology.[125–127] Vigevano and Fusco[125] described 10 children with 'hypnic tonic postural seizures', without neuroradio logical lesions who became seizure free with carbamazepine treatment. The seizures began at an early age and there was a family history of epilepsy in 8 of the patients. Frontal lobe epilepsy with autosomal dominant inheritance has been described with clusters of brief nocturnal motor seizures with tonic postural semiology or the hypermotor semiology.[126,128,129] While one cannot be sure of a mesial frontal lobe onset on the basis of seizure semiology alone, ictal SPECT evidence of regional hyperperfusion in the fronto polar and mesial frontal regions has been reported in these patients.[130] Onset is usually in childhood, mean 11.7 year, but a wide range of ages at onset is seen from 2 months to 52 years.[126] Not all of these patients are well controlled, the family history of epilepsy can be difficult to elicit and sporadic cases are thought to occur.[126,127] It is possible patients with idiopathic frontal lobe epilepsy are included in non-lesional surgical series.[131] A consistent feature in surgical series of frontal lobe epilepsy is the report of patients with no identified aetiology and non-specific findings in surgical specimens, yet some of these patients become seizure free in long term follow-up.[122,124]

A clinical syndrome of mesial frontal lobe epilepsy?

Tonic postural seizure semiology has often been presented as evidence for a diagnosis of mesial frontal lobe epilepsy.[39,115,125,126,132] However the tonic postural seizure is not specific for a seizure onset within the mesial frontal region or even the frontal lobe itself.[35,97] Additional evidence to support a mesial frontal lobe seizure onset may provided from structural neuroimaging studies showing circumscribed lesions[53,123] or functional neuroimaging such as positron emission tomography (PET)[133] and ictal SPECT.[76] Vertex or anterior frontal scalp EEG abnormalities[105,114] may be misleading and are not sufficient alone as support for a mesial focus.[35,134] Evidence of mesial frontal lobe seizure onset and

Table 36.1 Surgical outcome, mesial frontal resections

Series	Patients	Outcome
Talairach *et al.*, 1992[122]	31	Successful outcome[1] Anterior 50% Middle 18% Posterior 80%
Veilleux *et al.*, 1992[135]	8	4 patients Engel I and II no details on the other patients
Van Ness *et al.*, 1993[143]	20	4 patients Engel I 7 Engel II-III
Olivier, 1996[124]	28	6 patients Engel I, 7 Engel II-III, 6 Engel IVa, 9 Engel IVb
Smith & King, 1996[136]	12[2]	6 patients no or rare seizures, 2 >90% reduction in seizures, 4 < 90% reduction[3]
Mihara *et al.*, 1996[123]	5	4 patients seizure free 1 90% reduction in seizures
Spencer & Schumacher, 1996[138]	8	4 patients excellent outcome, 3 good outcome, 1 typical seizures continued
Toczek *et al.*, 1997[107]	9[4]	6 patients Engel I 2 Engel II 1 Engel III
So, 1998[145]	11	5 patients Engel I, 1 Engel II, 3 Engel III, 1 Engel Iva[5]

[1] Successful included those patients seizure free, with only rare seizures and with >75% reduction in seizures
[2] Four patients with structural lesions. Four of eight nonleisonal cases had previously undergone anterior corpus callosal sections to aid in localising EEG seizure onset.
[3] 12 month follow-up, subsequently; 2 patients lost to longer follow-up, 1 patient had sudden unexplained death, 1 (< 90% improvement) had second more successful surgery.
[4] All patients had section of the anterior portion of the corpus callosum
[5] One patient died in follow-up, drowning

involvement on the basis of invasive subdural or depth electrode studies is more rigorous a basis of case selection than semiology and scalp EEG.[33,34,43,45,50,135–137] However, intracranial electrode evaluations suffer from inherent sampling errors. Frontal epileptogenic regions are often large and there is rapid and complex seizure propagation patterns between cortical and subcortical regions.[35,50,134,134a] Series based upon seizure free outcome after frontal resections are the 'pure culture'[42, 121] from which seizure syndromes might be derived but the patients are not always separated into anatomical subsets such as mesial or lateral frontal lobe epilepsy and the patients only represent intractable symptomatic partial epilepsy with diverse aetiologies.

These caveats should caution us against accepting too readily a clinical syndrome of mesial frontal lobe epilepsy as there is remarkable diversity in terms of aetiology and prognosis once one gets beyond seizure semiology. The brevity, frequency and nocturnal occurrence of tonic postural seizures are not exclusive to the mesial frontal lobe epilepsy.[70,77] The predilection for tonic postural seizure onset during sleep may mitigate the disability arising from intractable epilepsy. There are several series examining surgical strategies in patients with seizures involving the supplementary sensorimotor area that provide some additional clinical details relevant to symptomatic mesial frontal lobe epilepsy.[13,45,123,124,136–138] In patients with medically refractory epilepsy tonic postural seizures very often occur daily and clusters of 5–20 seizures per day are not uncommon.[45,123,138] The majority of patients in surgical series have seizure onset at an early age: at the Cleveland Clinic; 17 patients, mean 10.4 years, range 3.5 to 22 years,[139] in Grenoble; 18 patients, mean age 7 years, range 6 months to 22 years,[137] at Yale University School of Medicine; 7/8 patients, had onset at 15 years or younger.[138] Normal neurological examinations and average intelligence are more commonly reported than focal signs or severe intellectual disability[138,139] although others have found a higher incidence of abnormal neurological signs. In the series of 100 frontal lobe surgery cases from St. Anne's Hospital in Paris 60% had motor or sensory signs and a third of these had intellectual deficits.[122] Specific neuropsychological deficit profiles have not emerged for mesial frontal lobe epilepsy to distinguish it from other subsets frontal lobe epilepsy.[140–142] A high incidence of abnormal interictal behaviour and psychiatric illness has been reported in patients with cingulate epilepsy.[1,85]

37 Basal frontal lobe epilepsy

AV Alexopoulos and N Tandon

Introduction

For neuroscientists and clinicians alike the basal frontal cortex is one of the least explored and least understood regions of the cerebral cortex.[1] Studies of the connectivity of the orbitofrontal region by invasive tract tracing in animals, and less invasive methods in humans, suggest that this region is part of a widely distributed network involving cortical and subcortical projections within the frontal lobes and limbic system.

Unlike seizures arising from other cortical sites, seizures originating from within the orbitofrontal region have not been extensively characterized in the existing literature. Several factors have tempered our understanding of basal frontal lobe epilepsy including the lack of a characteristic semiology and electroencephalographic findings, the inaccessibility of this region to surface electrodes and the resulting need for invasive recordings in order to demonstrate ictal onset within the orbitofrontal region. Not surprisingly, surgical experience in patients with pharmacoresistant epilepsy is relatively limited, when it comes to resections restricted to the basal frontal area.

The functional heterogeneity and widely disseminated connections of the basal frontal areas account for the protean clinical manifestations of seizures arising from this region. In this chapter we will review the anatomical and functional aspects of the orbitofrontal region and examine the characteristics of the few cases of basal frontal lobe epilepsy that have been reported in the literature.

Anatomic considerations

The basal surface of the frontal lobes (Figures 37.1 and 37.2a) is anatomically divided from front to back into right and left orbital cortices, right and left anterior perforated substances (which are partially covered by the temporal poles) and the midline interpenduncular (or intercrural) area.[2] The orbital surface of each frontal lobe is literally located 'above the orbit' and houses the orbitofrontal cortex, which is part of the prefrontal cortex.

Given that there is no single functional role or cytoarchitectonic structure common to all portions of the basal frontal area (as opposed to, say, the primary motor area or the primary visual cortex) the term orbitofrontal cortex may be somewhat misleading. The region is perhaps best described as *the orbitofrontal region*. Another term that is occasionally used to define this area is the term 'basal frontal lobe'. While this terminology intuitively suggests the anatomic location of the region under consideration, it may be confused to incorporate components of the basal ganglia that are intimately related to the fiber tracts of the frontal lobe. Therefore, we prefer to refer to this collection of structures as the orbitofrontal region (OFR).

Gross anatomy

Sulcation patterns in this region are highly variable. In most cases however, three principal sulci are noted on the basal (orbital) surface of the frontal lobe: the lateral and medial orbital sulci and the H-shaped sulcus. The two longitudinal orbital sulci (lateral and medial) divide the orbitofrontal region into lateral and medial orbital gyri and an intermediate orbital cortex[3] (Figure 37.1).

- *The lateral orbital sulcus* separates the orbital lobe from the lateral surface of the frontal lobe (from the inferior frontal gyrus).
- *The medial orbital sulcus* is synonymous with the olfactory sulcus – the longitudinal sulcus in which the olfactory tract and bulb are located. At its caudal end, the olfactory tract divides into the medial and lateral olfactory striae. Between these two striae lies a rhomboid-shaped region, the anterior perforated substance, whose other two boundaries are the optic tract (posteriorly) and the proximal anterior cerebral artery (ACA) postero-medially. Posterolaterally, it continues into the uncus and medially, it is continuous with the subcallosal gyrus. The anterior perforated substance is perforated by several minute blood vessels (including some lenticulo-striate arteries) arising from the ACA and the carotid artery and supplying several deep subcortical structures.[4]
- *The H-shaped orbital sulcus* lies in the largest section of the OFR – the intermediate region – and varies significantly among individuals. The typical H-shape is formed by two longitudinal rami, which are linked by a transverse ramus (the latter is also known as arcuate orbital or transverse orbital sulcus). This H-shape is not commonly seen; rather the name 'H-shaped sulcus' encompasses the complex sulci situated in the central region of the orbital lobe.[2,3]

The orbital sulci form five gyri on the basal surface of the frontal lobe. These are (from lateral to mesial):

(1) *The lateral orbital gyrus*, located between the lateral orbital sulcus and the H-shaped sulcus;
(2) and (3) *The anterior and posterior orbital gyri* situated on each side of the transverse ramus within the confines of the longitudinal rami of the H-shaped orbital sulcus;

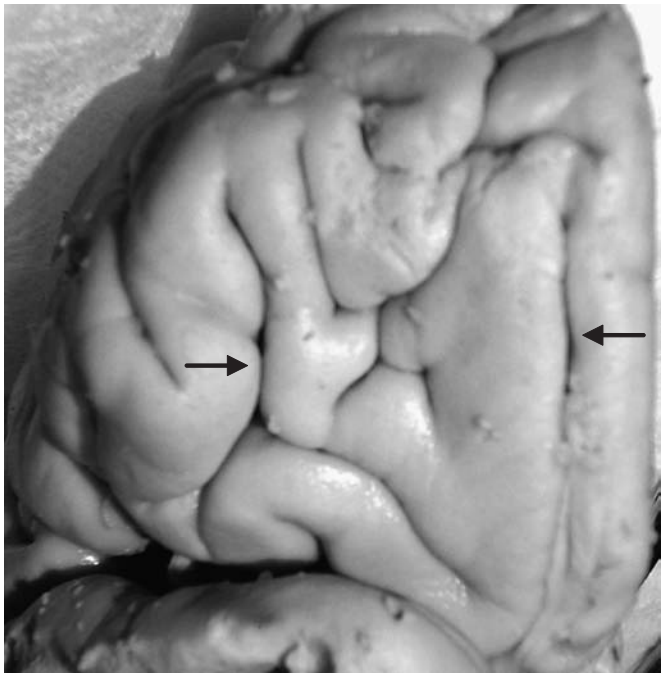

Figure 37.1 The basal surface of the frontal lobe – fresh cadaveric specimen. The two longitudinal orbital sulci (lateral and medial) – black arrows – divide the orbitofrontal region into lateral and medial orbital gyri and an intermediate orbital cortex.

(4) *The medial orbital gyrus* located between the H-shaped and the medial orbital sulcus; and
(5) *The gyrus rectus*, which lies along the medial margin of the orbital lobe and extends over the medial surface of the frontal lobe

Given the considerable variability with regards to the shape of the orbital sulci and gyri, some neuroanatomists prefer to generically label the convolutions between the olfactory sulcus and the inferior frontal gyrus (F3) as *orbital gyri*, and all of the corresponding sulci as *orbital sulci*.[5]

The anterior and posterior limits of the OFR are the frontal pole and the anterior perforated substance respectively. The frontal pole is a transitional area between the lateral, medial, and orbital surfaces of the frontal lobe.[2] The three longitudinally oriented frontal gyri (superior, middle and inferior) are interrupted by transverse folds, the *transverse frontopolar gyri*. A fairly constant and deep sulcus, the *frontomarginal sulcus*,[3] separates the *transverse frontopolar gyri* dorsally from the *frontomarginal gyrus* ventrally. The *frontomarginal gyrus*, can therefore be considered to constitute the inferior part of the frontal pole and to mark the boundary between the fronto-polar and orbital regions.

The inferior frontal gyrus (F3) merges into the orbital region, where *the pars orbitalis* (the most rostral part of the inferior frontal gyrus) continues into the *caudal part of the lateral orbital gyrus* and the *posterior orbital gyrus*. The continuation of the superior (F1) and middle frontal (F2) gyri in the orbital lobe is considered arbitrary.[2] In general, *the medial orbital gyrus* and *the gyrus rectus* are linked to *the superior frontal gyrus* (F1). Similarly, *the anterior orbital gyrus* and *the rostral part of the lateral orbital gyrus* are considered part of *the middle frontal gyrus* (F2).

Cytoarchitecture

Several investigators have developed cytoarchitectonic maps of the OFR in humans and monkeys. The pioneering investigations of Brodmann,[6] while detailed in other brain regions, were relatively cursory in the OFR. His maps of this region were essentially restricted to charting areas 10, 11, and 47.[7]

Subsequent studies of the same region in primates revealed that the cortex on the orbital surface of the frontal lobe can be categorized as Brodmann Area (BA) 14 medially (corresponding to the gyrus rectus), and 13 caudally. As it extends laterally to the inferior convexity the orbitofrontal cortex corresponds to BA area 12 caudally and 11 anteriorly (anterior orbital surface). Finally, the frontal pole corresponds to BA 10. There is now general agreement that the cyto-architecture of the orbital cortex is similar in humans and primates and earlier discrepancies have been largely reconciled.[8,9]

A recent detailed cyto-architectonic investigation of the human orbital and medial PFC (Figure 37.2b) revealed that all of the subdivisions recognized in the macaque have counterparts in humans.[10] The rostro-caudally organized granular to agranular gradient seen in the rest of the frontal lobe also manifests itself in the orbitofrontal region: The posterior orbital cortex is dysgranular in contrast to the anterior granular areas.[10] The lateral orbital cortex is recognized as BA 47/12. The rostral (anterior) orbital cortex is labeled as BA 11; it consists of a strongly granular cortex that is contiguous with the frontal pole (BA 10). Area 13 occupies the posterior medial orbital surface. Finally, area 14 embodies the cortex of the gyrus rectus at the ventromedial convexity of the frontal lobe. Thus, the OFR constitutes a region of cytoarchitectural transition between the agranular piriform olfactory cortex and the granular cortex of the dorsolateral PFC.[11]

The medial wall of the prefrontal cortex comprises of agranular areas 24 (anterior cingulate cortex), 25 (most posterior/subgenual portion of the medial wall) and 32 (paracingulate cortex).[10] These areas share some functions with portions of the OFR, but will not be discussed further in this chapter.

Connectivity and functional considerations

As described above, the primate orbitofrontal region occupies the entire ventral surface of the frontal lobe and is considered part of the prefrontal cortex.[7] The granular prefrontal cortex (PFC) receives projections from the medio-dorsal nucleus of the thalamus and constitutes a large expanse of cortex situated in front of the motor and premotor regions of the frontal lobe (Brodmann areas 4 and 6).[12] The PFC reaches its highest level of development in the human brain.[13]

The PFC can be sub-categorized on the basis of divisions of the medio-dorsal nucleus of the thalamus,[14,15] a critical relay structure, which in turn receives input from almost all other cortical areas:[16]

(1) The medial part of the medio-dorsal nucleus (pars magnocellularis) projects to the orbital (ventral) surface of the PFC, the so-called 'orbitofrontal cortex' or orbitofrontal region (OFR).
(2) The lateral part (pars parvocellularis) projects to the dorsolateral prefrontal cortex (DLPFC). This part of the PFC receives input from the parietal cortex and is involved in spatial short-term memory tasks.[14,15]

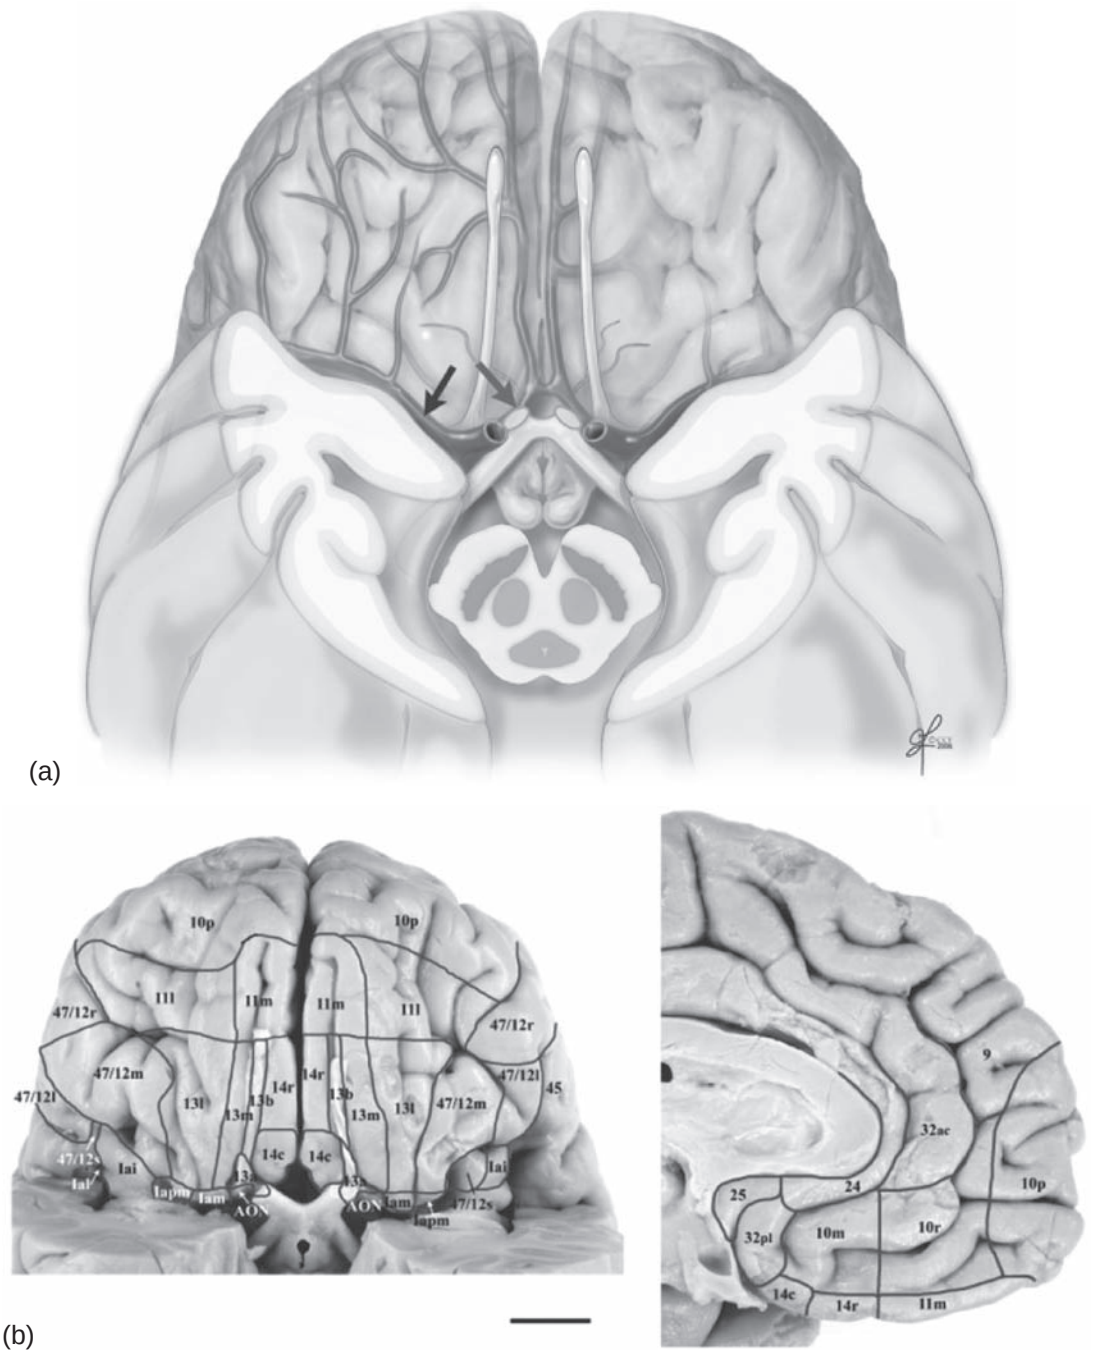

Figure 37.2a Relationships of the OFR with the olfactory tracts and the middle and anterior cerebral arteries arrows revealed after removing the right temporal pole. b: Architectonic subdivisions of the human orbitofrontal region (left) and medial frontal surface (right); scale bar = 10mm. Reproduced with permission from ref. 10.

(3) The pars paralamellaris (the most lateral part of the mediodorsal nucleus of the thalamus) projects to the frontal eye fields (Brodmann area 6).

In humans, indeed in all primates, the posterior part of the OFR is continuous with the rostral part of the agranular insula and abuts upon the para-olfactory component of the cingulate cortex, the anterior olfactory nucleus, and the piriform cortex. This part of the OFR is more primitive architectonically (non-isocortical OFR), and is hence regarded as more 'limbic' in character.[17] On the other hand, the rostrally-placed isocortical OFR has the appearance of granular isocortex and blends into the dorsolateral heteromodal components of prefrontal cortex.[17,18]

In addition to visceral information the OFR receives direct and indirect inputs from all sensory modalities (gustatory, olfactory, somatosensory, auditory and visual). Therefore, the OFR stands out as perhaps one of the most 'polymodal' brain regions.[7] As a rule, cortico-cortical connections are densest among areas with comparable architecture: the more anterior isocortical OFR is mostly linked with isocortical prefrontal, premotor and sensory (somatic, auditory and visual) cortical areas. By contrast, the more posterior nonisocortical sectors of the OFR are mainly

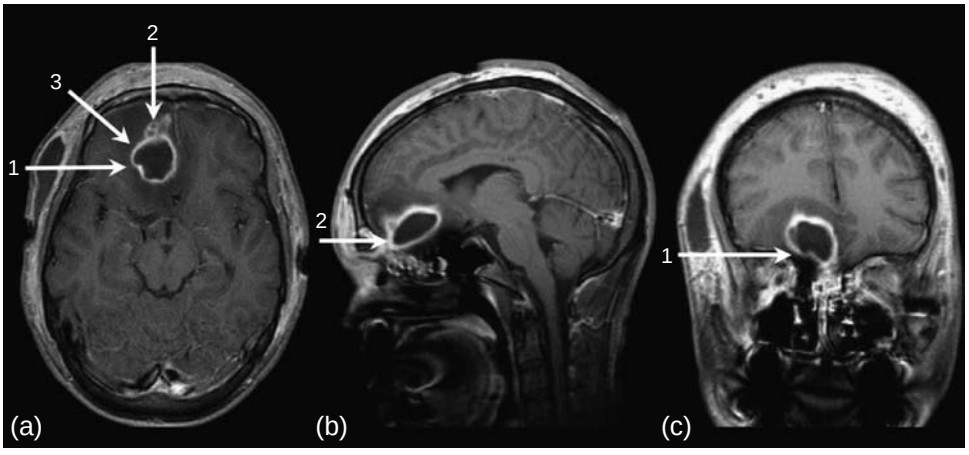

Figure 37.3 The three generally accepted surgical approaches to the OFR. These images show a brain abscess in the gyrus rectus, which could be approached by three possible directions: (1) Lateral approach: commonly performed when OFR resection is carried out after a period of extraoperative invasive recordings using subdural electrodes. (2) Anterior approach: used predominantly for lesionectomies in cases of smaller focal lesions. (3) Antero-lateral approach: may be used for larger lesions of the OFR and possibly combined with an orbito-zygomatic osteotomy. A principal advantage of the anterior and antero-lateral approaches is that the inferior frontal gyrus may be more easily spared.

connected with nonisocortical areas of the insula and temporal lobe, and with primary olfactory and gustatory cortices.[18]

The posterior orbitofrontal cortex receives gustatory and olfactory input through direct connections that originate from the primary taste and olfactory cortices or indirectly via the thalamus. The afferent pathways through the thalamus to the orbitofrontal cortex are thought to mediate conscious perception and discrimination of odors. As a consequence, patients with lesions of the orbitofrontal cortex may lose the ability to discriminate odors.[19]

The OFR has reciprocal connections with the amygdala both through the ventral amygdalofugal tract and through the

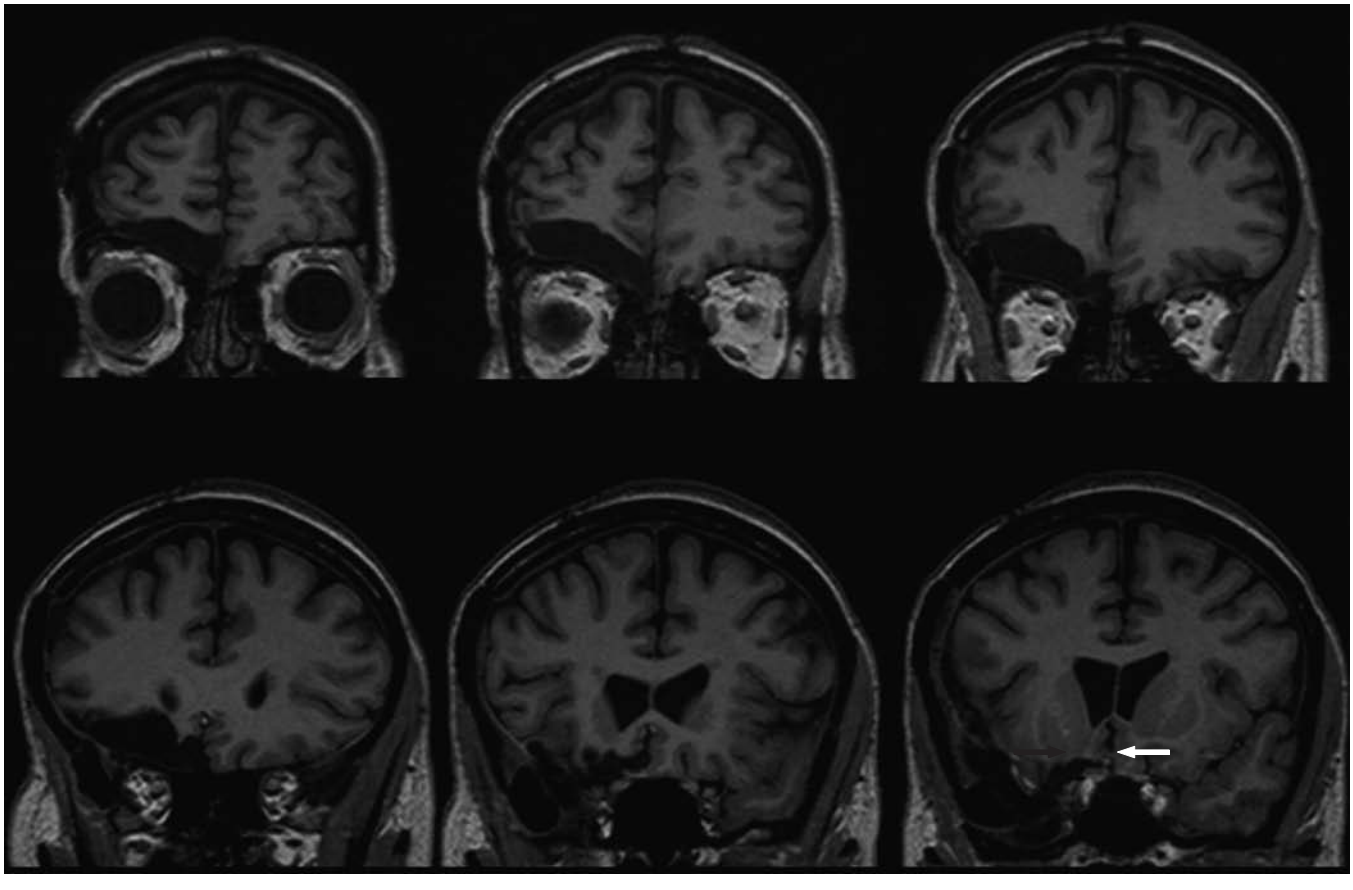

Figure 37.4 Coronal MRI views following extensive resection of the OFR and anterior temporal pole in patient with pharmacoresistant focal epilepsy. Note the preservation of the ventro-lateral prefrontal cortex and resection extending to the subcallosal gyrus (white arrow). Also note the proximity of the supero-medial edge of the posterior margin of the resection to the nucleus accumbens (black arrow).

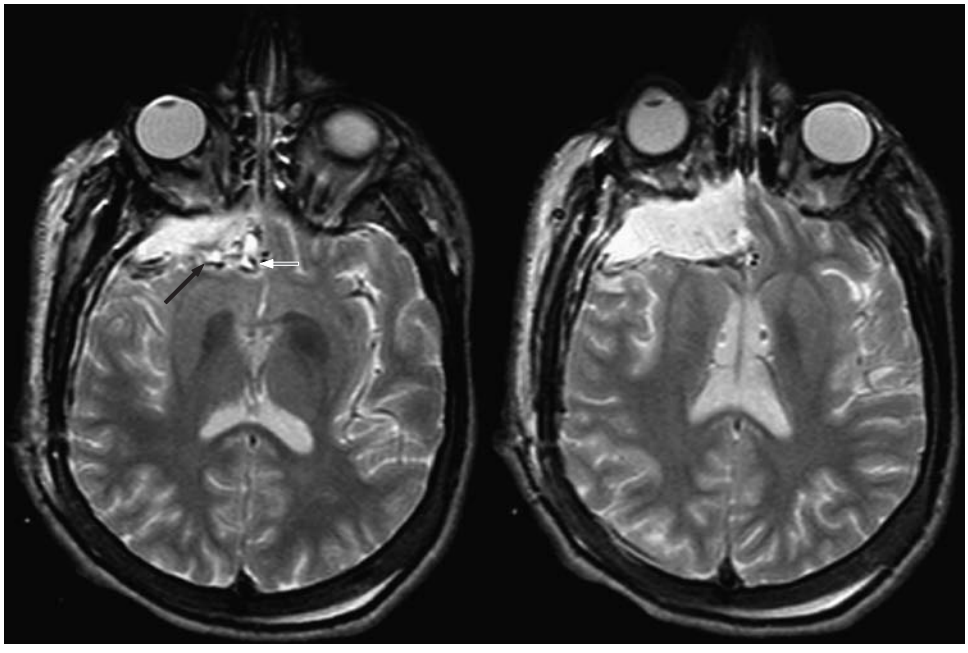

Figure 37.5 Axial views of a T2-weighted MRI after a 'complete' OFR resection. The posterior edge of the resection abuts the middle cerebral artery (black arrow) and the postero-medial edge abuts the anterior cerebral arteries (white arrow).

stria terminalis,[16] and projects back to the inferior temporal cortex, amygdala, as well as to the entorhinal cortex, which serves as 'the gateway to the hippocampus'. In addition the OFR has projections to the hypothalamus and various brainstem structures (including the periaqueductal gray matter, and ventral tegmental area), the caudate nucleus and the cingulate cortex.[18,20]

Epileptologists should be familiar with the main *bidirectional* association pathways linking the OFR with the temporal lobe and limbic system: the uncinate fasciculus and the so-called ventral and dorsal limbic pathways:[13]

- The fibers of the uncinate fasciculus arise from the most rostral part of *the superior temporal gyrus* (T1). They run as part of the uncinate fasciculus and terminate in areas of the OFR and the medial PFC.
- The ventral limbic pathway originates from *the parahippocampal gyrus* (T5). It consists of two segments: The rostral segment runs through the uncinate fasciculus towards the OFR and medial PFC. The caudal segment terminates in areas of the dorsolateral PFC.
- The dorsal limbic pathway arises from *the cingulate cortex* and runs as part of the so-called cingulum bundle. Some components of these association fibers are directed towards the PFC (and terminate in the OFR, as well as medial and dorsolateral PFC).[13]

In a recent stereo-EEG study Catenoix and co-workers investigated the functional anatomic connectivity between the hippocampus and OFR in humans by means of intracerebral hippocampal electrical stimulation[21] in three patients. Low frequency (≤ 1 Hz) bipolar stimulation of adjacent hippocampal contacts was found to result in reproducible evoked responses in the OFR with a mean, first peak latency of 222 ms, and confirmed the existence of functional connections between the hippocampus and the OFR in humans. The long latency of the main response indicates a polysynaptic projection from the hippocampus to the ipsilateral OFR, which, the authors speculate, may play a role in the interhemispheric propagation of discharges arising from mesial temporal structures. This hypothesis is supported by previous studies of ictal recordings obtained using bilateral mesial frontal and temporal depth electrodes, which show that the ipsilateral OFR is frequently and rapidly involved during propagation of seizures arising from the mesial temporal region.[22] In a series of eight patients, who were studied with bilateral, multicontact, orbitofrontal depth electrodes, Wilson and Engel observed that 5 mAmp stimulation of the OFR on one side was effective in evoking contralateral homotopic responses (responses recorded from the OFR on the other side) in the majority of cases.[23] The authors recorded an initial, short-latency, ipsilateral OFR response in contacts adjacent to the stimulated electrodes, followed by a clear response of slightly longer latency in the contralateral OFR. The ease, with which the contralateral OFR response was elicited and recorded, has led to the hypothesis that spontaneous seizure activity may in fact use similar interhemispheric pathways to propagate contralaterally.[23]

Lesions or damage to the OFR have been associated with significant changes in emotion, personality, behavior and social conduct. Patients often exhibit signs of disinhibition, impulsivity, inappropriate jocular affect (witzelsucht), emotional lability, poor judgment, lack of initiative and reduced concern for social conventions.[24] It has been suggested that these patients may suffer from impaired detection of emotional reinforcers such as voice or face expression, and exhibit impaired responses to changing reinforcers.[7] Indeed, the classical case of Phineas Gage, who was injured by a penetrating foreign object that lodged in both medial frontal lobes, may reflect the consequences of orbito-frontal region damage.[25,26] Many signs evident in the early months after head injury to the basal frontal regions seem to fade away with the passage of time, suggesting plasticity involving othermbic regions or the

contralateral homolog. The likelihood of residual personality changes is mainly determined by the severity of the injury.[27] Autonomic and visceral changes including intermittent vasomotor instability and gastrointestinal or cardiac abnormalities may also occur following lesions of the OFR.[28]

Functional imaging of the human OFR has generally confirmed its role in the assessment of potential reward and punishment as has previously been suggested by neurophysiological recordings in nonhuman primates. Additionally, a recent meta-analysis of 87 published functional imaging studies of the OFR suggests that there may be two trends of neural activity in the OFR. The first is a medio-lateral distinction, whereby the medial OFR activity is implicated in monitoring reward potential of different reinforcers – whereas lateral OFR activity is more related to the evaluation of punishers, which may lead to a change in ongoing behavior. The second is a posterior–anterior distinction in which complex or abstract reinforcers (such as monetary gain and loss) appear to be represented more anteriorly in the OFR compared to more simple (or visceral) reinforcers such as taste or pain.[7]

It is evident that the OFR has extensive connections with medial temporal structures as well as thalamic regions involved in various stages of memory processing. Nonetheless, the functional role of the OFR in relationship to memory is not well understood.[18] Dysfunction of the orbitofrontal cortex has been implicated in a number of psychiatric disorders. Neuroimaging studies have repeatedly implicated the OFR in the pathophysiology of obsessive-compulsive disorder (OCD) and depression. It has been consistently demonstrated that patients with OCD show increased uptake of tracers with SPECT and PET imaging measuring cerebral blood flow and metabolic activity.[11,16] Interestingly, this hyperactivity of the orbitofrontal area has been found to normalize following successful pharmacological or behavioral therapy.[29,30] On the other hand, hypometabolism of the OFR and adjacent brain regions has been observed in patients with secondary depression.[31]

Basal frontal lobe epilepsy

It is difficult to estimate the prevalence of basal frontal epilepsy. The true percentage of patients in the general population, who have seizures originating from the basal frontal lobe, is unknown. The literature contains only a handful of patients with pharmacoresistant epilepsy, whose seizures were clearly shown to arise from the orbitofrontal region.

The most reliable evidence for accurate localization of the epileptogenic zone is seizure freedom after epilepsy surgery.[32] This gold standard can only be applied to a small fraction of patients with focal epilepsy, namely patients with medically intractable seizures who are referred for surgical therapy and undergo successful surgical resections. One should remember, however, that a larger number of patients with basal frontal lobe epilepsy may not seek medical attention, may respond well to medications or may be misdiagnosed as having paroxysmal nonepileptic events.

The epileptogenic zone is most precisely defined as the area of cortex generating seizures, the complete removal of which is necessary in order to abolish seizures.[33] Therefore, under ideal circumstances the orbitofrontal origin of the epilepsy is deduced postoperatively on the basis of a surgical resection restricted to the OFR and leading to long-term cessation of seizures after surgery.

When patients do not undergo resective surgery, or are not completely seizure free following resection, or in cases where surgical resection extends beyond the boundaries of the basal frontal lobe, the origin of seizures within the OFR is surmised by intracranial ictal EEG recordings and/or by the presence of a structural lesion. It should be emphasized, however, that these latter criteria (localized intracranial ictal recordings and/or presence of a demonstrable lesion) can not be used as surrogates to the concept of the epileptogenic zone.[34]

Invasive recordings are currently required to demonstrate ictal onset within the OFR. In the subgroup of patients referred to tertiary epilepsy centers, estimates about the frequency of epilepsy arising from this region will depend on how frequently the OFR is investigated invasively.[35] A large stereo-EEG study of 60 patients, who presented with electroclinical patterns requiring differentiation between frontal or temporal seizure onset and underwent exploration with at least one orbital frontal electrode, was reported by Munari and Bancaud in 1992. Ictal discharges were felt to be 'primarily localized' in the OFR in eight patients.[36] The majority of patients in this highly selected group underwent 'acute' investigations lasting for less than 6 hours. Moreover, the authors did not comment on further surgical decisions, and extent of surgical resection and postsurgical outcome, when applicable. In a later review, Munari and co-workers concluded that their original stereo-EEG approach to the OFR 'was not entirely satisfactory', because it did not necessarily target the orbitofrontal cortex.[37]

Jobst and co-workers presented a series of 26 patients with intractable frontal lobe epilepsy. Of these, seven patients were deemed to have seizures arising from the orbitofrontal region.[38] All seven underwent tailored resections with excellent seizure outcome in five (mean follow-up was 52.2 months for the entire series). Individual results of scalp EEG, invasive recordings and brain MRIs were not listed. Similarly, the extent of surgical resection in each case was not provided. Given these limitations, patients from these two series are not included in our further discussions.

The authors of one of the best-documented cases of orbitofrontal epilepsy[39] set strict criteria to establish that seizures indeed arise from the OFR. These include: (1) the OFR should be the source of interictal and ictal activity, as defined by intracranial recordings; (2) resective surgery should be limited to the OFR, and (3) postoperatively the patient should remain free of seizures for at least 5 years. They also propose a fourth relative criterion: it would be preferable to include cases in which the resected surgical specimen from the orbitofrontal focus displayed specific histopathologic abnormalities.[39]

Table 37.1 presents a compendium of cases of presumed orbitofrontal epilepsy as reported in the literature.[37,39–53] An attempt has been made to include most, if not all, cases previously associated with the OFR (initial historical reports as well as more recent descriptions from the MRI era), and to retain the description of seizure semiology, results of neurophysiology, imaging and surgery, as provided in the original reports. Seizure outcome, when available, has been adapted according to the Wieser proposal for a new classification of outcome with

Table 37.1 A compendium of published cases of presumed orbitofrontal epilepsy (from 1951–2005)

respect to seizures following epilepsy surgery.[54] Careful review of these cases, with the above criteria in mind, reveals that in most instances localization of the epileptogenic zone within the OFR is either presumed or unconfirmed. Our inability to determine the extent of the epileptogenic zone and its relationship to the OFR, when surgical resection involves extra-orbital areas adjacent to the basal frontal lobe or when an extensive frontal lobectomy has been performed reflects a well-recognized inherent limitation of most human surgical studies.[35]

Seizure (clinical) semiology

The most widely used system for classification of epilepsies was revised in 1989 by the Commission on Classification and Terminology of the International League Against Epilepsy (ILAE).[55,56] The 1989 Proposal for the Classification of the Epilepsies and Epileptic syndromes describes a separate anatomically defined seizure pattern in regards to the orbitofrontal area: 'The orbitofrontal seizure pattern is one of complex partial seizures with initial motor and gestural automatisms, olfactory hallucinations and illusions, and autonomic signs'.[55]

The commission prefaces the 1989 report with a cautionary note: '... inferences regarding anatomical localization must be drawn carefully'. Attempts to classify seizures according to location (anatomic lobes or sublobar regions) are confounded by the fact that seizures usually give rise to ictal manifestations by virtue of propagation to eloquent areas of cortex. Large cortical areas in the anterior neocortex such as the prefrontal cortex may be clinically silent, when activated by seizure discharges or electrical stimulation. Consequently, the first clinical evidence of a seizure may reflect propagation to areas remote from the region of seizure origin.[57] Seizures arising from a distinct focus within the frontal lobe may rapidly involve multiple frontal lobe regions concealing specific seizure patterns.[58] On the other hand, extensive, nondiscrete, or multifocal epileptogenic zones and rapid spread patterns within the ipsilateral or contralateral frontal lobe will lead to overlapping, coincidental clinical phenomena. As a result of these limitations, attempts to classify frontal lobe seizures on the basis of distinct anatomic subdivisions may be restrictive and potentially misleading.[35,59]

Moreover, only a handful of patients with unequivocal focal epilepsy arising from the orbitofrontal area have been reported in the literature, as is evident from the earlier discussion and the cases listed in Table 37.1. In their comprehensive review of 'complex partial seizures of extratemporal lobe origin' Swartz and Delgado-Escueta remarked that only eleven cases of 'orbitofrontal complex partial seizures' existed in the literature in a period spanning almost 20 years (from 1957–1975; all 11 cases are included in Table 37.1). And only nine of these were thought to carry 'strong proof'.[60]

Electrical stimulation studies

Direct electrical stimulation of the cortex has been used to study the results of epileptic activation of various cortical sites.[61] Stimulation studies with an effective stimulus intensity reveal that the majority of human cortex is symptomatically silent, and provide further evidence to suggest that cortical activation by epileptiform discharges will not produce symptoms, unless the electrical activity spreads to adjacent eloquent cortical sites.[34]

Stimulation of the OFR has been reported to produce a variety of responses. Smith and co-workers report that stimulation of the lateral and mesial posterior OFR (including the apparent ictal onset zone in a patient with pharmacoresistant focal epilepsy) did not produce any observable clinical phenomena. Such findings lend support to the hypothesis that clinical manifestations of basal frontal epilepsies may in fact begin outside the basal frontal area.[51] The same group stimulated 13 posterior orbitofrontal sites using laterally placed depth electrodes in nine patients, who did not have evidence of focal epilepsy arising from the OFR. An assortment of sensations were elicited in this group including 'body tingling' on six occasions, and 'a spaced-out, confused feeling' on four; 'an unpleasant feeling', an ill-defined smell, an olfactory hallucination, a cephalic sensation, lightheadedness, and 'fuzzy vision' were reported on one occasion each.[51] In their series of orbitofrontal stereo-EEG depth electrode investigations Munari and Bancaud report that an olfactory hallucination can be elicited in the presence or absence of 'a localized afterdischarge' following posterior orbitofrontal stimulation.[36] Smith and co-workers postulate that such provoked olfactory symptoms may actually reflect activation of the adjacent lateral olfactory striae,[51] which is possible, given that afterdischarges related to electrical stimulation often activate a more extensive cortical region beyond the cerebral tissue surrounding the directly stimulated electrode.[61]

Lastly, autonomic responses resulting from OFR stimulation in humans were reported in older studies;[62,63] these include blood pressure elevation or bradycardia,[64] respiratory arrest or increased amplitude of respiration, and increased esophageal contractions or decreased gastrointestinal motility.

Ictal manifestations

As discussed earlier, the large prefrontal cortical region can be viewed as a collection of heteromodal association areas, which share elaborate connections with other frontal and extrafrontal cortical and subcortical structures.[65] Hence, seizures arising from several regions within the anterior part of the frontal lobe – including the orbitofrontal, frontopolar, anterior cingulate, and medial intermediate frontal regions – may display overlapping clinical characteristics as a result of the rapid and simultaneous activation of cortical sites within the PFC and its connections.[58,66] In general, seizures arising from the frontal lobe may start and end abruptly with little if any postictal confusion, and tend to have a shorter duration (lasting less than 30 seconds) and higher frequency (oftentimes occurring in clusters) compared to seizures of temporal lobe origin.[35] Ictal behavior is commonly characterized by prominent and often complex motor manifestations. Because of their bizarre appearance at times, frontal lobe seizures are not infrequently mistaken for nonepileptic, psychogenic events.[67] The somewhat circuitous and dichotomous term 'frontal lobe complex partial seizures' has been proposed by some authors to describe these events.[53,68,69] Stereotypic recurrence of the various clinical components in individual patients is key in establishing the correct diagnosis of seizures arising from the frontal lobe.[53,67]

Again, it is important to recognize that the observed seizure semiology reflects epileptic activation of the symptomatogenic zone.[34] When seizures originate from silent areas of the brain there will be no outward manifestations without propagation of seizure activity to the symptomatogenic zone. Studies with

depth electrodes have shown that ictal onset within the OFR may precede the onset of clinical manifestations by as much as 60 seconds suggesting asymptomatic activation of this area.[37,51,70] Two separate groups of investigators have observed that patients may in fact remain completely asymptomatic, when the epileptic discharge stays localized within the OFR.[37,47] Summarizing their experience of more than 150 patients, in whom the orbitofrontal region was investigated using stereo-EEG, Munari and co-workers concluded that 'the only clinical from characteristic of well-limited discharges in the orbital cortex was the absence of any objective clinical symptomatology'.[71]

Based on these observations, the limited number of well-documented published cases, and the functional heterogeneity of the OFR, it is difficult to assume a unique seizure semiology that is characteristic for this part of the frontal lobe. A review of reported cases reveals some common themes: lack of aura or nonspecific auras, autonomic changes, behavioral arrest and/or impaired awareness, complex motor and 'hypermotor' activity, vocalization, oculocephalic deviation, olfactory or gustatory hallucinations, occasional secondary generalization.[55,66,72] Occurrence in clusters, nocturnal preponderance, relatively brief duration and brief if any postictal confusion are also observed.

Based on the cases reported by Ludwig[41] (see Table 37.1) Bancaud and Talairach identified two 'recognizable seizure patterns' associated with seizures of orbitofrontal origin,[73] as follows:

(1) Olfactory auras, defined as seizures beginning with an olfactory hallucination or illusion. The olfactory symptoms may be accompanied by gustatory auras, autonomic changes, oroalimentary and/or gestural automatisms and 'thymic alterations'. These associated symptoms have been attributed to propagation of ictal discharges to the adjacent opercular-insular-amygdalar region (autonomic manifestations, gustatory hallucinations or illusions, and oroalimentary activity) and/or to anterior cingulate region (complex gestural activity 'automatic gesticulations', and mood changes).[36] Other studies have shown that olfactory auras usually point to seizures originating from the limbic mesial temporal structures, which are also involved in olfactory function.[74,75] In fact, published reports suggest that olfactory auras constitute an uncommon manifestation of seizures arising from the basal frontal region.[76]
(2) Autonomic seizures, defined as seizures of prevalent 'vegetative components'. They present with a variety of paroxysmal autonomic disorders including cardiovascular (heart rate changes, facial flushing, pallor), respiratory (apnea), digestive (sensation of hunger and/or thirst), urogenital (urge to urinate and periictal urination) and thermoregulatory disturbances (sensation of cold with piloerection and/or sensation of heat). Ictal 'vegetative' manifestations are thought to result from activation of the orbitofrontal and opercular insular regions.[35,73]

The so-called 'hypermotor seizures' constitute another ictal pattern commonly associated with this region. According to the Semiologic Seizure Classification hypermotor, seizures are defined as seizures manifesting with complex motor automatisms – organized motor activity, which primarily affects the proximal body segments and results in relatively large amplitude movements.[77] The term 'organized' refers to movements that imitate natural movements as opposed to dystonic, tonic or clonic movements, but does not specify whether they are voluntary, involuntary or semipurposeful (e.g., evoked in response to environmental stimuli).[78] When rapidly executed these movements may appear violent, for example thrashing, bicycling, vigorous kicking, frenetic striking or flailing of limbs and other rather peculiar motor behaviors.[76] The repetitive character of these motions has been attributed to the central role of the prefrontal and premotor areas of the frontal lobe in the sequential design of movements.[79]

In a large series of suspected frontal or temporal lobe epilepsies Manford and co-workers identified 13 patients with a CT and/or MRI-demonstrable lesion ('lesional focal epilepsy') and hypermotor seizures, characterized by early 'motor agitation'. The authors noted that the structural lesions involved the OFR in the majority of cases (7 out of 13). Lesions extended to the frontopolar cortex in Six of these Seven patients.[80] The remaining Six cases with early motor agitation showed no consistent lesion localization (their lesions resided in various other frontal or temporal areas). Such observations may support the 1989 ILAE classification of anatomically defined seizure types of possible orbitofrontal origin. It should be noted however, that this was not a series of patients undergoing resective epilepsy surgery, and that the definition of the presumed epileptogenic focus was based on somewhat loose and often discordant clinical, EEG and MRI/CT localization criteria. In his review of structural lesions in the frontal lobe Goldensohn found '… too few cases with discrete lesions with sufficiently detailed seizure descriptions of possible orbitofrontal and cingulate origin to allow separate categorizations'.[66] The author concluded that symptoms and signs commonly linked to orbitofrontal and/or cingulate epilepsy (such as autonomic or mood and affect changes, gestural automatisms, and versive movements preceding automatisms) do not appear to differentiate between lesion cases involving the orbitofrontal, anterior cingulate or other areas of the anterior third of the frontal lobe.[66]

Finally, it should be emphasized that epileptogenic foci within the OFR can give rise to seizures, which are electroclinically indistinguishable from temporal lobe seizures given the widespread connections between the limbic system and the OFR.[39,47,50] In other words, basal frontal epilepsy may manifest itself with seizure spread outside the lobe of origin, as illustrated by Shihabuddin and colleagues in their case of a small right orbitofrontal pilocytic astrocytoma. Invasive recordings demonstrated seizure generation in the right OFR with spread to the ipsilateral mesial-basal temporal region – seizures were eliminated almost completely following right mesial orbitofrontal lesionectomy.[50]

Electroencephalography

Surface EEG

The ability of the scalp EEG to detect interictal activity depends on the extent of the irritative zone, the location and proximity of the generator in relation to the scalp and the orientation of the dipole.[81] In general, interictal or ictal surface EEG studies are not very helpful in identifying epileptogenic foci residing in the basal frontal lobe because of the hidden, distant location of this part of the cortex with relation to scalp electrodes. Even long-term sleep-deprived interictal EEG

recordings may be completely normal despite activation procedures. This apparent lack of interictal and/or ictal EEG abnormalities is a well-known weakness of electroencephalography.[74]

When detected on scalp EEG, interictal epileptiform discharges are helpful in establishing the diagnosis of epilepsy. Prolonged daytime EEG studies with recordings of 1–2 hours of sleep, as well as nocturnal sleep recordings increase the yield of interictal epileptiform abnormalities in individuals with epilepsy.[82–84] Increased sampling using special electrodes (such as sphenoidal, anterior temporal or ear electrodes)[85,86] and closely spaced additional scalp electrodes[87–89] may be helpful in distinguishing temporal from frontal lobe foci.

Home videotape recordings, when available, can provide valuable diagnostic information by capturing ictal manifestations. Prolonged inpatient video-EEG monitoring is indicated in patients with pharmacoresistant epilepsy as well as patients with paroxysmal events of unclear etiology. Careful video analysis of ictal semiology may lend support to the diagnosis of frontal lobe epilepsy, even in some cases where EEG is inconclusive. Polysomnographic recordings with additional EEG montages should be considered, in cases of predominantly nocturnal paroxysmal phenomena.[90,91]

Typically, abnormalities that are detectable on scalp EEG do not allow for topographic localization of foci residing in the basal frontal lobe. When present, spikes or sharp waves may have a regional distribution or appear generalized as a result of secondary bilateral synchrony.[87] False localization to the anterior temporal region is not uncommon in patients with basal frontal epilepsies, who present with anterior temporal interictal epileptiform discharges (Figure 37.6) on their scalp EEG.[57] Occasionally, propagated epileptiform activity can be present over central or frontolateral regions.[76] Moreover, epileptiform abnormalities may have a misleadingly widespread appearance, because of the large distance and intervening cortical area that separates the epileptogenic zone from the scalp EEG electrodes.[81,92] Interictal sharp waves may be reflected over a wide bifrontal region as a result of volume conduction (Figure 37.7) such bilateral discharges may sometimes exhibit a shifting right or left preponderance or a misleading contralateral maximum.[35] The inaccessibility of the basal frontal surface and other areas of the frontal lobe to scalp electrodes, the widespread connectivity of the OFR, the variable size and location of epileptogenic foci within this region and the potential for bilateral epileptogenicity as a result of bifrontal injuries are among the factors accounting for the lack of adequate topographic scalp EEG localization in basal frontal lobe epilepsies.[33]

Large and somewhat blunted sharp waves were demonstrated by Tharp in his patients with presumed orbitofrontal epilepsy.[52] Case reports by Ludwig and co-workers highlighted the occurrence of bilaterally synchronous, paroxysmal epileptiform discharges, with a bifrontal or frontopolar maximum, as well as discharges involving one anterior quadrant, with or without evidence of additional temporal lobe involvement.[41] In the single patient described by Chang and colleagues sphenoidal recordings exhibited a consistent preponderance on the side of the epileptogenic OFR. In this well-documented case report the addition of sphenoidal and infraorbital scalp electrodes revealed that the observed bisynchronous discharges had a more basal distribution with a maximum in the infraorbital regions.[39]

The close anatomical connections between the mesial temporal and orbitofrontal regions have already been discussed. In their classic (1958) paper, Kendrick and Gibbs used the technique of strychnine neuronography in the course of temporal

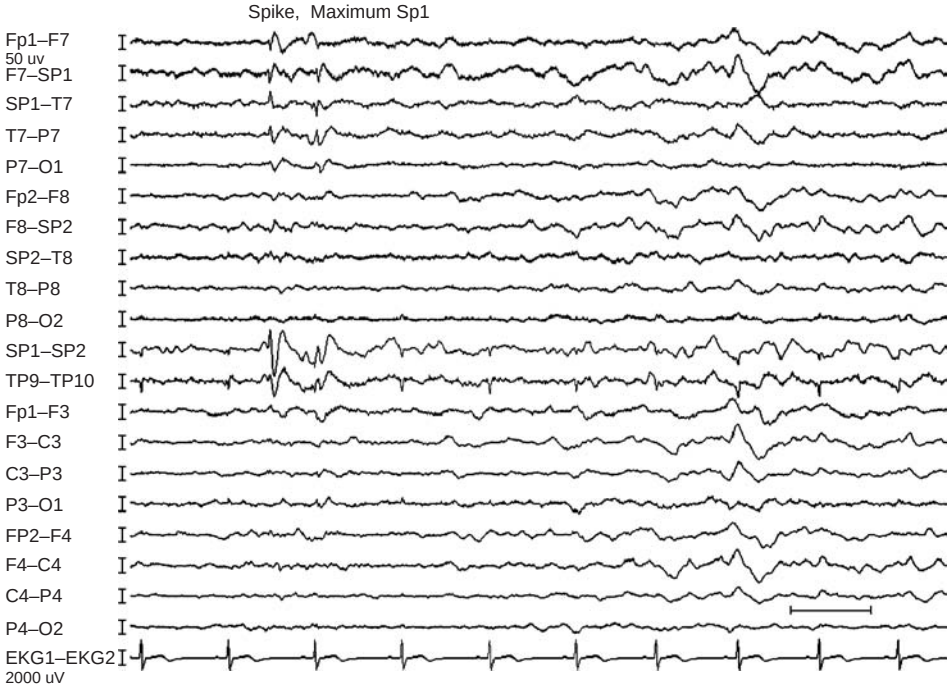

Figure 37.6 Interictal scalp EEG tracing. Predominant spike focus in the left anterior temporal region, maximum in the left sphenoidal electrode (Sp1), as seen on this longitudinal bipolar montage (the temporal chains have been extended to include the left and right sphenoidal electrodes).

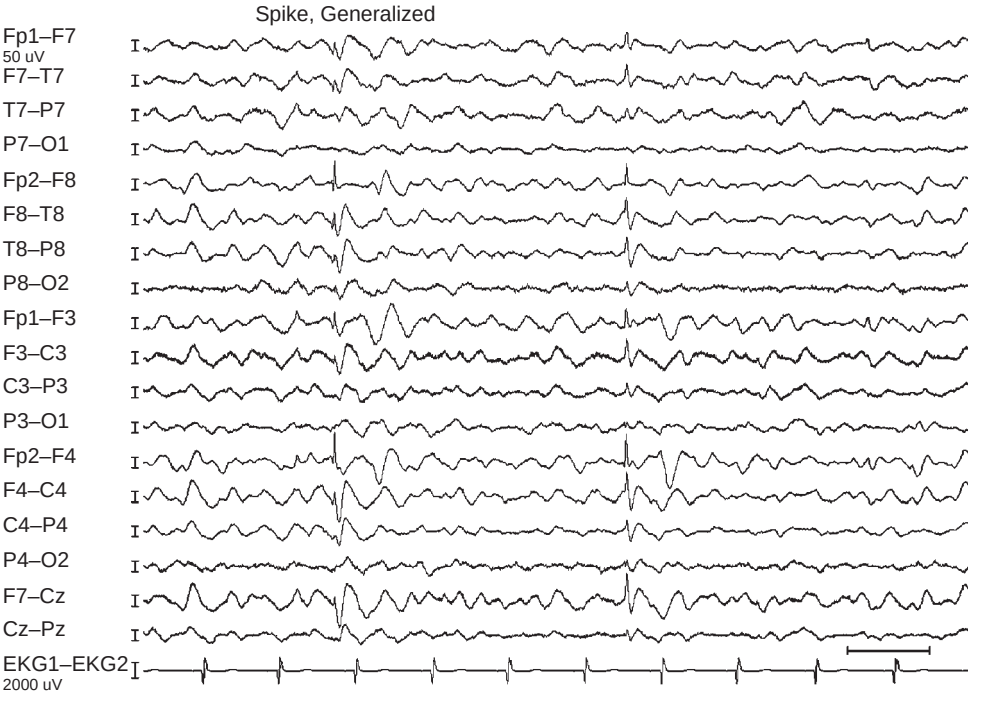

Figure 37.7 Interictal scalp EEG tracing. Less frequently, generalized epileptiform discharges (with a shifting bifrontal maximum; higher on the right side in this instance) were seen during prolonged video-EEG recordings, as illustrated on this routine longitudinal bipolar montage.

lobectomies to demonstrate the bidirectional interrelationship between these two regions in humans.[93] Local application of strychnine through needle electrodes produced 'artificial' spike foci in the frontal and temporal lobes of 34 patients. The authors observed that strychnine-induced spikes in the mesial temporal region commonly spread to the mesial orbital surface of the ipsilateral frontal lobe as well as to the tip of the ipsilateral temporal lobe. On the other hand, strychnine injected into the mesial OFR resulted in spike discharges that propagated first to the ipsilateral mesial temporal cortex, and later to the contralateral mesial OFR and to a lesser extent to the frontal poles. The authors concluded that discharges may spread in either direction – depending upon whether strychnine is first applied in the mesial temporal or orbitofrontal area – and implicated the 'pathway afforded by the uncinate fasciculus' to explain the observed spread patterns.

Ictal scalp EEG recordings (Figure 37.8) during seizures of frontal lobe origin, as a whole, may provide poorly localizing[94,95] or misleading information.[96] Seizure duration is usually short and muscle artifact often obscures ictal EEG activity. Furthermore, observed patterns and frequency of activity at the time of electroencephalographic seizure onset do not correlate with the cortical area generating seizures.[97] When ictal EEG is inconclusive or normal, diagnosis will rely on the history and ictal semiology. In cases where the clinical pattern does not provide additional clues with respect to lateralization to one hemisphere, detailed analysis of clinical seizure onset may be helpful in disclosing a clearly defined focal symptomatology.[98]

The localizing value of ictal scalp EEG is generally inferior in extra-temporal epilepsies.[33,99] Using lateralized rhythmic discharges, postictal slowing and EEG activity at seizure onset only 47–65% of extratemporal seizures are correctly lateralized, as opposed to 76–83% of temporal lobe seizures.[99] Surface ictal EEG recordings were retrospectively analyzed in a recent series of 46 patients with neocortical focal epilepsy, who became seizure free after surgical resection of a single lobe (lateral frontal=15, mesial frontal=8, neocortical temporal=10, parietal=7 and occipital=6). In this series, virtually all seizures that were either obscured by artifact or had no identifiable EEG change had a frontal lobe origin.[33] Localized EEG patterns were more common with seizures arising from the dorsolateral frontal region.

Intracranial EEG

Patients with suspected pharmacoresistant focal epilepsy should be referred to a comprehensive epilepsy center for a thorough presurgical evaluation, which includes prolonged video-EEG recordings, high-resolution structural and functional imaging and neuropsychological assessment. When results of presurgical studies are inconclusive or incongruent and epilepsy surgery is being considered, invasive EEG recordings with subdural grid and/or depth electrodes may be necessary to delineate the epileptic focus.

Invasive approaches to verify the location of the epileptogenic focus include: intraoperative electrocorticography, extraoperative invasive electrode recordings (using extradural, subdural and/or intracerebral electrodes), and stereo-electroencephalography.[60] It is important to emphasize that invasive electrodes record from limited parts of the cortex only, and do not provide the global picture of brain activity afforded by scalp electrodes.[100,101] Hence, intracranial electrode monitoring should only be utilized, once a reasonable hypothesis

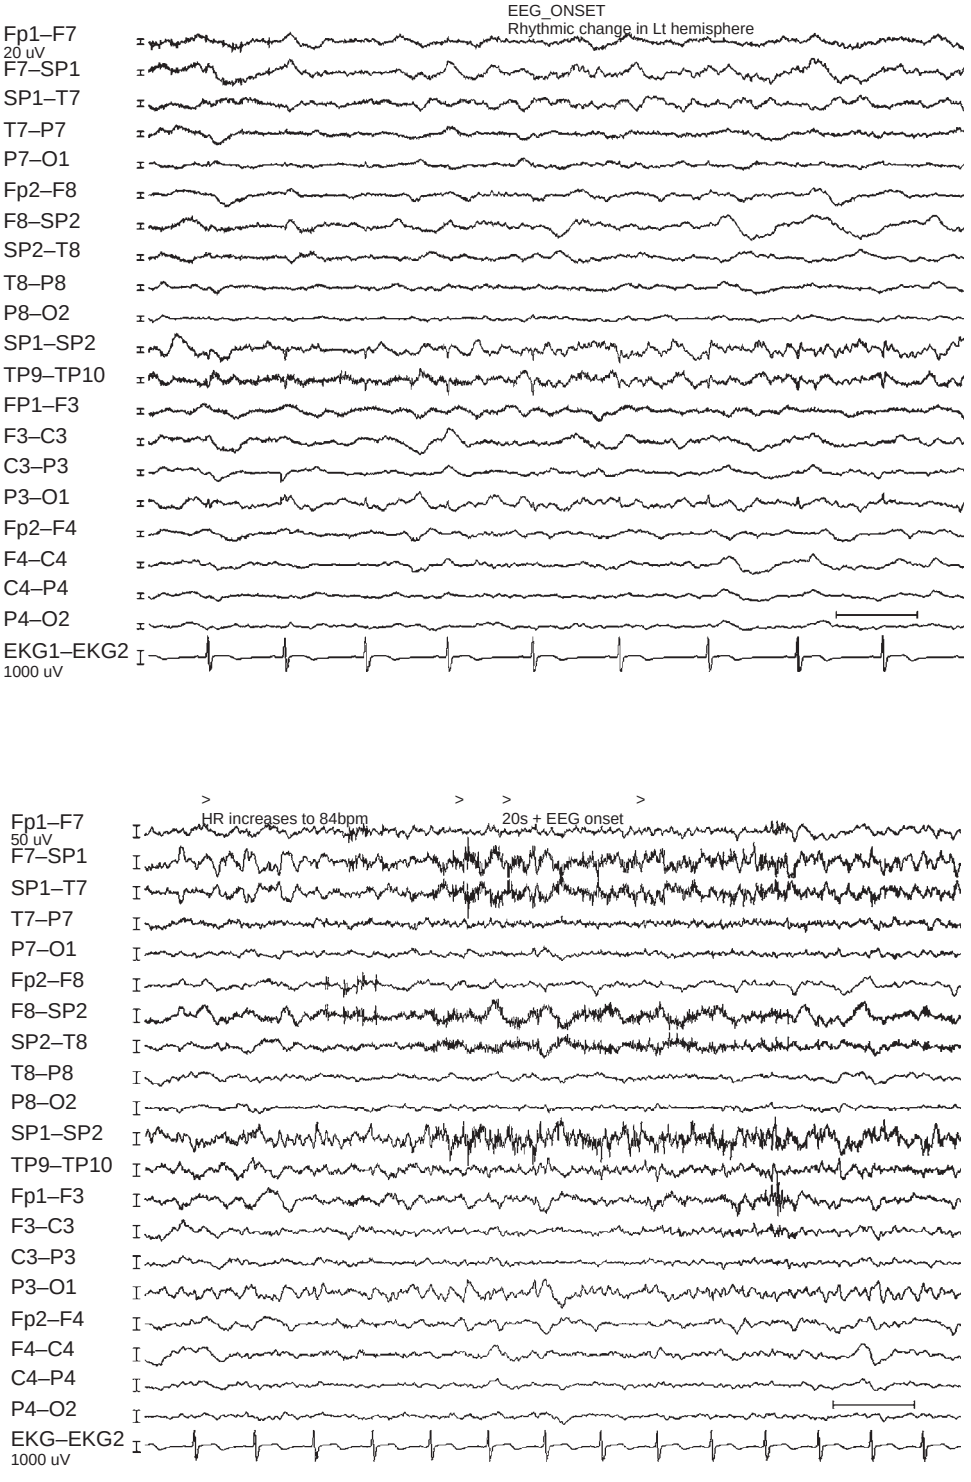

Figure 37.8 Ictal scalp EEG tracings on a routine longitudinal bipolar montage during a typical nocturnal seizure: (a) The electrographic onset (EEG onset) is punctuated by the appearance during sleep of an initial low voltage semi-rhythmic activity, which gradually evolves into more rhythmic and sharply contoured delta slowing over the left hemisphere; (b) 20 seconds later repetitive spikes within the ill-defined slowing.

about the possible location(s) of the epileptogenic zone has been made based on the results of a detailed presurgical evaluation.[102] When epileptogenicity involving the basal frontal lobe is suspected, electrode coverage of both the frontal and the temporal lobe may be necessary, to better localize the epileptogenic zone and differentiate between frontal and temporal involvement (Figures 37.9 and 37.10). Furthermore, use of bilateral frontal electrodes may be contemplated as a means of improving the investigators' ability to study lateralization and mode of propagation of ictal discharges.[103]

Stereotactically placed depth electrodes are useful in accurately targeting/evaluating deep structures, but sample only a restricted area. On the other hand, subdural electrodes provide better spatial resolution and can sample a larger expanse of cortex as they record directly from the cortical surface that underlies the pia matter. However, only about one-third of the

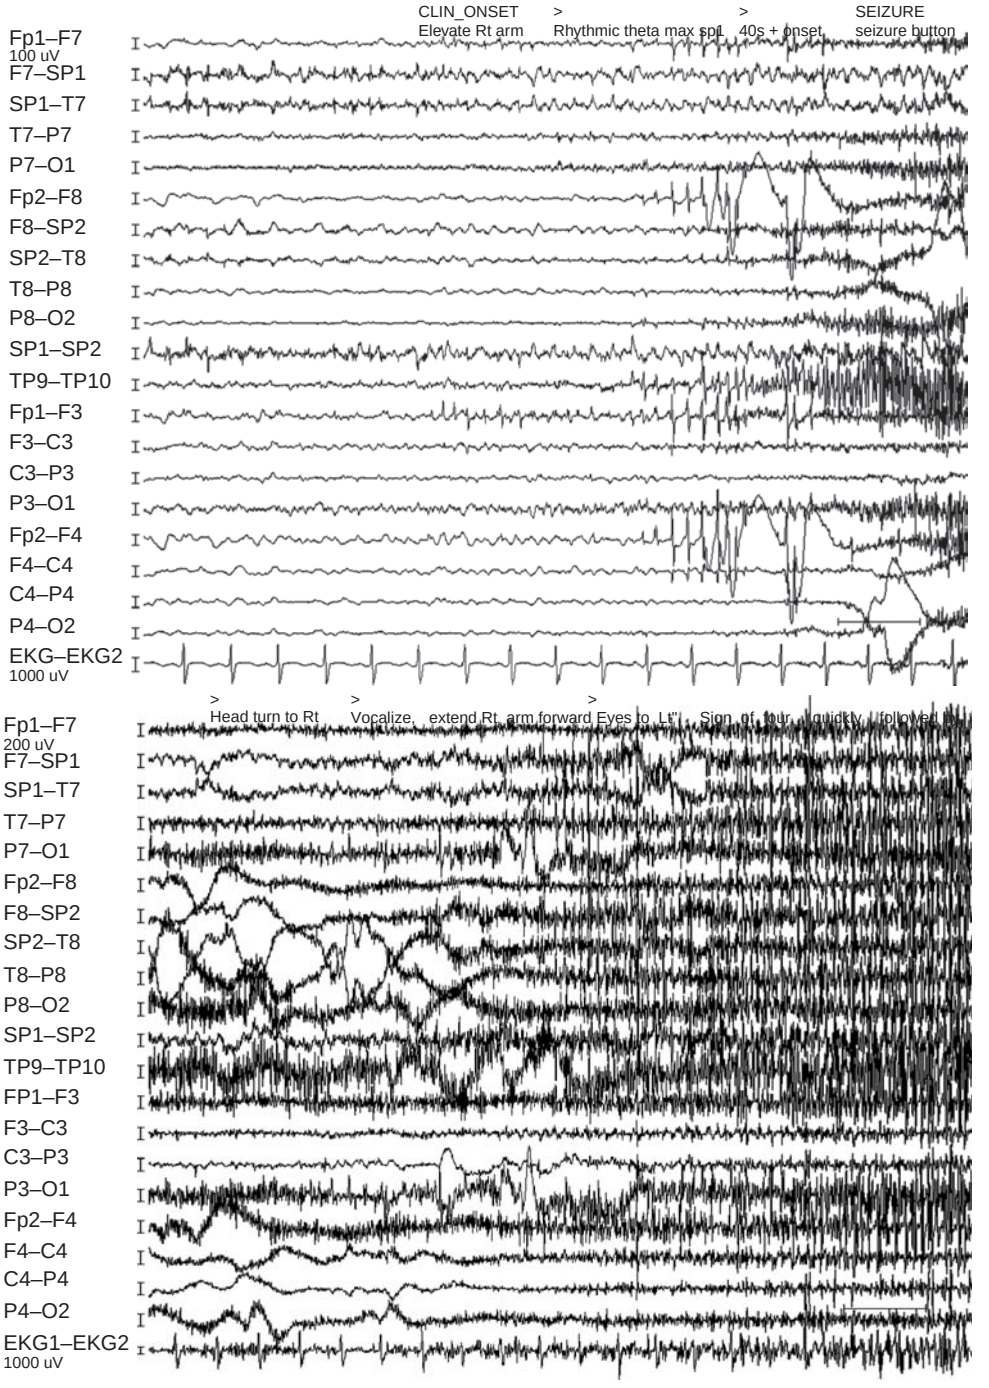

Figure 37.8, (c) low-amplitude repetitive spiking (~5–7Hz) seen over the left temporal region at the time of clinical onset, which occurs approximately 40 seconds following EEG onset. (d) muscle artifact obscuring EEG activity at the beginning of secondary generalization, which occurs approximately 50 seconds following EEG onset.

cortex is exposed, and generators located within the depth of a sulcus cannot be sampled adequately unless they extend to the cortical surface or crown.[104] Subdural grid or strip electrode arrays are inserted under general anesthesia following craniotomy and incision of the dura. Such arrays are usually slid under the edges of the exposed dura, in contact with the brain surface, without direct visualization for the purposes of recording from the orbitofrontal and adjacent inferior temporal areas.[105] The current approach at both the Cleveland Clinic Epilepsy Center and at the Texas Comprehensive Epilepsy Program is to sample the basal frontal region using a 4 × 4 subdural electrode array (Figure 37.9); made of four rows and four columns of platinum-iridium disk electrodes, each of which has a 4 mm diameter and is separated from neighboring electrodes by a center-to-center distance of 1 cm.[106]

As described above, the OFR has widespread connections with the anterior and mesial temporal regions, the insula, opercular areas and cingulate gyrus. Adequate sampling of these areas is recommended during invasive recordings in patients with suspected basal frontal epilepsies.[107,108] Good communication between the neurosurgeon and the epileptologist/neurophysiologist involved in the clinical management and interpretation of presurgical studies is essential during the planning stage. In addition, functional mapping by means of electrical cortical stimulation may be necessary to identify eloquent cortex such as language areas and motor cortex.

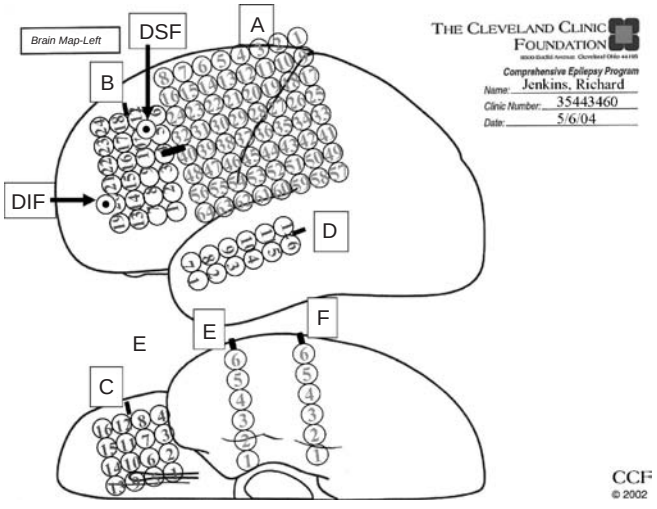

Figure 37.9 Invasive EEG evaluation using a combination of multiple subdural electrodes covering the left frontal and temporal lobes along with two intracerebral depth electrodes targeting the area of encephalomalacia. Subdural electrode arrays: A=8×8 plate, covering the left perirolandic region; B=4×6 plate, covering the left dorsolateral frontal region, anterior to the A plate; C=4×4 plate, covering the orbitofrontal area; D=2×6 plate, covering the lateral aspect of the temporal lobe; E and F=1×6 strips, covering the anterior and mid subtemporal regions. Intracerebral depth electrodes targeting the encephalomalacic area: DSF with entry point in the superior frontal gyrus, and DIF with entry point in the inferior frontal gyrus, as seen in this schematic representation.

Roper and Gilmore used a single subdural strip electrode to sample the orbitofrontal cortex in all cases of limbic epilepsy referred for invasive monitoring during a period of 1 year.[46] A total of 15 patients underwent invasive evaluations during this period (unilateral investigations with temporal, frontal, and orbitofrontal subdural electrodes were performed in eight and bilateral studies using bitemporal depth electrodes along with bilateral inferolateral temporal and orbitofrontal subdural electrodes were performed in seven patients). Three patients out of the 15 patients with intractable limbic seizures were found to have seizures originating from within the OFR (see Table 37.1). Subdural strip electrodes identified the OFR as the site of seizure origin (ictal onset zone), but were insufficient to define the actual boundaries of the epileptogenic zone. To better delineate the boundaries of the epileptogenic area the authors supplemented their investigations with the use of intraoperative electrocorticography (ECoG). These investigations and subsequent surgical excisions led the authors to conclude that unilateral OFR resections can be beneficial in a subset of patients with orbitofrontal epilepsy and can be performed without significant neuropsychologic impairment.

Stereo-electro-encephalography (stereo-EEG, sEEG) refers to the methodology of stereotactically-guided depth electrode recordings, which was originally developed by Bancaud and Talairach in France. Ictal anatomo-electro-clinical correlations based on sEEG recordings are utilized in identifying the cortical area(s) primarily involved in the generation of spontaneous ictal discharges, and provide a guide to tailored cortical resection.[109] For the school of stereo-EEG investigations *individualized* planning of electrode implantation is critical. The surgical team is assigned with the task of finding the best compromise between the 'ideal' position of the electrode and the constraints introduced by the various vascular segments, which the electrode may encounter along the length of its trajectory from the surface to the deeper brain targets.[103,110]

In their review of the electroclinical features of orbitofrontal seizures Munari and Bancaud summarized their experience in a series of 60 patients, who underwent stereo-EEG investigations with at least one orbitofrontal depth electrode. The majority of these stereotactically implanted multilead electrodes (total of 10 contacts, each 2 mm in size and 1.5 mm apart) were inserted via an orthogonal, lateral approach and aimed to explore both the medial and lateral aspects of the OFR.[36] An oblique approach was used in a few cases and a vertical approach was utilized in a single patient.

Spread between OFR and temporal lobe may occur extremely rapidly via the uncinate fasciculus as documented by stereo-EEG investigations of spontaneous seizures arising from the basal frontal lobe.[36] Other investigators have observed that 'orbitofrontal seizures' propagate more slowly compared to seizures arising from other extratemporal locations.[101] This observation comes out of a fairly small study of 10 patients with extratemporal neocortical epilepsy. A total of 25 seizures were studied with intracranial recordings using a combination of subdural strips, subdural grids, and depth electrodes implanted 'as clinically indicated'. Two patients in this group were thought to have seizures arising from the OFR and both underwent bilateral intracranial EEG investigations. A total of eight 'orbitofrontal seizures' were studied, although details on individual seizures were not provided. The authors defined the ipsilateral and contralateral propagation time as the time elapsed from electrographic seizure onset to first spread either to an adjacent ipsilateral lobe or to the contralateral hemisphere. For 'orbitofrontal seizures' spread to the ipsilateral temporal lobe occurred within a period ranging from 12.5 to 85 seconds, and to the contralateral frontal lobe within a period ranging from 9.8 to 92 seconds (compared to a more rapid ipsilateral or contralateral spread, as early as within 0 to 0.4 seconds, in some seizures arising from other frontal or parieto-occipital locations).[101] The small patient number and the potential spatial sampling limitations of invasive recordings need to be taken into account, when interpreting these results.

Structural and functional imaging

Structural imaging

High resolution anatomical MRI should be performed to search for focal intracerebral lesions, and ideally interpreted by expert radiologists, experienced in imaging of the epilepsies.[111] Identification of a structural abnormality by MRI adds substantially to the process of localizing the site of seizure onset and selecting favorable candidates for resective epilepsy surgery.[112] Structural abnormalities may be found in up to 80% of patients with refractory focal epilepsy using optimal anatomical MRI imaging.[113]

Structural MRI can provide reliable information about the pathology of the suspected epileptogenic lesion. Common MRI-identifiable pathologies include disorders of cortical development and foreign-tissue lesions (such as

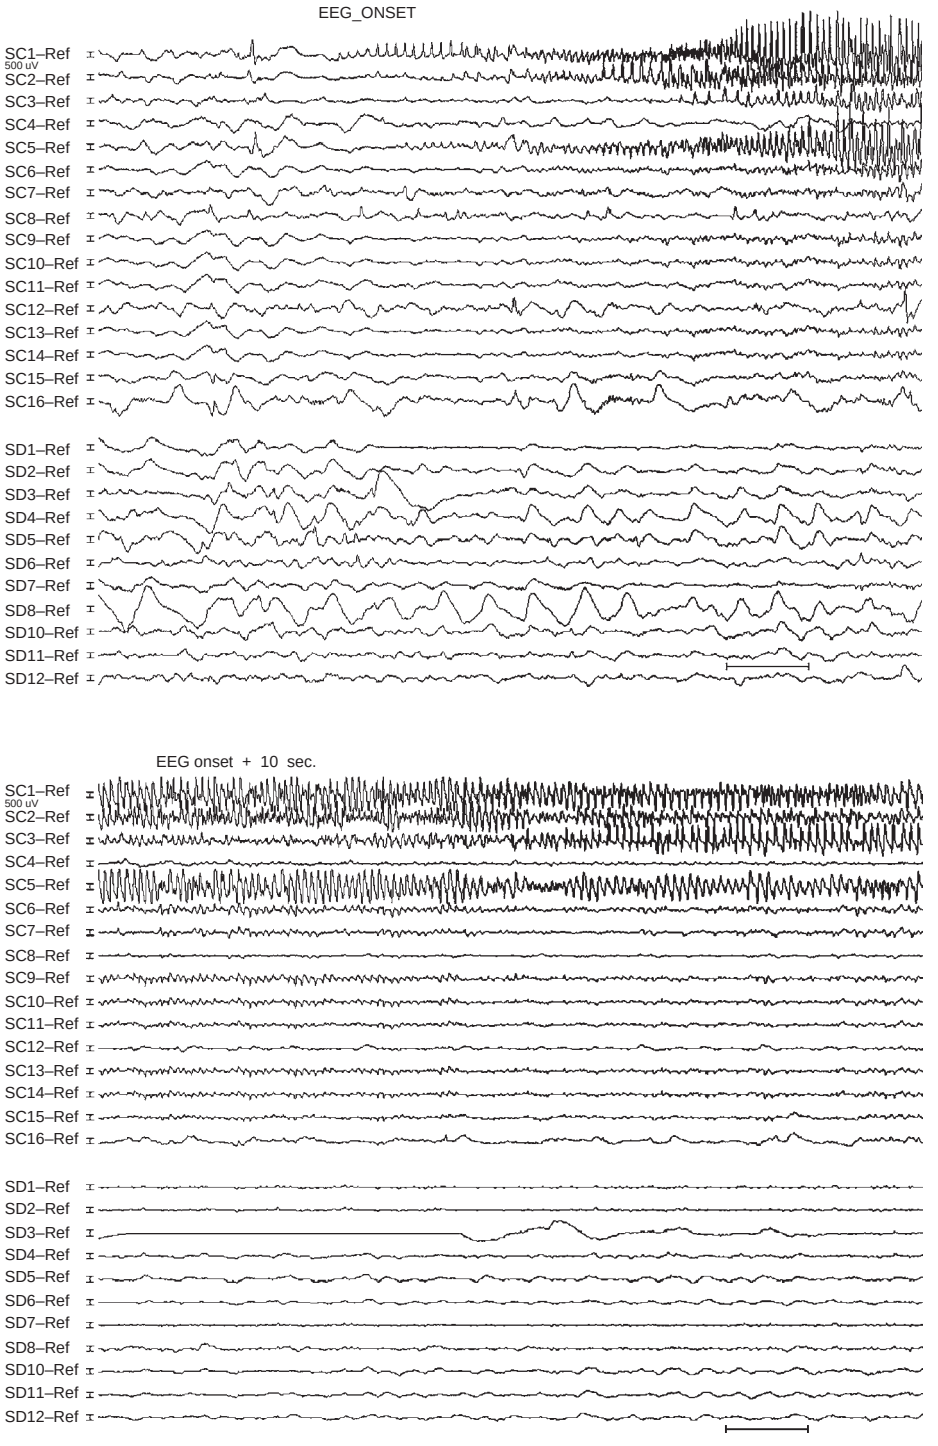

Figure 37.10 Ictal invasive EEG recordings on a referential montage displaying the electrode contacts on the C (orbitofrontal) and D (lateral temporal) plates: The electrographic onset is punctuated by the appearance of focal repetitive spiking involving the mesial, posterior corner of the orbitofrontal plate (electrodes C1 followed by electrodes C2 and C5). This activity remains confined to the orbitofrontal area without evidence of concurrent involvement of other electrodes for several (~25) seconds.

tumors and vascular malformations). Furthermore, findings on MRI help tailor the surgical procedure and assess the extent of resection postoperatively.[112] A particular challenge for T2 weighted MRI sequences investigating the human OFR using is the potential for susceptibility artifacts resulting in signal dropout or geometric distortion as a result of the close proximity of the OFR to the air-filled sinuses.[7]

When MRI is negative but EEG or other testing points to a potential area of focal epileptogenicity, dedicated MRI sequences[114] with thin cuts through the region(s) of interest should be obtained. Imaging with higher magnetic fields or three-dimensional MRI techniques may further increase the yield and allow for presurgical identification of epileptogenic lesions.[115] As illustrated in the case reported by Rugg-Gunn and colleagues[48] the use of diffusion tensor imaging and advanced postacquisition processing analyses can enhance the detection rate of subtle abnormalities in patients with so-called 'nonlesional' focal epilepsies.[116,117]

Functional imaging

Functional imaging with interictal PET and/or ictal SPECT studies may be employed as a means of identifying seizure foci in the basal frontal lobe and guiding surgical resection.

Interictal studies of brain metabolism using ^{18}FDG-PET (fluoro-deoxyglucose positron emission tomography) may disclose areas of hypometabolism in up to 60% of patients with frontal lobe epilepsy. However, almost 90% of these patients will have an underlying MRI-identifiable structural abnormality.[118] In neocortical epilepsy it is often difficult to interpret small or subtle focal areas of hypometabolism of questionable clinical relevance in the absence of a structural lesion.[119] Consequently, ^{18}FDG-PET studies may be of limited value in nonlesional frontal lobe epilepsies.

Single photon emission computed tomography (SPECT) has been used in patients with focal epilepsy to assess alterations of cerebral perfusion that may reflect the approximate location of the epileptic focus. Ictal SPECT is the only available, noninvasive modality practically suited for functional brain imaging during an actual seizure.[119] Digital subtraction techniques allow for comparison of an individual patient's interictal (baseline) and ictal SPECT images. The relatively low-resolution subtraction images afforded by SPECT can then be coregistered to the patient's anatomical MRI for more precise localization.[119] This computer-aided process was found to be diagnostically superior, when compared to routine side-by-side visual inspection of ictal and interictal SPECT scans.[120] Recent studies suggest that subtraction SPECT images are useful in guiding the location and extent of surgical resection in patients with extratemporal epilepsy.[121] There have been no specific reports related to subtraction/ictal SPECT imaging in patients with seizures arising from the basal frontal lobe. Because of their sometimes brief duration and propensity of frontal lobe seizures for rapid secondary generalization it may particularly difficult to obtain and interpret ictal SPECT studies.

In contrast to the aforementioned nuclear imaging techniques, magnetoencephalography (MEG) is a neurophysiological method with high temporal and spatial resolution. Results of MEG source localization can be co-registered to structural MRI data and produce the so-called magnetic source imaging (MSI), which is currently explored as a means of improving noninvasive localization of epileptogenic foci. The conjugation of noninvasive neurophysiology and anatomical neuroimaging using MEG/EEG along with MRI can provide important insights into the generation and spatiotemporal evolution of neocortical discharges. However, the results obtained require careful clinical analysis, integration and comparison with available preoperative testing and further validation.[122] MSI[123] along with ictal SPECT studies[124] may play an increasingly important role in directing placement of electrodes in patients with suspected frontal lobe epilepsy, being considered for resective surgery.[125] At this time, however, the role of MSI in the presurgical evaluation of patients with suspected basal frontal lobe epilepsies remains unclear.

Etiologies of basal frontal lobe epilepsy

Out of the 23 cases assembled in Table 37.1, a brain abscess was identified in two patients, and a tumor in another two (one had a pilocytic astrocytoma; the tumor type was unknown in the second case). Two more patients were found to have cortical dysplasia, while four patients were suspected to have a posttraumatic etiology. Histo-pathological examination showed nonspecific 'gliosis' in five patients and no abnormalities in three. Details on histopathology of resected tissue were not provided/not known in the remaining five cases.

The OFR is a common site for closed-head injury. Nonpenetrating head traumas may produce forces that move the basal frontal brain parenchyma across the underlying uneven surface of the orbital roof.[126] Falls or blows on the front of the head produce direct frontal lobe damage, while trauma to the occipital region produce basal frontal and fronto-polar injury by a contre-coup mechanism. Hence, posttraumatic epilepsy following closed head injury often involves the frontal and/or temporal lobes. The diffuse nature of nonpenetrating head injuries often limits localization of the epileptogenic focus, especially in patients without distinct, MRI-identifiable focal lesions.[127] It should also be noted that extensive cortical abrasions and/or lacerations in the orbitofrontal region may not be easily detected by CT and/or MRI because of the relatively limited three-dimensional volume of these lesions and the artifacts introduced by the surrounding bony irregularities of the cribriform plate.[128]

The prognosis and risk of later epilepsy depends on the severity of the trauma and concomitant cerebral complications.[129,130] Post-traumatic epilepsy refers to the recurrent, unprovoked seizures developing more than one week after penetrating or closed head injury.[131] Nearly 40% of seizures appear within the first 6 months, and 70–80% by the first 2 years after the injury.[132] The risk of posttraumatic epilepsy falls rapidly as the post-injury seizure-free interval increases, but does persist for more than 15 years after the injury, especially in cases of moderate to severe trauma.[130]

The olfactory nerves are located immediately below the OFR and are similarly susceptible to injury following closed head trauma. Post-traumatic anosmia usually results from shearing of the olfactory nerve fascicles as they traverse the cribriform plate to enter the olfactory bulb.[133] Because of this shared mechanism of injury posttraumatic anosmia may serve as an important clinical sign of concomitant orbitofrontal damage. Significant hypoperfusion in the OFR has been demonstrated with the use of HMPAO-SPECT in a series of 18 patients, who had been rendered completely anosmic as a result of a remote head injury.[134] In a similar study of 11 anosmic patients with a history of prior head injury quantitative PET studies showed evidence of hypometabolism in the OFR as well as in the medial temporal region compared with controls.[135]

In a similar series of 20 head-injury patients the finding of marked post-traumatic anosmia was taken as a strong indication of damage to the OFR.[128] Most of these patients appeared intact on psychometric neuropsychological testing and were generally preserved in areas such as intelligence, memory and language. Nevertheless, they faced major psychosocial difficulties; most of them were unemployed and showed evidence of poor empathy, poor judgment and absent-mindedness. It is not uncommon for patients with OFR injuries to perform normally on a variety of standard neuropsychological tests.[128,136] More specialized testing is required to expose deficits related to decision making and executive planning. The authors concluded that posttraumatic anosmia has a close and specific relationship with a particular locus of injury (OFR) and a

specific set of neurobehavioral symptoms that constitute the so-called 'orbitofrontal syndrome'.

Another common insult with predominant temporal and/or orbitofrontal localization that deserves mentioning in this section is herpes simplex encephalitis. Herpes simplex virus (HSV) is the cause of the most common sporadic viral encephalitis in adults and children older than 6 months.[137] Encephalitis due to HSV infection (both primary and recurrent infection) is a serious disease with an untreated mortality approaching 70% and substantial morbidity despite antiviral therapy.[138] Pathological studies of HSV encephalitis have shown predominant viral-related damage in limbic structures as well as neighboring areas including the mesial temporal lobe (hippocampal formation, amygdala, parahippocampal gyrus, and perirhinal cortex), orbitofrontal region, insula and cingulate gyrus.[139] The selective and often remarkably segregated involvement of temporal and orbitofrontal locations may in part reflect the route of entry of the virus into the host. In primary infection HSV may gain access to the brain via an olfactory route reaching the olfactory bulbs through the cribriform and subsequently spreading along the base of the frontal lobe. In reactivation of latent HSV infection the virus may spread from the trigeminal ganglion along meningeal branches of the trigeminal nerve.[137,140]

The long-term sequelae of rigorously confirmed HSV encephalitis in the era of antiviral therapy (with acyclovir) were investigated in a retrospective study from New Zealand, in which a total of 42 acyclovir-treated patients were followed for a period of up to 11 years.[141] The mortality rate was 12% at 1 month and 14% at 6 months. All but one of the surviving patients had persistent neurological impairment. The most common and most disabling complication was that of memory dysfunction (especially short-term memory). Personality and behavioral disorders occurred in almost half of the long-term survivors, albeit less severe compared to reported disability before the introduction of acyclovir. Epilepsy was present in 24% of surviving patients. Of note, two-thirds of survivors were found to have unilateral or bilateral anosmia, although may of these patients were unaware of the deficit.[141]

Other common substrates of extratemporal focal epilepsy include tumors, vascular anomalies and developmental disorders. The importance of MRI-identifiable lesions involving the deeply situated orbitofrontal region should not be underestimated. Studies of anatomically defined lesions in various locations of the brain cortex indicate that these lesions will more often than not harbor the site of the epileptogenic focus.[142] In this case complete excision of the lesion along with the surrounding 'epileptogenic tissue' provides an excellent chance for a seizure-free outcome.[38,66] Studies have shown that one of the best prognostic factors in epilepsy surgery is in fact the completeness of such lesionectomies.[143] Poor surgical results are more common in cases, where postoperative MRI provides evidence of incomplete resection of the lesional pathology.[144]

With improvements in neuroimaging, cortical dysplasias and other developmental disorders are increasingly recognized as causes of pharmacoresistant focal epilepsy. It is estimated that nearly 30% of surgical specimens from patients with neocortical epilepsy contain some type of malformation of cortical development.[145] In fact, dysplastic lesions (ranging from heterotopias to subtle cytoarchitectural abnormalities) are the most common histopathological finding in some surgical series of frontal lobe epilepsies.[38]

Among the various vascular anomalies, cavernous angiomas (cavernous malformations, CM) and arteriovenous malformations (AVM), are more likely to cause seizures. The epileptogenicity of these lesions is believed to result from pathological changes imparted on tissue surrounding the vascular malformation due to ongoing microhemorrhage and hemosiderin deposition.[146] Therefore, surgical excision should not only target the lesion but extend to the adjacent hemosiderin-stained tissue.[147]

Frequently encountered tumoral pathologies associated with pharmacoresistant epilepsy include gangliogliomas, dysembryoplastic neuroepithelial tumors (DNETs) and low-grade gliomas. In cases involving the basal frontal lobe, a gross total resection to clear margins provides the best chance for control from both the oncology and epilepsy standpoint.[148]

Gliosis as a result of previous anoxia, head trauma, or other unknown causes may be the only identifiable in pathology in surgical specimens obtained from patients with focal epilepsy. Lastly, a curious clinicopathologic entity of intracranial choristomas involving the gyrus rectus has been reported recently in two adult patients with seizures. In both cases the epileptogenic lesions were composed of heterotopic epithelial, glial and mesenchymal components. The histogenesis of these lesions is unclear, but the preferential involvement of the gyrus rectus, which is in close proximity to the frontal bone, led the authors to speculate a common origin from neural crest progenitors.[149]

Medical therapy

Seizures arising from the basal frontal region may respond to standard anticonvulsant agents (AEDs). As the seizures are focal in origin carbamazepine (or phenytoin) has been recommended as first line of treatment.[150] Alternatively monotherapy with a newer AED such as lamotrigine, oxcarbazepine, topiramate or gabapentin could be considered based on drug-drug interactions and side-effect profile.[151] If patients do not respond to monotherapy trials at maximum tolerated doses a second agent may be added. Valproic acid may have a role in preventing secondarily generalized seizures. Other adjunctive agents include levetiracetam, zonisamide and tiagabine.[152] Approximately 65% of patients with focal epilepsy respond to appropriate anticonvulsant therapy.[153,154] When medical therapy provides inadequate control of seizures or unacceptable side effects, the possibility of resective surgery should be explored. Patients with evidence of pharmacoresistant focal epilepsy should be referred to a specialized epilepsy center for presurgical evaluation and management. Patients who are not favorable surgical candidates or have failed surgical resection may be considered for implantation of a vagus nerve stimulator (VNS). Unfortunately, it has not been possible to predict which patients will benefit from chronic VNS before implanting the device.[155]

Surgical approaches to the OFR

The surgical anatomy of and surgical approaches to the orbitofrontal region have not been well characterized in the published literature. One possible reason for this may be

the fact that prior to the widespread application of invasive electrophysiology in surgical epilepsy programs the OFR has generally not been viewed as a target for resection. While portions of the basal frontal lobe are routinely retracted during neurosurgical procedures for vascular or neoplastic abnormalities, resections of the OFR itself are uncommon. A notable exception is the resection of the gyrus rectus that is carried out to facilitate exposure during pterional/subfrontal approaches to aneurysms involving the anterior communicating artery and proximal A2 segment of the anterior cerebral artery. The epilepsy surgeon accessing the OFR should, therefore, familiarize him/herself with the anatomy of the region and discuss the goals of the planned procedure with the treating epileptologist.

Invasive monitoring of the OFR

The investigation of nonlesional basal frontal lobe epilepsy is challenging, yet necessary, given the 'buried' nature of the cortex in this region. We prefer the use of subdural electrodes to depth electrodes to investigate the OFR. If a fronto-temporal craniotomy is planned, it is extended anteriorly to expose most of the frontal operculum; if burr holes and strip electrodes are planned, one burr hole is placed over the pterion ('the keyhole'). In the case of a craniotomy, a 4×4 electrode array, with its lead situated laterally, is placed over the orbital roof, to cover a significant portion of the OFR. If burr holes are used, a 4-contact strip electrode is placed over the posterior portion of the OFR.

Resections of the OFR

The surgical approach to the OFR is dictated by the surgeon's familiarity with a particular approach, the pathologic process being treated (lesion resection versus regional OFR excision for intractable epilepsy), the location of the lesion, and whether or not the resection involves the (presumed or apparent) dominant hemisphere. Another important consideration during surgical planning should be the connections of this region with the anterior and medial temporal lobe and the cingulate gyrus. Incomplete resection of epileptogenic cortex left attached to these structures, may compromise surgical outcome. Given that these connections extend from the posterior edge of the OFR, and that the posterior boundary is intimately linked to multiple structures (anterior perforated substance, optic nerve and anterior cerebral artery) – damage of which can result in significant deficits – an intimate knowledge of the anatomy of the OFR is crucial to successful surgical outcomes.

Prior descriptions of surgery in the OFR have variously delineated the posterior extent of orbito-frontal excisions as being about 1–2 cm in front of Broca's area in the language-dominant hemisphere or extending posteriorly to the ipsilateral internal carotid artery[156] and the intersection of the optic and olfactory nerves.[107] We find a subpial approach combined with intraoperative frameless stereotactic navigation to be safer, and prefer to use the proximal anterior and middle cerebral arteries (viewed through intact pia) to delimit the resection margins (Figure 37.2).

The OFR may be approached using three possible trajectories, depending on the nature and location of the lesion (Figure 37.3):

- Lateral frontal;
- Anterior frontal; and
- Intermediate or anterolateral approach, which may be combined with orbito-zygomatic osteotomy.

The lateral frontal is by far the commonest approach for an OFR resection in the context of epilepsy surgery. This is because many such resections occur in the context of a large fronto-temporo-parietal craniotomy performed for placement of subdural electrodes for invasive electrophysiology. The resection is usually carried out at the time of electrode removal, and the orbital cortex is therefore approached from its lateral aspect. An en bloc resection of all, except the most posterior aspect, of the lateral, posterior and medial orbital gyri, and a portion of the anterior inferior frontal gyrus is carried out. This is followed by subpial aspiration of gyrus rectus. The ipsilateral anterior cerebral artery (ACA) is identified and traced posteriorly to the rostrum of the corpus callosum. Finally, the posterior limits of the orbital gyri and the subcallosal (rostral) cingulate gyrus are aspirated using a subpial technique (Figures 37.4 and 37.5). Identification of the ACA helps determine the posterior extent of the medial resection. The M1 segment of the middle cerebral artery (MCA) may be used to define the posterior edge of the resection. Use of a subpial technique during the medial and posterior aspect of the resection is crucial in minimizing risks to the anterior perforated substance, olfactory tract, and optic nerves.

The anterior approach is principally used for excisions of overt OFR lesions and resections in the context of depth electrode recordings. Preoperative placement of a lumbar drain minimizes the need for retraction. A bicoronal scalp incision is made, following which a frontal craniotomy bone flap is elevated – from just above the frontal sinus, just lateral to the midline (and anterior sagittal sinus) and extending laterally to the anterior attachment of the temporalis muscle. A frameless stereotactic system may be used to demarcate the edges of the craniotomy and facilitate approach to the lesion. The dura is opened, with its base on the sagittal sinus, following which the lesion is resected. Subpial techniques should be used when there is a need to remove abnormal (gliotic, hemosiderin stained etc.) cortex surrounding the lesion. A principal advantage of the anterior and antero-lateral approaches is that the inferior frontal gyrus is more easily spared (Figure 37.7).

The antero-lateral approach, combined with an orbito-zygomatic osteotomy may be useful in cases where a large lesion is situated in the postero-medial OFR, and the intention is to minimize dissection and retraction of uninvolved cortex. A frontal craniotomy incision extending to the contralateral midpupillary line is used, following which a frontal craniotomy and orbito-zygomatic osteotomy are carried out. The dura is then opened with its base on the orbital contents, and resection of the lesion is performed. A lumbar drain placed prior to the craniotomy further helps in minimizing retraction.

Occasionally invasive recordings may suggest independent ictal onsets originating from both the medial temporal and orbitofrontal regions. These cases can be managed with concurrent resections, possibly guided by the judicious use of intra-operative electro-corticography (ECoG) to measure the impact on electric activity in one region after the other is resected. Routine resection of the OFR concurrent with a temporal lobectomy is not recommended – although some authors have adopted a combined approach guided solely by the apparent location of interictal abnormalities.[157]

Possible complications related to surgery in the OFR include: infection of the surgical site, osteomyelitis and/or CSF fistulae from opening the frontal sinus mucosa during craniotomy; hemorrhage from injuring the anterior sagittal sinus; venous infarcts when sacrificing veins leading into the sinus; visual deficits following injury to the optic nerve; ischemic events following injury to perforating vessels in the anterior perforating substance; CSF rhinorrhea through the cribriform plate and anosmia if the olfactory nerve and tracts are destroyed; and inadvertent injury to the contralateral frontal lobe if the medial frontal pial layer is not recognized and respected. In addition, there may be impacts upon personality and social behavior following OFR resections – such deficits are not adequately assessed with the current, standard neuropsychological measures employed in patients undergoing epilepsy surgery.

Outcome

There is no systematic study of outcomes related to resections for the treatment of basal frontal lobe epilepsy, and studies examining neuropsychological function in patients with epilepsy arising from this region are lacking. In general, just as for other extratemporal epilepsies, outcomes following resective epilepsy surgery anywhere in the frontal lobe are considered to be 'not as good' as those after temporal lobectomy.[121,144]

The presence of a lesion on neuroimaging increases the chances for seizure-freedom or significant improvement.[35] Cumulative results of surgical treatment for various frontal lobe epilepsies in the pre-MRI era have been characterized as 'unsatisfactory' or 'mediocre'.[103] As a rule, results following removal of discrete frontal lesions are superior to those with more diffuse lesions or without demonstrable lesions.[66] In a study of 68 consecutive patients, who underwent epilepsy surgery involving the frontal lobe good outcome at last follow-up was reported in 72% of patients with evidence of a lesion on neuroimaging, as compared to only 41% of the 'nonlesional' cases.[158]

We recently performed a retrospective review of all frontal lobe resections performed by a single neurosurgeon for the treatment of pharmacoresistant focal epilepsy at the Cleveland Clinic Foundation during a 6-year period (from 1998 to 2004). All cases had undergone a comprehensive presurgical evaluation including high-resolution preoperative MR imaging and presentation at a multidisciplinary patient management conference. Out of a total of 130 patients, who had frontal resections during the study period, basal frontal lobe epilepsy was suspected in eight patients.[159] In these patients, MRI demonstrated a lesion restricted to the OFR, and/or invasive recordings provided clear evidence for ictal onset within the OFR. Patients with more extensive MRI lesions were excluded. Only two cases were nonlesional (i.e., there was no identifiable structural abnormality on high-resolution anatomical MRI); in three of the six 'lesional' cases the MRI detected blurring of the gray-white junction in the medial OFR. Histopathology revealed malformations of cortical development in the majority of patients (5 of 8); cavernomas were found in two, and gliosis in one patient. Resections were restricted to the OFR only in four of the eight patients; the other four underwent larger resections that extended into the lateral frontal region. In this study median follow-up was only 14 months. Seven patients were seizure free, while one had rare seizures postoperatively (Wieser class 3).[54]

Illustrative case presentation

The patient is a 33-year-old, right-handed young man with frequent pharmaco-resistant seizures dating back to the age of 26 years. The patient has a history of a motor vehicle accident at the age of 21 years, when he drove into a telephone pole. He lost consciousness upon impact, and had peritraumatic amnesia and a left-sided skull fracture. He did not require neurosurgical intervention and did not experience seizures at the time of the accident.

Seizures started approximately 5 years later. Initial seizures were primarily nocturnal occurring out of sleep. Family members described 'whole body convulsions' followed by stertorous respirations and loss of urine control lasting for less than 1–2 minutes. Postictally the patient reported tiredness, muscle soreness and occasional tongue biting. These seizures have been disabling and have persisted despite several trials of antiepileptic agents with an average frequency of at least one to four per month.

A second 'mild seizure type' was reported. During wakefulness he would have a warning described as 'feeling unwell' or having 'a funny feeling in the head' lasting for a few seconds, and followed by loss of awareness. Family members described staring and unresponsiveness for 2–3 minutes. During this period the patient had been observed to have complex movements involving the legs and hands. Patient was not sure as to the frequency of this second seizure type. He reported having auras at least once a month.

He had no history of prolonged, unremitting seizures or physical injury as a result of seizures. He has been unable to work for the last 7 years, because of seizures.

Examination and investigations

Physical and neurological examinations were normal. Routine outpatient EEG was normal. Magnetic resonance imaging revealed an area of focal encephalomalacia in the ventral and basal aspects of the left anterior frontal lobe abutting the roof of the left orbit. The patient was admitted for video-EEG monitoring. Background EEG was normal. Interictal epileptiform activity was recorded predominantly arising from the left temporal region (maximum at the left sphenoidal electrode (Figure 37.6). Less frequent generalized epileptiform discharges with a shifting bifrontal maximum were also present (Figure 37.7). In addition, rare right temporal sharp waves were described.

Three typical nocturnal seizures were recorded during sleep. They were characterized by an early change in facial expression and unresponsiveness, followed by tonic stiffening and elevation of the right arm (sign of four, right arm extended with the left arm flexed at the elbow), and right head turning preceding the onset of the secondarily generalized tonic-clonic seizure.

Interictal FDG-PET showed mild decrease of FDG uptake in the left orbitofrontal region, corresponding to the area of MRI abnormality. Wada testing (with intracarotid administration of methohexital) demonstrated left hemispheric dominance for language and bilateral memory representation. Baseline neuropsychological evaluation suggested bilateral frontotemporal dysfunction. The patient appeared to have greater difficulties with verbal than visuospatial intellectual measures. He exhibited evidence of compromised executive function in the course

of problem solving, impaired verbal memory performance and some deficiencies in vocabulary, naming and reading.

The case and results of presurgical studies were discussed in a weekly, interdisciplinary patient management conference attended by experts in clinical epileptology, electroencephalography, structural and functional neuroimaging and neuropsychology. The impression was that the patient's epilepsy may be arising from the left orbitofrontal region 'perhaps deep in the area of encephalomalacia'. A temporal onset could not be excluded. An invasive evaluation with a combination of chronically implanted subdural and depth electrodes was recommended to further delineate the seizure onset zone, and its relationship to the encephalomalacic lesion (Figure 37.9). In addition, this approach would allow functional mapping of adjacent eloquent cortex (anterior language area) by means of extraoperative electrical cortical stimulation.

Six typical nocturnal seizures were recorded in the span of 8 days of invasive recordings. All seizures were characterized by focal EEG changes restricted to the mesial, posterior edge of the orbitofrontal plate (Figure 37.10). Based on three-dimensional MRI reconstructions of the electrode location and underlying epileptogenic lesion the area of seizure onset was found to correspond to the posterior edge of the encephalomalacia.

Treatment and outcome

A resection of the left orbitofrontal and anterior ventral frontal regions was performed. Postoperatively the patient experienced a single breakthrough seizure at 3 months and a cluster of three seizures within one day (in the context of a flu-like illness) at approximately 6 months. At his last follow-up the patient has been seizure-free since for more than a year on a stable combination of lamotrigine and levetiracetam.

Summary

The basal frontal lobe is perhaps one of the least explored and least understood regions of the human cerebral cortex. This highly multimodal area is characterized by its functional heterogeneity and widespread connections within the frontal lobes and limbic system. The anterior part of the OFR has the appearance of granular isocortex and is connected to the heteromodal prefrontal cortex. The posterior OFR has a more primitive, dysgranular architectonic appearance and is intimately connected with the limbic system.

Localization of epileptogenicity arising from the basal frontal lobe is particularly difficult because of the absent or potentially misleading information derived from scalp EEG recordings, and the lack of distinct ictal manifestations. The advent of sophisticated neuroimaging techniques (especially high-resolution anatomical MRI) and the increasing capability to perform invasive recordings from the OFR has made it possible to delineate epileptogenic foci within this region. A limited number of patients with identifiable lesions in the orbitofrontal area and very few patients without evidence of MRI abnormalities have been reported to be seizure free after localized surgical resections. The intimate spatial and functional relationship of the OFR with limbic structures and the reported successes following targeted resections underscore the utility of evaluating this region closely in cases of focal epilepsy presumed to originate in the frontal or temporal lobes.

38 Parieto-occipital lobe epilepsy

V Salanova

Introduction

Occipital lobe epilepsy was first recognized by Gowers in 1879[1] when he described a 30-year-old man with 'epileptoid attacks with visual aura'. The patient described a very brilliant image before him 'like a gold serpent'. This patient at other times had episodes of transient blindness. The patient was found to have an occipito-parietal tumor at autopsy. Gowers interpreted the aura as follows: 'at first there was apparently an over action of the center – a bright light; afterwards paroxysmal defective action, due to temporary exhaustion or inhibition, shown in the narrowing of the field of vision'.

When Gowers examined his records,[2] he found that 84 of his 1000 patients with epilepsy exhibited a 'special sensory aura' which was referred as 'the organ or sense of sight', he subdivided these 'ocular and visual warnings' into five categories: a sensation in the eyeball itself, diplopia, an apparent increase or diminution in the size of the objects, loss of sight, and distinct visual sensations such as elementary visual hallucinations.

The symptomatology of occipital epilepsy was further defined in 1927 by Gordon Holmes[3] when he studied patients who had sustained gunshot wounds to the occipital region who exhibited occipital auras, characterized by elementary visual hallucinations or transient blindness, and in 1941 by Penfield and Erickson,[4] who described the clinical manifestations of several patients with 'visual seizures', including blindness, and coloured moving lights, and were able to elicit the auras by cortical stimulation.

In 1951 Penfield and Kristiansen[5] reported that 11 of 222 patients with focal epilepsy treated surgically had 'visual sensations' as the first manifestation of their seizures, characterized as sensations of lights, darkness of colour, and five patients reported that the visual image was 'revolving' or 'rotating'.

Penfield and Jasper,[6] described several patients with 'visual seizures', including the patient C.Fr. with a traumatic scar of the pole of the right occipital lobe who had an incomplete left homonymous hemianopia. The patient felt that the seizures were induced by a bright light, to the point that he refused to have the examiner shine a light in his eye. Wilder Penfield stated that 'This is an example of sensory precipitation of a visual seizure'. The patient described lights followed by blurring of the vision progressing to complete blindness and then a sensation of stiffness in the left hand, and right hand, followed by a generalized seizure. Penfield stated 'The somatic sensation in both hands suggests that the spread of discharge was from the calcarine cortex to the supplementary area within the sagittal fissure. At the onset of the generalized seizure the head and body turned to the left'.

Penfield and Jasper[7] also reported two patients whose spontaneous seizures began with elementary visual hallucinations, followed by complex visual images. In both patients the habitual complex visual hallucinations were elicited at surgery by stimulation of the right posterior temporal region, suggesting that during the spontaneous attacks the hallucinations probable represented spread of the ictal discharge to the temporal lobe.

Ludwig and Ajmone Marsan[7] reported the clinical manifestations in 55 patients with electrographic evidence of occipital lobe involvement, and noted that as many as two-thirds had lateralized visual manifestations, Blume *et al.*[8] found that in 13 of 19 (68%) of their patients the most common initial ictal symptoms were visual phenomena, and Williamson *et al.*[9] reported that in 22 of 25 patients (88%) with occipital lobe epilepsy, early signs or symptoms 'would had provided clues for the correct diagnosis'. In the series from the Montreal Neurological Institute[10] in more than two-thirds of the patients the clinical manifestations indicated the occipital onset of the seizures.

Functional anatomy

Von Economo[11] divided the occipital cortex into striate, peristriate, and parastriate regions. The striate cortex contained within the walls of the calcarine fissure, constitutes Brodmann's area 17, and it is recognized by the thick strip of granular cells in layer IV that is split by the geniculocalcarine band of Gennari. All layers of this cortex reveal marked granularization.

All six layers of cortex are delineated in the peristriate and parastriate cortices (areas 18 and 19). Numerous pyramidal cells are found in layers II, III, and V and giant pyramidal cells populate area 18, immediately bordering on the striate cortex.

Jones and Powell[12] studied the distribution of projection pathways emanating from areas 17, 18, and 19 by selectively ablating these areas in adult rhesus monkeys. The striate cortex projected to areas 18 and 19, whereas areas 18 and 19 projected fibers to area 8 in the frontal lobe and the adjacent temporal and parietal association cortices. The pathways include the superior longitudinal, the inferior longitudinal and the fronto-occipital fasciculus. Areas 18 and 19 also project deep fibers to the midbrain tegmentum.

Further elucidation of the occipital lobe functional anatomy arose from electrical cortical stimulation studies in

humans undergoing epilepsy surgery. Wilder Penfield and Theodore Rasmussen in the Cerebral Cortex of Man,[13] found that 22 patients reported gross visual sensations as the result of stimulation. These visual responses were elementary sensations of light, darkness, and color. They also reported that 'complicated visual hallucinations do occasionally result from epileptic or electrical stimulation, but these are phenomena of another order and are associated with activation of the temporal lobes'. They observed that 'the visual responses appear in the secondary visual areas of Brodman (18 and 19) as well as in the primary calcarine area 17. They noted that 'in general, it would appear that the calcarine image was more often colored while images produced from the secondary visual zone more often consisted of colorless light'.

Symptomatology and pathophysiology of occipital lobe seizures

An analysis of 42 patients with refractory occipital lobe epilepsy treated surgically at the Montreal Neurological Institute (MNI) between 1930 and 1991[10] showed that the clinical features of occipital lobe epilepsy can be divided into those representing seizure phenomena of occipital lobe origin, which include elementary visual hallucinations, ictal blindness, blinking and ocular movements and those resulting from ictal spread to adjacent cortical areas.

Fifty-nine percent had visual field deficits. Seventy-three percent of the patients had visual auras. In those patients where the data were available, the elementary visual hallucinations were contralateral to the epileptogenic area. One patient with left occipital microgyria and a right homonymous hemianopsia described 'dancing lights, whirling lights to the right' followed by right head and eye deviation, and right head and eye clonic activity. Another patient with left occipital microgyria and a right homonymous hemianopsia described a slowly rotating disk of light in the right visual field. Others described flashing colors, and change in perception of shapes and colors. Another patient with left occipital cortical dysplasia and right upper quadrantanopsia described 'circles, triangles squares, all colors', and a visual sensation of movement, followed by conscious right head and eye deviation and right arm posturing. A patient with left occipital gliosis described 'colored squares of light' followed by blindness, right head and eye deviation and postictal dysphasia.

Four patients had elementary visual hallucinations followed by complex visual hallucinations: a 12-year-old with a history of birth trauma and right occipital gliosis had elementary visual aura characterized by colored triangles followed by a complex hallucination in which he saw a robber, or a man with a gun; sinister characters from comic books, followed by conscious adversion to the left, nystagmoid eye movements, left arm clonic activity and postictal left hemiparesis. Another patient with a left hemianopia described 'a square with a circle in it', faces, pictures like Rembrandt's self portrait. The reason for these complex visual hallucinations is most likely ictal spread to the posterior temporal region, as Penfield and Perot[14] found that complex visual hallucinations could be elicited by posterior temporal stimulation near the occipital cortex, and Gloor *et al.*[15] reported that experiential phenomena (visual and auditory) 'did not occur unless a seizure discharge or electrical stimulation involved limbic structures'.

Ictal blindness has been a consistent symptom of patients with occipital lobe epilepsy. Twenty-eight percent of patients from the MNI had ictal blindness as an initial manifestations of their seizures which lasted as long as a few minutes. A 24-year-old patient with left occipital gliosis described a shadow moving to the right, 'ombrage' followed by blindness, and conscious adversion to the right.

Russel and Whitty[16] reported blurring or extinction of vision in 40% of their patients with traumatic occipital lobe epilepsy, and Williamson *et al.*[9] reported that 10 of 25 (40%) of their patients with occipital lobe epilepsy exhibited ictal amaurosis. Barry *et al.*[17] reported five patients with ictal blindness and electrographic (EEG) monitoring revealed that complete blindness occurred with ictal spread to the contralateral occipital lobe, demonstrating that ictal blindness is caused by seizure induced bilateral occipital lobe dysfunction.

Other authors have also reported lateralized visual auras in patients with occipital lobe epilepsy, Sveinbjornsdottir and Duncan,[18] Aarli and Engelsen,[19] Geller *et al.*,[20] Boesebeck *et al.*,[21] Taylor *et al.*,[22] and Blume *et al.*[23]

Other occipital manifestations in the MNI series included eye pulling or moving sensations, blinking, nystagmoid eye movement and contralateral eye movements. Nineteen percent of the MNI patients exhibited blinking and 7% had contralateral nystagmoid eye movements. In one patient, studied with depth electrodes, the nystagmoid eye movements were contralateral to the seizure discharge.

Munari *et al.*[24] described 16 patients with stereo EEG who had seizures with ocular deviation within the first 10 seconds of the seizure onset. In 14 patients the ocular deviation was tonic and in all was contralateral to the ictal discharge, which generally originated in the medial occipital structures. Cortical stimulation studies in animals and humans demonstrate that eye movements can be initiated by occipital mechanisms.[25,26]

Contralateral head and eye deviation was present in half of the MNI patients. Two of these patients were studied with depth electrodes and had contralateral head and eye deviation while the seizure remained localized to the occipital lobe. Ludwig and Ajmone-Marsan[7] reported contraversive movements of head and eyes in 29% of their 55 patients.

Automatisms similar to those from patients with temporal lobe epilepsy occurred in 50%, and focal motor activity in 38% of the MNI patients, and one-third of the patients had more than one seizure type. Ajmone-Marsan and Ralston[27] suggested that seizures originating in the occipital lobe could have multiple spread patterns. Subsequently this was confirmed by intracranial recordings in humans[28,29] and animal experimental data.[30] The inferior longitudinal, superior longitudinal and the fronto-occipital fasciculus are involved in this spread.

Etiologies of occipital lobe epilepsy

Rasmussen,[31] identified the etiology of refractory occipital lobe epilepsy, established by history and pathological findings in 23 patients; one-third had a history of head trauma or anoxia; 9% had gliomas and 13% postinflamatory brain scarring. In 26% of patients no cause could be determined. The remaining patients had other lesions including pial angiomatosis. In the updated series of 42 patients from the

MNI, 21% had a history of significant head trauma with loss of consciousness, 24% had a history suuggestive of birth trauma or hypoxia, 7% had a history suggestive of encephalitis, and 10% had slow growing glial tumors. Others had focal cortical dysplasia.

Ludwig and Ajmone-Marsan[7] reported that 24% of their patients had a history of birth injury, hypoxia, and severe head trauma; 13% had a history of encephalitis or meningitis; 14% vascular lesions, and 7% expanding lesions. In 25% the etiology was unknown. A recent series from the Yale Epilepsy Center, of 35 patients with intractable occipital lobe epilepsy treated between 1986 and 1995, reported that most of their patients had developmental abnormalities or tumors,[32] and Lee *et al.*[33] reported that 20 of 26 of their patients with occipital lobe epilepsy had a pathological diagnosis of cortical dysplasia.

EEG findings in occipital epilepsy

In the MNI series, the most common location of interictal epileptiform discharges was the posterior temporal-occipital region (46%). Interictal epileptiform discharges were localized to the occipital lobe in only 18% of patients. One-third of the patients had synchronous lower amplitude epileptiform discharges from the contralateral homologous head regions, suggesting secondary bilateral synchrony. Bitemporal interictal epileptiform discharges were recorded, in 24% of the patients. This is probably a manifestation of secondary bilateral synchrony and/or secondary epileptogenesis.[34,35]

The most common type of surface ictal onset was regional involving the posterior temporal occipital region. Ictal onsets on surface recordings restricted to the occipital lobe were seen in only four out of 24 patients (17%). Six patients had intracranial recordings with depth electrodes. Ictal onsets were predominantly regional rather than focal and involved widespread areas of the mesial and lateral occipital cortex, often involving the supra and infracalcarine structures and, in some seizures, the posterior temporal region. The most common pattern of spread involved the ipsilateral temporol-mesial structures.

Aykut-Bingol *et al.*[32] found that of 35 patients who had occipital lobe epilepsy surgery between 1986 and 1995, interictal scalp EEG was localized to the occipital, temporal, and occipitotemporal regions in 17%, 27%, and 24% of patients, respectively. Ictal events were recorded in 30 patients. Ictal onset was localized to the occipital lobe in 30%, and temporal and occipitotemporal in 27%; in the rest it was more diffuse. Nineteen patients underwent intracranial EEG studies. Foldvary *et al.*[36] analyzed the localizing value of ictal EEG in focal epilepsy, and found that 'false localization/ lateralization occurred in 28% of occipital seizures.'

Parietal lobe epilepsy

Historical background, and functional anatomy

Wilder Penfield, Theodore Rasmussen, and their colleagues divided their patients with refractory epilepsy into those whose epileptogenic areas involved the frontal, central (sensorimotor area), parietal and occipital regions.[4,6,13]

Patients with epileptogenic lesions involving the pre- and post-central gyrus were grouped together, because lesions in this cortex produced sensorimotor deficits, and as Penfield and Erickson[4] stated 'the precentral and postcentral gyri in man constitute a functional unit. Close interrelationship of motor and sensory cortical areas is established by the numerous connecting U-shaped fibers which pass under the bottom of the central fissure'.

Penfield and Rasmussen,[13] noted that 'by Parietal area is meant that portion of the classical parietal lobe which lies behind the post central gyrus', 'if the lower parietal area which constitutes the parietal speech area on the dominant side be excluded, the superior parietal cortex could be removed with a comparatively small functional penalty'. Penfield and Erickson[4] had described that ablation of the parietal association cortex left little obvious functional deficits though 'disturbances of speech and disturbances in perception of form in the opposite homonymous visual field has been noted'.

Rasmussen[37] continued to use the functional division of the brain developed by Foerster and Penfield,[38] since their definition of the parietal lobe differs from the generally employed in reviewing the MNI series of parietal lobe epilepsy, we refer to 'parietal association area' to define the region behind the postcentral gyrus and in front of the occipital lobe.

Foerster and Penfield,[38] described patients with epileptogenic lesions and 'parietal field attacks', characterized by painful sensations, vertigo, paresthesias, head and eye deviation, a sense of movement of one extremity, visual illusions, and complex movements of arms and legs, and reproduced these symptoms by faradic stimulation.

Cushing[39] expanded on these observations when he described 12 patients with parietal meningiomas; nine of them had a contralateral sensory aura, described as numbness, tingling, painful sensation or a feeling of warmth or heat. Since then few series of patients with parietal lobe epilepsy have been reported.

Clinical manifestations and pathophysiology

Patients with parietal lobe epilepsy with epileptogenic areas in the parietal cortex behind the postcentral gyrus, comprised 6% of patients operated at the Montreal Neurological Institute (MNI) between 1929 and 1980.[40,41]

Eighty-two patients had nontumoral parietal lobe epilepsy (Figure 38.1), with a mean age of seizure onset of 14.1 years and mean duration of epilepsy 8.1 years. Twelve patients had contralateral sensory deficits which were found during detailed examination and consisted of contralateral impaired two pointpoint discrimination, isolated diminished stereognosis, without two point discrimination, was reported in only two patients. Sixteen percent of patients had smallness of the contralateral extremities, 8% contralateral visual field deficits, most commonly inferior quadrantic defects. Impairment of spatial orientation and right–left disorientation were described in three patients, disturbance in the field of written language, and mild aphasia in two others.

Ninety-four percent of patients exhibited auras. The most common were somatosensory, described by 52 patients as tingling or numbness; they were contralateral to the epileptogenic zone in 51 patients and bilateral in one; 13 of these patients described a painful, and five a thermal sensation. The second most common auras were disturbances of body

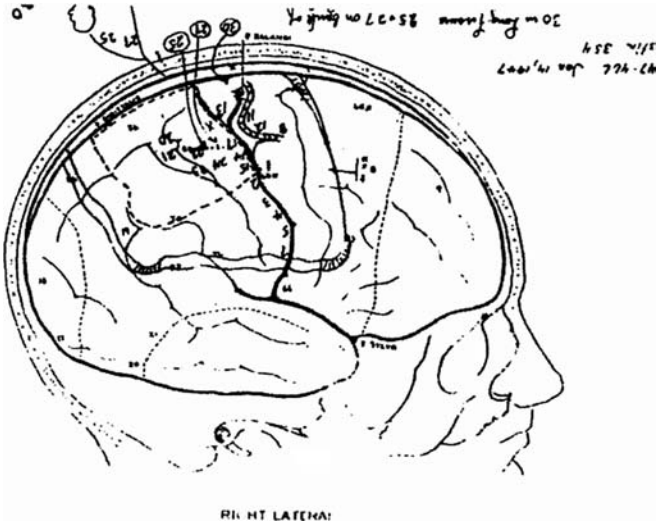

Figure 38.1 Original operative map of patient A. H. operated on by Dr Penfield in 1946. 25 year old with history of head trauma. The seizures were described as 'does not know where he is, cannot concentrate, cannot see well', followed by turning to the left.

image exhibited by nine patients; three patients mentioned a sensation of movement in one extremity, and another a sensation that the leg was absent. Twisting or turning sensations of the extremities were also described.

Visual illusions were reported by nine patients as 'figures look larger' or 'things on the wall turning'. A few patients exhibited complex visual or auditory hallucinations, suggesting ictal spread to temporo-limbic areas.[15] Eighty patients underwent intraoperative cortical stimulation studies and the habitual auras were reproduced in 55% of patients. These included auras with a disturbance of body image or visual illusions, indicating an epileptogenic zone in the parietal association cortex. However, somatosensory auras also occurred in patients with lesions limited to the parietal association cortex, suggesting ictal spread to the somatosensory cortex. Thus, the symptomatogenic zones were distant from the epileptogenic zones in the parietal association cortex, Luders and Awad.[43]

Other seizure characteristics

The other clinical manifestations were due to ictal spread. The ictal semiology indicated several dominant spread patterns, including spread to the sensorimotor cortex, the premotor eyefield, supplementary motor area, and the temporolimbic region. Twenty-eight percent had tonic posturing of the extremities, 57% had focal motor activity, 17% had oral-gestural automatisms, and 4% had complex automatisms. Forty-one percent had head deviation, 22% had Todd's paralysis and 7% had postictal dysphasia.

Many patients had more than one seizure type reflecting the different spread patterns. Sixty-one percent of patients with tonic posturing had epileptogenic zones which included the superior parietal lobule, and 79% of those with automatisms had epileptogenic zones extending into the inferior parietal lobule. This suggest preferential spread with ictal activity from the superior parietal lobule more commonly spreading to the supplementary motor area, and the one from the inferior parietal lobe to the temporo-limbic areas. This pattern of spread is supported by Reesnick *et al.*,[44] who used subdural electrodes in the evaluation of patients with refractory epilepsy, and is a reflection of the connection of the parietal lobe with the supplementary motor area, and with the temporo-limbic region,.[45,46]

Other authors and recent reviews have also reported asymmetrical tonic seizures and automatisms in patients with parietal lobe epilepsy, and have emphasized that many of these patients have more than one seizure type.[18,47–50]

Etiologies of nontumoral parietal lobe epilepsy

Thirty-five patients from the MNI series had a history of head trauma, and 16% had a history of birth trauma. The remaining patients had a history of encephalitis, febrile convulsions, gunshot wounds to the head, forme fruste of tuberous sclerosis, hamartomas, vascular malformations, tuberculoma, arachnoid or porencephalic cysts, microgyria and post-traumatic thrombosis of the middle cerebral artery.

Tumoral parietal lobe epilepsy

Thirty-four of 116 patients (29%) from the MNI series with parietal lobe epilepsy had slow growing tumors (Figure 38.2), most commonly astrocytomas (62%) and meningiomas (14%). The remaining patients had hemangiomas, oligodendrogliomas, and mixed astrocytoma and oligodendroglioma.

Forty-seven percent had impaired two point discrimination in the contralateral fingers, 38% had mild contralateral weakness, 6% aphasia, 3% smaller extremities contralateral to the epileptogenic zone, one right to left disorientation and acalculia and two spatial disability. Only one patient exhibited definite astereognosis without coexisting primary sensory cortical deficit.

Seventy-nine percent exhibited auras, most commonly somatosensory, contralateral to the the epileptogenic zone in

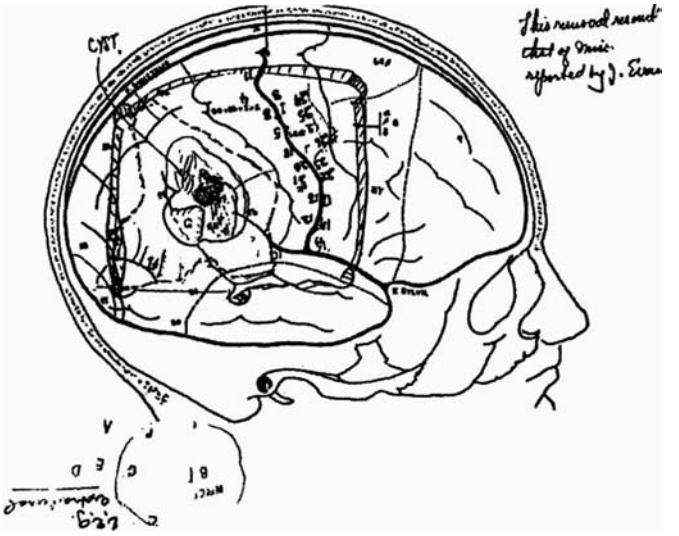

Figure 38.2 Original operative map of patient E. O'k. operated on by Dr Penfield in 1947. 25 year old with weakness of left foot and absent two-point discrimination in left leg. The seizures began by a sensation in the left great toe, tingling in the left vulva, spreading to left breast (not sexual), followed by left leg and left arm jerking.

all except for one patient. Four described a painful sensation. Twelve percent had visual illusions, 9% aphasic aurae, 6% disturbance of body image, 3% complex auditory hallucinations, and 3% a feeling of movement in one arm. Some patients had two or more auras.

The clinical manifestations indicated different spread patterns; 21% had tonic posturing of the extremities, 28% had focal clonic activity always contralateral to the epileptogenic lesion, 15% had head deviation, 9% automatisms, and 6% difficulty speaking. Thirty-two percent had Todd's paralysis and 18% had post-ictal dysphasia.

EEG findings in parietal epilepsy

Surface EEG was available in 66 patients of the nontumoral parietal lobe epilepsy MNI series and seizures were recorded in 36 patients. The interictal epileptiform discharges were recorded from the fronto-centro-parietal region in 33% of patients, parieto-posterior temporal in 14%, parietal in 14%, parieto-occipital in 9%, fronto-centro-temporal in 4.5%, fronto-temporal-parietal in 4.5%, hemispheric, maximum posterior head region in 9%, and bilateral in 4.5%. No interictal epileptiform discharges were recorded in 7.5% of patients. Secondary bilateral synchrony was described in 32% of patients. Ictal discharges were predominantly lateralized, in some patients the maximum ictal activity was recorded over the centro-parietal region and in others over the posterior head region. Localized parietal seizure onset was recorded in four patients.

Williamson *et al.*[47] and Cascino *et al.*[48] emphasized that surface EEG monitoring is often non-localizing in parietal lobe epilepsy, and Foldvary *et al.*[36] reported false localization/lateralization in 16% of parietal lobe seizures.

Conclusions

In more than two-thirds of the patients with occipital lobe epilepsy, clinical manifestations indicated the occipital onset of the seizures. Visual auras were reported in 47–73% of patients. Most patients exhibited contralateral elementary visual auras, and a few exhibited ictal blindness. Seven to nine percent of patients exhibited nystagmoid eye movements. Many of the disabling clinical manifestations resulted from ictal spread to adjacent cortical structures, 29–88% of patients exhibited automatisms typical of temporal lobe epilepsy, and 38–47% had focal motor activity. Some patients had more than one seizure type reflecting these different spread patterns. Contralateral visual field deficits were reported in 20–59%, and abnormal imaging studies in 37–72% of patients. EEG recordings often showed posterior temporal-occipital interictal epileptiform discharges, and ictal onsets were regional often involving the posterior temporal region. A quarter of patients had bitemporal independent interictal epileptiform discharges, and one-third had bilateral synchronous epileptiform discharges over the posterior head regions.

Ninety-four percent of patients with parietal lobe epilepsy exhibited auras. The most common auras were somatosensory, including painful sensations. However the auras experienced by some patients, like disturbance of body image may have indicated an epileptogenic zone in the association parietal cortex. The ictal semiology indicated several dominant spread patterns; 28% had tonic posturing of extremities, 57% focal motor clonic activity, and 17% had oral-gestural automatisms. The surface EEG was often lateralizing rather than localizing. Brain tumors are often the cause of parietal lobe epilepsy and were found in one-third of 116 MNI patients.

39 Insular epilepsy

J Isnard, P Ryvlin, and F Mauguière

Introduction

The concept of insular epilepsy was debated in the early fifties when it was observed that insular stimulation could evoke symptoms very similar to those of temporal lobe seizures. This similarity could be such that confusion between insular and temporal lobe seizures might explain some of the failures of temporal lobectomy. In 'Historical background and basic concepts' we review the historical background and concepts on which are grounded recent depth Stereotactic EEG (SEEG) studies aiming at identifying the actual symptoms reflecting discharges located in the insular lobe. 'The insula as an ictal symptomatogenic area' is devoted to the description of an ictal symptomatic sequence, which occurs in full consciousness, and is highly suggestive of an epileptic discharge in the insular lobe. Based on SEEG recordings of spontaneous seizures and stimulation data, this sequence includes an initial pharyngeal and/or laryngeal discomfort with thoracic oppression or dyspnea, unpleasant paresthesiae, warmth or pain sensation in the perioral region or spreading to a large somatic territory, followed by dysarthric or dysphonic speech and ending by focal somato-motor manifestations. Several cortical areas, with which the insula is connected, are involved in most of the focal seizures originating in, or spreading to, the insula. Based on clinical observation of ictal symptomatology, invasive EEG investigations must be targeted to explore the whole extent of the suspected epileptogenic network in order to assess the role of the insula in seizure development. 'The insula as a mode in distributed epileptogenic networks' provides the arguments supporting identification of three major epileptogenic networks (temporo-perisylvian, temporo-limbic and mesial-orbital frontal) where the insula participates as a node in the building of ictal symptomatology, including that of nocturnal frontal hypermotor seizures where the antero-superior part of the insula can be a clinically silent seizure onset zone. The final three sections are devoted to the review of etiologies, presurgical evaluation and treatment of insular epilepsies. Most cases reported in the literature as insular epilepsies are symptomatic of a focal epileptogenic lesion located in the insula, some of which were successfully operated upon, while the few cases of cryptogenic epilepsies hitherto available are those reported in this chapter. EEG plays a minor role for investigating insular epilepsies because interictal paroxysms and seizures originating in the insula are unlikely to be detected by scalp recordings. The roles of MEG and functional interictal neuroimaging remain incertain as well as the results of insular surgical resection based on SEEG data or of SEEG-guided thermo-coagulation in cryptogenic cases. Conversely seizure freedom can be obtained after surgical resection of the lesion in symptomatic cases, provided that ictal symptoms are compatible with an epileptogenic zone located close to the lesion in the insular lobe.

Historical background and basic concepts

The insula as the fifth lobe of the brain

In an article published in 1896 that was devoted to the comparative anatomy of the insula, Clark[1] quoted 39 synonyms used in anatomical literature to name the fifth lobe of the brain buried in the lateral sulcus and covered by the opercular parts of the frontal, parietal, and temporal lobes, among which the term insula, first proposed by Reil in 1804, has prevailed. The anatomical situation of the insula and its cytoarchitectonic organization lent some substance to the view that it might be an isolated lobe of the brain mostly devoted to the processing of body and visceral sensation including gustation, pain and other emotions, and to viscero-motor and autonomic control. In monkeys the insula includes Brodmann's areas 13 to 16 and shows a caudo-rostral sequence of distinct cytoarchitectonic areas namely; a granular cortex, at its upper and posterior part, very similar to that of the second somatosensory (SII) area and involved mostly in somatosensory, pain and auditory functions; a transitional dysgranular field localized in its antero-superior part involved in gustation and and viscero-sensitive functions; an antero-ventral agranular field, which is in continuity with the temporal pole and olfactory proisocortex, and related to olfactory and autonomic functions (see ref 2 for a review).

For the past 10 years the question of insular physiology has been addressed by numerous studies using neuroimaging, evoked potentials and direct stimulation in humans as well as microelectrode studies in monkeys. These studies have confirmed the role of the insula in:

- Somatosensory and pain sensation as assessed by numerous anatomical,[3,4] functional imaging studies[5–8], as well as by our recent studies of somato-sensory and pain evoked responses[9] and direct electric stimulation of the Insular cortex[10, 11]
- Visceral sensation and viscero-motor control[12–14] including processing of visceral pain[15]
- Cardiovascular function as demonstrated by insular stimulation in epileptic patients before temporal lobectomy that produced changes in heart rate or in blood pressure

in 50% of cases,[16] thus leading to suspect a role of insular discharges in cardiac arrhythmias causing sudden death during epileptic seizures.
- Gustation as assessed first by the stimulation studies of Penfield and Faulk[17] and further confirmed by neuroimaging studies[18, 31] as well as by microelectrode recordings of a large number of insular neurons in monkeys,[20] these physiological findings being consistent with the altered taste perception observed in patients with insular lesion.[21]
- Audition and language, in particular allocation of auditory attention, tuning in to novel auditory stimuli, temporal and phonological processing of auditory stimuli.[22] Furthermore several studies suggest that both right and left insulae are involved in the control of speech production.[23–28]

More recently, some studies suggested that the insular lobe could belong to the mirror-neuron system that characterizes regions of the brain that are able to respond when the subject performs an action and when the subject observes another individual doing a similar action (see ref 29 for a review), but also regions able to encode for a sensation (or emotion) perceived by the subject and to respond to the observation of others experiencing that sensation (or emotion). In the human insula regions involved in visceral sensation or viscero-motor responses also respond to faces expressing disgust.[30,31] Similarly the human insula responds to both pain perception and empathy for others' pain.[32]

From what precedes one can conclude that the insula represents a highly organized lobe with specific functions comparable to the other lobes of the brain and, therefore, consider that an epileptogenic zone located in this area will cause seizures characterized by a specific ictal symptomatology. This point is addressed in details in the second section of this chapter where we discuss the localizing value of a sequence of ictal symptoms that are highly suggestive of an epileptic discharge affecting the insula.

The insula as a node in distributed cortical networks

As the other lobes of the brain, the insula is characterized by anatomical borders that are defined by a limiting sulcus (the circuminsular fissure) but also by fuzzy cytoarchitectonic borders with neighboring cortical areas and by a dense network of cortico-cortical connections with adjacent or more distant cortical areas. Therefore its function, as well as its implication in epileptic seizure development, cannot be sketched as an isolated functional center, as suggested by the term 'insula'. A complete description of insular connections is given in the review by Augustine[2] showing that the insula is connected with the limbic areas, the amygdalar nucleus, the basal ganglia, and all of the cortical lobes, except the occipital lobe. Several attempts have been made to identify functional networks in which the insula could play the role of a functional node.[33–35] Among these networks the perisylvian-insular, the temporo-limbic-insular, and the mesial-orbito-frontal-insular networks deserve the attention of epileptologists because epileptic discharges propagating in each of them will produce seizures where the symptoms attributable to the insula will reflect only part of the ictal symptomatology. In part III of this chapter we discuss the difficulties in identifying insular epilepsy among epilepsies where the epileptogenic zone spreads outside the limits of the insular lobe, and the utility of the concept of epileptogenic networks for planning the depth electrodes implantation in the presurgical evaluation of these patients.

The concept of insular epilepsy

In the late forties and early fifties Guillaume et al.[36] followed by Penfield and Jasper[37] were the first authors to call attention upon the concept of insular epilepsy. Penfield and Faulk[38] concluded the review of their personal experience of insular stimulation by noting that the majority of the positive responses to stimulation of the insula consisted either in sensations resembling that produced by stimulation of the superior bank of the sylvian fissure (SII area), or in abdominal feeling secondary to motor change in the gastrointestinal tract. This latter finding suggested that seizures originating in the insular cortex were able to mimic temporal lobe seizures to such a degree that confusion between the two types of seizures might explain part of temporal lobectomy failures.[36] This concept was mostly based on data from electrocorticography (EcoG) carried out during the surgical treatment of patients suffering from temporal lobe epilepsy (TLE) under local anaesthesia. Moreover EcoG recordings revealed a rich interictal spiking paroxysmal activity in about half of these patients.[34] However, in spite of an EcoG strategy exploring systematically the insula, Penfield and his collaborators never succeeded to record spontaneous epileptic discharges with a focal onset in the insular cortex. Furthermore they were unable to provide the argument that insular cortectomy, as a complement to conventional temporal lobectomy in TLE patients, could improve the surgical outcome.[39] Thus the concept that specific symptoms could reflect insular discharges into the insular lobe fell into dereliction. More recently, several case reports showed that seizures could be stopped by the surgical removal of insular lesions[40–42] and reactivated the research for identifying the insula as a symptomatogenic area in focal epilepsy.

The insula as an ictal symptomatogenic area

Identification of a given cortical area as a symptomatogenic zone is mostly based on correlations between the ictal symptomatology and data from ictal discharge recordings using invasive EEG procedures.[43] In the case of the insular lobe such correlations are often uneasy because, even though the insula is frequently involved during temporal lobe seizures, most insular discharges develop concomitanty in the temporal, perisylvian, or frontal cortex, so that symptoms reflecting discharges in the insular cortex are difficult to disentangle from those related to the involvement of these neighboring areas in the building of ictal symptomatology. The patients' file of our department reflects the rarity of focal seizures involving exclusively, or preferentially, the insular lobe. Of the 180 patients with temporal lobe epilepsy (TLE) referred to our department for presurgical evaluation since 1996, 83 were explored using depth electrodes implanted in the lateral and mesial regions of the temporal lobe, of whom 50 also had depth electrodes implanted in the insular. We have been able to identify an ictal symptomatic sequence associated with a focal discharge restricted to the insula in only eight of them (16%).

Ictal symptoms reflecting seizure activity in the insula

What we know about the electroclinical manifestations of insular seizures mostly stems from SEEG data from a few patients referred mostly for TLE surgery. Electrode implantation in the insula is usually decided on the basis of ictal symptoms or scalp video-EEG data suggesting an early spread of seizures either to the suprasylvian opercular cortex, such as tonic or clonic mouvements of the face, dysarthria or motor aphasia, gustatory hallucinations, hypersalivation, post ictal facial paresis,[44] or to the infrasylvian opercular cortex such as auditory hallucinations or early sensory aphasia.[45] For the description of insular ictal symptoms we selected seizures that were characterized by a SEEG discharge involving selectively the insula at any moment of the seizure development. In six patients discharges originated from the insula itself (cases 3 to 8 in Figure 39.1) and in two (cases 1 and 2 in Figure 39.1) discharges originated in the hippocampus but propagated exclusively to the insular cortex without spreading to any other cortical structure. Video recordings of patients' behavior during insular seizures are illustrated in Figure 39.1. The five ictal features that were invariant in repeated seizures in a given individual and observed when the ictal discharge selectively involved the insular cortex are the following:

(a) Consciousness and contact with the environment are fully preserved
(b) Paresthesiae (lines B and C in Figure 39.1) represent the second feature that is reported by all patients during insular discharges. They are described as an unpleasant sensation of electricity or warmth that can be painful (2/8). They are either restricted to peri-or intra-oral areas (line B in Figure 39.1), or distributed to a large cutaneous territory (face-shoulder-arm and trunk, upper limb-trunk-lower limb) most often opposite to the insular discharge (line C in Figure 39.1), or bilateral (2/8) affecting either territories close to midline, such as mouth and oral cavity (1B and 2B in Figure 39.1), or more distal somatotopic areas such as both lower limbs (3C in Figure 39.1). Although the onset site and spreading of paresthesiae can vary from one seizure to the other, there is usually no somatotopic Jacksonian march as often reported in SI somatosensory seizures.[46]
(c) Motor and sensory pharyngo-laryngeal symptoms are other frequent manifestations (6/8) that are accompanied by the spontaneous gesture of seizing the neck with the hand ipsi- or contralateral to the discharge, or with boths hands, as illustrated in patients 1–6 in Figure 39.1 (line A). This sensation can be isolated or preceded, or followed, by other sensations such as a retro-sternal or abdominal heaviness that can be accompanied by rumbling noises and vomiting (image 1B in Figure 39.1), or a short breath with dyspnea as reported in the early descriptions of anterior insular stimulations by Penfield and Faulk.[38] Its intensity is variable according to patients and is described either as an unpleasant sensation of throat constriction, or as the sensation that the salivary glands are under pressure preceding hypersalivaltion (image 2A–5A in Figure 39.1), or even as a terrifying sensation of strangulation with suffocation (images 1A and 6A in Figure 39.1).
(d) A dysphonic and dysarthric speech evolving progressively toward a complete muteness is as frequent as the laryngeal sensation described above (6/8). It may persist several tens of seconds after the end of the discharge.
(e) Finally, the clinical manifestations of insular seizures often (5/8) end with motor symptoms (cases 4–8, line D in Figure 39.1) that are either lateralized and opposite to the discharge (tonic spasm of face and upper limb), or more diffuse (head and eyes rotation, generalized dystonia). In a given patient the occurrence of motor symptoms is usually inconstant from one seizure to the other.

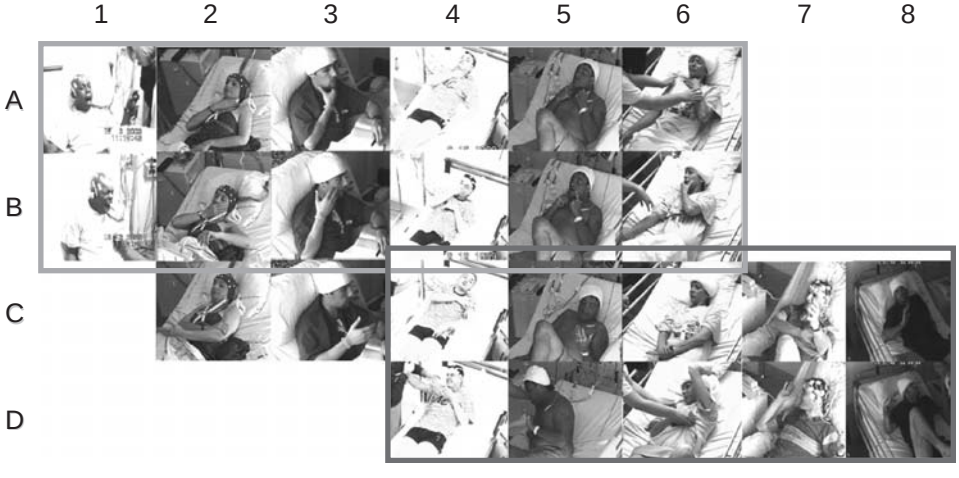

Figure 39.1 Video sequence of ictal symptoms in the eight patients with insular seizures. Empty areas correspond to missing symptoms in the sequence. All illustrated seizures are simple partial seizures with complete preservation of contact during phases A, B, and C of the sequence. A brief loss of contact occurred in phase D for patients 6 and 7 in association with intense somatomotor convulsive symptoms. A: Laryngeal constriction (6 patients). B: Paresthesiae in the perioral region (6 patients). C: Lateralized somatosensory symptoms in upper limb (7 patients). D: Focal somatomotor symptoms (5 patients). *For patient 3 somatomotor symptoms(D) did not occur during the three Video-SEEG recorded seizures, while most of spontaneous seizures in patient's history ended by this type of symptoms. Colored frames distinguish rostral (green) from caudal (red) insular seizures. Green frame: symptoms associated with anterior insular ictal discharge Red frame symptoms associated with posterior insular ictal discharge.

When observed at any given moment in the seizure such symptoms suggest that the insular lobe is included in the symptomatogenic zone; when observed at the onset of seizures they indicate that the insula should be involved in the surgically resected area to achieve postsurgical control of seizures; when an insular lesion is present their occurrence at seizure onset suggests that the epileptogenic zone is close to the lesion. This latter statement is illustrated by the patient whose brain MRI is shown in Figure 39.2. This female patient, aged 22, had suffered since the age of 16 from seizures beginning by unpleasant and intense paresthesiae that involved a large proportion of the left side of her body including face, whole upper limb and trunk followed by a 'strange taste' in her mouth. Her seizures ended with hypersalivation and clonic jerks in her left face. MRI showed a cavernous angioma located in the posterior insular cortex, the removal of which was followed by the disappearance of seizures. Since surgery this patient has remained free of seizures and antiepileptic drugs, with a postsurgery follow-up of two years.

Localization specificity of insular ictal symptoms: data from direct electric cortical stimulations

Electric stimulation of the insula in patients presenting with one or more of the above listed ictal symptoms is useful for mapping the symptomatogenic area when it reproduces symptoms that are immediately identified by the patient as identical to their spontaneous ictal symptoms. Thus lateralized and widely distributed paresthesiae could be triggered by stimulation in five of the eight patients whose ictal behavior is shown in Figure 39.1 (cases 1, 3, 5, 6 and 8), focal perioral paresthesiae in four (cases 1, 2, 3, and 6), laryngeal sensation in three (cases 2, 4, and 5), dysarthric speech in one (case 5) and abdominal pain in one (case 1).

More generally direct stimulation of the insula, even in patients whose seizures are of extrainsular origin, is able to elicit all of the ictal symptoms of insular seizures. In our experience, the insula is one of the most eloquent cortical areas when electrically stimulated by shocks[47] or trains[11] at low intensities (1–3 mA). Insular stimulation sites explored in our group of 50 consecutive patients are plotted in Figure 39.3. Of these 144 sites, 125 were clinically responsive to stimulation in the absence of any after discharge, and a total amount of 139 evoked clinical responses could be collected (Figure 39.3b). Thirty-one of them were identified by the patients as identical to one of the ictal symptoms of their spontaneous seizures, 108 were reported as unknown and not belonging to the usual ictal symptomatology. As for ictal symptoms, these responses can be subdivided into five main categories: somatosensory (Figure 39.3Ca), viscerosensitive (Figure 39.3Cb and c), auditory (Figure 39.3Cd), dysarthria and missing words (Figure 39.3Ce), others including sensation of unreality, whole body sensations, olfacto-gustatory hallucinations, and vegetative responses (Figure 39.3Cf).

Somato- or viscero-sensory responses represent nearly two-thirds of evoked responses, of which more than half concern the cervical-laryngeal region. There is thus converging evidence from seizure analysis and stimulation data that these somatosensory symptoms, particularly in case of warmth or pain sensation, suggest an ictal involvement of the posterior insula.

Similarly the laryngeal and visceral sensations reported by our patients during their seizures, and reproduced by electric stimulation suggest an anterior insular propagation of the epileptic discharge. This conclusion contrasts with the commonly accepted view that visceral and laryngeal ictal sensations indicate a hippocampal or amygdalar origin when observed in the context of TLE seizures.[48, 49]

Auditory symptoms and dysarthric speech immediately follow somatic and visceral sensations, in terms of frequency, in the list of responses evoked by insular stimulation. Auditory symptoms are currently attributed to ictal discharges in the temporal operculum and first temporal gyrus. Our data suggest that they may also reflect an insular propagation of the discharge. However, there are no types of auditory illusions or hallucinations that can be considered as specific to insular ictal semiology, because stimulation of the Heschl's gyrus can evoke auditory symptoms very similar to those produced by insular stimulation. Conversely, though dysarthria is considered to reflect frontal opercular discharges,[50] we never observed this symptom in isolation when stimulating this region outside Broca's area. Moreover, ictal dysarthria was associated with discharges in the nondominant hemisphere for language in the three patients whose insular seizures included this symptom, and it was reproduced as often in the right or left hemisphere by direct cortical stimulation.

Somato-motor ictal manifestations differ from others in that they usually cannot be reproduced by insular stimulation and reflect seizure propagation outside the insular lobe. They have been considered as predictors of a bad outcome in

(b) (c)

Figure 39.2 Sagittal (a), coronal (b) and axial (c) MRI slice showing a right posterior insular cavernous angioma in a patient with painful seizures on the left side of the body, who became seizure free after lesionnectomy (see text for details).

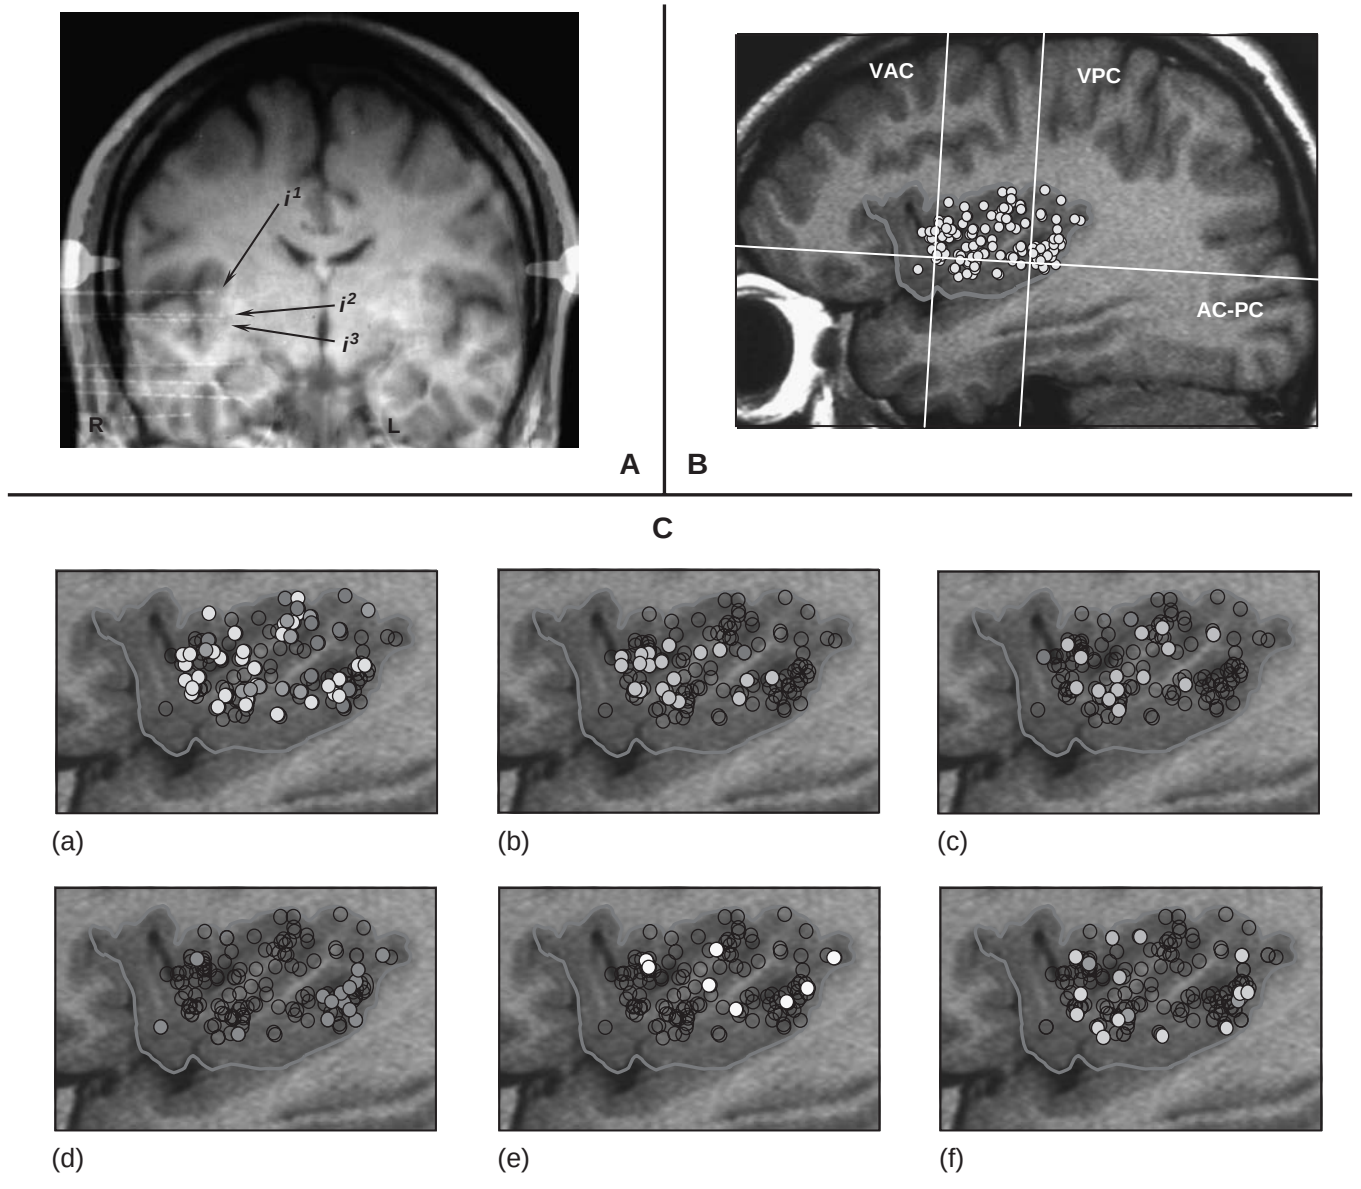

Figure 39.3 SEEG exploration of the insular lobe. A: Fusion of skull radiography and coronal MRI slice in the anterior commissure vertical plane at scale 1. This picture illustrates the positions and trajectories of the electrodes exploring the insular cortex (i1, i2, and ***i3***) in an individual patient. The two deepest contacts of each electrode are located in the insular cortex. The more superficial contacts are located in the suprasylvian (i1) and infrasylvian opercular cortex (i2 and i3). (R: right, L: left). B: Plotting of the 144 insular contacts (yellow dots) in the 50 patients on a sagittal MRI slice of the insula. The borders of the insular lobe are drawn in red. Most of the insular surface has been explored except its most anterior part. The white lines represent the axis of the bicommissural stereotactic space of Talairach and Tournoux.[97] AC-PC: anterior commissure-posterior commissure horizontal plane; VAC: vertical anterior commissure plane orthogonal to the AC-PC plane; VPC: vertical posterior commissure plane orthogonal to the AC-PC plane C: Functional mapping of the insula. This figure illustrates data from direct electrical stimulations of the insular cortex in the 50 patients of this study. In each of the six Ca to Cf insets all of the 144 stimulated points are plotted as black circles (see ref. 11 for details on stimulation procedure, safety and accuracy). The 138 responses evoked by electrical stimulations are represented according to the functional categories detailed in the results section. Ca: Somatosensory responses. Simple paresthesiae are represented in yellow, paresthesiae with warmth sensation in orange and painful paresthesiae in red. Cb: Viscero-sensitive responses are in blue, of which one was painful (in red). Cc: Sensations of laryngeal constriction are in green, of which two were painful (in red). Cd: Auditory responses (lilac). Ce: Dysarthric speech and missing words (cream white). Cf: Miscellaneous responses: Sensation of unreality (light blue); Olfacto-gustatory responses (orange); Vestibular responses (pink), Vegetative responses (purple). From Isnard et al. 2004 with permission.[69] (See Color plates.)

temporal lobectomy and their occurrence makes questionable the diagnosis of TLE.[51] Indeed such symptoms are exceptional in seizures originating in the mesial temporal lobe, while they occur at the end of nearly two-thirds of insular seizures. Thus, in patients whose ictal symptomatology is compatible with TL seizures, their occurrence during the development of the seizure strongly suggests a seizure onset in the insular lobe.

Finally, 10% of the responses evoked by insular stimulation (Figure 39.3Cf) reproduce ictal manifestations that are only occasionally observed in spontaneous insular seizures such as vegetative responses, feeling of unreality, olfacto-gustatory and visceral sensations. The insular origin of these rare symptoms is in agreement with the functional role of the insular lobe in the control of taste[52–56] and visceral functions.[31, 57]

None of our patients with SEEG documented insular seizures reported vertigo or sensation of body tilting as part of their ictal symptomatology and insular stimulation exceptionally produced a vestibular sensation (3/139: 2.1%, purple points

in Figure 39.3Cf). This finding contrasts with some observations where parieto-insular strokes manifested by such sensations.[58–60] It is in line with cortical stimulation data by Penfield and Jasper[37] and more recently by Kahane et al.[61] showing that vestibular sensations are mostly observed after stimulation of the superior temporal neocortex and lateral aspect of the inferior parietal cortex.

What, if anything, is an insular seizure?

Based on the above detailed observations is it possible to add an 'insular' category to the list of epileptogenic zones that can be used as one of the dimensions of a patient-oriented epilepsy classification?[62] In other words, is there any sequence of symptoms that are specific enough to locate the epileptogenic area in the insula and to predict that the removal of the insular cortex is necessary to make the patient seizure free? Even though SEEG-documented seizures are scarce an affirmative answer can be given to this question when, during spontaneous seizures, the patient experiences in full consciousness a symptomatic sequence made of a pharyngeal and/or laryngeal discomfort with thoracic oppression or dyspnea, unpleasant paresthesiae, warmth or pain sensation in the perioral region or spreading to a large somatic territory, followed by dysarthric or dysphonic speech and ending in focal somato-motor manifestations. Knowing that in patients illustrated in Figure 39.1, most of the antero superior quadrant of the insula has not been explored (see Figure 39.3), two variants can be distinguished according to whether the insular discharge originates from the anterior or posterior part of the insula. In rostral insular seizures viscero-motor and laryngeal symptoms are predominant (green frame in Figure 39.1), while in caudal insular seizures the ictal symptomatology is dominated by somato-sensory symptoms, which are all the more so specific that they affect a large, eventually bilateral, territory and manifest as a warm or painful sensation (red frame in Figure 39.1)! Thus most of the insular seizures can be described as a combination of vegetative and somatosensory auras according to the semiological seizure classification proposed by Lüders et al.[63]

The insula as a node in distributed epileptogenic networks

As for any other types of partial seizures, the concept of a distributed epileptogenic network can be applied to describe insular seizures where the insular cortex is involved as a node, or as a relay in seizure propagation, and not as a single focus. This situation is likely to be more frequent than that where seizures remain confined to the insular cortex. The occurrence of a sequence of ictal symptoms reflecting the insular involvement at seizures clinical onset, as described above, proves effective to delineate the various clinical situations where epileptic discharges might originate in the insula. It must be reminded, however, that identification of these symptoms does not allow to firmly conclude on the insular origin of seizures, since they might as well follow the primary involvement of noninsular portions of a larger epileptogenic network where the seizure onset zone can keep clinically silent.[64] Thus, apart from the situation where a clear-cut epileptogenic MRI lesion, such as a cavernous angioma or a low grade tumor, is observed within the insula, invasive EEG investigations, based on clinical observation of ictal symptomatology, must be targeted to explore the whole extent of the suspected epileptogenic network in order to assess the exact role of the insula in seizure development. Three major types of epileptogenic networks involving the insula can be distinguished:

- Temporo-perisylvian-insular networks that include the various brain regions bordering the sylvian fissure, i.e., the frontal, parietal and temporal operculum, together with the insula;
- Temporo-limbic-insular networks, which primarily involve the mesial temporal structures and/or the temporal pole;
- Mesial and orbito frontal-insular networks, in the context of the so-called nocturnal frontal lobe epilepsy.

This subdivision remains partly artificial, however, since some patients combine electro-clinical features that belong to at least two of these networks, as detailed below.

Temporo-perisylvian-insular networks

The concept of 'perisylvian epilepsy' was originally introduced by Munari et al.,[50] in an attempt to distinguish this form of epilepsy from temporal lobe epilepsy proper. It should be noted, however, that in perisylvian the epileptogenic zone often encompasses the first temporal gyrus, accounting for the frequent presence of simple auditory hallucinations in this form of epilepsy, and explaining why the term 'temporo-perisylvian' is preferable to that of 'perisylvian'. Apart from simple auditory hallucinations, temporo-perisylvian seizures are characterized by the presence of symptoms reflecting the involvement of the frontal and parietal operculum (hemifacial motor or somato-sensory symptoms, gustatory hallucinations, hypersalivation), the secondary somato-sensory area (various types of ipsilateral, contralateral or bilateral somatosensory symptoms), and the temporo-perisylvian vestibular cortex (vertigo).[61]

Part of the semiology initially ascribed to frontal or parietal opercular ictal discharges in the early study of Munari et al.,[50] which did not benefit from the placement of depth electrodes within the insula, does in fact reflect the involvement of the insular cortex. One such example is that of gustatory hallucinations, previously thought to reflect a fronto-parietal opercular discharge,[52] but that can be elicited by stimulating the insula rather than the opercular region.[17] Furthermore, both the insular cortex and parietal opercular somato-sensory (SII) cortex can be responsible for similar ictal somato-sensory symptoms affecting large cutaneous territories, even though the somatotopic fields are much larger in the insula than in SII[65] Finally, the tight anatomical connections and cytoarchitectonic continuum observed between the fronto-parietal and temporal perisylvian cortex on one hand, and the insula on the other, also militates for including all these brain regions within the temporo-perisylvian network that must be explored by SEEG recordings before surgery. For instance, in two of the patients presented in section II (#4 and #5), one of whom presented with a parietal cortical dysplasia (#4), the SEEG involvement of part of the

opercular regions was judged important enough to lead to a surgical resection or a thermolesion of that structure together with the posterior insula, resulting in seizure control in both patients (class Ib of Engel).

In another recent series,[66] the role of the insula in a temporo-perisylvian epileptogenic network can be suspected in six patients in whom temporal lobe surgery was unsuccessful in controlling seizures despite intracranial EEG evidence that the temporal lobe participated in seizures genesis. In these patients a somato-sensory aura was interpreted as reflecting a discharge in the parietal lobe and the inferior parietal region was indeed also involved at ictal onset on intracranial EEG recordings, but its secondary removal did not result in better seizure control. The authors acknowledged that the insula might have participated to the complex epileptogenic network observed in their patients, inasmuch as one presented with an insular hyperperfusion on ictal SPECT. They could not confirm this hypothesis, however, due to the lack of intracerebral electrodes directly placed within the insula.

Temporo-limbic-insular networks

One major challenge in epilepsy surgery remains to understand the origin of postoperative seizure recurrence in a still significant proportion of operated patients, despite the presence of typical clinical and MRI features of mesial temporal lobe epilepsy. Part of these surgical failures might reflect the involvement of the insular cortex within a larger epileptogenic network encompassing the sclerotic mesial temporal structures.[67] This issue is well illustrated by patient #6 in Figure 39.1, whose history has been further detailed in a recent review.[68] Indeed, this patient fulfilled the major criteria used to define mTLE, including a rising and distressing epigastric sensation at seizure onset rapidly followed by oroalimentary automatisms, MRI signs of unilateral hippocampal sclerosis; ipsilateral temporo-limbic interictal FDG-PET hypometabolism, and an anterior temporal scalp-EEG ictal discharge. However, other ictal signs and symptoms suggested a rapid involvement of the perisylvian region, including early simple auditory hallucination and rapid occurrence of mastication and left face tonic contraction, leading to the decision of performing an invasive SEEG monitoring. The latter revealed that the patient suffered two seizure types, one arising from the sclerotic mesial temporal structures that secondarily propagated to the ipsilateral insula and opercular regions, and another arising from the posterior insula before invading the ipsilateral mesial temporal and opercular regions. Interestingly, the insular seizure type, but not that arising from the temporal lobe, selectively occurred during sleep. Resection of the epileptogenic temporal lobe controlled daytime seizures type for a few months only, whereas nocturnal seizures have continued unchanged. Overall, this case report illustrates the possibility of observing insular seizures in a patient with the major clinical and MRI features of mesial temporal lobe epilepsy, suggesting an epileptogenic zone encompassing the temporo-limbic regions and the insula. This patient also demonstrated an intense and rapid involvement of other temporo-perisylvian regions, suggesting that these different networks might be intermingled and overlapping in the same patient.

Other patients might present with comparable ictal semiology, EEG and neuroimaging data, and will eventually prove to have an epileptogenic zone limited to the temporo-limbic cortex. This alternative situation is illustrated by another patient from our series (#2 in Figure 39.1) whose intracerebral EEG recordings demonstrated a mesial temporal ictal discharge that invaded the insula very rapidly and intensively, suggesting that the insular cortex might be part of the epileptogenic zone.[69] However, long-term seizure freedom was achieved after an anterior temporal lobectomy. More generally, seizures originating in the mesial temporal lobe are likely to propagate to the ipsilateral insula, though less rapidly and intensively than in the above patient, and this propagation[70] does not preclude seizure freedom after temporal lobectomy.

Several issues remained unsolved regarding the connections involved in the propagation of ictal discharges between the temporo-limbic system and the insula. Due to the frequent participation of the temporal pole at ictal onset,[71] we prefer using the terminology 'temporo-limbic' rather than 'mesial temporal', knowing that part of this brain region is located outside the mesial aspect of the temporal lobe and is closely connected to the insula.

In fact, according to Mesulam's description of the paralimbic regions, two major belts should be considered, one including the orbito-frontal cortex, the temporal pole, and the insula, while the parahippocampal and cingulate gyrus form the other.[33] Indeed, as already discussed, the insula has strong reciprocal connections with the temporal pole, but also with the entorhinal cortex and the amygdala. In addition, it projects to the anterior hippocampus but does not receive major direct afferents from this structure. It is yet unclear which of the above regions is predominantly involved in the insular propagation of temporo-limbic ictal discharge. Conversely, the posterior and anterior-inferior aspects of the insular cortex are predominantly involved in seizures propagating to the mesial temporal structures.[68,69]

Mesial and orbital frontal-insular networks

A recent issue concerns the role of the insula as a part of the epileptogenic network in fontal lobe epilepsies and, more precisely, in NFLE, which is is primarily characterized by seizures occurring exclusively or predominantly during sleep, the semiology of which suggests a frontal lobe origin, as for example nocturnal paroxysmal dystonia (NPD) or hypermotor seizures.[72] An autosomal dominant inheritance (ADNFLE) is found in 8–43% of patients, and several mutated genes have been identified.[72–76] However, many uncertainties persist regarding the neural networks underlying the cryptogenic and idiopathic forms of NFLE, inasmuch as very few patients have been investigated with intracranial EEG recordings.[77,78]

We have recently reported three patients with a typical form of nocturnal hypermotor seizures suggesting cryptogenic NFLE in two, and autosomal dominant NFLE (ADNFLE) in another, whose ictal onset zone proved located in the antero-superior portion of the insula.[79] In the two patients presenting with a seemingly cryptogenic NFLE, intracerebral EEG recordings demonstrated a very focal interictal focus in that same region, consisting of frequent bursts of high frequency discharges and high amplitude spikes (Figure 39.4). In the ADNFLE patient, the epileptogenic zone appeared larger, extending to the frontal operculum.

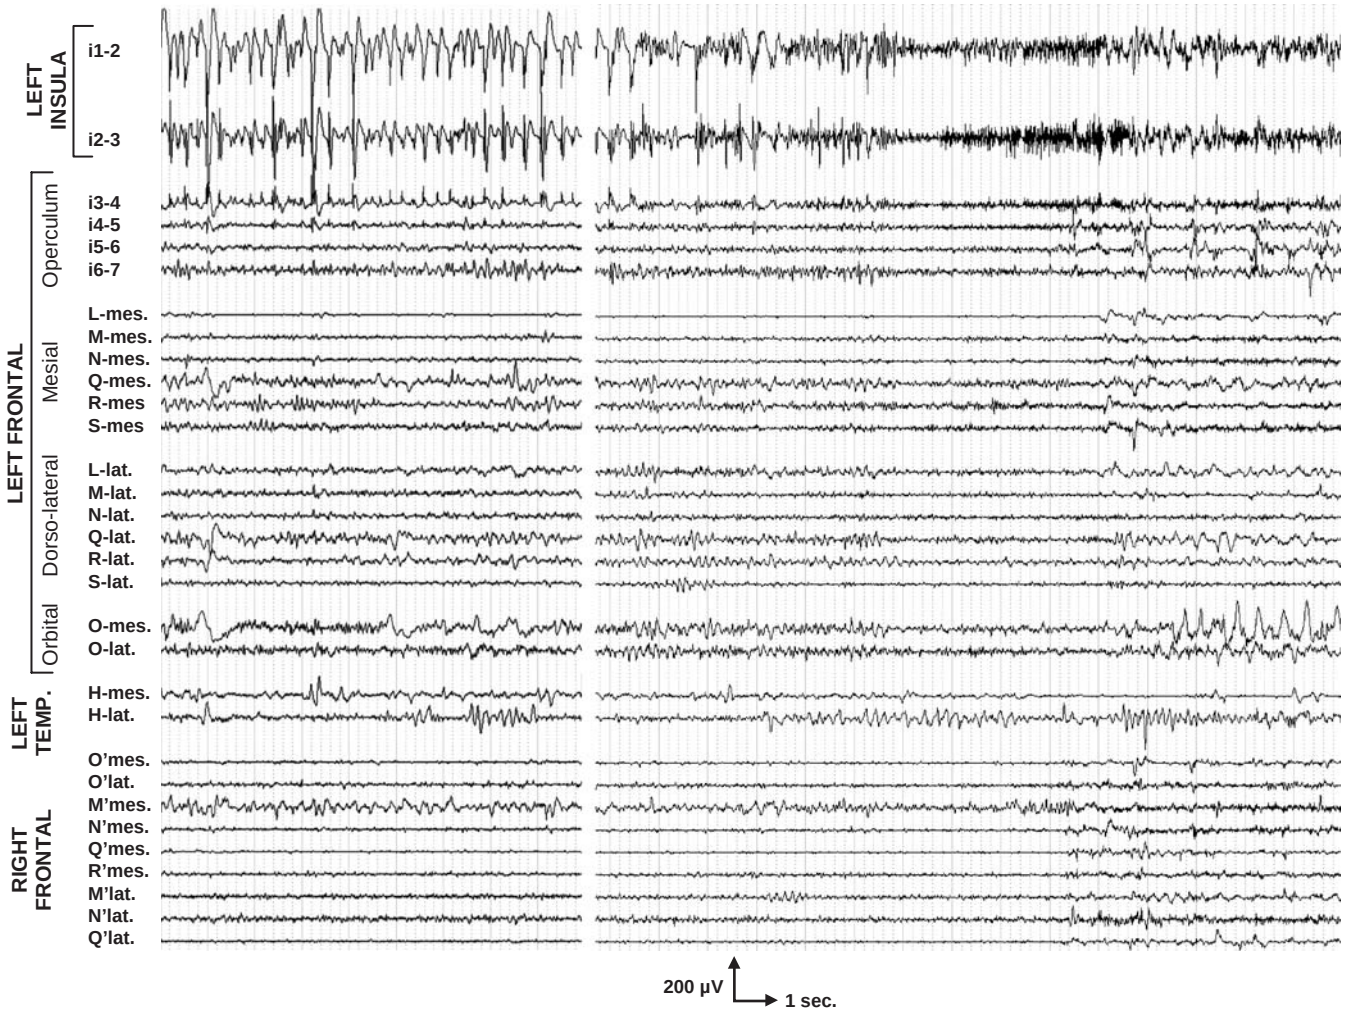

Figure 39.4 Intra-cerebral EEG investigation of a patient with a clinically-defined cryptogenic nocturnal frontal lobe epilepsy showing almost permanent high amplitude spikes (left EEG traces), and a high frequency discharge at ictal onset (right EEG traces) in the antero-superior portion of the left insula (i1,i2), slightly diffusing to the nearby deepest aspect of the frontal operculum (i3–4), but not to more lateral probes. Note that all leads are displayed with a similar amplification.

High frequency electrical stimulation of the antero-superior portion of the insula, but of no other region, could elicit a typical aura or full-blown seizure in two patients. However, because none of the three patients underwent epilepsy surgery, we cannot firmly conclude on the precise extent of their epileptogenic zone. Interestingly, these three patients represent 30% of all those with nocturnal hypermotor seizures and no MRI brain lesion who underwent an intracerebral EEG investigation in our study. Among the seven other patients, a mesial or anterior frontal seizure onset was demonstrated and resected, but three continued to suffer postoperative seizures. One might speculate on the role of the insula in these patients seizures, provided that it was not investigated during their intracerebral EEG recordings.

Overall, an insular seizure onset zone might be responsible for a significant proportion of so-called cryptogenic NFLE, at least among those resistant to antiepileptic drugs. At the present time, no clear indicator other than intracerebral EEG recordings allows to distinguish these patients from those presenting NFLE proper. In fact, our patients with an antero-superior insular ictal onset started their hyperkinetic behavior only when the mesial frontal cortex was invaded.

The propensity for insular seizure to occur during sleep has not been previously reported. However, it is interesting to note that this propensity was also observed in one of our patient with temporo-insular epilepsy (see previous section). The role of the insula in sleep physiology is not known, but recent functional neuroimaging studies have shown a marked deactivation of the anterior insula during sleep.[80, 81]

Overall, insular seizures might be associated with various types of ictal semiology, reflecting the subregion of the insular cortex primarily affected, as well as the related multilobar network: the posterior and antero-inferior aspect of the insula appears to be mostly involved in temporo-perisylvian and/or insulo-temporo-limbic epileptogenic networks mimicking the different forms of TLE; the antero-superior portion of the insula seems to play a more important role in the insulo-frontal networks mimicking NFLE. At the present time, there is no available data suggesting a primary role of the insular cortex in seizures originating from other brain areas than those listed above.

Etiology of insular epilepsy

Lesional insular epilepsy

The majority of cases reported in the literature as insular seizures or epilepsies derives from patients with an obvious

epileptogenic brain lesion located in the insula, some of which were subsequently and successfully operated upon. [41,42,54,69,82,–85] These lesions primarily included low grade brain tumors, including gliomas and dysembryoplastic neuroepithelial tumors, cavernomas, and cortical dysplasia. However, all potentially epileptogenic brain lesions might be observed in the insula, such as stroke or encephalitis.[86,87]

Cryptogenic and idiopathic epilepsy primarily involving the insula

To our knowledge, the only published cases of cryptogenic epilepsy primarily involving the insula are those published by our group.[68,69] They represent a very limited number of patients, none of whom underwent a surgical resection of their epileptogenic but MRI negative insula. No pathological data is thus available, but SEEG findings suggested the possibility of a MRI occult cortical dysplasia in a minority of patients. For instance, one of our patients with NFLE of insular origin presented an intracerebral SEEG pattern typical of an underlying cortical dysplasia, with very focal and permanent high amplitude spikes intermingled with bursts of high frequency discharges (Figure 39.4).[79] In the same series, one who presented with a typical form of ADNFLE, but none of the known mutation of the α 4 and β 2 subunits of the nicotinic acetyl-choline receptor, should be considered to suffer an idiopathic form of partial insulo-opercular epilepsy, according to the familial inheritance of his epileptic disorder and the result of his SEEG investigation.[79,88] To our knowledge, no other patient with ADNFLE has undergone an intracerebral EEG investigation, and we therefore ignore the proportion of such patients who might also demonstrate an insular epileptogenic zone.

Presurgical evaluation

Noninvasive investigations

EEG and MEG

According to the deep location and specific gyral organisation of the insula, interictal or ictal epileptiform discharges originating in this lobe are unlikely to be detected by scalp-EEG recording, unless these discharges propagate to lateral neocortical regions. This has been shown in our first description of insular discharges[70] and is also illustrated by Figure 39.4. Accordingly, neither interictal nor ictal scalp-EEG abnormality could be recorded in this patient, accounting for the fact that the epileptic origin of his seizure disorder has been strongly debated.

However, scalp-EEG recordings might provide some clue regarding a temporo-perisylvian epileptogenic zone, indirectly reflecting the potential involvement of the insular cortex. In particular, both interictal and ictal EEG abnormalities will display a more widespread distribution over the infra- and supra-sylvian elecrodes.

To our knowledge, a single case report has assessed the diagnostic value of MEG in a patient with an insular epileptogenic DNET, and concluded that MEG could detect epileptiform abnormalities within the concealed insular cortex.[82]

Functional interictal neuroimaging

In patients with typical TLE, [^{18}F]FDG-PET and [^{11}C] Flumazenil-PET studies have reported that interictal hypometabolism and decreased benzodiazepine receptor density observed in the temporal lobe could extend to the insula in some patients.[89–92] At the present time, the presence of such insular abnormalities have not been clearly associated with a higher risk of postoperative seizure relapse, but this issue still needs to be addressed in larger populations.

In the few well-documented cases of insular epilepsy, [^{18}F]FDG-PET, [^{11}C]Flumazenil-PET, and ictal SPECT did not demonstrate distinctive features from those encountered in TLE or NFLE, and in particular no clear cut insular abnormality.[67,68]

Finally, [^{18}F]FDG-PET and ictal SPECT have shown abnormal findings in the insula of a few patients with uncertain epileptogenic zone, where one might speculate on the involvement of the insula.[66,93,94] These include patients with nocturnal hypermotor seizures,[93,94] as well as one patient with somato-sensory aura and a seemingly temporo-parietal ictal onset zone not controlled by surgery sparing the insula.[66]

Overall, whether functional imaging will eventually prove useful in the clinical assessment of insular epilepsy remains an open issue.

Invasive investigations

In the stereotactic implantation technique first described by Talairach and Bancaud,[95] intracerebral electrodes are implanted perpendicular to the midsagittal plane using Talairach's stereotactic grid and can be left in place chronically up to 15 days.[96] The position of each contact can be plotted on the corresponding slice of the atlas of Talairach and Tournoux[97] and by fusing the frontal skull radiography with the coronal MRI slice, both at scale 1/1, corresponding to the electrode trajectory (Figure 39.3a). Oblique electrode trajectories can be also useful to explore the insula.[79]

Interictal insular recordings

The few available data from literature on interictal insular paroxysmal activities in surface or depth recordings were reported in the fifties.[36,98,99] These early studies showed that spikes or spike-waves are recorded in the insula of nearly 50% of TLE patients. In SEEG recordings they are present in all patients with insular seizures. They are sporadic or intermittent in TLE and most often frequent in patients with insular seizures, particularly in those with focal dysplasia.[91] Since the early study of Silfvenius et al.[39] it has been acknowledged that their presence is not predictive of a poor outcome of temporal lobectomy in TLE, so that they do not indicate an insular epileptogenic zone. Spikes in the amygdala, hippocampus or temporal pole usually co-exist, and are most often asynchronous, with insular paroxysms. Contacts located in supra- or infrasylvian opercular cortex or adjacent amygdalo-hippocampal structures are often blind to insular paroxysms, which are thus unlikely to be recordable by subdural electrodes grids placed over the sylvian fissure or on the mesial surface of the temporal lobe (Figure 39.5).

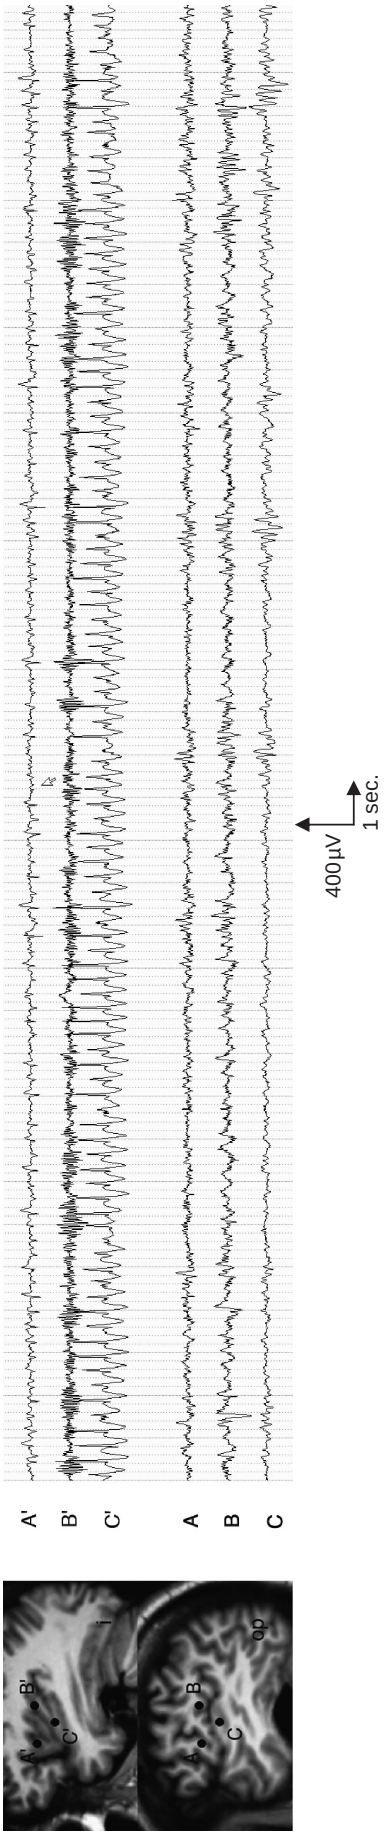

Figure 39.5 SEEG recordings in patient 8 using three transopercular electrodes exploring the right insular lobe (cf Figure 39.3a). An abundant paroxysmal interictal activity made of subontinuous spikes and spike-waves is picked up by the insular contacts (A', C'), to which which more superficial opercular contacts are blind. (i) MRI sagittal slice in the insular plane. (op) MRI sagittal slice in the opercular plane. A, B and C: postions of the insular contacts; A', B' and C': positions of the opercular contacts.

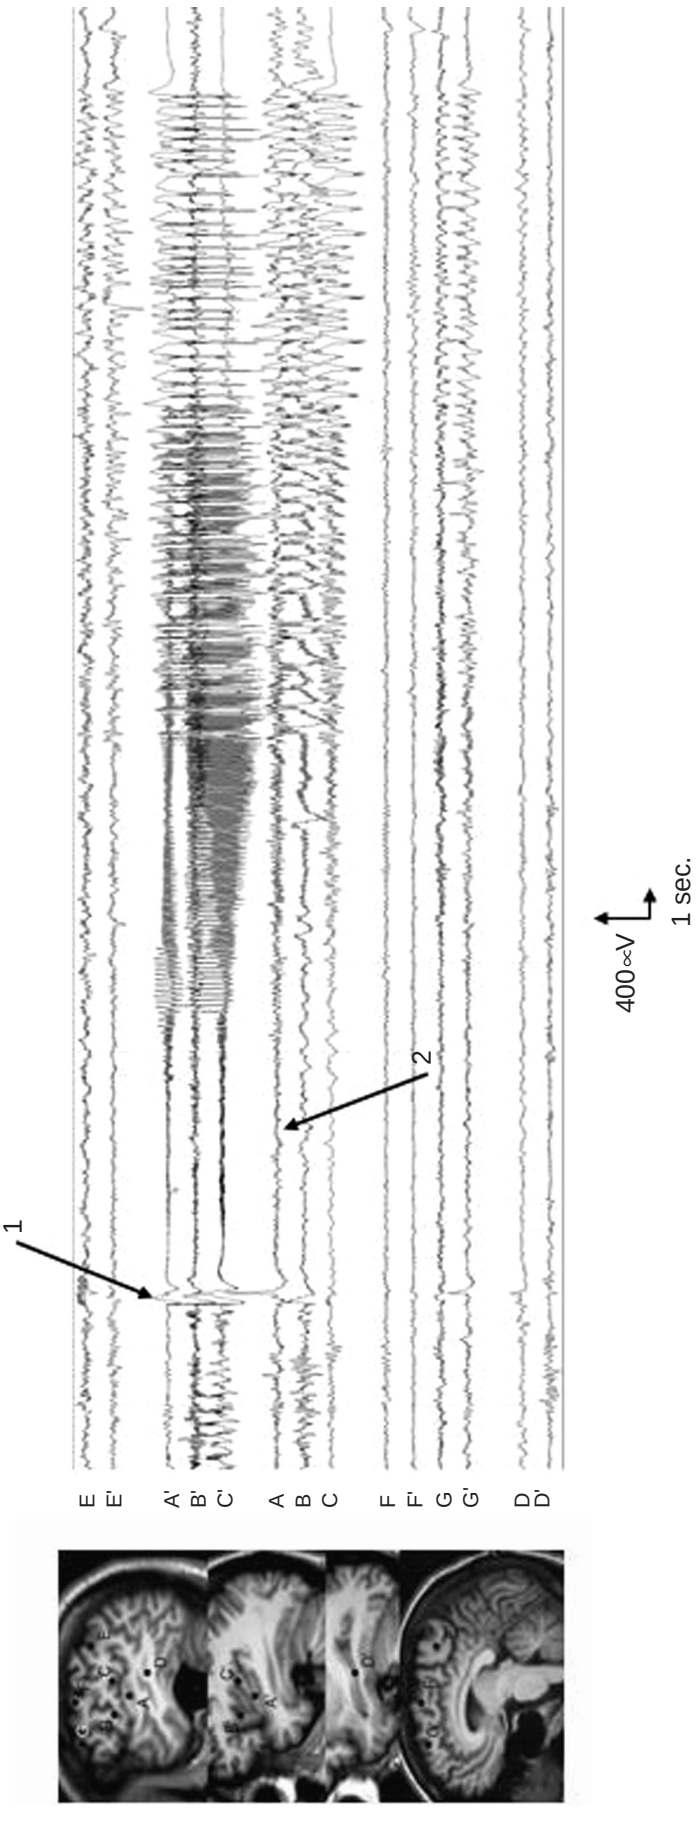

Figure 39.6 SEEG recording of an ictal discharge in patient 8 beginning in the insular cortex (Arrow 1) by a large spike-wave complex followed by a low voltage fast activity and a recruiting discharge of high frequency spikes and spike-wave affecting preferentially the posterior insula. This ictal spiking activity reaches the opercular cortex 8 seconds after the insular onset time (Arrow 2). This discharge spreads later on to the frontal (G, G') and parietal (E, E') lobe, sparing the temporal lobe (D, D').

Ictal insular SEEG recordings

In terms of onset site, propagation and morphology, the insular discharge patterns are very similar from one seizure to the other in a given patient, suggesting an individual organization of the insular epileptogenic neuronal network. They are made of a low voltage fast activity (LvFA) that may begin abruptly, or be preceded by changes in interictal activity. These preictal changes manifest by an increase in the frequency of spikes that become more regular or rhythmic and/or by the appearance of spikes and poly-spike-waves. Ictal LvFA can remain confined in the insula during several tens of seconds, or spread outside the insula in a few hundreds of milliseconds. During their intrainsular development LvFAs are not detectable by SEEG contacts located in neighbouring structures, in particular in the temporo-parieto-frontal opercular cortex, the activity of which is either unchanged or shows only rhythmic slow waves without sharp paroxysms during insular LvFA discharges (Figure 39.6).

We have never observed an insular LvFA not spreading, either step by step to perisylvian cortical areas, or more abruptly at distance to ipsilateral amygdala, hippocampus or posterior mesial frontal cortex. Lastly, in two patients with a bilateral SEEG exploration we could observe that an insular LvFA can propagate to the contralateral insula. This anecdotal observation does not allow any conclusion as to the frequency of insular seizures bilateralization, but suggests that the insula is not only a possible relay for intrahemispheric propagation of focal seizures (see section III), but also a route for their interhemispheric transfer.

Treatment

Based on electrocorticography, insular resections were attempted as early as the late forties to improve the surgical outcome of temporal lobectomy.[36,39,98,99] This procedure has been abandoned because it proved to have a much greater morbidity than the usual temporal lobectomy alone without improving significantly the seizure control. Progress in surgical techniques now allows, with an acceptable risk level, the removal of focal epileptogenic lesions located in the insula, such as tumors[42] and cavernous angiomas.[100,101] The outcome in terms of seizures control is usually good,[102] so that a lesionnectomy can be proposed, without presurgical invasive EEG recordings, whenever an insular lesion manifests clinically by seizures with insular ictal symptomatology, as in the case illustrated in Figure 39.2.

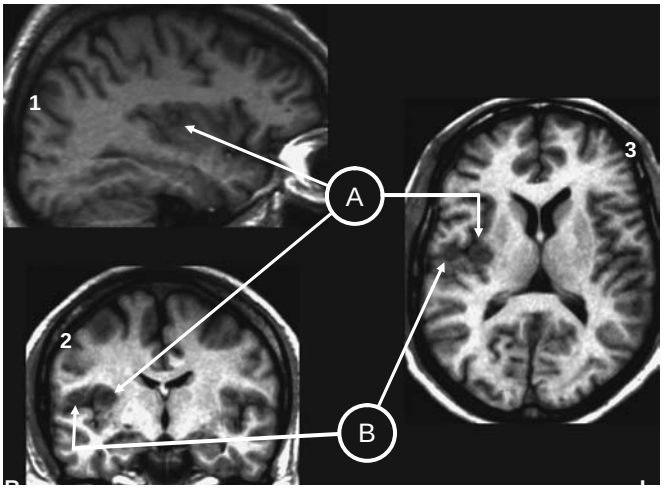

Figure 39.7 Sagittal (1), coronal (2) and axial (3) control brain MR images after insular radio frequency thermo lesions using the SEEG electrodes contacts implanted in the epileptogenic areas of patient 5. This procedure was performed immediately before SEEG electrodes removal and thus did not entail the risk of additional electrodes implantation. These RM images acquired 15 days after this procedure show the thermo-lesions located at the insular onset site of seizures (A), and in the parietal opercular cortex (B), which was the first propagation relay of insular discharges.

Partial or subtotal resection of the insular cortex is also feasible in a patient without a space-occupying lesion (case 4 in Figure 39.1). However, this remains an aggressive procedure that necessitates the removal of part of the opercular parieto-frontal or temporal cortex, and entails a lesional risk in the deep territory of the middle cerebral artery. In the absence of a lesion no tailored insular cortectomy can be undertaken without presurgical SEEG exploration of the entire cortical network suspected as epileptogenic (see the third main section), with recordings of several spontaneous seizures and insular stimulations.

An alternative to cortectomy is represented by SEEG guided radio-frequency (RF) thermocoagulation.[71] RF thermocoagulation is performed using adjacent contacts of SEEG electrodes in sites where discharges have been recorded. It produces focal lesions of 5–7 mm diameter with minimal risk (Figure 39.7). Two of the eight patients reported in this chapter (see the second main section) have benefited from RF thermocoagulation (# 5 and 8), with a follow up of 36 and 17 months, respectively. Both are free of disabling seizures (class Ib of Engel).

40 Cingulate epilepsy

E Garzon and HO Lüders

Introduction

Between the 1940s and 1950s, studies on experimental animals and observations on human beings with destructive lesions led to the discovery of a possible relationship between the anterior portion of the cingulate gyrus (CG) and behavioral disorders. Those studies also led to the use of surgical ablation of the anterior portion of the CG or of cingulum disconnection for the treatment of severe behavioral illnesses. Many advances have been made in the last 20 years and, even if a clear understanding of all its connections and functions is still far in the future, the CG has been shown to be, indeed, a heterogeneous structure.

Because of peculiarities of its vascular irrigation (the pericallosal artery and its branches irrigate the medial portion of the frontal lobe and part of the medial portion of the parietal lobe), ischemic or hemorrhagic lesions circumscribed to the CG are rare. Small tumors or malformative lesions relatively restricted to the CG are also uncommon. These facts limit our ability to study CG function based on lesional observations.

Noninvasive neurophysiological studies provide only partial or inconclusive data because of the anatomical location of the CG (medial and distant from the cerebral surface, with significant portion of the CG buried in the depths of the pericallosal and cingulate sulci). This makes it difficult to define the ictal clinical manifestations of the CG as a symptomatogenic zone.

The objective of the present chapter is to describe the clinical characteristics of epileptic seizures most probably originating in the CG. As an introduction a brief review of the cytoarchitecture, connections and functions of the CG of humans and experimental animals will be presented.

Cytoarchiteture

Brodmann's cytoarchitectural map of the cerebral cortex has been used as the standard for human brain research. The CG is divided into anterior and posterior parts (Figure 40.1). The anterior part consists of the perigenual portion, areas 25 and 33, and of the midcingulate portion, areas 24 and 32. The posterior cingulate consists of the posterior cingulate cortex, areas 23 and 31, of the retrosplenial portion, areas 29 and 30, and the ectosplenial portion, area 26. Areas 29, 30, and 26 are narrow and located in the isthmus of the CG.[1]

More recent cytoarchitecture studies have confirmed that an important part of the CG cortex is buried in the depth of the sulci (Figure 40.1). The anterior cingulate cortex (ACC) is agranular, with a prominent Va layer. Not all the cortex of area 24 is exposed on the surface[2] and histological differences exist between the caudal and rostral parts of area 24, which is, therefore, subdivided into 24a, 24b, 24c, and 24d.[3] The main difference resides in the composition and thickness of layers Va and Vb.[3] Area 24c lies primarily within the ventral bank of the cingulate sulcus.[2] This area is called the cingulate motor cortex, since pyramidal Betz cells have been demonstrated in layer Va.[4] Compared with the Betz cells of the primary motor field, those of the cingulate area display numerous primitive traits.[5]

In non-human primates, in addition to cytoarchitectural differences there are differences in inputs. While the rostral portion of area 24 receives substantial input from the amygdala, the caudal portion receives a large component of parietal lobe afferents.[6]

The posterior CG consists of the posterior cingulate cortex (PCC), areas 23 and 31, and the retrosplenial and ectosplenial areas 29, 30, and 26. Areas 29, 30, and 26 are buried in the depths of the pericallosal sulcus. Area 23 is located in the caudal portion of the CG and extends into the caudal part of the cingulate sulcus before it arches to form the marginal sulcus. The PCC is characterized by granular layers II and IV,[2] except for area 30 whose layer IV is dysgranular.[7]

Area 23 is subdivided into 23a, 23b, 23c, and 23d as a function of the degree of differentiation of layer III and of the size and distribution of neurons of layers IV and Va.[3]

Connections

The cingulate cortex is considered to be part of the limbic system and is also a component of the Papez circuit. Outputs from the amygdala, septal area, entorhinal cortex, and hippocampus travel via the fornix to the mammillary bodies of the hypothalamus; from there via the mammillothalamic tract, to the anterior thalamic nucleus (anteroventral subdivision); and via the thalamocortical fiber system to the CG, and then back to the hippocampus via the cingulum and entorhinal areas. This closed circuit of connections was described by Papez[8] and became known as the Papez circuit.

Studies in rhesus monkeys using retrograde tracer horseradish peroxidase have shown that both the ACC and the PCC receive thalamic inputs. Although each area of the CG receives inputs from distinct thalamic nuclei, the anterior thalamic nucleus (anteromedial subdivision) sends afferent fibers to areas 25, 24, and 23, thus forming a certain connectional link between all cingulate areas.[9]

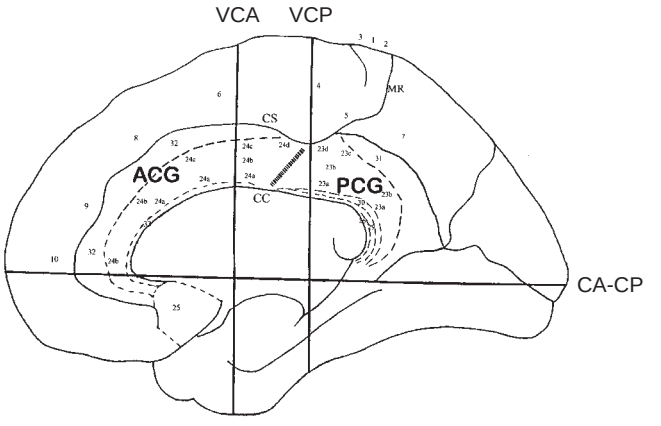

Figure 40.1 Cingulate gyrus cytoarchitectural areas. Areas 24, 25, 23, and 31 are located on the mesial surface. Small portions of areas 24 and 23 are buried in the depth of the cingulate sulci. Areas 32, 33, 26, 29, and 30 are buried in the depth of the cingulate and pericallosal sulcus (ACG = anterior cingulate gyrus; PCG = posterior cingulate gyrus; CC = corpus callosum; CS = cingulate sulcus, MR = marginal ramus)

The ACC and PCC also receive a large contingent of afferents from the frontal lobe, especially the dorsolateral and orbital areas, and also from the parietal lobe. Most of the frontal cortical afferents reach area 24, whereas area 23 preferentially receives inputs from the parietal lobe.[6] The ACC also receives afferents from the insula cortex and the PCC receives a small proportion of afferents from the occipital lobe, area 19.[6]

The CG also has extensive efferents connections. Studies on rhesus monkeys have shown that areas 23 and 24 have extensive and widespread projections to several regions of the cerebral cortex (Figure 40.2). Area 24 projects to the premotor region (areas 6 and 8), the orbito-frontal cortex (area 12), the rostral part of the inferior parietal lobe, the anterior insular cortex, the perirhinal cortex, and the laterobasal nucleus of the amygdala. Area 23, likewise, sends its connections to the dorsal prefrontal cortex (areas 9 and 10), the rostral orbital cortex (area 11), the parietotemporal cortex (posterior part of the inferior parietal lobule and the superior temporal sulcus), the parahippocampal gyrus, the retrosplenial region, and the presubiculum.[10]

The anterior cingulate cortex also sends projections to brainstem motor systems including the caudate, pontine, and red nuclei.[11,12]

Functions

Structural lesions, surgical ablations, or functional alterations due to electrical stimulation of the CG in animals and humans shed some light on the function of the CG. These studies have been complemented by microelectrode recordings, and positron emission tomography in experimental animals and human beings.

Changes in behavior can occur due to lesions in area 24, although in many of these reports on humans and experimental animals additional damage was also evident in the adjacent areas 6, 8, 9, 10, and 25 and in the corpus callosum.

In monkeys, ablation of area 24 was marked by increased restlessness, hyperactivity, loss of their previous apprehension to certain aspects of their environment, apparent loss of fear, increased

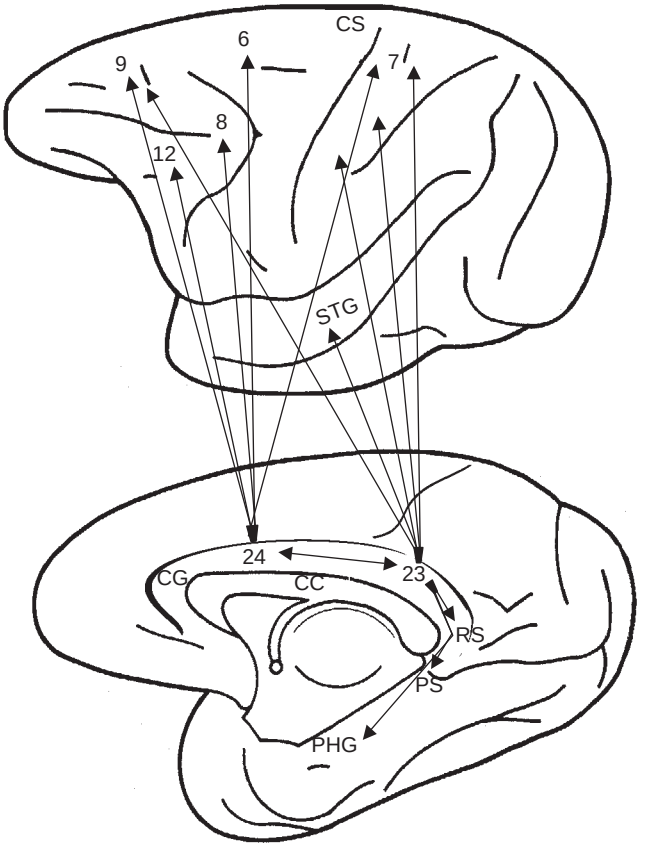

Figure 40.2 Cingulate gyrus simplified sketch showing efferent connections from areas 23 and 24 in the monkey's brain (CC = corpus callosum; CG = cingulate gyrus; PHG = parahippocampal gyrus; PS = presubiculum; RS = retrosplenial area; STG = superior temporal gyrus).

tameness, and reduction of aggression.[13] In animals with a longer survival time these changes tend to be reduced or to disappear.

Behavioral changes such as indifference, docility, inappropriate urination, severe lack of attention, lack of social restraint, heightened sexuality, bulimia, and aggressiveness have also been reported to occur in humans as a consequence of unilateral[14] or bilateral[15] lesions in the anterior portion of the CG.

Bilateral lesions of area 24 also cause the so-called anterior cingulate gyri syndrome which clinically manifests as apathy, akinesia, mutism, urinary incontinence, and indifference to pain.[16]

Structural lesions and studies of cortical stimulation have also correlated the anterior cingulate with autonomic phenomena such as piloerection,[13] changes in blood pressure, tachycardia, mydriasis, and increased respiration frequency.[17,18,19] The structural basis for involvement of area 25 in visceromotor activity is well known. Area 25 projects directly to the parasympathetic nucleus of the solitary tract,[20] dorsal motor nucleus of the vagus, and to the sympathetic thoracic intermediolateral cell column.[21]

The anterior cingulate is also involved in the emotional aspects of pain perception.[22,23]

The ability of the anterior cingulate to participate in or execute motor functions has been studied extensively. The presence of Betz cells in area 24 supports the hypothesis of the possible existence of a motor area in the CG. In experimental animals the lower bank of the anterior cingulate sulcus is involved in self-initiated movements.[24] There is also evidence

that areas 24c and 23c send inputs to the motor and supplementary motor cortices in a somatotopic distribution.[25]

Additionally, there are reports that cortical stimulation of the ACC evokes motor responses in man.[26–29] The nature of the responses obtained differ among the various studies, but include repetitive movements of the hands, fingers, and lips that can be classified as automatisms, tonic contractions involving the hands and arms, or an irresistible urge to grasp something.

The posterior CG probably integrates visual information recognized in the visual cortex and an emotion-related substrate is processed in the anterior cingulate.[30]

Electrical activity of PCC is detected during eye movements in several species while assessing large visual field patterns. The activity is linked to the position of the eye in the orbit and the direction and amplitude of saccadic eye movements.[31–33] Several observations have suggested that the PCC contributes to orientation of the animal in the environment and to spatial memory. Lesions of the posterior cingulate disrupt a rat's ability to swim to a hidden platform.[34] The observation of the deficits due to lesion of the retrosplenial region of rats has led to the assumption that the damage may disrupt the integration and transmission of both movement-related information and visuospatial information from cortex to hippocampal formation. The hypothesis is that the retrosplenial region is important not for memory of landmarks or other visuospatial cues, but rather the functional role of this region may be to purposefully organize the movements with respect to surrounding visual landmarks.[35]

Cingulate seizures

Overview

The semiologic characterization of epileptic seizures originating in the CG cortex is a challenge in epileptology. As mentioned before, the anatomical location of the CG makes neurophysiological studies with scalp electrodes difficult. Similar problems are encountered with invasive neurophysiological recordings. The presence of large caliber blood vessels on the medial surface of the brain and the fact that a considerable proportion of the cortex is located inside sulci make invasive evaluation of this area difficult.

Ideal cases for the study of ictal clinical manifestations would be small medial epileptogenic lesions practically limited to the CG. These cases are relatively rare and literature data are limited to case reports or relatively small series. Thus, the semiologic aspects of the epileptic seizures of this region are still poorly defined. Most cases in the literature do not provide direct evidence that the epileptogenic zone was in the CG or actually limited to the CG. The gold standard would be cases in which a resection of an epileptogenic zone limited to the CG renders the patient free. Such cases do not exist in the current literature. Therefore, the following review of the literature refers to cases in which the lesion was mainly in the CG, even if there was no direct proof that the seizures originated from the CG, i.e., patients were not necessarily seizure free after surgery and/or the surgery was not limited to the cingulated gyrus.

Although auras are considered rare,[36] autonomic symptoms such as tachycardia, mydriasis, and changes in respiratory frequency are considerate common.[37] Other descriptions are sensation of fear, dizziness,[37] and painful sensations.[38]

In general, reports in the literature tend to stress that seizures originating from the cingualte gyrus are frequent, brief, nocturnal and do not include significant preictal or postictal alterations.[36]

The ictal semiology that has been related to the anterior cingulate is relatively varied. Some ictal manifestations like complex automatisms, laughter, and altered level of attention or consciousness have been described more frequently.

Table 40.1 summarizes literature cases with seizures originating in the anterior portion of the cingulate, as confirmed by scalp video-EEG evaluation and/or invasive recording in lesional and non-lesional cases. Complex gestural movements,[36–40] laughter,[36,38,39,41] tonic contraction,[36] lapses of attention, blinking, and oroalimentary automatism[40] were the most common clinical manifestations.

For comparative purposes, on the basis of described data, we reclassified the seizures according to the semiological seizure classification (Table 40.1).[42] The most frequent types of epileptic seizures reported as originating from the anterior portion of the CG were bilateral asymmetric tonic seizures, gelastic seizures, hypermotor seizures, and complex motor seizures. In two cases the seizures were preceded by a somatosensory and autonomic aura respectively. In one case an autonomic seizure was documented (mydriasis).

Dialeptic seizures were reported in only one report. This patient by history had atonic and complex motor seizures, but dialeptic seizures were documented during evaluation by video-EEG.[40]

Stimulation with depth electrodes have shown that continuous movements may be elicited by electrical stimulation of the anterior region of the CG. These movements were classified as automatisms and primarily involved the fingers, hands, lips, and tongue. The movements were 'primitive' and simple such as touching, leaning, rubbing, stretching, or sucking. The movements were frequently integrated with more complex movements that were adapted to the situation and thus represent, as a whole, what the authors called 'types of behavior'.[19,26]

Cleveland clinic series

In an attempt to better define the semiology of seizures originating from the CG, we reviewed the Cleveland Clinic Epilepsy database. To analyze the semiology and the electroencephalographic findings of seizures originating from the CG, patients of any age range evaluated by video-EEG and with symptomatic focal epilepsy secondary to a single structural lesion identifiable by magnetic resonance and localized in the CG, anterior, or posterior region were selected. No attempt was made here to define if the observed ictal semiology was due to direct activation of the CG (symptomatogenic zone in the CG) or due to spread an activation of extra-CG symptomatogenic areas such as, for example, the adjacent supplementary sensory-motor area.

Only cases in which at least 90% of the lesion was located in the CG were included. Patients with extensive lesions with a small proportion in the CG or with extensive lesions widely involving the CG and adjacent regions as also non-lesional cases were excluded.

Of patients evaluated between 1990 and 2005 who had received a diagnosis or a diagnosis of probable cingulate epilepsy, 76 were selected. The clinical data and the

			Seizure 2. Sagged and lay down, bilateral clonic jerks with secondary deviation of the head toward the right 3. (invasive evaluation): Pupils dilated and eyes deviated to the left and upwards. Uncoordiante violent and agitated movements of te lower half of the body and trunk accompanied sign of language and gestures of intense fright. Several unsystematized and belated buccal movements.						
Levin & Duchowny, 1991[40]	Case report	Female 2.5 yrs	1.Brief atonic seizures, gradually diminished over several months and then started with 2.lapses of attention with stereotyped automatisms including humming, lip smacking, bruxism, and hair fixing 3.Behavioral arrest, associated with eye blinking and oroalimentary automatism	up to 40 sec 10–15/day 2. 10–20 sec	1.Atonic seizure 2. Complex motor seizure 3. Dialeptic seizure	Generalized, maximum right frontal	–	Depth electrode Discharges at right ACG	Resection of right ACG. Seizure free follow-up 15 mo.

ACG = anterior cingulate gyrus, AVM = arteriovenous malformation, CA = cavernous angioma, CG = cingulate gyrus, MCD =malformation of cortical development, MCG = midcingulate gyrus, SSMA = somatosensory supplementary motor area

neuroimaging exams were reviewed. Only eight of 76 patients satisfied the inclusion criteria listed above.

To correlate the semiologic data with the location of the lesion, sagittal sections of MRI were selected and the best section for the visualization of the anterior and posterior commissures and of the structural lesion was chosen for each individual. The horizontal plane, anterior commissure-posterior commissure line (AC-PC) and the vertical anterior commissure line (VAC) and the vertical posterior commissure line (VPC) of the vertical plane of the Talairach and Tournoux[43] coordinates were traced.

The CG was thus divided into three portions: anterior, middle, and posterior. The anterior portion is located rostral to the VAC line, the middle portion is caudal in relation to the VAC line and rostral in relation to the VPC line, and finally the posterior portion is caudal in relation to the VPC line.

The lesion was then carefully identified on the three magnetic resonance planes – sagittal, coronal and axial – and their rostrocaudal and ventrodorsal extension was represented on a map on the sagittal plane.

Considering the cytoarchitectural data, area 24 occupies a large part of the anterior and middle portion (Figure 40.1), so the anterior and middle portions of the CG were considered to be anterior cingulate.

According to the location of the structural lesion, the cases were divided into anterior CG lesion group (ACGL-group) when the lesions were located in the anterior cingulate (the entire extension rostral to the VPC line) and posterior CG lesion group (PCGL-group) when the lesions were located in the posterior cingulate (caudal portion in relation to the VPC line).

Clinical data such as age at the onset of seizures, semiologic description provided by the patients and their relatives and complaints of behavioral changes, seizures recorded during video-EEG monitoring, and interictal and ictal recordings were reviewed. Wieser *et al.*'s classification of outcome following epilepsy surgery was used for the classification of surgical outcome.[44]

Demographic data

Of the eight patients, six were males and two were females. Age ranged from 8–52 years, with a mean of 23.7 years. Five of the eight patients were 14 years old or younger. Age at the onset of seizures ranged from 7–44 years, with a mean of 18.2 years. Three patients had a recent history of onset of seizures (<1 year) and the interval between the onset of seizures and evaluation ranged from 0–22 years, with a mean of 4.7 years (Table 40.2).

All patients had a normal neurological examination and seven had normal intelligence; only one was in the mentally deficient range.

Four patients (1, 2, 3, and 4) had anterior CG lesions (ACGL-group), and four (5, 6, 7, and 8) had posterior CG lesions (PCGL-group) (Figure 40.3).

The results of the anatomopathological analysis of the seven patients who had surgery were low grade astrocytoma in five cases, reactive astrocytosis in one case, and ganglioglioma in one case.

Four of the eight patients reported mood changes, depression, and reduced school performance. Of these four, only one belonged to the ACGL-group, while the remaining ones belonged to the PCGL-group. The data obtained by psychiatric evaluation or using the back depression inventory are presented in Table 40.2. The patient from the ACGL-group had adjustment disorder with depressed mood. Only one of the three patients from the PCGL-group had a more severe psychiatric disorder (major depressive episodes and reduced school performance). The remaining two patients of the PCGL-group had affective distress and emotional distress with mild to moderate feeling of depression, respectively.

Seizure characteristics

The ictal semiology data obtained from the clinical history were provided by patients and relatives and are listed in Table 40.2.

All patients presented frequent – daily or weekly – seizures. Only patient 1 (ACGL-group) had a lower frequency of seizures – one to four seizures per month.

By history, the seizures' duration varied from seconds to minutes in both groups. The most prolonged seizures reported lasted about 2–3 minutes, namely patients 1 and 2 from the ACGL-group and patients 5 and 8 from the PCGL-group. Shorter seizures lasting 10–20 seconds occurred in patient 3 from the ACGL-group and patient 6 from the PCGL-group

Auras

Five patients reported auras, two in the ACGL-group and three in the PCGL-group. The two patients in the ACGL-group presented clinical manifestation lateralized contralateral to the structural lesion. One patient described pins and needles in the contralateral arm and the other complained of a heavy contralateral leg. The latter also reported a nonspecific complaint described as dizziness.

The three patients in the PCGL-group who reported auras described them as tingling in both legs, and dizziness (patient 5), depersonalization feelings (patient 7) and abdominal sensations (patient 8).

Semiologic analysis of the seizures by video-EEG examination

Semiological seizure classification

When auras were excluded and the initial presentation of the epileptic seizures was evaluated as documented in the video-EEG, the following types of seizures were observed: ACGL-group: complex motor seizures, hypermotor seizures and bilateral asymmetric tonic seizures; PCGL-group: automotor seizures and dialeptic seizuress (Table 40.3).

Analysis of the seizure evolution (Table 40.3) shows that all the patients, except for patient 6, showed a changing seizure manifestation. Regarding the motor manifestations, we shall first consider the initial pattern of the seizure and then the seizure evolution.

Motor manifestations

ACGL-group

All four patients in the ACGL-group exhibited motor manifestations. In two patients the seizures were characterized by relatively complex movements that imitated natural movements involving different parts of the body (patients 1 and 2). In patient 2 the movements were more abrupt and ample and

predominantly involved the trunk. The initial seizure of patient 1 was classified as complex motor seizure and that of patient 2 as hypermotor seizure.

The motor manifestations of the other two patients were characterized by bilateral and asymmetric tonic contractions mainly involving the upper limbs, i.e., bilateral asymmetric tonic seizure.

The initial seizures progressed to clonic or focal tonic seizures contralateral to the structural lesion or to seizures with complex automatisms, i.e., complex motor seizures. In patient 1 the initial motor seizure evolved into a predominantly unresponsive phase (dialeptic seizure). In patient 2 the initial hypermotor seizure progressed to a focal tonic seizure involving the contralateral arm and the leg. Patient 3 progressed from a bilateral asymmetric tonic seizure to a contralateral clonic seizure involving the shoulder and the arm or the arm and the leg. Patient 4 progressed from a bilateral asymmetric tonic to complex motor seizure manifesting as complex movements of lower limbs, trunk and head.

Patients 2 and 3 progressed to secondary generalization, which was tonic-clonic in both cases. Patient 2 presented relatively asymmetric clonic movements during the phase of clonic seizure. While the side contralateral to the lesion was more tonic, the ipsilateral half of the body, and mainly the upper limb, presented more evident clonic contractions.

PCGL-group

Of the four patients in this group, only three had seizures that were documented by video-EEG. Two of them had motor manifestations during the initial phase of the seizure, characterized by automatisms of the distal segments of the body, particularly the fingers and hands (patients 5 and 7). These automatisms were characteristic of automotor seizures.

In patient 6, the seizure was characterized by impairment of consciousness, with minimal motor manifestations, i.e., a dialeptic seizure.

No seizure was recorded for patient 8 but the clinical history revealed that his seizures consisted predominantly of impairment of consciousness, without clear motor manifestations (dialeptic seizure).

The initial automotor or dialeptic seizures of this group progressed to contralateral focal clonic or versive seizures.

Patient 5 progressed from automotor seizure to focal clonic seizure in four of eight recorded. automotor seizures. Of these four seizures, three manifested with clonic jerks involving the proximal portion of the contralateral upper limb, shoulder, and trunk. The upper limb exhibited clonic contractions simultaneous with elevation and abduction movements. In one seizure, the clonic contractions involved the trunk bilaterally and the proximal region of the arm ipsilateral to the side of lesion.

Patient 7 progressed from automotor seizures to contralateral versive seizure.

Two of the three patients in this group presented secondary generalization.

Patient 5 presented a secondarily generalized tonic-clonic seizure. The tonic seizure started in the arm contralateral to the side of lesion and this arm remained extended. The clonic phase also started in the contralateral arm and became generalized but asymmetric, predominating in the body half ipsilateral to the lesion. At the end of the generalized seizure, this patient presented a clonic seizure in the arm ipsilateral to the side of lesion (paradoxical clonic seizure) which lasted approximately 5 seconds.

Other motor manifestations

Other motor manifestations associated with the main seizure type described above were also observed. These motor manifestations consisted of head deviation ipsilateral to the side of lesion during a generalized clonic seizure (patient 3) or during an automotor seizure (patients 5, 7), grimacing during a hypermotor seizure and dialeptic seizure (patients 2, 6), looking around during a hypermotor seizure and dialeptic seizure (patients 2, 6), blinking during a bilateral asymmetric tonic seizure (patient 4), and grinning (patient 5) during an automotor seizure.

Automatisms

ACGL-group

The automatisms of the patients in this group were predominantly characterized by complex movements involving the

Table 40.3 Video-EEG: semiologic and electrographic findings

Patient	Background	Non-Epileptiform Abnormalities	Epileptiform Abnormalities (%) Frequency (*F*)	Clinical Symptoms	Seizures duration	Seizure (*s*) classification (*s*)	A Range of EEG versus Clinical Onset B. EEG Description C. EEG Classification
1	Slow	IS, generalized	SW, regional, left temporal (85%) F:1 every 30–40 minutes. SW, regional, right temporal (15%) F: 1 every 2 hours.	2 seizures both recorded out of sleep. Awakening → Complex motor seizure (sudden generalized jerk → intermittent body wiggling → sighing → bilateral hand and leg automatism (open hands, palm of the left hand over the right and alternating this position with interlaced hands; wide leg movements as if straightening the sheet that covers him) → brief episode of lip-smacking) Dialeptic seizure (motionless and fixed gaze for about one minute). Tachycardia during the seizure (HR=120, basal HR 60–70). Total amnesia of events. Postictal confusion for 20 minutes, with automatisms, scratching head and genitals.	70 sec	Complex motor seizure → Dialeptic seizure	A. 0 to (+) 2 seconds B. Arousal → Diffuse EMG intermixed with irregular theta 4–6 Hz → Diffuse regular delta (2 Hz) activity C. Non-localizable
2	N	–	–	3 seizures recorded out of sleep. A. Suddenly awakened → Hypermotor seizure (turned around → looked around and looked scared → flexed the trunk → grimace → made noises (grunts) → tremor of the right hand → sat up in bed → moved his trunk → grabbed the bed rails) (2 seizures). Patient	Background	Non-Epileptiform Abnormalities	Epileptiform Abnormalities (%) Frequency (*F*)	Clinical Symptoms	Seizures duration	Seizure (*s*) classification (*s*)	A Range of EEG versus Clinical Onset B. EEG Description C. EEG Classification
				B. A → Clonic seizure (right arm and shoulder in one seizure and right arm and leg in the other) → Tonic seizure (generalized: turned the body to the left, left arm extended, right arm elevated) → Clonic seizure (generalized: clonic jerks more marked in the lower limbs, head to the left) (2 seizures). LOC			
4	N	IS, generalized, maximum posterior regions IS, lateralized, right hemisphere ST, regional, right frontocentral	–	4 seizures recorded out of sleep. Awoke → eyes opened → bilateral asymmetric tonic seizure (tonic contraction, right arm elevated, left arm elevated with elbow flexed, blinking, moaning) → Complex motor seizure (tongue protrusion, restless movements of the legs, tried to sit up, balanced his head) not responding during the seizure. LOC, immediately after the seizure he was reponsive and went back to sleep quickly Seizure 4: Postictal left arm and hand weakness	40 sec	Bilateral asymmetric tonic seizure → Complex motor seizure Lateralizing sign: postictal Todd's paralysis (left, arm, hand)	A. (–) 1.9 to (+) 1.6 seconds. B. High voltage slowing with a 4–6 Hz rhythm for 1–4 seconds, followed by high voltage (1–3 Hz) rhythmic delta activity that was generalized but maximum over midline frontal, vertex, parietal. C. Non localizable
5	N	IS, regional, left temporal	SW, regional, left temporal (100%) F: 1 every 3 min during sleep	16 seizures recorded A. Aura described as dizziness and tingling and numbness in both legs (8 recorded) B. A → Automotor seizure (grinning, sighing, decreased responsiveness or unresponsiveness, bilateral hand automatism (mainly involving the hands, grabbed closest objects, rubbed the sheet with the palm of the hand moved and turned the identification bracelet and rubbed rubbed the suprapubic region), head turned (non-versive) to the left (4 seizures). LOC. No postictal confusion. C. A→B→ Clonic seizure (right arm with elevation, abduction and clonic jerks no right shoulder including superior portion of the trunk) (3 seizures). In one seizure the initial clonic manifestation involving the right shoulder and trunk was followed by flexion of the left leg with some clonic shaking. LOC.	A. Hard to define precisely the duration B. 70 sec D. 80 sec E. 85 sec c	A. Somatosensory aura B. Somatosensory aura → Automotor seizure (LOC) C. Somatosensory aura → Automotor seizure (LOC) → Clonic seizure (right, shoulder, trunk) D. Automotor seizure (LOC) → Clonic seizure (trunk) → Tonic seizure (generalized) → Clonic seizure (generalized)	A. (–) 26 to (+) 10 seconds B. Rhythmic sharp waves in the parietal-vertex region, maximum at Pz electrode, lateralized slightly toward the right side. These evolved to high amplitude sharp waves, intermixed with delta activity over the centroparietal region, maximum in the left superior parietal region (electrodes, P3, P1). C. Regional, midline parietal-vertex

				D. B → Clonic seizure (head deviating to the left, trunk with clonic contractions apparently more marked on the left, left leg flexed) → Tonic seizure (left arm extended, right arm and head flexed to the left) → Clonic seizure (generalized, but with more marked clonic contractions on the left. (1 seizure). LOC			
6	N	–	SPK, regional, vertex (100%) F: max 2 per 10 sec during sleep	9 seizures recorded, all out of wakefulness. Dialeptic seizure → minor change in facial expression (as if he were absent minded), grimaced, looked around, unresponsive for a very brief period and sniffed frequently. He had total amnesia of events, but no postictal confusion.	25 sec	Dialeptic Seizure	A. (–) 3.4 to (+) 14 Seconds B. Paroxysmal fast activity in the right sphenoidal electrode for 2–4 seconds which evolved to a more widespread theta activity maximum Sp2. C. Regional, right temporal
7	N	IRS, regional, left temporal	SPK, regional, left temporal (100%) F: 0–1 per page	2 seizures recorded, both upon awakening Automotor seizure (the patient appeared confused → he tried to sit up in bed → left hand automatism: rubs the sheet between his thumb, index and middle finger) → Right versive seizure (vocalization, right version, left arm extension) → Tonic seizure (generalized: upper extremities extended, left leg flexed, evolving to bilateral leg extension) → Clonic seizure (clonic contractions started in the right arm and became generalized but asymmetrical,more marked on the left) → Clonic seizure (left arm) LOC.	85 sec	Automotor Seizure (LOC) → Versive Seizure (right) → Tonic seizure (generalized) → Clonic seizure (generalized) → Clonic seizure (left arm)	A. 0 – (–) 6.2 seconds B. Lateralized left rhythmic theta (4–5 Hz) activity, which spread to involve the right hemisphere in approximately 5–6 seconds and finally evolved to rhythmic slow 3–4 Hz generalized
8	N	IS, regional, right temporal	SW, regional, right temporal	No seizures recorded		Dialeptic seizure (by historical)	C. Lateralized left

HR= heart rate, IRS = intermittent rhythmic slow, IS = intermittent slow, LOC= loss of consciousness, SPK= spike, ST= sharp transient, SW = sharp wave.

upper and lower limbs and the trunk. In patient 1 the automatisms involved the hands, head, trunk, and legs. The hands remained open with the palmar surface of the left hand on the dorsal surface of the right hand, with the fingers interlacing intermittently. Under the sheet, the legs exhibited ample and alternating movements at times with the right leg and at times with the left leg. He also showed body and head wiggling and lip-smacking. The automatisms of patient 2 were characteristic of hypermotor seizures and involved the trunk (he sat up in bed, flexed his trunk and alternately turned it to the right and to the left) and upper limbs (he grabbed the bed rails). In addition, he also exhibited a repetitive tremor-like movement of the right hand. Patient 4 presented tongue protrusion and wide movements of the lower limbs and trunk and balanced his head, alternately turning it to the right and to the left.

PCGL-group

The automatisms of this group were characterized by more distal movements predominantly involving the hands. Patient 5 presented automatisms involving the hands bilaterally. The most frequent was smoothing the sheet that covered him with his open hand. The automatisms were also directed at nearby objects; for example, the patient handled the bracelet on his left hand while his left hand showed opening and closing movements. He also had scratching of the suprapubic region. Patient 6 sniffed several times during the seizure. In both seizures of patient 7 the automatisms involved the hand ipsilateral to the side of lesion. Holding the sheet between his thumb and fingers he made movements by rubbing the thumb and fingers together.

Vocalization

Excluding the vocalization typical of the beginning of secondary generalized seizures, only patients in the ACGL-group presented ictal vocalization. Patient 2 grunted and patients 3 and 4 moaned.

Facial expression

Changes in facial expression were more marked in patients 2 and 3 in the ACGL-group, who appeared to be scared. Patient 6 (PCGL-group) showed a discrete change in facial expression, looking more still and barely expressive.

Level of consciousness

Excluding the auras, in the ACGL-group, one patient presented total amnesia of all his seizures, two patients could remember some motor manifestations during the seizures, and one patient was very sleepy and poorly responsive after seizures recorded by video-EEG, although by history this patient was aware during his motor manifestations. In the PCGL-group, out of the three patients whose seizures were recorded, two had loss of consciousness and one had total amnesia of seizures.

Autonomic phenomena

Patient 1 presented tachycardia, with his basal heart rate of 60 reaching 120 during the seizure. On the basis of history data, patient 6 had mydriasis, which was not documented during the video-EEG.

Duration of seizures

In the ACGL-group the seizures without secondary generalization lasted 30–70 seconds, while those with secondary generalization lasted on average 90 seconds. In the PCGL-group, the duration of seizures without generalization ranged from 25–80 seconds, while the duration of seizures with secondary generalization lasted about 85 seconds. Patient 3 only presented seizures with secondary generalization which lasted on average 85 seconds.

Postictal manifestations

Except for the seizures with secondary generalization, one patient in the ACGL-group presented a prolonged period of postictal confusion lasting as long as 20 minutes and another presented Todd paralysis involving the leg and arm contralateral to side of the lesion.

Lateralizing signs

Lateralizing signs were frequent both in the ACGL-group and in the PCGL-group. In five of the eight patients, it was possible to infer the side of the lesion on the basis of the clinical characteristics of the seizures.

Of the four patients in the ACGL-group, two had focal tonic or clonic seizures involving the arm, leg, or shoulder contralateral to the side of structural lesion. One patient presented Todd paralysis involving the arm and leg contralateral to the lesion. On the basis of clinical history, in this group the auras were unilateral, involving the arm or leg also contralateral to the side of lesion.

Of the four patients in the PCGL-group, one presented a focal clonic seizure contralateral to the lesion (shoulder and trunk) and one presented a versive seizure preceding secondary generalization, also contralateral to the side of lesion, and a paradoxical clonic seizure at the end of a seizure with secondary generalization.

Relation of the seizures to the wakefulness-sleep cycle

All patients in the ACGL-group had seizures during sleep.

All the three patients in the PCGL-group with recorded seizures had seizures while awake, although one seizure occurred shortly after the awakening.

Eletroencephalogaphic recording

Interictal epileptiform findings

Interictal epileptiform abnormalities were recorded in six of the eight cases (75%). Among these six patients, the epileptiform discharges were exclusively ipsilateral to the side of lesion in three, independent bilateral in one but with a marked predominance (85%) also ipsilateral to the side of lesion, and on the vertex region in two (Table 40.3).

Among the ACGL-group, only two patients showed epileptiform discharge, one regional temporal (bilateral, but mainly ipsilateral to the side of lesion) and one regional on the vertex region.

All patients in the PCGL-group showed interictal epileptiform discharges, three regional on the temporal region (all of them ipsilateral to the side of lesion) and one regional at vertex.

Ictal findings

Among the seven patients with seizure recordings, the ictal EEG was regional in four, lateralized in one and non-localizable in two (Table 40.3).

Among the seven cases with seizure recordings, the ictal EEG would predict correctly the side of lesion in only three patients.

Regarding location, the ictal EEG was on the fronto-vertex-parietal areas with or without clues for lateralization also in three of seven cases (42.8%). In the remaining four cases, the ictal recording was non-localizable in two, lateralized and ipsilateral to the side of lesion in one and regional temporal and also ipsilateral to the lesion in the other.

Although the number of patients was small, we observed that there seemed to be a greater difficulty in lateralization in the ACGL-group. Only one of the four patients presented an ictal recording over the centroparietal region with lateralizing data. In another patient the recording was over the midline with no evidence for lateralization, and the last two cases were non-localizable.

Among the three patients in the PCL-group with ictal recording, the EEG was regional in two and lateralized in one. The regional ictal EEG was over the midline, involving the vertex and the parietal region without lateralizing data in one and over the temporal region ipsilateral to the side lesion in the other. The lateralized ictal recording was ipsilateral to the side of structural lesion.

The ictal rhythm consisted of varied patterns in both groups, with no predominance of any particular type. Theta or delta activities of regular or irregular morphology were observed, as well as rhythmical sharp waves and also paroxysmal fast and electrodecremental patterns.

In patient 5, the ictal recording preceded the clinical seizure by as much as 26 seconds. The most delayed electrographic recording started 21 seconds after the onset of the clinical seizure in patient 2.

Invasive recording

In this series, two patients were submitted to invasive evaluation, one in the ACGL-group and the other in the PCGL-group, patients 2 and 5, respectively.

In patient 2, the ictal recording was diffuse, involving all the recording contacts positioned in the mesial frontal region.

In patient 5, the ictal recording was focal in only one contact positioned over the lesion and later involved the adjacent contacts that were positioned over the lesion and outside the lesion.

Follow-up after surgery

Seven of the eight patients were submitted to surgery. Five had lesions in the hemisphere dominant for language (Table 40.4). Except for one who was lost to follow-up within a period of less than 1 year, the others had a follow-up of 2–5 years. No patient presented neurological deficits or behavioral alterations after surgery. Among the patients who were submitted to neuropsychological evaluation after surgery (full scale, verbal, and performance IQ), the scores obtained in the post-operative evaluation were basically unchanged compared to those obtained preoperatively (Table 40.4).

One patient was submitted to a second surgery for more extensive resection due to residual tumor after the first surgery.

Seizure outcome

Of the seven patients submitted to surgery, one patient had only a 6 month follow-up and was seizure free for 2 months. After seizures recurrence a modification in his drug treatment changes were made. In his last follow-up, 6 months after surgery, he was seizure free. Of the other six, one patient in the ACGL-group and one in the PCGL-group remained seizure free (outcome classification 1) up to the last evaluation (Table 40.4). The remainder did not become seizure free, two of them with outcome classification 3 (1–3 seizure-days per year) and two with outcome classification 4 (4 seizure-days per year to 50% reduction of baseline seizure-days) on the of the last follow-up.

Discussion

There are several ways to study the clinical symptomatology of epileptic seizures arising from a given cerebral cortical area. The so-called 'gold standard' is to analyze the seizure semiology of patients who became completely seizure free after a relatively restricted cortical resection.[45,46] Other methods used are based on information obtained from the onset of the ictal-EEG with intracranial electrodes,[47] or on the relationship between ictal semiology and the anatomical location of structural lesions, as long as the lesions are not extensive or diffuse.[48,49]

In the present series, all patients presented structural damage, with the lesion being of neoplastic nature in all cases but one.

Although the specific pathophysiological mechanism by which acquired and developmental brain tumors may cause epilepsy is unclear, there are several hypotheses including chronic changes in surrounding cortex, i.e., by direct mechanical or vascular mechanisms,[50] hemosiderin deposition,[51] and partial isolation of cortical areas.[52,53,54] These factors, separately or as a whole, possibly cause alterations in inhibitory and excitatory mechanisms in local circuits. In addition, developmental tumors may be associated with areas of cortical dysplasia[55] having intrinsic epileptogenic potential.[56] On the basis of these factors, it is quite probable that the clinical manifestations of the epileptic seizures described here were triggered by epileptic discharges originating in the cingulate gyrus and spreading to involve one or more symptomatogenic areas[57] close to the structural lesion.

Semiologic analysis of the epileptic seizures in the ACGL-group and PCGL-group studied here permitted us to conclude that, whereas the seizures of the anterior cingulate were predominantly motor (complex motor, hypermotor, and bilateral asymmetric tonic seizures), the seizures of the posterior cingulate were characterized by impairment of consciousness (dialeptic seizures) or automatisms of the distal portions of the limbs (automotor seizures), i.e., seizure types frequently present in patients with temporal lobe epilepsy.[58,59]

The supplementary motor area is considered to be the symptomatogenic zone for bilateral asymmetric tonic seizures,[27,60] whereas the symptomatogenic zone of hypermotor seizures, which frequently occur in patients with frontal lobe epilepsy, is uncertain but may be related to activation of the frontal lobe and/or anterior CG.[61,62]

It is not possible to determine if the semiologic ictal manifestations of these series are due to the activation of the CG or are related to the propagation of the ictal discharge. However, the semiology of some seizures, such as bilateral asymmetric

* WAIS-III ** WISCIII *** WAIS R

tonic seizures, suggest that they were produced by involvement of the supplementary motor. Involvement of the temporal lobe may also explain the ictal semiology of those patients who presented dialeptic seizures or automotor seizures.

Although some of our patients presented lesions very close to what we define as a dividing line between the anterior and posterior cingulated (VPC), we should remember that this division is not arbitrary, but based on cytoarchitectural criteria. Namely, the anterior and posterior CG have cell layers with distinct neuronal populations and distributions and different connections. Even though the CG is extensively connected, each area has preferential efferent connections. In addition to these considerations, it should be pointed out that by selective criteria none of our cases presented large portions of the lesion involving areas outside the CG. These considerations may explain why the semiologic ictal manifestations of epilepsies arising from the anterior cingulated differed from the semiologic manifestations of seizures originating from the posterior cingulate. In other words, while the epileptic seizures of the anterior region most likely spread to involve areas in the adjacent frontal lobe, those of the posterior cortex of the CG tend to involve structures of the temporal lobe.

The cases reported in the literature support this hypothesis. In the anterior CG group, except for one case whose main clinical manifestation was alteration of consciousness,[40] all others suggested involvement of the frontal lobe with hypermotor seizures, tonic seizures, bilateral asymmetric tonic seizures, and gelastic seizures.[36–39,41]

It is also worthwhile to stress that the ictal scalp recordings only had limited localizing or lateralizing value in this series. The interictal discharges involved either the region of the vertex or the temporal electrodes in both groups. Only two patients had vertex spikes, four patients had temporal spikes and two patients had no epileptiform discharges. In the ACGL-group two patients had no epileptiform discharges, one had vertex, and one had bitemporal discharges. Of the four patients in the PCGL-group, three had regional interictal discharges in the temporal lobe and one had vertex interictal epileptiform discharges.

Ictal recordings correctly lateralized the lesion in only three cases No patient presented a contralateral ictal recording. Although the number of patients was small in each group, there seemed to be a tendency to greater difficulties of lateralization and localization in cases with lesion of the anterior cingulate.

The motor signs during the seizures were lateralizing in four of the eight patients and were characterized by a focal tonic seizure, focal clonic seizure, and versive seizure contralateral to the side of structural lesion. One patient also presented Todd's paralysis during the postictal period. Thus, the semiologic data of the seizures correctly predicted the side of the structural lesion in five of eight patients. The patient with a versive seizure also presented a focal paradoxical clonic seizure (clonus in the upper limb ipsilateral to the lesion) after the end of a secondarily generalized seizures.

In this series, in contrast to literature data which consider auras to be rare[36] in cingulate epilepsy, five of eight patients reported auras, two of four in the ACGL-group reported pin and needles in the contralateral arm or a heavy contralateral arm, one of four patient in the PCGL-group reported tingling in both legs. This is consistent with the finding that contralateral or bilateral somatosensory symptoms can be produced by electrical cortical stimulation in the superior portion of the mid-CG and in the supplementary sensorimotor area.[27,63]

Abdominal auras and psychic auras were also reported by patients in the PCGL-group. Cortical stimulation studies have shown that abdominal aura can be obtained when the superior bank of the sylvian fissure or the adjacent insula region were stimulated.[64] Besides, recent studies with stereo-EEG in patients with temporal epilepsy have demonstrated viscerosensitive manifestations characterized by nausea, pain and constriction of the abdominal and thoracic region when the ictal rhythm invades the insula.[65] Psychic auras are usually attributed to the temporal neocortex. More recently, structural lesions have been demonstrated in the parietotemporal transition zone of patients with depersonalization feelings.[66] All these considerations and the evidence that the posterior CG has extensive connection with the temporal lobe and to the insula, lead us to the conclusion that these auras are most probably due to extension of the epileptic discharges into the temporal lobe and insula.

All patients had frequent seizures whose duration, however, ranged from a few seconds to a little more than 1 minute in both patient groups. All patients in the ACGL-group had sleep-related seizures, whereas in the PCGL-lesion seizures had no clear relationship to sleep.

In the ACGL-group two patients were aware during the motor manifestation, while in the CGL-group all patients had loss of consciousness.

Brief and frequent nocturnal seizures with no impairment of consciousness during the initial motor manifestation (the patient remembers initial motor manifestation) are characteristic features of frontal lobe epilepsies. Therefore, these characteristics seen in seizures of patients with ACGL-group may reflect primarily the pattern of seizure propagation from the anterior cingulate to the frontal lobe.

Three of the four patients with an anterior lesion had vocalization. Stimulation of the region close to the rostrum of the corpus callosum provokes vocalization in experimental animals. Although the lesion of patient 1 was located exactly in this area, this was the only patient in the ACGL-group that did not produce vocalization.

The only autonomic manifestation documented was tachycardia. It has been demonstrated that tachycardia is a common phenomenon in focal seizures,[67,68] and the anterior cingulate cortex, as well amygdala, and anterior insula are the areas considered the central autonomic network.

Except for two patients who had invasive monitoring, the remaining ones had stereotactically guided tumor lesionectomy. Lesionectomy or small resections in the anterior or posterior CG did not cause neurological deficits or behavioral disorders; however, it is interesting to note that of the seven patients submitted to surgery, only two became completely seizure free.

The relation between the tumor mass or the epileptogenic lesion and the epileptogenic zone is extremely important for resections with a favorable outcome regarding seizure control. Although in the presence of tumors the area of ictal onset usually is not associated with a focus remote from the lesion[69] and a limited lesionectomy may result in a favorable outcome in selected cases, [70,71] it has been well determined that the area of ictal onset and the epileptogenic zone do not always fully coincide topographically with the structural lesion.[69]

There is no clear explanation for the relatively poor outcome for epilepsy surgery in this series. Invasive recordings, even when it localized the seizure onset to one electrode placed in close proximally of the MRI lesion, did not influence the final outcome.

Conclusions

Epileptic seizures secondary to structural lesions localized in the anterior portion of the CG present clinical manifestations relatively different from those of lesions localized in the posterior portion of the CG. Anteriorly localized lesions evolve with predominantly motor manifestations such as bilateral asymmetric tonic seizures, hypermotor seizures and complex motor seizures, while posterior cingulate cortex epilepsies tend to have predominantly alterations of consciousness (dialeptic seizures) and automatisms of the distal portions of the limbs (automotor seizures) as the main clinical manifestations.

This suggest that epileptic seizures of the anterior cingulate cortex are primarily an expression of seizure spreading into frontal areas, whereas seizures of the posterior cingulate cortex reflect involvement of the temporal lobes.

On the basis of the clinical characteristics (focal clonic, focal tonic, versive seizures, postictal Todd's paralysis, and paradoxical clonic seizures), it is possible to predict the side of the lesion in a high percentage of the patients.

On the other hand scalp interictal and ictal EEG only lateralize or localize the seizures correctly in less than 50% of the cases.

Lesionectomy in the CG does not cause a neurologic or behavioral deficit, but only a relatively small percentage of patients (29%) remained seizure free with surgical treatment.

These results suggest that most probably more extensive resection will be necessary to achieve seizure freedom in a higher percentage of cases.

41 Hypothalamic hamartomas

AS Harvey

Summary

- Hypothalamic hamartoma (HH) are malformations of the hypothalamus that are associated with epilepsy and precocious puberty.
- Gelastic seizures arise from the HH are characterized by ictal laughter and autonomic symptoms, often with minimal change on concurrent scalp-EEG.
- Complex partial seizures with loss of consciousness, automatisms and focal motor features, and focal spike-wave on scalp-EEG, occur in some patients as a result of seizure propagation from the HH to frontal and temporal cortex.
- Generalized tonic/atonic seizures and generalized scalp-EEG abnormalities develop in many children with HH, seemingly as a result of secondary epileptogenesis affecting the neocortex.
- The neurobiological basis for the range of seizure severity and associated neurobehavioral disturbances seen in patients with HH is not understood.
- An important distinction to be made on MRI is between intraventricular HH attached to the mamillary bodies and infraventricular HH attached to the tuber cinereum, the former more commonly associated with seizures.
- Seizures associated with HH are invariably resistant to medication.
- The best published outcomes in HH surgery are with transcallosal, interforniceal resection or disconnection. Endoscopic procedures are being currently evaluated. Gamma Knife radiosurgery is promising but there is limited outcome data.

Hypothalamic hamartoma (HH) are tumor-like malformations of the hypothalamus which arise from the tuber cinereum and/or the mamillary bodies on one or both sides. The term HH was first coined by Le Marquand and Russell[1] in 1934 to describe such a lesion found at post mortem in a boy with central precocious puberty. HH vary in size, attachment and extension into the third ventricle and suprasellar cistern. Histologically, HH consist of gray matter in which there is some variation in neuronal size, shape, and aggregation.[2–9]

HH usually come to clinical attention through their association with central precocious puberty and epilepsy, characteristically epilepsy with gelastic (laughing) seizures. HH and gelastic seizures occur with a prevalence in childhood of approximately 1 in 200 000,[10] with a greater proportion of males affected.[11] The current literature is biased towards patients with refractory epilepsy and associated neurological problems, largely related to reports of surgical treatments, making it difficult to determine the true spectrum of neurological manifestations. Central precocious puberty occurs in about a third of patients with HH and epilepsy,[11,12] usually following the onset of seizures. HH may be asymptomatic, though the prevalence of this is unknown.

Seizure manifestations

The first report of epilepsy associated with a (likely) HH was in 1932,[13] in a boy with precocious puberty and mental retardation who died from status epilepticus. The first report of HH associated with gelastic seizures specifically was in 1938.[14] Numerous case reports and small patient series were published over the subsequent 50 years. In 1988, Berkovic and colleagues provided the first detailed electroclinical and imaging descriptions of what they proposed was a recognizable and possibly progressive epileptic syndrome of HH and gelastic epilepsy.[15]

Gelastic seizures occur in nearly all patients with HH and epilepsy. Onset of gelastic seizures early in life, even from birth, is characteristic.[7,10,11,15–19] Gelastic seizures are often described as attacks of inappropriate and mechanical or mirthless laughter. Many patients also have dacrystic (crying) seizures,[4,19–26] or seizures in which the facial expression, rhythmic quality of the respirations, and sound produced are discordant mixtures of crying and laughing. Consciousness is usually preserved during brief gelastic seizures.[15,19,27] Autonomic features such as flushing, pupillary dilation and breath holding often accompany laughter in gelastic seizures. Recurrent gelastic seizures during wakefulness and sleep are not uncommon in infancy, and when occurring in a relentless fashion have been described as 'status gelasticus'.[28,29] A mild form of gelastic epilepsy is described, usually in adults with small HH, in which seizures manifest with only a 'pressure to laugh'.[30,31] It should be remembered that gelastic seizures may also occur in patients with neocortical epilepsies of frontal and temporal origin,[32,33] as well as in patients with brainstem lesions and degenerative diseases.[34]

Hypermotor automatisms, oroalimentary automatisms, head and eye deviation, and tonic or clonic facial contraction are often seen in older patients during gelastic seizures. These additional clinical manifestations are invariably seen with impairment of consciousness and described as complex partial seizures, with the implication of frontal and temporal lobe involvement.[15,19] Lateralized motor manifestations are

typically contralateral to the side of greater hypothalamic attachment in asymmetric HH.

In more than half of patients with HH and epilepsy, there is a further 'epileptic progression' with development of generalized tonic/atonic seizures and tonic-clonic seizures.[11] Many patients develop a Lennox-Gastaut syndrome with disabling drop attacks.[7,15,35–38] Tonic seizures and spasms associated with HH are often asymmetric, and laughter may precede or follow them. Infantile spasms are reported as a presenting seizure type in patients with HH.[10,37,39,40]

Neurobehavioural manifestations

Cognitive disturbances in patients with HH and epilepsy are common, especially those in whom seizures begin in childhood. Global developmental delays are particularly common in patients with refractory seizures that begin in infancy and evolve rapidly to partial and generalized seizures with associated generalized EEG disturbances. Cognitive disturbances vary in severity from patients with normal cognition, to patients with impairments of memory, attention, and learning,[10,15,31,30,41,42] through to patients with moderate-severe intellectual disability.[7,10,35,36,38] Deficits in memory and new learning are most commonly reported but the exact nature of the memory dysfunction is difficult to determine from the reported studies, due to the variable nature of testing and the often associated intellectual impairments. One study suggested cognitive deficits are correlated with seizure frequency and size of HH.[42]

Aggressive behavior, rage attacks, anxiety disorder, autism, and other psychiatric comorbidities are widely reported in patients with HH.[10,15,35,38,43,44] The relationship between behavior disturbances, seizures and intrinsic hypothalamic dysfunction is uncertain.

Sleep disturbance is common in patients with HH and epilepsy. In infants and young children, gelastic seizures may occur every few minutes and impair normal sleep-wake cycling.[17,19] Similar manifestations are reported in adults,[40,45] whereby frequent subclinical gelastic seizures are associated with recurrent sleep arousals. Sleep disturbance may be further exacerbated by continuous epileptic activity on EEG and antiepileptic drugs.

Electroencephalographic findings

Scalp EEG findings in patients with HH vary depending on the age of the patient and the evolution of the seizure disorder. In infants and young children with gelastic seizures only, and in adults with the mild phenotype characterized by only an 'urge to laugh', the interictal and ictal EEG are usually normal.[46] Such normal EEG findings with gelastic seizures are not widely appreciated and often lead to delayed or incorrect diagnosis.

Interictal scalp EEG abnormalities may not appear until later childhood,[47] often coinciding with the appearance of complex partial and generalized seizures.[11] Initially the EEG may only show epileptiform activity when asleep.[27] Spike-wave activity predominates over the frontal and temporal regions, either in a bilaterally-synchronous or predominantly unilateral fashion.[11,48] Unilateral EEG abnormalities tend to occur on the side of predominant HH attachment in asymmetric and unilateral HH. In patients with tonic/atonic seizures, background slowing is common and multifocal or generalized spike-wave activity, paroxysmal fast activity, and electrodecremental patterns are recorded, often with electrical status in sleep.[37]

Scalp EEG recordings of seizures in patients with HH and chronic epilepsy usually show suppression of interictal discharges and attenuation of background rhythms, with or without widespread low voltage fast activity.[10,15,49] Lateralized and regionalized ictal rhythms or spike-wave activity may follow, potentially giving the misleading impression of frontal or temporal lobe origin of seizures.[48] Computerized source analysis of scalp EEG may reveal subcortical sources of early rhythmic activity prior to more superficial cortical sources.[49]

Depth EEG recordings from HH[4,18,45,50,51] show gelastic seizures are associated with an ictal discharge within the HH that, in most cases, remains confined to the HH. Electrical stimulation of HH using depth electrodes may provoke characteristic ictal laughter. In contrast, depth EEG recordings of tonic seizures reveal ictal onset in cortical regions remote from the HH,[4] with medial frontal and lateral temporal areas being prominent.[50]

Neuroimaging findings

HH vary in size from 5–40 mm and vary in their attachment and extension (Figure 41.1). MRI is far superior to CT brain in revealing and characterizing HH.[15] Small HH may be difficult to detect unless the hypothalamic region is specifically examined. T2-weighted sequences in the three orthogonal planes are well suited to displaying the HH in relation to the heavily-myelinated hypothalamic nuclei and tracts. HH usually have increased signal on T2-weighted and FLAIR sequences and low signal on T1-weighted sequences, compared to grey and white matter. They do not enhance with contrast and on serial imaging remain in proportion with the rest of the brain.[12] HH associated with Pallister-Hall syndrome are often larger than sporadic HH and are isointense with gray matter on T2-weighted images.[52] Proton magnetic resonance spectroscopy (MRS) demonstrates relatively decreased N-acetylaspartate and increased myoinositol levels compared to normal gray matter,[12,53] suggesting neuronal attenuation and relative gliosis. Increased signal on T2-weighted images is correlated with gliosis on MRS and histological examination.[53]

Several anatomically-based classifications of HH based on MRI features have been proposed, distinguishing different sizes and patterns of hamartoma attachment to the hypothalamus.[2,36,54–58] The most important categorization from clinical, pathophysiological and surgical perspectives is the distinction between HH within the third ventricle that are attached to the mamillary bodies and/or the medial hypothalamus (sessile, intraventricular, intrahypothalamic), from HH beneath the third ventricle with attachment to the tuber cinereum (pedunculated, extraventricular, parahypothalamic).

In a systematic review of MRI in 72 patients with epilepsy and HH, Freeman and colleagues reported mamillary body attachment in all, with intrahypothalamic extension between

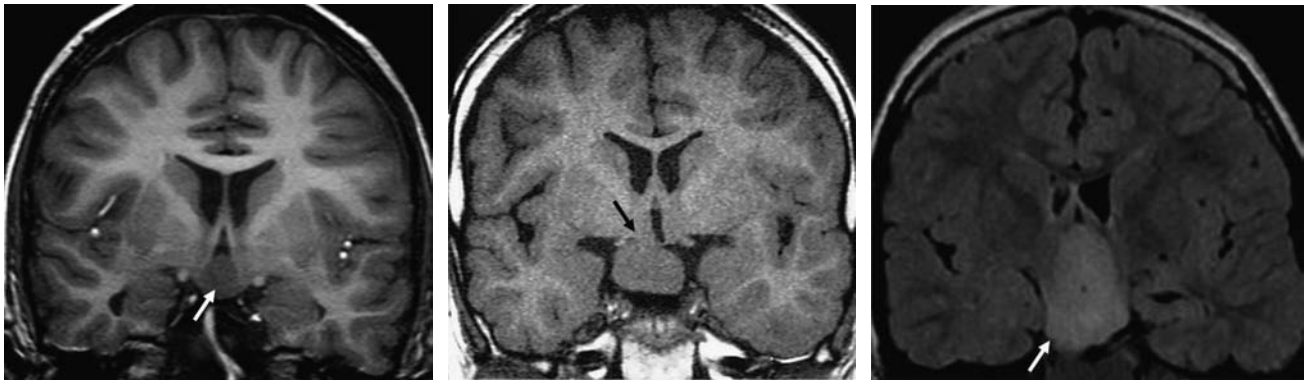

Figure 41.1 Coronal MRI scans of HH in three patients with gelastic epilepsy. (a) and (c) show intraventricular HH attached to the medial hypothalamus bilaterally; (B) shows a pedunculated HH attached predominantly to the tuber cinereum on the right, although still with a small intraventricular connection. The HH in (a) and (b) are relatively isointense with gray matter on the T1-weighted images, while the HH in (c) is hyperintense on the FLAIR image compared to the rest of the cerebrum.

the fornices and mamillothalamic tracts seen in the majority.[12] In contrast, HH associated with isolated precocious puberty tend to be pedunculated and not involve the third ventricle.[59] The association of HH size with endocrine versus neurological manifestations is variably reported, with no consistent relationship identified.[12,30,52,59] A possible interpretation of the data is that large HH are associated with the combination of endocrine and neurological manifestations, due to attachment and distortion of multiple hypothalamic regions; conversely, small pedunculated HH are more commonly associated with isolate precocious puberty[59] and small intrahypothalamic HH are more commonly associated with isolated[12] and sometimes milder epilepsy.

Occasionally, HH are seen in association with dysgenesis of the corpus callosum, gray matter heterotopias, arachnoid cysts, and microgyria.[2,12,60] Anterior temporal lobe white matter changes are seen in a minority of patients with HH, but despite the severity and frequency of seizures in many patients, hippocampal sclerosis is not reported.

Positron emission tomography (PET) studies are few but report areas of cortical hypometabolism, lateralization usually being concordant with the side of HH attachment.[7,61] PET during a period of 'status gelasticus' revealed hypermetabolism in the HH.[29] Ictal single-photon emission computed tomography (SPECT) during gelastic seizures have consistently reported focal hyperperfusion in the region of the HH (Figure 41.2).[17,18,62,63] Asymmetric cerebral perfusion during seizures is common in patients with HH,[10] with hyperperfusion ipsilateral to the side of predominant HH attachment, suggesting preferential cortical spread of seizure activity from the HH.[64] Group analyses of seizure propagation with ictal SPECT suggest preferential cortical spread to medial frontal and lateral temporal regions,[64] consistent with depth EEG studies.[50]

Epileptogenesis associated with hypothalamic hamartoma

HH usually occur sporadically and in isolation. Rarely, HH may occur as part of the autosomal dominant Pallister-Hall syndrome which includes HH, hypopituitarism, polydactyly, midline defects, and imperforate anus.[65] Patients with Pallister-Hall syndrome have mutations of the transcription factor gene *Gli3*,[66,67] but the role of *Gli3* in patients with sporadic HH is unknown[68] and thus the etiology of sporadic, nonsyndromic HH remains uncertain.

Distortion of the hypothalamus or brainstem by HH was originally believed to be the basis of seizures in this syndrome,[22] as irritation of the third ventricular floor and mamillary bodies was known to induce laughter.[69,70] With later appreciation of the severe and often generalized nature of seizures and neurological disturbances in many patients with HH, it was later proposed that patients with HH had widespread occult cerebral dysgenesis.[15,71] This view that HH were perhaps just an epiphenomenon of more significant epileptic disturbance in the neocortex led to unsuccessful temporal and frontal resections in many patients with localized EEG patterns.[8,20,72,73]

From the mid-1990s, evidence accumulated proving that gelastic seizures arose from HH, evidence coming from stereotactic depth EEG recording of seizures from HH,[4,18,50,51,74] reproduction of ictal symptoms with electrical stimulation of HH,[4,18,50] and demonstration of HH hyperperfusion with ictal SPECT[18,62] and PET.[29] HH have been shown to be intrinsically epileptogenic,[75] with pacemaker-like spontaneous repetitive firing demonstrated in small HH neurons within cell clusters.[76]

The reasons for the variability in onset and severity of epileptic manifestations of epileptogenic HH is however unknown. As discussed above, the attachment of HH is more important than their size in determining endocrine versus neurological manifestations, with mamillary body involvement and third ventricular distortion being strongly correlated with epileptogenicity,[12,54,55,59] however variability of neurological manifestations between patients with epileptogenic HH is not understood.

Clinical evidence suggests that complex partial seizures in patients with HH result from seizure propagation to medial frontal and lateral temporal cortical regions,[49,50,64] and that generalized tonic seizures represent independent neocortical phenomena.[4,50] Similarly, interictal scalp EEG abnormalities arise from secondary cortical regions, either independently or triggered by discharges arising in the HH.[4,37,50] In patients with

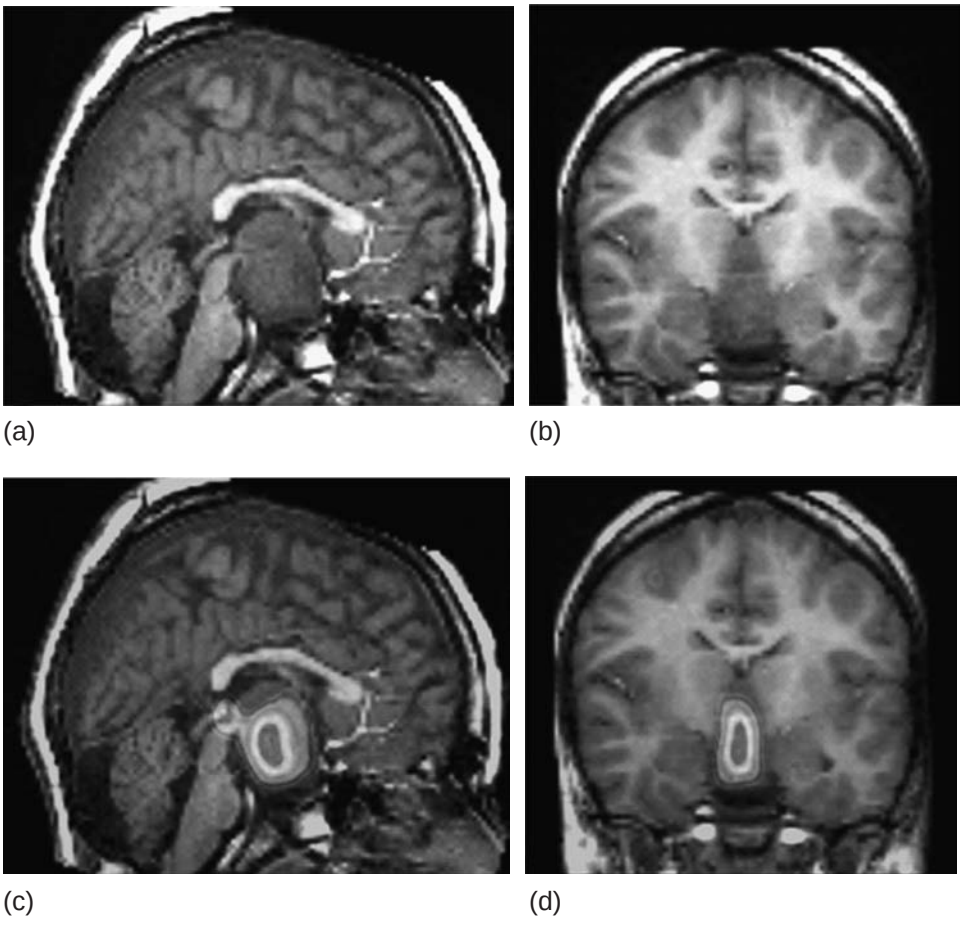

Figure 41.2 Sagittal (a) and coronal (b) T1-weighted MRI scans in an intellectually disabled boy with gelastic epilepsy showing a large HH occupying and distorting the third ventricle and interpeduncular cistern. Subtraction ictal-interictal ^{99m}Tc-HMPAO SPECT of a gelastic seizure coregistered with the sagittal (c) and coronal (d) MRI scans, showing relative hyperperfusion in the HH. (Courtesy Dr Jeremy Freeman, Royal Children's Hospital, Melbourne).

symptomatic generalized epilepsy (SGE), generalized and multifocal interictal epileptiform discharges persist over the neocortex and scalp immediately following resection of the HH,[37] frequently reducing in the weeks and months that follow, providing further evidence of the independent nature of scalp EEG abnormalities. The apparent epileptic progression in many patients with HH, and in particular the electroclinical and behavioral features of SGE, may in fact represent a process of secondary epileptogenesis affecting the cerebral cortex,[4,37,50] perhaps mediated through mamillo-halamo-cingulate pathways.[50]

Surgical treatment

Antiepileptic medications are generally ineffective in the treatment of seizures associated with HH.[10,15] While they may have some impact on the severity or frequency of partial and generalized seizures, antiepileptic drugs usually have little impact on gelastic seizures. Some patients gain partial benefit from vagal nerve stimulation.[10,77] The management of precocious puberty associated with HH is no longer surgical, with patients now treated with gonadotrophin releasing hormone agonists.

In the last two decades, there have been numerous reports of successful surgical treatment of epilepsy associated with HH, with more than 200 operated patients reported in the English literature by 2006. Today, epilepsy due to HH is considered a surgically-remediable condition.[75,78–80] Many microsurgical, endoscopic, and radiosurgical techniques for resection, disconnection, and ablation of HH are reported and a brief review is provided below. The diagnostic evaluation for patients with HH undergoing epilepsy surgery is similar to that for patients with refractory epilepsy of cortical origin except for the need for perioperative endocrine assessment, the need for high-resolution imaging of midline brain structures, and a reduced emphasis on scalp EEG localization of seizures and interictal discharges.[81]

Pterional and frontotemporal resection and disconnection

Pterional and frontotemporal craniotomies provide access to the inferior part of the HH via subtemporal, subfrontal, transsylvian or transcortical approaches, sometimes performed with temporal pole or orbital cortical resection.[7,36,47,55,82,83] These approaches to epileptogenic HH are often ineffective in controlling seizures, as only the infraventricular portion of the HH can be resected, leaving the important intraventricular component attached to the mamillary bodies and medial hypothalamus.[7,75,78] Furthermore, endocrinopathies, stroke and third nerve palsies are not infrequent complications with these approaches.[7,36]

Transcallosal, anterior interforniceal resection, and disconnection

An interhemispheric, transcallosal approach to resection of HH was first reported by Rosenfeld and colleagues.[84] This approach passes between the columns of the fornices and leaves of the septum pellucidum to enter the third ventricle, allowing direct vision of the intraventricular component of the HH. With microsurgical technique, the neurosurgeon can obtain complete or near-complete resection or disconnection of the HH at its attachment to the mamillary bodies and medial hypothalamus, down to the floor of the third ventricle (Figure 41.3). In the 56 reported patients who have undergone transcallosal resection or disconnection of HH at two centers,[35,38] seizure freedom or >90% seizure reduction is reported in 80% with associated improvement in behavior and learning in the majority of these. Most striking in these series was the improvement in patients with SGE, in whom there was often marked improvement or remission of tonic seizures, generalized spike-wave discharges on EEG, and language and behavioral problems.[35,37,38] Morbidity in these series consisted of short term memory impairment, weight gain, hypothyroidism, and transient hypernatremia,[35,38,85] with neurovascular complications being rare.

Stereotactic radiosurgery

Several radiosurgical approaches to treatment of epilepsy associated with HH are reported. All deliver ionizing radiation to a stereotactically defined intracranial target, with a steep radiation fall-off outside of the treated volume, the aim being to cause tissue damage or physiological change in the HH. Gamma Knife is reported in 46 patients,[56,57,86–90] but seizure outcome is reported in only 16 (6 seizure free or > 90% seizure reduction). Stereotactic radiosurgery with the linear accelerator[4,91] and implantation of ^{125}I seeds[92,93] are reported by a few centers, with seizure-free or near seizure-free outcomes reported in about half. Minimal morbidity and short hospital stay are clear advantages of stereotactic radiosurgery, whereas delayed seizure reduction is a potential disadvantage and certainly limits outcomes presently reported in the literature. Radiosurgery may be best suited to the treatment of smaller HH, or perhaps the intrahypothalamic component of large HH.

Minimally-invasive stereotactic techniques

Radiofrequency thermocoagulation, via stereotactic or open approaches, produces small necrotic lesions in the HH by radiofrequency heating of the tip of an electrode, often following recording and stimulation of seizures. Relatively low

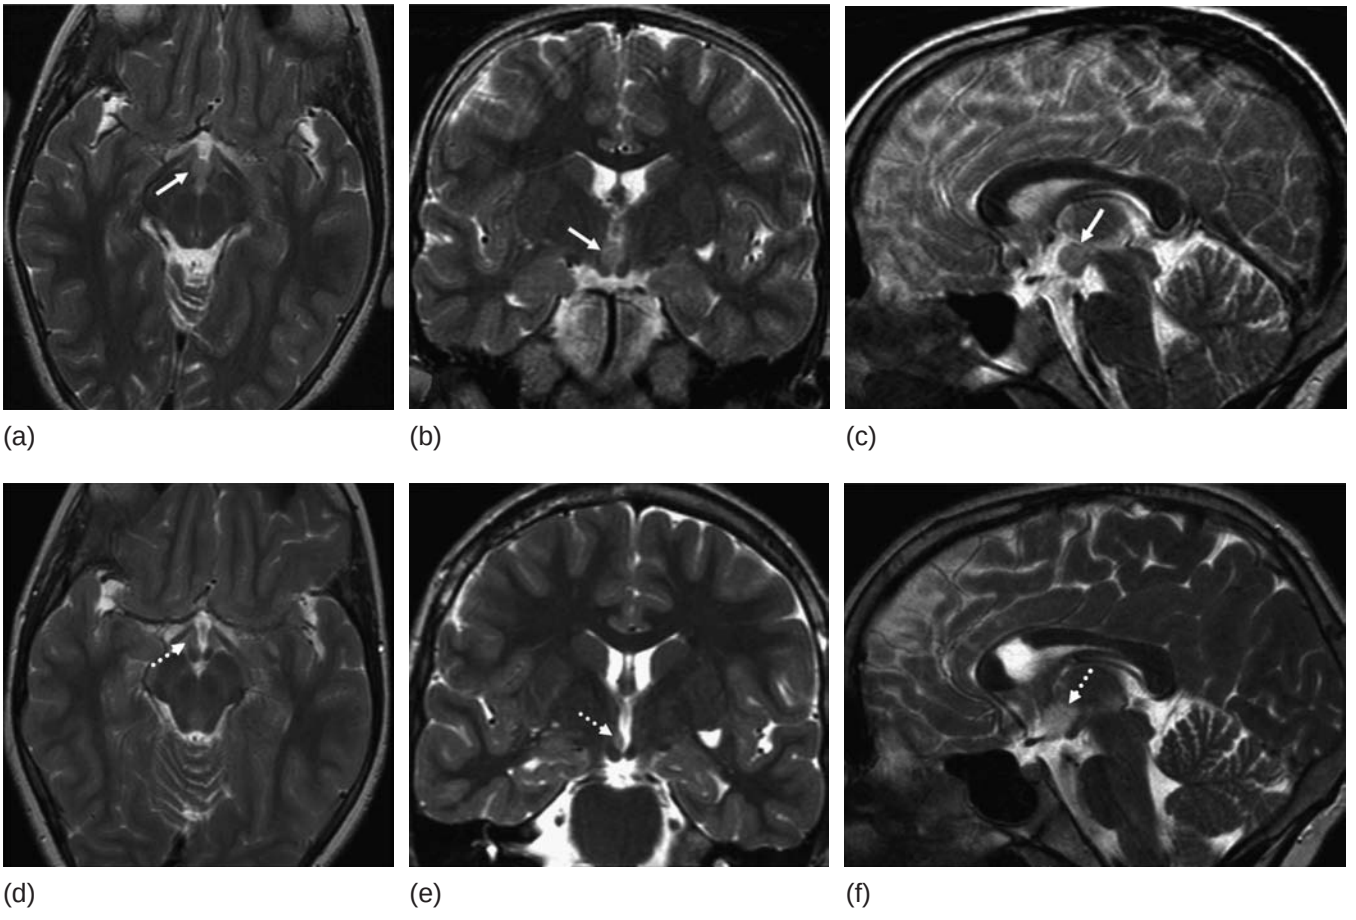

Figure 41.3 Axial (a,d), coronal (b,e) and sagittal (c,f) T2-weighted MRI scans in an intellectually normal girl with a small intraventricular HH. The top row are preoperative scans. The bottom row shows postoperative scans following transcallosal resection of the majority of the HH; there is residual HH attached to the right mamillary body (e). The patient suffered no endocrine or memory impairments following surgery and is seizure free with short follow up. (Courtesy Ms Wirginia Maixner, Royal Children's Hospital, Melbourne).

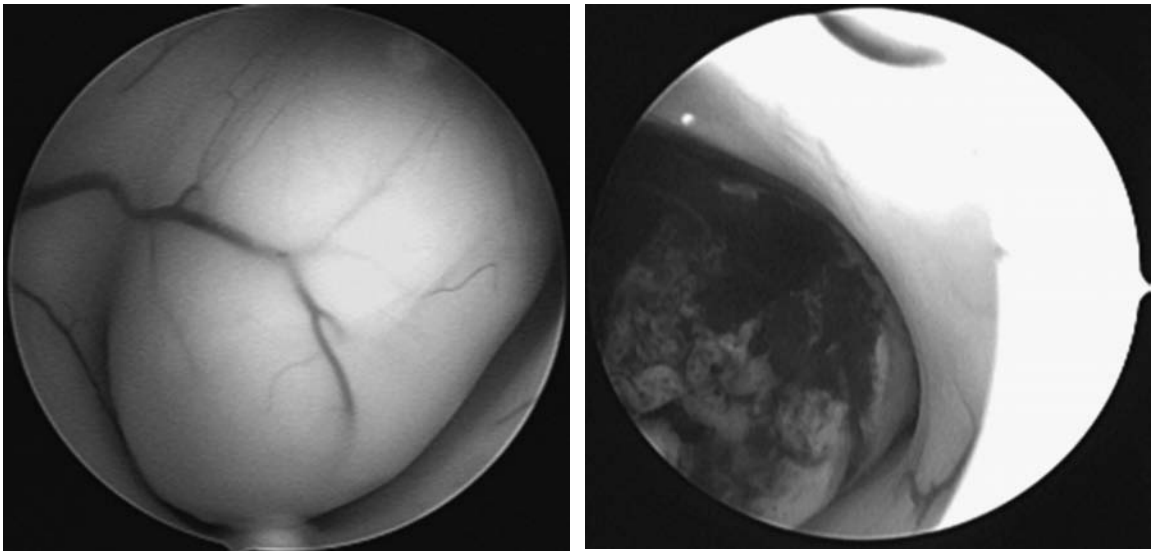

Figure 41.4 Endoscopic view of a small intraventricular HH attached to the left medial hypothalamus before (left) and after (right) partial endoscopic resection. (Courtesy Drs John Ragheb and Glenn Morrison, Miami Children's Hospital).

seizure-free rates are reported (only half being seizure free or having >90% seizure reduction) and repeat procedures are not uncommon.[18,23,40,94,95] Like stereotactic radiosurgery, radiofrequency thermocoagulation may be best suited for small HH.

Neuroendoscopy is being increasingly reported as a means of resection or disconnection of HH (Figure 41.4),[7,36,95–97] with seizure freedom or >90% seizure reduction reported in about 60% patients. Third ventricular access is generally transcortical, through the lateral ventricle and foramen of Monro. Delalande employs both frontotemporal and transcortical endoscopic approaches to disconnection of infraventricular and intraventricular components of HH.[36] Endoscopic surgery is presently limited by tools for safe and complete resection of HH tissue, though recent technical advances are reported.[97,98] Postoperative hospital stay is reduced but there is limited data on efficacy and safety to compare third ventricular endoscopic surgery with transcallosal surgery and stereotactic radiosurgery.

Overall, short-term Engel class I or II outcomes are reported in about two thirds of patients undergoing transcallosal or endoscopic resection and/or disconnection of HH from within the third ventricle, these approaches being superior in efficacy to reported outcomes from pterional and frontotemporal resections and radiofrequency ablative techniques. When greater than two year seizure outcomes are reported from a prospective study of Gamma Knife surgery in HH,[56] it may become apparent that stereotactic radiosurgery is an equal or superior technique, at least in older patients with small HH and time to wait for seizure improvement. Callosotomy, neocortical resection and pterional/frontotemporal HH resections are inferior surgical approaches that are no longer advocated.[36,48,99]

Conclusions

Previously an uncommon, poorly-understood, neurologically-devastating and untreatable epileptic syndrome, HH and gelastic epilepsy is now better understood and surgically-remediable. Optimum management of patients requires awareness of pathological laughter as a potential seizure symptom, acceptance of normal scalp EEG findings early in the course of the epilepsy, careful imaging and inspection of the hypothalamic region with MRI, recognition of the potential detrimental effects of seizures on neurological development, and early referral to a neurosurgical center with experience in treatment of HH. Further studies of surgical outcomes, with large patient numbers and adequate follow-up, are awaited to compare the merits of different approaches and timing of surgical interventions.

42 Rasmussen syndrome

CG Bien

In 1958, the Montreal neurosurgeon Theodore B. Rasmussen published a report on three pediatric patients under the title 'Focal seizures due to chronic localized encephalitis'.[1] This is an unusual condition typically developing in childhood, and is characterized by the occurrence of refractory partial epilepsy, often with *epilepsia partialis continua* (EPC), associated with progressive hemiparesis and cognitive impairment. Neuroimaging reveals progressive unilateral hemispheric atrophy. The Montreal Neurological Institute continuously treated patients with this disorder. However, it took another about thirty years until reports started to appear from other parts of the world. From this time on, most researchers and clinicians have adopted the term Rasmussen syndrome (RS) or (Rasmussen encephalitis) for this condition.[2,3]

Clinical presentation and seizure semiology

Typical features

The 'typical RS patient' can be described as follows: he or she (there is no gender predominance in RS) starts experiencing intractable unilateral focal motor seizures or temporal lobe seizures at the age of six years. Later on, when the disease process spreads across the affected hemisphere, new seizure semiologies indicating new epileptogenic areas are often observed. EPC is not infrequently seen. This type of focal motor status epilepticus is characterised by repetitive, brief, regular or irregular, quite monomorphic myoclonic jerks. Distal rather than proximal muscle groups are affected. Physical exercise, sensitive stimulation or psychic exertion may increase the amplitude and frequency of the myoclonic jerks. The upper half of the body is more frequently affected than the lower one. EPC more often continues during sleep – sometimes in a milder form – than does it stop.[4] This seizure type is not a unique feature of RS.[5–7] However, in childhood, RS is its most frequent cause. Within a few months of the manifestation of epilepsy, progressive loss of neurological function associated with one hemisphere starts. Typical features are hemiparesis, hemianopia and (if the dominant side is affected) aphasia.[8,9] After on average eight months, the main decline is over, and the patient passes into a residual stage with a rather stable neurological deficit and cerebral hemiatrophy.[9] Seizure frequency is still high but not as much as during the previous 'acute stage'.[9] In reality, this 'average' or 'typical' RS patient is rarely seen. Due to the complexity of potential symptoms, the presentation of RS can take a variety of different forms.

Less common presentation forms of RS

Since the original description of RS, a variety of other presentations have been recognized. Although RS typically develops in children, the condition has also been described in adult life.[10–12] In the majority of these cases the course appears to be slower and less severe. Villani *et al.* distinguished two phenotypes in adults: an 'epileptic' form, characterised by focal motor epilepsy refractory to antiepileptic drug treatment, and a 'myoclonic' form, in which EPC and/or unilateral cortical myoclonus (focal or multifocal) are the prominent features. Although secondary spread of seizures to the contralateral side, or a minor degree of contralateral atrophy is sometimes seen in patients with RS, true bilateral involvement in the form of bilateral inflammation has only rarely been described.[13–15] The bilateral nature of these unusual cases became apparent within 13 months of disease onset. Of note, no case of subsequent spread to the opposite side has been reported following the successful hemispheric surgical treatment of unilateral RS.

Dual pathology, i.e. a second cerebral abnormality such as cortical dysplasia, vascular abnormality or tuberous sclerosis in association with RS has been found in approximately 10% of patients,[16] leading to speculation that a breach in the blood–brain barrier may play a part in the genesis of the disease.

Patients with an otherwise typical RS course have been observerd who experienced delayed seizure onset,[17] or even the absence of seizures.[18]

In a few patients, movement disorders including hemiathetosis and hemidystonia have been described in addition to EPC.[19,20]

Diagnostic tests

Brain imaging

Magnetic resonance imaging (MRI)

Brain MRI has become a mainstay of diagnostic evaluation and follow-up in RS.[21,22] Serial investigations reveal focal cortical and subcortical T2/FLAIR signal increases followed by progressive, centrifugal hemiatrophy of the cerebral hemisphere contralateral to the affected side of the body. The onset of MRI visible first changes is usually noted around the Sylvian fissure. The head of the ipsilateral caudate nucleus is usually included in this hemiatrophic process, and is particularly easily ascertained.[21,22]

Other neuroimaging techniques

Positron emission tomography (PET), single photon emission computed tomography (SPECT) and magnetic resonance

spectroscopy (MRS) are techniques not suitable for defining the inflammatory nature of the condition (for a literature survey, see ref. 23). However, these techniques may be helpful in confirming the unihemispheric nature in patients with suspected recent onset disease.

Electroencephalography

The most characteristic EEG abnormalities in RS are polymorphic delta waves over the affected hemisphere. These waves are for the most part found in temporal and central leads. Epileptiform abnormalities with frequent evolvement into electrographic seizures are regularly observed. During the disease course, background activity shows progressive flattening. In the majority of patients, contralateral asynchronous slow waves and epileptiform discharges occur.[24] Later on, these contralateral abnormalities may be even more frequent than the ipsilateral ones.[25,26] It must be emphasized that these contralateral abnormalities are not sufficient to make the diagnosis of bilateral disease. They are likely to arise from rapid spread from the primarily affected hemisphere, and they should not be taken as a cause to reject an otherwise suitable patient from hemispherectomy. As with other conditions with cortical epileptic myoclonus, EPC in RS is not always accompanied by ictal contralateral EEG discharges on surface EEG.[25]

Laboratory tests

CSF studies

Only about 50% of RS patients have abnormal cerebrospinal cell counts (16–70 cells/μl, predominantly lymphocytes) and protein content (50–100 mg/dl).[8,27] Oligoclonal bands have been an inconsistent finding, ranging from 0–67%.[24,28,29] Standard CSF studies (in combination with serological tests) are helpful to rule out a CNS infection by a known neurotropic agent during the process of excluding differential diagnoses. Stand-alone standard CSF tests, however, are not sufficient to exclude or confirm the diagnosis of RS.

Blood tests

The serum test for antibodies to the glutamate receptor subunit 3 antibodies (GluR3 abs), published in the mid-1990s,[30] is no longer considered sensitive of specific for the diagnosis of RS. This has become evident from several recent studies.[31–33] To conclude, this test can no longer be regarded as a useful diagnostic method. At present, no other diagnostically helpful blood test is available for patients with suspected RS.

Brain biopsy

Recently, an international consensus has been made on the role of brain biopsy in the diagnosis of RS.[23] It is indicated only in patients in which the diagnosis of RS is suspected but can neither be sufficiently supported by cross-sectional, non-invasive assessment (part A criteria of the European consensus criteria, see Table 42.1) nor by demonstration of the progressive nature of the condition (part B criteria, #1 and 2). This is usually the case in patients with very recent onset of clinical symptoms suggestive of RS – e.g., in a patient with otherwise unexplained recent onset EPC. Such a patient may profit from rapid definite diagnosis by brain biopsy because subsequent timely initiation of long-term immunotherapy (see below)

Table 42.1 Diagnostic criteria for Rasmussen syndrome (with permission from ref. 23). Rasmussen syndrome can be diagnosed if either all three criteria of part *A or* two out of three criteria of *B* are present. Check first for the features of part *A*, then, if these are not fulfilled, of part *B*

Part A:		
1.	Clinical	Focal seizures (with or without Epilepsia partialis continua) *and* unilateral cortical deficit(s)
2.	EEG	Unihemispheric slowing with or without epileptiform activity *and* unilateral seizure onset
3.	MRI	Unihemispheric focal cortical atrophy *and at least one of the following:* gray or white matter signal T2/FLAIR hyperintense signal, hyperintense signal or atrophy of the ipsilateral caudate head
Part B:		
1.	Clinical	Epilepsia partialis continua *or* progressive* unilateral cortical deficit(s)
2.	MRI	Progressive* unihemispheric focal cortical atrophy
3.	Histopathology:	T-cell dominated encephalitis with activated microglial cells (typically, but not necessarily forming nodules) and reactive astrogliosis. Numerous parenchymal macrophages, B cells or plasma cells or positive signs of viral infections (viral inclusion bodies or immunohistochemical demonstration of viral protein) exclude the diagnosis of RS.

*'Progressive' means that at least two sequential clinical examinations or MRI studies are required to meet the respective criteria. To indicate clinical progression, each of these examinations must document a neurological deficit, and this must increase over time. To indicate progressive hemiatrophy, each of these MRIs must show hemiatrophy, and this must increase over time.

may prevent irreversible loss of brain tissue and related neurological functions. An open brain biopsy collecting a piece of brain with an intact relation of meninges, gray and white matter is preferable. Stereotactic biopsies have a relatively high probability of leading to false negative results (frequent sampling error due to small specimen size). In RS brains, pathological and seemingly normal brain areas may lay closely together. Even in the case of an open brain biopsy, extensive neuropathological evaluation of serial sections may be necessary to detect the characteristic inflammatory changes. The biopsy should ideally be obtained from a non-eloquent brain area with increased T2/FLAIR MRI signal.[21] A systematic study of a large sample of hemidecortication specimens revealed that frontal or temporal lobe areas are more likely to contain diagnostically valuable inflammatory infiltrates than more posteriorly collected specimens.[34] There are less histopathological differential diagnoses than sometimes assumed. Main alternative diagnoses are chronic viral encephalitides[35] and – in adults – paraneoplastic encephalitis[36,37] and nonparaneoplastic limbic encephalitis.[38] These disorders can be distinguished by the clinical presentation, neuroimaging and additional laboratory studies. If the results of brain biopsy are not clearly abnormal and therefore considered inconclusive, this may be due to the above mentioned sampling error. In this case, further clinical and MRI follow-up studies (e.g. every 6 months) are needed to establish or exclude the progressive nature of the condition.

Neuropsychology

Neuropsychology testing does not provide positive diagnostic evidence in favour or against a diagnosis of RS. Repeated testing, however, may provide highly valuable information on the progression of cognitive decline. Language studies are of particular importance because aphasic disturbances may suggest involvement of the language dominant hemisphere. If hemispherectomy is considered, language laterality must be determined. Language functional MRI testing may in selected cases be an adequate tool for this purpose. However, its applicability can be impaired in RS patients by their frequently reduced ability to follow the instructions and by the limited morphological comparability of the two hemispheres due to unilateral atrophy and subsequent hemispherical asymmetry.[39] Determination of language lateralisation therefore mostly requires the performance of a Wada test.

Diagnostic criteria of RS

The most characteristic and unique features of RS are the progressive unilateral loss of function and the progressive hemispheric atrophy occurring over several months or a few years. This acute stage is followed by a quite stable residual stage. Prior to the acute stage, a non-specific prodromal period with less frequent seizures and sometimes a mild neurological deficit can be observed.[9]

To standardize the diagnosis of RS, a European consensus panel recently proposed formal diagnostic criteria,[23] which are given in Table 42.1

Differential diagnoses

Lists of potential differential diagnoses are long. In reality, however, most can be relatively quickly checked and ruled out or confirmed. The major alternative diagnoses are those of non-inflammatory unilateral epileptic syndromes such as malformations due to abnormal cortical development, Sturge-Weber syndrome, stroke, hemiconvulsion-hemiplegia-epilepsy syndrome, and tumours including gliomatosis cerebri. Rarely, other causes of EPC have to be excluded, particularly: metabolic disorders (mitochondrial encephalopathy, lactic acidosis and stroke-like episodes; renal or hepatic encephalopathy) or inflammatory conditions (vasculitis, HIV, Russian spring-summer meningoencephalitis and a few others). For an extensive list, see the recent consensus statement.[23]

Pathophysiology

The neuropathological hallmarks of RS are inflammation, neuronal loss, the presence of microglia activation, microglial nodules and astrogliosis. These characteristics have been described as early as in the index publication;[1] they have been elaborated in more detail by the Montreal group.[40] Pathological investigations in RS have been focused on the nature of the inflammatory response. Many earlier studies have dealt with (herpes-)viruses as potentially causative factors.[41–46] Still, although these reports suggested the presence of viruses, and treatment with ganciclovir decreased seizures temporarily in some patients,[47] a causal association of RS with a specific virus was never found. As mentioned above, neuronal damage by an antibody-mediated immune response through antibodies directed to the glutamate receptor subunit 3 (GluR3) was postulated.[30] Subsequent studies suggested that such antibodies not only killed neurons via an antibody or complement mediated attack,[48] but also that such antibodies might kill neurons via direct activation of the receptor ion channel.[49] Later, it became clear that anti-GluR3 antibodies were not present in all RS patients and were also found in other forms of epilepsy.[31–33] However, there is continuous evidence that plasmapheresis or immunoadsorption are effective in some patients. It seems likely that in these patients indeed autoimmune antibodies contribute to pathogenesis. The antigenic specificity of the underlying antibodies remains unclear. Recently, antibodies against the neuronal alpha7 acetylcholine receptor have been found in two RS patients.[50]

Recent reports have analysed the composition of the immune cells in the brains of patients with RS and found evidence that cytotoxic T cells play a role in RS. The T lymphocyte fraction in the brain parenchyma is mainly composed of $CD8^+$ cells. $CD4^+$ cells are present, but accumulate in the perivascular space of blood vessels rather than migrate into the parenchyma.[51] Other immune cells coming from the bloodstream, like macrophages, B cells, plasma cells and natural killer cells are present in low numbers.[36,51] The infiltration of T lymphocytes and density of microglia nodules (focal accumulations of activated microglial cells) are inversely correlated with disease duration as well as with neuronal loss.[21] Whereas during the course of disease neuronal loss increases, the presence of T lymphocytes gradually subsides to a level which,

however, is still well above that found in normal individuals.[21] About one tenth of the T cells in the inflammatory lesions are GranzymeB$^+$ cytotoxic T lymphocytes.[51] Some of these cells were found in close apposition to neurons with polarisation of the cytotoxic granules towards the neuronal membrane. This suggests that a cytotoxic T cell response against neurons might be responsible for neuronal loss. Further evidence suggests a specific T cell mediated destruction of neurons in RS: restricted T cell populations have expanded from a few precursor T cells specifically directed against distinct antigenic epitopes.[52]

Another prominent feature of RS is astrocyte activation. Moreover, a recent study showed that in RS there are also areas that reveal a dramatic loss of these astrocytes.[53] These astrocytes apparently also die by apoptosis induced by Granzyme-B$^+$ cytotoxic T cells. Astrocytes support neurons by many different functions, such as maintenance of potassium homeostasis and regulation of GABA and glutamate, neurotransmitters critically involved in epileptic processes. Therefore astrocytes are indispensable for normal functioning of neurons. Both the presence of hypertrophic astrocytes as well as their loss may have a serious impact on the disease severity.

Treatment

Treatment in RS has two aims: first, to reduce (or ideally: eliminate) the epileptic seizures, and secondly, to counteract the progressive tissue loss during the acute disease stage in order to improve the functional long-term outcome of patients.

Anti-seizure treatment

Antiepileptic drugs are started as soon as seizures start, but the seizures are often refractory to treatment. These drugs have no effect on the underlying course of the disease. Treatment should be adjusted to cause only a minimum of side-effects.[54] Injections of botulinum toxin have been successfully applied against localised EPC and other involuntary movements.[55,56]

The most efficient treatment against seizures has been hemispherectomy with seizure freedom rates of up to 85% (for a summary of outcome studies, see ref. 23). The anatomical hemispherectomies originally performed have now been largely superseded by functional hemispherectomy, involving disconnection techniques. Most neurosurgeons agree that in experienced centres, the individual technique of deafferentation should not influence seizure outcome, but only the rate of complications (lower with less invasive procedures). The exclusion of one hemisphere leaves the patient with a spastic hemiparesis without fine finger movements but usually with preserved walking ability (if there has not been a major surgical complication, if the patient was ambulatory prior to the operation and if he is not left with extremely frequent seizures afterwards).[57] In addition, a hemispherical procedure inevitably leads to a homonymous hemianopia. Patients seem to adapt rather well to this kind of disability.[58] Exclusions of the dominant hemisphere lead to high-grade aphasias. Whereas in such patients some receptive abilities may be regained postoperatively, no more than a telegraphic speech output is achieved by them.[59] The cognitive performance beyond the language aspect is not relevantly impaired by exclusion of the diseased hemisphere.[60] Sometimes (apparently because of the postoperatively lowered or even totally eliminated drug load and seizure activity), patients achieve a strong relief and a clear improvement in their day-to-day abilities.[61] The mortality of hemispherectomy in its modern variants (in RS and other conditions) has been 0–4%, the complication rate (including hydrocephalus requiring shunt placement) 0–44% [57,58,60,62–65]. Such a wide range in complications is striking. One important variable that accounts for this is the surgical methodology utilized, whether based on resection or disconnection. Disconnective techniques (functional hemispherectomy and hemispherotomy) are associated with a lower incidence of complications.[65–68] It must be noted that more focal resections have never been reported to be successful. They lead to an improvement in seizure control only in the short term, if at all.[62,69]

Treatment directed against hemispheric cerebral degeneration

Existing data indicate that in RS brain cells degenerate because of chronic inflammatory processes. Immunosuppressive or immunomodulatory treatments are therefore promising candidates to prevent tissue loss and improve the functional long-term outcome of affected individuals. Several treatment approaches have been reported in case reports or small, usually uncontrolled patient series, mostly with beneficial effects. As judged from these publications, most positive experience exists with long-term corticosteroids,[13,70,71] intravenous immunoglobulins (IVIG),[70–72] plasmapheresis or protein A immunoabsorption, [71,73,74] and oral tacrolimus.[75]

Suggestions for individual treatment regimens

The majority of RS patients suffer from epileptic seizures. Therefore, anticonvulsive pharmacotherapy is usually indicated. Epilepsy due to RS is often refractory to treatment and EPC is notoriously difficult to control: it is important to avoid excess treatment, and particularly polytherapy with multiple antiepileptic drugs, with their associated adverse effects, most prominently sedation.[54] Injections of botulinum toxin may be helpful in the management of involuntary movements and localised myoclonus associated with RS.[55,56] If, as is common, intractable seizures persist, the option of hemispherectomy should be considered and the potential benefit should be weighed against the deficits that are to |be expected. Most centers would not perform this operation in patients with still functional fine finger movements or patients with language representation within the affected hemisphere. If, however, the condition or its treatment causes such severe impairments that the expected benefits of surgery appear to outweigh the likely deficits, hemispherectomy may be offered.

In those patients in whom hemispherectomy is considered inappropriate, long-term immunotherapy with one of the above named treatments is indicated if the condition is still progressive (as judged by the clinical and neuroradiological course over the previous 6–12 months). The principal aim of this type of intervention is prevention of structural and functional

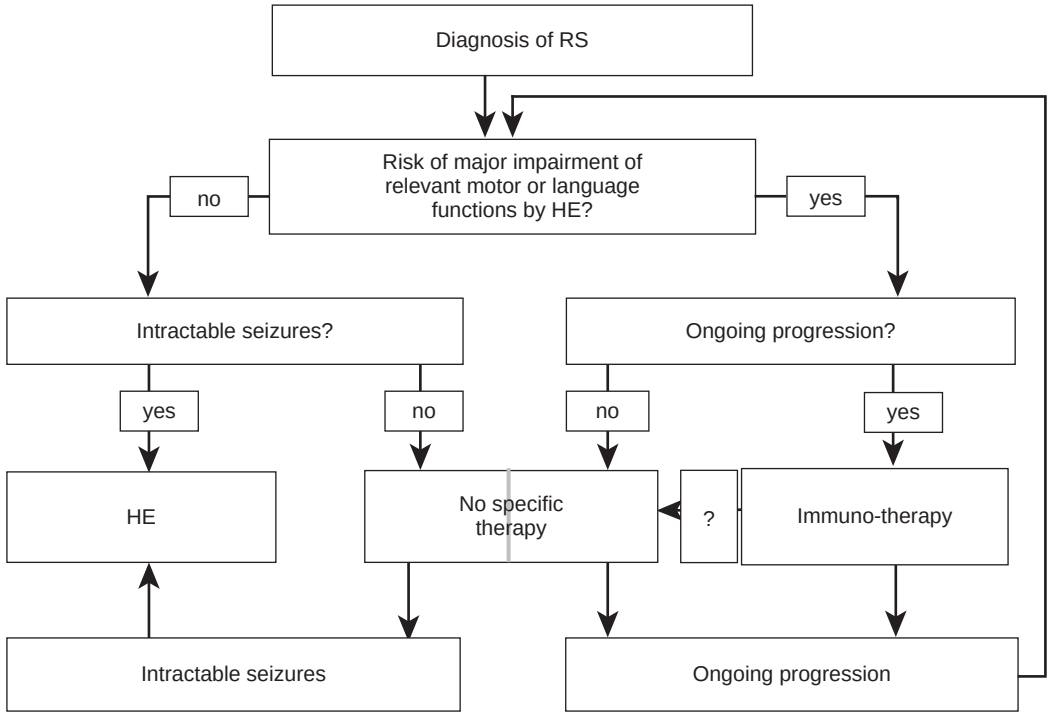

Figure 42.1. Therapeutic approach to a patient with Rasmussen syndrome (with permission from ref. 23). HE = hemispherectomy in one of its modern variants.

decline of the affected hemisphere. There is insufficient evidence to recommend any specific regimen. The most frequently reported successful regimens are: (1) long-term corticosteroids[13,70,71,76]; (2) intravenous immunoglobulins (IVIG)[70–72,77–79]; (3) corticosteroids plus IVIG[70,80,81]; (4) plasmapheresis or protein A IgG immunoadsorption[71,73,74,82]; and (5) tacrolimus.[75]

In general, the tolerability and the effect of long-term immunotherapy should be evaluated every 6–12 months. If the disease progresses during this time in the form of additional neurological deficits or increasing cerebral hemiatrophy, the treatment should be changed. When treatment is able to prevent further disease progression, it is unclear when immunotherapy may be discontinued. One might estimate that it would be reasonable to continue treatment until the patient's condition has been stable for at least 3 years (rather, for a longer period of time).

Management algorithm

The European consensus recommendations for therapeutic management of RS[23] are shown in Figure 42.1.

43 The Landau–Kleffner syndrome

AM Kanner, A Balabanov, TP Hoeppner, and R Byrne

Introduction

The Landau-Kleffner Syndrome (LKS) is an acquired epileptic aphasia or verbal auditory agnosia of childhood that results from an epileptogenic lesion in speech cortex (or that impacts speech cortex) during a critical period of language development. LKS is a disorder that occurs in children who have already developed age-appropriate language function and it is one of the epileptic encephalopathies with the electrographic pattern of Continuous Spikes and Waves during Slow Sleep (CSWS). The LKS was described in 1957 by William Landau and Frank Kleffner[1] in a report of six children, five of whom developed an acquired aphasia in association with an epileptic seizure disorder consisting of 'petit mal' 'grand mal' and myoclonic seizures. The aphasia had developed over days to months and persisted from 2 weeks to several years. These authors attributed the language dysfunction to the impact of the epileptic activity in language cortex. Indeed, they identified bilateral epileptiform activity in the children's EEG recordings pointing out the predominant involvement of the temporal lobes and suggested a relation between the severity of the paroxysmal discharges on EEG and the severity of language disturbance. In 1989, LKS was included in the International Classification of Epileptic Syndromes,[2] giving it legitimacy as a recognized clinical entity.

Epidemiologic aspects

The actual incidence and prevalence of LKS remains unknown at this time. Its prevalence is rare if the strict clinical diagnostic criteria proposed by Landau and Kleffner are applied. Recognition of LKS has increased over time as 81 cases were reported between the years of 1957 and 1980 and 117 cases between 1980 and 1990. Yet, the reported cases are more likely to include children with the more severe forms of the disease, while those in whom language disturbances remit spontaneously after a short period of time are less likely to be recognized and reported.

Ascertainment of the actual prevalence and incidence of LKS has been further complicated by the 'dilution' of its diagnostic criteria in the last decade. Indeed, the term 'LKS-look-alike' disorder has been applied to children with language disturbances who in the past would have been considered to suffer from an Autistic Spectrum Disorder (ASD) or children with the CSWS syndrome.[3] This diagnostic confusion has significant implications when the surgical option is being considered, as epilepsy surgery is thought to be more likely to improve language disturbances in children with 'true' LKS, while this does not appear the case in children with LKS-look-alike or those with CSWS syndrome or ASD (see below).

Etiology of LKS

The LKS does not have a single etiology. For example, an analysis of neuropathologic specimens of 22 consecutive children that underwent epilepsy surgery at the Rush Epilepsy Center revealed a variety of abnormalities: astrocytosis was identified in 11 (52%), ectopic neurons in two (9.5%), focal displasia in another two (9.5%), while no abnormal findings were identified in six patients (29%); no specimen was available for analysis in one child. Likewise, Cole and collaborators[5] have identified a variety of pathologic entities in their series of children with LKS including neurocysticercosis, encephalitis, vasculitis, subpial gliosis and neuronal migration disorder. It should be noted that the absence of pathologic findings in several of these children may be a function of having taken an insufficient amount of tissue for neuropathologic analysis as there is hesitation to remove tissue from presumed language areas, even if they show the most active epileptic discharges and the mapping of eloquent cortex is not an option when language is so severely impaired.

Clinical manifestations of LKS

The diagnosis of LKS is based on a set of clinical, electrographic and neuropsychological characteristics.

Clinical criteria

The clinical manifestations of LKS include language disturbances, behavioral problems with or without sleep disturbances, epileptic seizures (and/or very abnormal EEG recordings with epileptiform activity), and abnormal findings in verbally mediated cognitive functions with sparing of visually mediated functions.[6–9] The symptoms of LKS appear between the ages of 2 and 8 years in children who had a normal language development with an acute or subacute onset, though occasionally they may take a stuttering initial course.

Language disturbances present initially as problems with verbal comprehension that progress in severity to a total inability to understand what is being said to them as well as to recognize common sounds (auditory agnosia). It is not

infrequent for these children to be initially misdiagnosed with acquired deafness.[6,7] Concurrent with, or a short time after the onset of receptive language disturbances the child starts displaying signs of expressive language deficits such as paraphasias and phonological errors. The establishment of normal language development is of the essence in distinguishing children with LKS from children with other types of language disturbances including children with an autistic spectrum disorder (ASD). In fact, it is not infrequent that parents may give an 'erroneous impression' of normal cognitive developmental milestones in their child. Yet, a careful analysis by speech pathologists of home video-tapes during the 'asymptomatic' development of these children can often reveal delayed expressive and/or receptive language functions relative to the chronologic age.

The onset of language disturbances (and of other clinical symptoms) has been linked in-time with the onset of clinical seizures or a short time after. Electrographic evidence of epileptiform activity presenting as a pattern of CSWS or long runs of bisynchronous or unilateral epileptiform discharges in temporo-parietal and frontal derivations can be identified in patients without obvious clinical seizures at the time of onset of language disturbances. These electrographic data coupled with the language disturbances help clinicians to consider the possibility of LKS.

Language disturbances can progress in a steady or fluctuating manner to a state of complete mutism in the course of a few days to a few weeks, or as stated above, in a few children, they may follow a stuttering course.[8,9] The duration of language disturbances may vary among patients. At one end of the spectrum are children that are symptomatic for periods of only days to weeks followed by complete spontaneous remission.[6] At the other end, are children whose language disturbance progresses to a global aphasia and auditory agnosia, occasionally with a waxing and waning course but with no meaningful recovery of any functional language despite multiple pharmacologic interventions.[9–17] In some children a careful history can often reveal fluctuations in the severity of language disturbances with intermittent periods of improvement in expressive and/or receptive language functions of variable magnitude. These fluctuations in symptom severity can often, but not always be associated with a parallel improvement or worsening of seizure frequency.

Children with LKS are often able to communicate through nonverbal means such as sign language. For example among 22 consecutive children with classic LKS evaluated at the Rush Epilepsy Center for epilepsy surgery, 11 (50%) had learned to use sign language.[4]

There have been unfortunately few studies that have investigated the long-term course of language disturbances in LKS patients. Mantovani and Landau[10] found a significant recovery in language functions in four of nine patients who were re-evaluated 10–28 years after the onset of their symptoms. On the other hand, only one of seven patients followed by Deonna *et al.*[11] into adulthood recovered language functions completely; a second patient recovered functional language but was left with severe dyslexia, a third patient exhibited significant deficits in comprehensive language while the other four patients continued to suffer from global aphasia. Various investigators have concluded that spontaneous recovery of functional language in the long-term is unlikely in patients with persistent language disturbances for more than one year.[9,10,12–17]

While the onset of language disturbances can be in general temporally linked to the onset of seizures, their remission does not immediately follow the control of seizures or abolition of epileptiform activity with steroids or epilepsy surgery (see below).[18]

Seizures are usually of mild severity and are often nocturnal; their clinical manifestations vary widely ranging from generalized tonic-clonic seizures (GTC) to complex partial and simple partial seizures often displaying very subtle clinical signs such as brief clonic deviation of the eyes, at times associated with eye blinking, head dropping, and minor automatisms.[18] Up to 20–30% of patients with LKS are never found to have epileptic seizures[8] and in some children seizures are identified for the first time in the course of a prolonged video-EEG monitoring study (V-EEG). Unlike the language disturbances, seizures tend to respond readily to pharmacotherapy with AEDs,[8,9] and generally subside by the age of 15.[19]

Behavior disturbances are very common in patients with LKS; their onset can precede, appear concurrently or follow the language disturbances. Motor hyperactivity, impulsivity and poor frustration tolerance are among the most frequently reported symptoms seen in up to 50% of children[8,9] and this cluster of symptoms is often indistinguishable from a severe Attention Deficit Hyperactivity Disorder (ADHD). In a study of 18 children with LKS, Robinson *et al.*[20] found behavioral disturbances in nine children, which was associated with frontal lobe discharges in *awake* EEGs.[18] Sleep disturbances can also be common and present as difficulty falling asleep and/or middle of the night awakenings associated with bouts of screams and agitation.

At the height of the auditory agnosia, some children have been reported to exhibit autistic-like features such as withdrawn and self-stimulatory behaviors. Nevertheless, children with LKS do not loose their social relatedness to others. Failure to recognize this important difference has resulted in the misdiagnosis of children with an ASD as suffering from LKS.

Behavioral disturbances can often be extremely disruptive at home and in school often requiring the use of symptomatic treatment with psychotropic drugs, such as central nervous system stimulants (methylphenidate and dextroamphetamine), antipsychotic (risperidone, haloperidol, etc.) and antidepressant drugs (i.e., selective serotonin-reuptake inhibitors [SSRI]) and alpha-adrenergic blockers such as clonidine, all of which have been found to yield mixed results. Behavioral disturbances can be expected to improve to various degrees in many but not all children following the remission of clinical seizures and/or of epileptiform activity on EEG recordings. Following epilepsy surgery, behavioral improvement can precede the recovery of language functions.

Pathophysiology

The relationship between epileptiform activity and language disturbances has been considered as the 'core' pathogenic mechanism of LKS,[1,12,18,21] but remains to be universally accepted by all investigators.[22] Deonna reviewed the arguments both for and against the role of epileptic causality of language disturbances.[21] Supportive evidence included speech recovery in some patients, coincident with the disappearance of EEG abnormalities when treated with steroid, antiepileptic agents or epilepsy surgery with multiple subpial transection (MST). Holmes *et al.*[22]

suggested that both the epileptic discharges and language disturbances were epiphenomena of underlying pathologic abnormalities in the speech areas. Arguments against an epileptic cause include the development of clinical seizures in some children long before or long after the onset of language dysfunction and the persistence of language disturbances after remission of electrographic epileptic activity. Additionally, some children never develop clinical seizures, although they typically do have abnormal EEG recordings with epileptiform activity.

Morrell suggested the following hypothesis to explain the development of LKS:[12,18]

> It is well known that different neural systems have critical periods in development during which the adult patterns of synaptic engagement are gradually established. At such times, there is first a superabundant outgrowth of axon terminals resulting in a temporary hyper-innervation of the synaptic target; this extravagant outgrowth appears to be entirely under genetic control. Over the remainder of the critical period, the synaptic contacts are extensively pruned. The pruning is selective; it is dependent on and controlled by synaptic use, i.e., environmental input. Synaptic contacts activated by use become cemented, so to speak, while those not environmentally engaged wither away.[23–29] Neural networks for linguistic function develop late and their circuitry remains malleable during the first 8 to 10 years of life.[30–33] We hypothesize, then, that the impact of epileptic activity originating from this anlage of speech cortex may result in chaotic and behaviorally meaningless activation of synaptic contacts that would have been 'pruned' under normal circumstances. Such epileptic activity may set up permanent, inappropriate and nonfunctional linkages.

Data from experimental studies in animals support Morrell's hypothesis showing that epileptogenic lesions induced during a critical period for circuit development cause the emergence and fixation of long-lasting or permanent aberrant connections.[34,35] Morrell's hypothesis and the data of Baumabach and Chow[34] and of Grigonis and Murphy[35] provide an explanation for the development of language deficits associated with the temporal gap between the onset of epileptiform activity (and/or seizures) and the failure to regain language functions after remission of electrographic epileptiform activity.

Diagnostic evaluations

An initial evaluation consists of a thorough and detailed clinical history aimed at identifying all the clinical signs and symptoms cited above and the temporal relation between the onset and course of language/behavioral disturbances and seizure activity. Auxiliary studies include a high resolution magnetic resonance imaging of the brain (MRI), an EEG study with awake and sleep recordings and a neuropsychological evaluation that includes a speech evaluation and evaluation of nonverbal cognitive functions.

EEG studies as part of an initial evaluation

As stated above, the CSWS pattern is the characteristic electrographic finding of LKS. It consists of runs of spike- and slow-wave that take up *at least 80% of slow-wave sleep* and hence the EEG study has to be scheduled to be of long enough duration to record slow-wave sleep. This may be facilitated by the use of 25 mgs of amytriptyline in a single dose. The epileptiform activity presents typically as 'apparent' bisynchronous runs of spike- and slow-wave with a wide distribution maximal in posterotemporal regions (see Figure 43.1), but in some patients it may have a unilateral distribution.

Mapping of the bisynchronous epileptiform activity can often reveal the unilateral source that propagates to the contralateral side with a 20–25 millisecond gap (see Figures 43.2a and 2b).[12,18,36]

Awake electrographic recordings may show epileptiform discharges with a focal distribution in frontal, temporal or parietal regions and usually in a discontinuous pattern,[18,19] though temporal spikes are most frequent. Background activity during wakefulness may be normal. Serial EEG recordings may vary within the same patient in the amount and degree of focality of epileptiform discharges.[9] Furthermore, a normal sleep record does not necessarily rule out the diagnosis of LKS, as fluctuation in the severity of EEG abnormalities is a rather common finding. The absence of epileptiform activity may be often encountered in children with steroids or benzodiazepines, even in the absence of any clinical improvement.

Electrophysiological studies as part of a presurgical evaluation

Epilepsy surgery for the treatment of LKS follows the same principles that any other type of epilepsy surgery: there has to be concordance between interictal and ictal data obtained during V-EEG and with other neurophysiologic studies such as MEG. Thus, the first study is a V-EEG with scalp electrodes with the aim of identifying the presence of a sylvian dipole and establishing whether the epileptogenic zone extends beyond the intra and perisylvian region. In addition, the goal of the V-EEG is to identify clinical seizures that may have gone unrecognized up to then by the parents (up to 30% of children with LKS are reported not to have seizures), because of their subtle clinical manifestations.

Sylvian dipole

As stated above, the mapping of epileptiform discharges with referential montages or with source localization programs can identify a dipole with negativity in the frontal regions and positive polarity in temporal electrodes.[37] Thus the epileptiform discharges in LKS reflect a generator source represented by a tangential dipole in the inferior bank of the sylvian fissure (on the superior surface of the temporal lobe); therefore we refer to this pattern as the sylvian dipole. The search of a sylvian dipole must be done in the first discharge of a run of epileptiform discharges, as subsequent discharges may reflect the area of spread of the epileptic activity beyond the perisylvian area.

Methohexital suppression test (MHXST)

The vast majority of patients' electrographic recordings reveal a CSWS pattern with 'apparent' bisynchronous discharges with a wide field of distribution but with maximal electronegativity in temporal lobe derivations. The onus of the

Figure 43.1 Electrographic pattern of CSWS.

electroencephalographer is to determine whether the epileptiform activity has a unilateral source within the sylvian region, or is of bilateral independent origin.

The use of methohexital (MHX) is aimed at identifying independent epileptiform activity within the CSWS; it is a barbiturate known to block excitatory synaptic transmission and, at low doses, to enhance inhibitory synaptic action.[38,39] During intravenous infusion of MHX at doses high enough to cause electrocerebral silence, almost all excitatory transmission is abolished, with the exception of a few oligosynaptic systems with high safety factors, such as the direct thalamocortical relay (see Figures 43.3a and 3b). Under these circumstances, autonomous and truly independent epileptogenic lesions show a marked resistance to synaptic blockade and continue to fire; the epileptiform discharges stand out sharply against a flat EEG background.

Conversely, epileptogenic lesions that are not independent and depend on synaptic input (i.e., epileptic discharges secondarily driven from a primary focus) are silenced along with the ongoing EEG rhythms.

The MHX suppression test (MHXST) is carried out by administering the drug at a rate of 100 mg/min until a 60 s period of total electrocerebral suppression is reached. The test is carried out in the V-EEG monitoring unit at the patient's bed side with an anaesthetist present, since at the deepest levels of MHX anaesthesia, a few minutes of apnoea occurs. The anaesthetist provides bag-breathing with room air. Intubation has never been necessary in more than 400 cases and the only morbidity has consisted of mild transient acceleration of the heart rate and transient hiccups.

Magnetoencephalography studies

In the last ten years, MEG has become one of the presurgical tests of LKS. MEG is sensitive to epileptic activity originating from the depths of sulci, such as the sylvian fissure, because it reveals magnetic fields generated by transmembrane synaptic currents oriented in a plane tangential to the skull surface.[40–42] MEG performed on a small number of patients with LKS revealed a focus of epileptiform activity in the posterior temporal area adjacent to the sylvian fissure, supporting an origin in the dorsal surface of the superior temporal gyrus (see Figure 43.4a) and propagation to homotopic regions contralaterally (see Figure 43.4b).[12,42]

The use of MEG has been useful in identifying children with Autistic Spectrum Disorder (ADS) that may have been misdiagnosed as LKS. Indeed, Lewine *et al.*[40] compared the MEG data between six children with LKS and 50 children with ADS. In all the children with LKS, MEG revealed primary or secondary epileptiform involvement of the left intra/perisylvian region, with all but one child showing additional involvement of the right sylvian region. In all cases of LKS, independent epileptiform activity beyond the sylvian region was absent, although propagation of activity to frontal or parietal regions was seen occasionally. MEG identified epileptiform activity in 41 of the 50 (82%) children with an ASD that included intra/perisylvian regions in 85% of the cases and

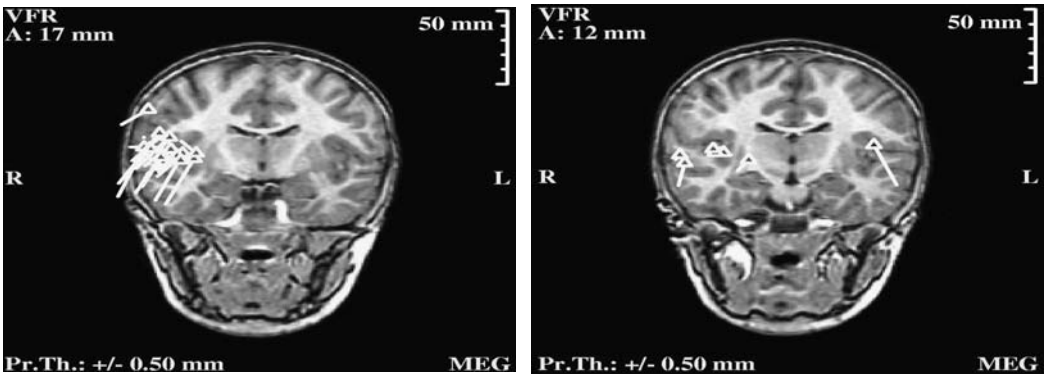
Figure 43.3 (a) Compressed recording of the initial phases of the MHXST. The initial segments of the recording reveal an activation of epileptiform activity followed by the appearance of periods of electrocerebral suppression of longer duration as the infusion of MXT progressed at a rate of 100 mg/min. (b) Following the disappearance of the background activity, a superimposition of recordings from homologous electrodes reveals an initial discharge in the left that rapidly propagates to the right side.



(a) (b)

Figure 43.4 (a) MEG dipole co-registered on MRI reveals a right intrasylvian source of epileptic activity. (b) Red triangles indicate the source of the epileptic activity in the right sylvian cortex, while the blue triangles represent the propagated dipole to the contralateral side.

75% of the ASD children with epileptiform activity demonstrated additional nonsylvian zones of independent epileptiform activity. Thus, this study documented the utility of MEG to identify different location(s) of epileptogenic zones in LKS and in ASD, as well as the different electrographic patterns of their recorded epileptiform activity.

The valuable use of MEG has been reported in other small case series of LKS children. Thus, Pateau *et al.*[41] carried out an MEG in four children. In all patients, the earliest spike activity originated in the intrasylvian cortex, spreading in one subject to the contralateral sylvian cortex within 20 ms. Secondary spikes occurred within 10–60 ms in ipsilateral perisylvian, temporo-occipital, and parietal-occipital areas. A single intrasylvian pacemaker initiated all epileptic activity in two patients, whereas the other two had independent left- and right-hemisphere circuits or focal spikes. MEG source dynamics predicted the results of the methohexital suppression test in two patients and was confirmed by surgery outcome in one patient, in whom all epileptic activity ceased after a small transection of the sylvian pacemaker.

Sobel and colleagues found that 13 of 19 patients with LKS had perisylvian MEG spikes.[42] In 10 of the patients, the spikes were bilateral, and in three they were unilateral. Four children had nonsylvian spikes. Interestingly enough, these children displayed various other behavior and cognitive dysfunction in addition to the aphasia, which questions their diagnosis of LKS and confirms the data reported by Lewine *et al.*

V-EEG with intracranial recordings

In the case of discordant data derived from MEG and scalp-V-EEG or if lateralization of the source of epileptic activity cannot be achieved with non-invasive studies, repeat V-EEG with intracranial electrodes is considered. At the Rush Epilepsy Center, two or three pairs of eight contact epidural electrodes are used. These are placed parallel to the sylvian fissure, one about 1 cm. superior to the fissure, the second over the fissure and the third about 1 cm inferior to the fissure. A repeat MHXST is carried out with these electrodes and at the time of surgery, the electrodes contralateral to the side of surgery are kept in place for recording of the epileptiform activity throughout the procedure.

Neuroimaging studies

MRI

High resolution MRI studies must be carried out in all presurgical evaluations of LKS, as they may reveal subtle malformations of cortical development that may go undetected with standard MRI. In addition, this new technology lends itself to volumetric measurements of various neuroanatomical structures. A case in point is illustrated in a recently published study by Takeoka *et al.* who compared the cortical volume of the superior temporal areas corresponding to the auditory association cortex in four children with LKS and four children with other types of focal epilepsy.[41] The authors divided the entire neocortex into parcellation units and counted the number of voxels in each parcellation unit. All children with LKS had a reduction of 36–51% in the cortical volume of the superior temporal areas. It is not clear, however, whether the smaller volume reflects a cause or consequence of this disorder.

Positron emission tomography studies (PET) have been carried out in a small number of patients with LKS. In studies performed in the awake state, PET with 2-[^{18}F] fluoro-2-deoxy-D-glucose (^{18}F-FDG) have shown an area of decreased blood flow or glucose utilization, while the opposite occurs when the radionucleotide is injected during slow wave sleep when recordings reveal a CSWS pattern. For example, Da Silva *et al.*,[44] evaluated 17 children with LKS with 18-FDG PET; 15 out of the 17 patients had bitemporal glucose hypometabolism and in two the area of hypometabolism was unilateral. The patients were awake for the uptake period of FDG. On the other hand, studies done on sedated patients with induced continuous spike-and-wave discharges showed a focal area of increased blood flow or glucose utilization.[12,45,46] Maquet and colleagues reported that some patients who underwent [^{18}F]FDG-PET after the resolution of the active phase of spike-and-wave discharges showed persistent hypometabolism in the areas that previously showed hypermetabolism, documenting long-lasting metabolic alterations.[45] Of note, areas of cortical hypermetabolism are not specific to LKS and can be seen as well in children with CSWS syndrome.[46]

Neuropsychologic and speech evaluation

The purpose of the neuropsychological and speech evaluations is twofold: to identify the type (i.e., expressive vs. receptive vs. both)

and severity of language disturbances; and to establish whether cognitive problems are restricted to verbally mediated functions or if there is involvement of nonverbal cognitive functions. Two tests are typically (but not exclusively) used for evaluation of language functions. The Peabody Picture Vocabulary Test-revised (PPVT-R) is a measure of receptive vocabulary. During the test the child is asked to point to one of four pictures displayed on a card as depicting the word spoken by the examiner. The Expressive One Word Picture Vocabulary Test-revised (EOWPVT-R) is a test of expressive vocabulary. The child is shown a picture and asked to name it.

The findings of neuropsychological testing have been associated with different discharge patterns of epileptiform activity. For example, Guilhoto and Morrell[47] carried out a retrospective analysis of 19 cases referred with a presumptive diagnosis of LKS, and with the EEG pattern of CSWS. They separated the children into two groups: group 1 included those erroneously thought to have LKS (also known as 'LKS-look-alikes', $n = 8$) and group 2 those with 'true' LKS (cognitive disturbances restricted to the verbal domains, $n = 11$). Mapping of the distribution of electrical abnormality revealed that 6/8 patients in Group I had widespread, multifocal discharge. One out of the eight cases had bilateral high parietal disturbance and 1/8 had a primarily left-sided abnormality that became bilateral and multifocal during slow-wave sleep. All of the patients in group 2 (11/11) showed discharges limited to the parietal-temporal region of both hemispheres which revealed the characteristic sylvian dipole with frontal negativity and temporal positivity, as described above.

Differential diagnosis

The differential diagnosis of LKS includes CSWS syndrome, the ASDs and secondary aphasias.

CSWS syndrome

As stated above LKS is not the only epileptic encephalopathy with a CSWS electrographic pattern. The CSWS syndrome has been recognized as a distinct entity by the Commission on Classification and Terminology of the International League against Epilepsy (Commission on Classification and Terminology of the International League Against Epilepsy and by the International Classification of Diseases (ICD-10).[2,48] This syndrome was initially described by Patry *et al.* in 1971 as 'subclinical electrical status epilepticus during sleep'[49] and then retitled by Tassinari as electrical status epileptic during sleep (ESES) in a report of six children, aged 7 to 12 years old, five of whom were mentally retarded and all exhibited language disturbances, epileptic seizures and very abnormal EEG recordings consistent with a CSWS pattern described above. The epileptic seizures were of various types including tonic, atonic, clonic, generalized tonico-clonic and atypical absences. The severity of mental retardation was related to the age of onset.[48] Tassinari later changed the name of this syndrome to CSWS syndrome.[3]

The following differences between LKS and the CSWS syndrome can be identified based on data from publications by Beaumanoir[50] and Bureau,[51,52] that included analyses of clinical and electrographic findings in 71 children with LKS and 103 children with CSWS syndrome. Landau-Kleffner syndrome tends to affect a slightly younger population, presenting first with language dysfunction and behavioral deterioration. In CSWS syndrome, the affected children tend to be slightly older, presenting with more global neuropsychologic and behavioral deterioration in addition to the language dysfunction.[51,52] The severity of the seizures and EEG abnormality are more pronounced in CSWS syndrome in which seizures are more likely to be significantly more frequent of all types including atonic seizures with falls, absence and atypical absences, GTC and hemiclonic seizures. The spike-and-wave discharges are maximal in the centro-temporal or posterior temporal regions in LKS and in the frontal head region in CSWS syndrome. The seizures in CSWS syndrome are often difficult to control, primarily among the subgroup of patients with atypical absence seizures and drop attacks which are resistant to treatment with AEDs. The patients with CSWS syndrome had more frequent MRI abnormalities (33%) than children with LKS (13%). Interestingly enough, seizure remission was comparable between the two groups after resolution of the CSWS pattern.[49,52]

Autistic spectrum disorders are behaviorally defined syndromes with various etiologies that are manifested by deficits in verbal and nonverbal communication, social interaction deficits and repetitive behaviors or a restrictive array of interests.[53] About 30% of children with ASD experience a language regression and one-third develop epilepsy by the time they reach adolescence.[54] Furthermore, interictal epileptiform discharges in centro-temporal regions have been identified in a certain percentage of children with ASD that never go on to experience clinical seizures.[54,55] Recently, the term of autistic epileptiform regression has been coined to refer to children with autistic regression in the context of an epileptiform EEG.

Tuchman[54] has investigated the association of epileptic seizures and language regression in 585 children with ASD. No difference was found in seizure occurrence between the children with or without language regression. On the other hand, the EEG recordings of children with language regression were significantly more likely to exhibit interictal epileptiform discharges (14% vs. 6%, $p = 0.02$).

In contrast to LKS, a normal development of language cannot be traced in many children with ASD. Rapin[53] has also suggested that in patients with reported 'normal' language development, a careful history may in fact reveal that such was not the case. As stated above, a review of family video tapes may help the speech pathologist establish whether the child already exhibited a developmental delay before the 'more overt' evidence of language deterioration was identified by parents. Children with ASD have been found to exhibit a compromised drive to communicate, difficulty with comprehension of gestures, facial expression and tone of voice and immediate echolalia (pronoun reversal) delayed echolalia (scripts, formulaic speech) and perseveration. In addition they display self-stimulatory behavior, marked difficulty with adjusting to minimal changes and loss of social relatedness.[53,56] From a cognitive standpoint, these children display across the board cognitive deficits.

The differential diagnosis of LKS also includes differentiation with developmental language disorders with or without an epileptiform EEG, which consist of lack of development of age appropriate language skills in an otherwise cognitively and behaviorally normal child.[54] Finally, since hearing difficulties

may present as apparent language impairment, auditory function should be assessed by behavioral and/or electrophysiological means.

Nonsurgical treatment

Pharmacologic treatment

There is a dichotomy in the response to AEDs of clinical seizures and language disturbances. Indeed, remission of clinical seizures is readily achieved in a majority of patients, while the opposite is true when it comes to cognitive disturbances. Often, the improvement of language functions may be more an expression of a spontaneous remission than a real therapeutic effect of AEDs, above all in the early phases of the disease. Furthermore, due to the rarity of the disorder controlled clinical trials have not been done.

Pharmacologic treatment of LKS has included trials with AEDs, steroids and IV immunoglobulin (IVIG).

Antiepileptic drugs

Using the trial and error approach some investigators have suggested that AEDs like valproic acid (VPA) benzodiazepines and ethosuximide can yield (at least partially and/or temporarily) a therapeutic impact in both language and seizure disturbances while carbamazepine, and phenytoin can worsen the course of LKS.[57] In fact these two AEDs were found to increase the duration of spike-wave activity in sleep; phenobarbital was thought to have no therapeutic effect on language functions but to worsen the child's behavioral problems.

In most cases an initial trial with valproic acid is usually carried out before trying any of the other AEDs. Clobazam has been reported to significantly reduce continuous spike-wave discharges in several small studies, associated with language improvement.[57,58] Vigabatrin,[59] felbamate,[60] lamotrigine, and recently levetiracetam have also been reported as effective as well.

Diazepam has been successfully tried in the management of language and behavioral disturbances in children with LKS. In a protocol that calls for the administration of rectal diazepam (Diastat®) at a dose of 1 mg/kg under V-EEG on day one, Riviello *et al.* have found suppression or reduction of the epileptiform activity associated with an improvement of language functions in a small group of children with LKS. The child is then placed on a maintenance oral dose of 0.5 mg/kg/day and kept on this dose for three to six months (*Riviello JJ*, unpublished data). In the case of bisynchronous epileptiform activity, the administration of rectal diazepam resulted in suppression of the propagation of the epileptiform activity to the side contralateral to the seizure focus (*Kanner*, unpublished data).

Steroids

The use of steroids in LKS has included trials with prednisone and ACTH. Oral prednisone has been given as daily doses or as pulse doses on a weekly basis to minimize potential adverse events. Trials have ranged from 3–6 months to long-term trials, depending on clinical response, tolerability and the preferences of individual centers. Some reports have suggested a favorable acute and long-term response of short and long-term duration.[62–64]

The use of ACTH calls for 80 U/day with a three-month taper. Most centers have preferred the use of oral prednisone. At the Rush Epilepsy Center, it is started at a dose of 2–3 mg/kg/day and tapered down over the course of 3 months. The trial of prednisone may be extended at minimal effective doses, provided that the child has derived a significant improvement in language function and *in the absence* of significant adverse events such as behavioral problems (such as aggressive behavior, motor hyperactivity, impulsivity (beyond that already caused by the LKS), sleep disturbances, hypertension, diabetes, obesity. Long-term use of steroids can be frequently associated with the risk of developing the above-cited problems in addition to a Cushingoid appearance, cataracts and osteopenia/ osteoporosis.

Sinclair and Snyder[62] recently reported on their experience with long-term steroid therapy in eight children with LKS and two with CSWS; three were females and seven males and the age of onset ranged from 2–11 years (mean 7.5 years). The patients received prednisone 1 mg/kg/day for 6 months, 1 year, then yearly. After a mean follow-up period of 4 years (range 1–10 years), all but one patient manifested significant improvement in language, cognition, and behavior, which persisted after discontinuation of steroids. Side-effects were reported in four patients and were transient; they included weight gain (2), behavioral change (1), and hypertension (1). Tsuru *et al.*[63] have reported on the use of high-dose IV steroids in two children with LKS. Both patients were treated with high-dose methylprednisolone sodium succinate (20 mg/kg daily) for three consecutive days. This infusion was repeated three times with a 4-day interval between treatments, which resulted in a rapid improvement in speech ability. After intravenous therapy, prednisolone was given orally (2 mg/kg daily for 1 month, then gradually withdrawn), which maintained the clinical improvement in language functions. Lerman *et al.*[64] reported on the treatment of four children with LKS with early and prolonged ACTH or corticosteroid therapy, with high initial doses. In all four cases the EEG promptly became normal, with subsequent long-lasting remission of the aphasia and improvement of seizure control. Three to 6 years after discontinuation of hormone therapy the children were off medication and free from seizures and language disability. Marescaux[58] treated three children with LKS with steroid therapy which resulted in improved speech, suppression of seizures, and normalization of the EEG in the three. These authors advocated the administration of corticosteroids in high doses as soon as the diagnosis is established and to maintain on these doses for several months or years to avoid symptom recurrence.

While steroid therapy is the pharmacologic treatment most likely to yield to significant improvement in language disturbances, its discontinuation is often followed by symptom recurrence or loss of gains made. For example, in a study of 22 children with LKS evaluated at the Rush Epilepsy Center,[4] 20 underwent a trial with prednisone. Nine of these children (45%) regained functional language but steroids had to be discontinued because of adverse events. Of note, a recovery of functional language with steroids was a predictor of a recovery of functional language six months after epilepsy surgery.

Intravenous immunoglobulin

The use of IVIG has been reported in isolated cases or small patient series. Mikati *et al.*[65] reported the first case of a

31-month-old child with LKS treated with IV IG 500 mg/day for 4 days followed by remission of language disturbances and electrographic epileptiform activity. In one series of 11 patients, however, only two patients had long-lasting improvement of language functions.[66]

Clearly, pharmacotherapy of LKS has been disappointing with respect to the treatment of language disturbances, either because of lack of efficacy (of AEDs) or significant adverse events (of steroid therapy).

Surgical treatment

When should surgery be considered for the treatment of LKS?

The role of surgical treatment of LKS continues to be a source of debate among epileptologists and pediatric neurologists with some advocating[18,67] and others questioning it.[68] The aim of epilepsy surgery for LKS is to yield a remission of the language disturbances and render the patient free of any clinical seizures. In most patients, the latter goal can usually be reached with AEDs, thus the most frequent reason to consider the surgical option is to achieve the former aim. The authors that favor the use of epilepsy surgery base their decision on the favorable results of this treatment modality in a group of children in whom less aggressive treatments are not an option. Thus, in 1995, Morrell *et al.*[18] published the first series of 14 children with LKS who underwent surgical treatment consisting of MST of the epileptogenic area localized in intra and perisylvian cortex. Morrell's rationale for suggesting the use of MST in LKS included the following arguments: (1) children with LKS whose language disturbances failed to remit spontaneously after one year or longer were unlikely to have functional language in adulthood. (2) Pharmacotherapy with AEDs is more often than not unlikely to yield a remission of language disturbances, while therapy with steroids may result in significant improvement but is associated with potentially serious long-term adverse events. (3) The surgical technique MST was developed with the specific aim of abolishing epileptic activity from eloquent cortex. Thus, Morrell and his group suggested that epilepsy surgery could be considered in children with LKS that had failed to regain functional language for a period of at least 2 years despite multiple pharmacologic trials with AEDs and steroid therapy. The authors that oppose the consideration of surgery in LKS have questioned the effectiveness of MST which they claim 'does not substantiate the perioperative complications'. This section of the article will address this dilemma.

Experience from previous case series

In their case series of 14 children with LKS, Morrell *et al.*[18] found that seven children exhibited significant improvement of language functions, with four additional children having some improvement. Among the three children in whom the surgical procedure had no impact, two had bilateral independent (ictal) foci and below age appropriate nonverbal cognitive functions, while one child was found to have a focal Rasmussen's encephalitis. In a subsequent study, Grote *et al.*[69] reported on the language changes established with neuropsychological testing following MST in 14 children with LKS, 10 of whom were part of the initial series and four patients that had undergone surgery since the publication of the initial case series. Eleven of the 14 children exhibited significant postoperative improvement on measures of expressive or receptive vocabulary, but only four (29%) were in a regular class without receiving any special services at school. Grote identified a positive correlation between the pre- to postsurgical scores and the postsurgical follow-up duration. In contrast to observations made by Bishop[13] and Dulac[14] in nonsurgical case series, age of onset of LKS was not predictive of language recovery after surgery. On the other hand, Grote *et al.* found an inverse correlation between the time elapsed between onset of LKS symptoms and time of surgery and language improvement.

Irwin[70] reported a series of five children with LKS who underwent MST at Guy's Hospital in London. All five children experienced a significant improvement of language functions, but none had achieved an age-appropriate level. The CSWS pattern that was present in all patients before surgery was eliminated after MST.

The different postsurgical language outcome between Grote's[69] and Irwin's studies can be explained by a longer postsurgical follow-up in Grote's study, as he clearly demonstrated a correlation between degree of language improvement and duration of postsurgical follow-up. The second difference may reside in an earlier surgical intervention after the start of symptoms in Grote's study, as he shows an inverse relationship between recovery of receptive language functions and time between onset of symptoms to surgery. This observation seems to be in agreement with Irwin's observations made by his colleagues at Guy's hospital.[20] Indeed in a study of 18 children with LKS followed up for 67 ± 46 months, five of whom were treated with MST[70] and 13 with only pharmacotherapy, recovery of language functions either spontaneously or after pharmacotherapy or MST seemed to be unlikely after 3 years of a CSWS pattern.

In addition to MST, temporal lobectomy has been used for the treatment of LKS. Cole *et al.*[71] reported two patients with LKS both of whom were mute prior to surgery. One patient was speaking in full sentences after 10 months. The patient experienced a recurrence of language disturbances and was lost to follow-up. The second patient had surgery as an adult by which time she had learned to communicate by sign language. One year after surgery her language functions had improved but were not normal.

As with any type of epilepsy surgery, the proper selection of surgical candidates is of the essence to ensure a successful postsurgical outcome. Unfortunately, the total number of surgeries performed so far is too small to generate analyzable data that can help identify the variables associated with the best postsurgical outcome. Based on the experience of the first 14 patients operated at the Rush Epilepsy Center, Morrell *et al.*[16] concluded that the ideal surgical candidates are children that meet the following criteria: (1) acute (or sometimes stuttering) onset of aphasia and auditory agnosia in an otherwise normal child who has already developed age-appropriate language; (2) failure to show any signs of improvement of linguistic functions for 2 years; (3) severe, clearly epileptiform, EEG abnormality characterized by unilateral or bilateral spike-wave discharge in slow-wave sleep; (4) electrophysiological evidence of a unilateral origin of the bilateral epileptiform

discharge; (5) neuropsychological test findings indicating relative preservation of nonverbal cognitive capacities in the presence of devastating loss of verbal skills. Of note, the presence of clinical seizures is not mandatory. Morrell made a point of emphasizing the risk of considering surgery in children with the 'LKS-like' diagnoses, which in reality are likely to be suffering from a pervasive developmental disorder.

Surgical technique

Multiple subpial transection

Why MST?

In 1995 Morrell *et al.*[18] suggested using MST for the treatment of LKS, since this is a surgical technique developed with the aim of eliminating epileptic activity from eloquent cortex (i.e., language cortex) without interfering with its function. The technique is based on the following three principles: (1) interruption of intracortical horizontal fibers which are necessary for the propagation and synchronous discharge of epileptic activity without which a seizure cannot occur.[72,73] (2) The preservation of the vertical columnar organization of the cortex which constitutes the basic functional unit of cortical physiology.[74–77] (3) Transections done at 5 mm intervals throughout the epileptogenic area, since the critical mass of cortex for synchronization of epileptiform discharges is at least 5 mm.[78]

Operative procedure

As stated above, the typical source of epileptic activity involves intrasylvian cortex only or in conjunction with perisylvian cortex, though in occasional cases an additional epileptogenic area has been identified in frontal and anterolateral cortex. Accordingly, the extent of the craniotomy is aimed at exposing the sylvian fissure, anterior and posterior language areas, including the angular and supramarginal gyrus. Opening of the sylvian fissure must always precede any MST of perisylvian cortex as the edema ensuing from MST may make the opening of the sylvian fissure more difficult (see Figure 43.5). The location and extent of the opening of the sylvian fissure is based primarily on MEG data.

Transections are carried out with a transection hook, which has a handle, a malleable shaft and a tip that is 4 mm long (which parallels the cortical width) and 1 mm in width. The tip has been designed to be blunt and angled at a 105° in order to minimize the risk of snagging or injuring vessels (see Figure 43.6).[18,79]

In general, the cortex accessible for transection is limited to the crown of the gyrus, while that at the depth of the sulcus remains outside of the transected cortex. The gyral cortical pattern is fairly constant among individuals, but the microgyral pattern of individual gyri may vary considerably. Accordingly, a careful inspection of each of the gyri, its microgyral pattern and vascular supply is of the essence before the transections are carried out. Transections are done perpendicular to the long axis of the gyrus at 5 mm intervals. They are first performed in the more dependent areas to avoid the problem of subarachnoid blood obscuring the other areas. At the edge of the visible gyrus, in an avascular area, a 20-gauge needle is used to open a hole in the pia, through which the tip

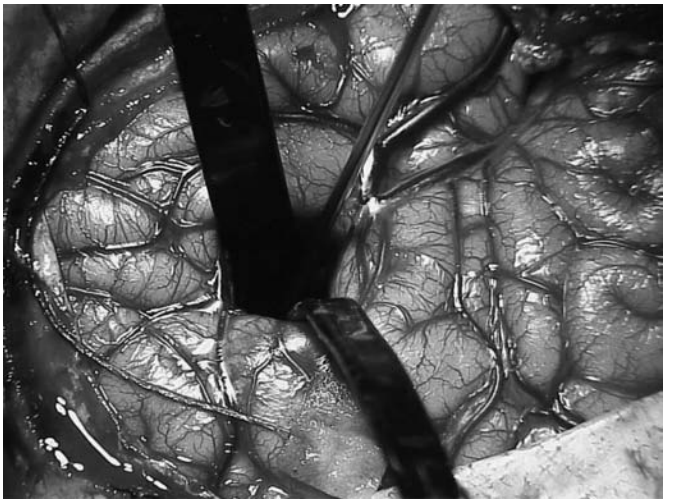


Figure 43.5 Opening of the sylvian fissure prior to the start of MST in intrasylvian and perisylvian cortex.

of the transector is introduced into the gray matter layer and advanced to the next sulcus in a direction perpendicular to the long axis of the gyrus. At the Rush Epilepsy Center, the neurosurgeon keeps the tip of the transector upward and visible immediately below the pia. At other centers, neurosurgeons have elected to introduce the transector with the tip oriented downwards with positive outcomes.[80] It is important that the pia be left undisturbed to minimize vascular injury and scarring. Furthermore it is essential that the surgeon keep the 4 mm tip of the transector within the gray matter layer to ensure that the white matter is undisturbed. Once the epileptogenic area is transected, the transection lines take on a striped appearance from the petechial hemorrhages along the way (see Figure 43.7).

The technique of MST appears to be relatively simple to the observer. Yet, it is more complicated than it actually appears, as transections must be done perpendicular to the cortical surface, not an easy achievement, given the variable microgyral patterns that can result in oblique or parallels transections.[81,82] Needless to say there is a learning curve in the acquisition of these skills. To that end, neurosurgeons are encouraged to carry out transections in brains of cadavers or

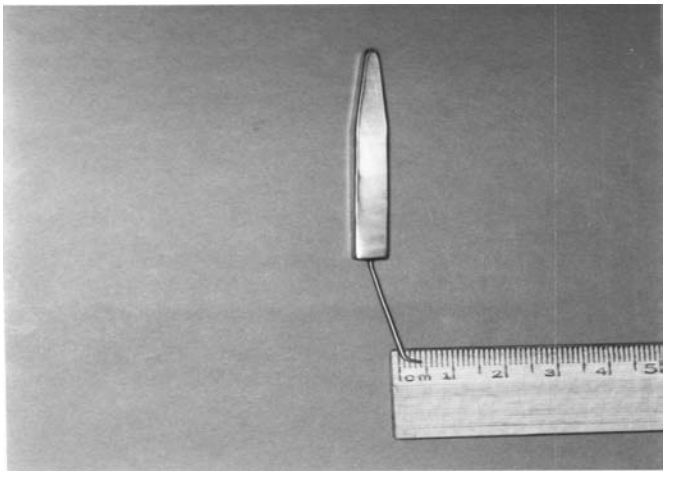

Figure 43.6 Transector used for MST.

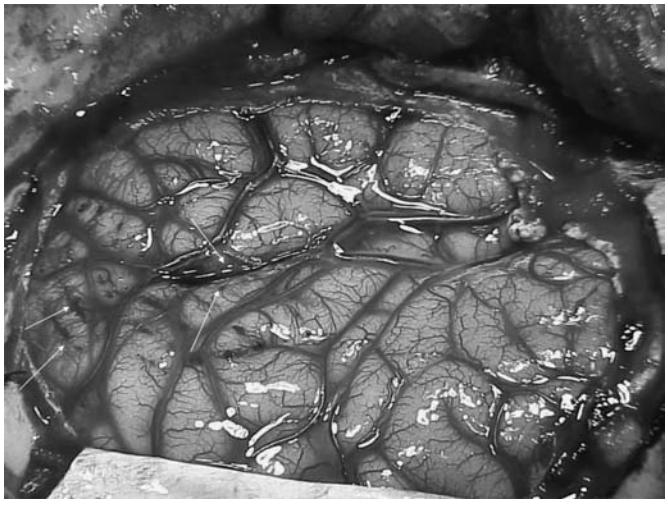

Figure 43.7 Appearance of transected cortex in perisylvian region. The sylvian fissure is open and the planum temporale has also been transected.

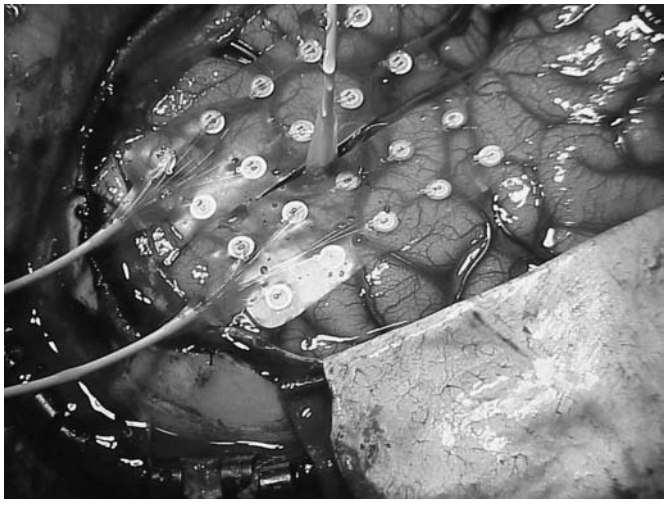

Figure 43.8 Electrodes typically used for intraoperative electrocorticography after the opening of the sylvian fissure.

in cortical tissues destined to be resected (i.e., antero-temporal resections) and examine the transected tissue under the microscope.

Anesthesia

At the Rush Epilepsy Center surgery has been carried out under general anaesthesia with MHX. While this drug can activate interictal epileptiform activity, activation is restricted to the epileptogenic zone.[83–87] Enflurane or isoflurane are avoided as anaesthetic agents at our centre, since the latter has been reported to suppress epileptiform activity in 26% of patients while enflurane can activate epileptiform discharges beyond the area of the epileptogenic focus in 30%.[88]

Intraoperative electrocorticography (ECoG)

Once exposure of perisylvian cortex and opening of the sylvian fissure are achieved ECoG is carried out to guide the extent of the transacted area. Mapping includes localization of the source of epileptic discharges, and the central sulcus. The central sulcus is identified by the recording of evoked potentials to electrical stimulation of median nerve, which aides in the localization of the pre- and postcentral gyri. Identification of the source of the epileptogenic area with ECoG is based on a spatial-temporal analysis of epileptiform discharges in which the onus on the electroencephalographer is to identify those spikes originating within 'abnormal cortex' (as evidenced by the presence of abundant focal slow-wave activity) that propagate to adjacent and/or distant cortical regions. It is therefore essential that electrodes cover the areas suspected to be the potential source of epileptic activity (i.e., planum temporale and superior cortical surface within the sylvian fissure and at times, perisylvian cortex) and areas of propagation (i.e., temporal lateral, frontal-lateral and perisylvian cortex). To that end, a 20-electrode pad is moved throughout the exposed lateral convexity of the hemisphere; in addition, one or two six-contact strips are placed within the sylvian fissure, three contacts covering the inferior and three the superior cortical areas (see Figure 43.8). On occasions, additional six-contact cylindrical electrode strips are used for coverage of subtemporal, mesial frontal and mesial parietal cortex.

The locations of pre- and postcentral gyri are ticketed. The extent of the epileptogenic area to be transacted is demarcated with an easily visible thread. Photographs are taken prior to, and following, the last transaction, so that reconstruction of the transected areas could be made. It is important to emphasize that opening of the sylvian fissure can be associated with technical difficulties in some children. Furthermore, in some children the source of the epileptiform activity can be established to be intrasylvian (i.e., before it propagates to perisylvian cortex) but no *discrete* source can be identified 'within' the exposed intrasylvian cortex; in such cases, the neurosurgeon needs to expand the opening of the sylvian fissure and transect both superior and inferior cortical surfaces in toto. Following a successful MST, the background activity of the transected cortex is expected to be attenuated.

Some epilepsy centers using MST, rely on extra operative data in determining the extent of the area to be transected. In our opinion, Intraoperative ECoG is of the essence prior to and following the transections, as epileptiform activity may not be necessarily abolished. Indeed, it is important to remember that only the cortex at the crowns of the gyri is usually accessible for transection, while the sulci remain untouched. Additional transections may be necessary in some cases after the initial ones fail to abolish the epileptiform discharges, in which case the possibility that these discharges are originating from a distant cortex or from within the depth of a sulcus should be considered. In order to transect the depth of a sulcus safely, the tip of the transector should be turned away from the sulcus as the instrument is advanced. Without post-transection ECoG, the neurosurgeon may not know whether the transection achieved the intended goal.

Results of MST

The interpretation of the surgical outcome of previously published surgical series has to take into account several methodological problems among which the most important include the small numbers and the inclusion of cases that may not meet the original diagnostic criteria of LKS. To overcome the first problem, multicenter studies using the same diagnostic

protocols, inclusion criteria for surgery and surgical technique is necessary given that classic LKS is a rare disorder. To overcome the second problem, we reviewed the surgical outcome of children who met the classic diagnostic criteria and who underwent epilepsy surgery at the Rush Epilepsy Center[4] between the years 1990 and 2003.

This study included 22 children, 14 boys and eight girls who were 6.95 ± 1.95 years old at the time of surgery. The mean age of onset of LKS was 4.3 ± 1.4 and the mean duration of the disease before surgery was 2.5 ± 1.3 years. Among the 22 children, 21 had nonfunctional language for a period of at least 18 months; one child had functional language but had been experiencing frequent and recurrent language regressions that failed to be prevented with pharmacotherapy with AEDs and steroids. The mean baseline score of the language test used for evaluation of expressive vocabulary, the Expressive One Word Picture Vocabulary Test-revised (EOWPVT-R) [expressed as age equivalent in months old] was 12.8 ± 9.0 months, while the mean baseline score of the Peabody Picture Vocabulary Test-revised (PPVT-R) which is used for evaluation of receptive language was 14.6 ± 12.9 months. Behavioral problems were reported in 19 children; four children had an abnormal MRI and three had never experienced any clinical seizures.

Among these 22 children, presurgical data obtained with noninvasive tests were sufficient to proceed to surgery, while in eight patients V-EEG with bilateral intracranial epidural electrodes as described above had to be carried out. In twelve patients (54.5%) only MST was carried out in intra- and or perisylvian cortex. In seven (32%) a combination of MST and resection of temporal lobe structures were carried out, while three children underwent a pure resection of the planum temporale.

Postsurgical neuropsychological and speech evaluation was carried out after a mean period of 34.1 ± 19.9 (7–75 months). At that point, the mean EOWPVT and PPVT scores were 144 ± 72.9 months and 144 ± 73.8 months, respectively ($p < 0.0001$ for both analyses) with mean gains of 124 ± 60.1 months and 129 ± 59.2 months, respectively. A significant correlation between improvement in the scores of these two tests was found ($r = 0.86$, $p < 0.0001$). There was a significant correlation between the duration of postsurgical follow-up and the gains made on the PPVT ($r = 0.56$, $p = 0.02$) and a statistical trend for the EOWPVT ($r = 0.4$, $p = 0.09$). At that point in time, 20 of the 22 patients were still receiving speech therapy. Following a mean postsurgical follow-up period of 48.3 ± 30.2 months, 16 children (72%) had regained functional language as defined by the ability to use complex sentences and understand what was being said to them. Despite these significant gains, only nine of these children (41%) were in a regular class without a need of assistance or further speech therapy.

Among the 19 children with clinical seizures before surgery, 15 (79%) had become seizure free, two had rare seizures, one had >90% and one had <90% seizure frequency reduction. Of note, residual spikes at the end of ECoG and at the last EEG were not associated with a worse postsurgical outcome. Behavioral improvement was reported in 17 of the 19 patients (89.5%).

Prior to surgery, a trial with prednisone was carried out in 20 children, nine of whom regained functional language defined by the ability to use sentences to express themselves. Response to prednisone was a predictor of functional language at 6 months after surgery, but not at the last follow-up.

Morbidity

Two patients sustained small infarcts caused by vascular manipulation, probably at the time of opening the sylvian fissure. These took place among the first cases in whom the opening of the fissure was done. In one patient, the infarct involved the posterior white matter and was not associated with any clinical deficits. The second patient had weakness of the right arm which cleared over a three-month period.

Conclusions

The data presented here suggest that MST can be an effective therapy for children with LKS who, after losing linguistic abilities, have failed to show any signs of improvement for at least 18 months to 2 years. However, not every child with a severe form of LKS may benefit from this surgery. We believe that demonstration of a unilateral, well-localized, source of the epileptic activity and a relative preservation of nonverbal cognitive functions in children who had a normal development of language functions are prerequisites for surgical consideration. The positive response to steroids in a significant percentage of children (9 of 20 in our study) raises the question of what criteria should be followed in the selection of surgery versus pharmacotherapy with steroids. No definite answer is available as no head-to-head comparison has been carried out between these two treatment modalities. In our center, surgery was considered for children who had not responded to steroids and in children who had responded but had experienced adverse events which precluded their long-term use. Thus, until the safety and efficacy of these two treatment modalities are compared in multicenter, randomized controlled head-to-head study, surgery should be considered in children with LKS who are not candidates for pharmacotherapy with either AEDs or steroid therapy.

44 The Lennox–Gastaut syndrome: a surgically remediable epilepsy?

C Dravet

Introduction

Historically the Lennox–Gastaut syndrome is a generalised epilepsy. In the last international classification of epileptic syndromes and epilepsies,[1] it is listed as 'cryptogenic or symptomatic generalized epilepsy'. That means it is usually related to a known or suspected disorder of the central nervous system. In the new proposal published in 2001[2] it is listed under the heading of 'epileptogenic encephalopathy' which means a condition in which the epileptiform abnormalities themselves are believed to contribute to the progressive disturbance in cerebral function. Before discussing whether and when it could be considered as surgically remediable, I will briefly describe the syndrome.

Description

Among childhood epilepsies, the Lennox–Gastaut syndrome (LGS) is one of the most severe epileptic syndromes, due to the frequency of seizures, the occurrence of sudden falls, a marked pharmacoresistency, and the occurrence of mental and behavioral disturbances.[3] The physiopathogenic mechanisms of LGS are not well understood and the borderlines with other types of severe epilepsies are not easy to define. Without a precise knowledge of the clinical and electroencephalographic (EEG) characteristics of the patient concerned, it may be difficult to distinguish between LGS and other childhood epilepsies such as the Doose syndrome (myoclonic-astatic epilepsy), epilepsy with continuous spike-and-waves (SWs) during slow sleep, and focal epilepsies with bilateral secondary synchrony.

LGS is defined by several criteria:

1. polymorphous epileptic seizures, with mainly atypical absences, axial tonic and atonic seizures;
2. EEG patterns consisting of diffuse slow SWs and bursts of fast rhythms at 10–12 Hz during sleep; and
3. permanent psychological disturbances with psychomotor delay or personality disorders or both.

However, other seizure types can be seen (myoclonic, focal, generalized tonic-clonic). The seizure frequency is high and they often repeat themselves in episodes of status. Focal and multifocal abnormalities can be associated with diffuse slow SWs in the EEG. These electroclinical features can occur in a previously normal child, without pathological antecedents and without signs of brain lesion, usually between 1 and 8 years (constituting the *cryptogenic* form of LGS). They also can occur in a child with prior signs of brain damage, sometimes following another type of epilepsy, such as West's syndrome or a focal epilepsy (*symptomatic* form). In the latter, the age at onset can cover a wider range (between 1 and 15 years).

Etiological circumstances are various; ante-, peri- or postnatal: anoxo-ischemia, vascular accident, cerebral and cerebromeningeal infection, hemiconvulsion-hemiplegia-epilepsy syndrome, brain malformation and migration disorders, tuberous sclerosis, Down's syndrome, hydrocephalus, head trauma, brain tumor, radiotherapy for brain tumor. Neuroimaging studies show abnormalities related to etiology. In some cases, in spite of a psychomotor retardation before the onset of seizures, or of a cerebral atrophy demonstrated by computerized tomography (CT) scan and magnetic resonance imaging (MRI), there is no recognizable etiology. When epilepsy starts in the first year of life, it is often in the form of West's syndrome, followed by LGS. Otherwise the LGS can be preceded by focal seizures or can have the full-blown presentation from the very onset on. The typical features of LGS can be observed only transiently in some patients. In the cryptogenic forms, there is by definition no recognized etiology.

The underlying mechanisms are still unknown.[4] Pathologic studies are rare. They have shown anomalies mainly at the synaptic and postsynaptic levels: selective neuronal necrosis,[5] poor dendritic arborization and disturbed synaptic development,[6] perhaps related to an autoimmune process, also hypothesized by Eeg-Olofsson.[7] However, the immunologic approach[8] did not reach significant results. Even the neurophysiological pathways leading to the expression of generalized slow SWs on the scalp are not explained. The same processes as in the idiopathic generalized epilepsies could play a limited part, since abnormal sleep patterns seem to originate outside the usual thalamo-cortical circuit.[9] Secondary bilateral synchrony could be at the origin of the apparently generalized EEG changes. Recently, Bonnani *et al.*[10] have demonstrated that the spikes preceding the myoclonic jerks in the LGS were propagated from one frontal lobe, unlike in the idiopathic myoclonic astatic epilepsy where they were diffusely distributed without lateralization. LGS seems to be one specific age-dependent condition which looks like a diffuse encephalopathy, and we do not know the reason why it appears in either normal or brain-damaged patients.[4] However, LGS is not as strictly age-dependent as

West syndrome. When it has started in childhood it may continue in adulthood, and it may appear at various ages, from baby to adolescent and, exceptionally, to adult.

Ictal symptomatology

Tonic seizures constitute one of the main signs of this syndrome. They are axial, axial and proximal, or global, and symmetrical or asymmetrical. They involve sudden flexion of the neck and body, raising the arms in a semi-flexed or extended position, extension of the legs, contraction of the facial muscles, sometimes restricted to the lower lip, rolling the eyes, apnea and facial flushing. Enuresis can occur and pupils are usually dilated. This can lead to sudden falling. Loss of consciousness does not occur in all instances. Return to normal consciousness is always concomitant with the end of the EEG discharge. They are diurnal and nocturnal. During sleep, they are often short, with only rolling of the eyes and change in the respiratory rhythm, and they can escape attention. Alternatively, when they are long, they can culminate in a tremor pattern. In other cases they can be followed by a phase of gestural automatisms.

On the EEG, the tonic seizures correspond to a discharge of bilateral rapid rhythms, of variable voltage, higher in the anterior areas and in the vertex, sometimes preceded by a short flattening of the background, and followed by diffuse slow-waves or spike-waves (Figure 44.1). There is no postictal silence.

Atypical absences are also observed in the majority of cases. Often they are difficult to clinically detect because they begin and end progressively, and the loss of consciousness is incomplete. Eyelids and perioral myoclonias and drooling are usual. Decrease in muscle tone of variable intensity can lead either to a progressive head drop or complete fall ('atonic absences').

On the EEG, atypical absences correspond to irregular, diffuse slow spike-waves, at 2–2.5 Hz, more or less symmetrical, difficult to differentiate from the interictal slow spike-waves (Figure 44.2).

The third characteristic seizure type is represented by *the drop attacks*. This term is only phenomenological and does not correspond to an epileptic seizure type. It designates all the sudden falls, whatever their mechanism: atonic, myoclonic, myoclono-atonic or tonic, which are often impossible to distinguish without a video and polygraphic EEG recording (Figure 44.3). They correspond to various EEG patterns which can be combined: brief flattening, diffuse poly-SW or fast rhythms. It has been demonstrated that drop attacks were mainly due to a tonic mechanism.[11,12] However, in the literature the term 'atonic seizures' is often used to designate seizures with sudden fall without any demonstration of the mechanism responsible for the fall. That is confusing, and it is preferable to use 'drop attacks'.

All these types of seizures can be repeated in status, particularly atypical absences and tonic seizures.

Seizures of other types, not typical for the syndrome, focal and generalized tonic clonic, are observed in some patients.

Interictal symptomatology

Clinical

There is no neurological sign specific to LGS and those signs observed in some patients are due to the previous brain lesion in the symptomatic forms (hemiparesia).

Cognitive impairment and personality disorders are constant but different in the cryptogenic and in the symptomatic forms. In the latter they are often pre-existing to the LGS onset and will worsen during the course of the syndrome. In the former, the first changes seem to be slowness in the ideation and verbal expression. In children aged three to five, slow psychomotor development, instability and behavioral disorders occur. In older children, attention disorders preclude satisfactory school work and make further learning difficult or even impossible. Relationships with other children and adults are distorted by the high frequency of seizures, associated with slowness, verbal and comprehension difficulties,

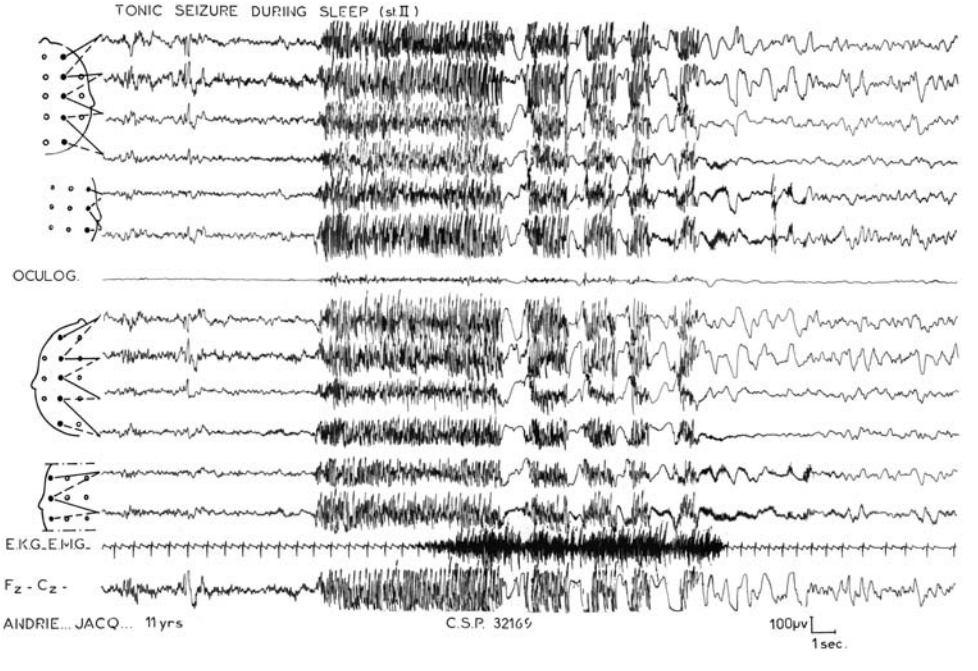

Figure 44.1 Axial tonic seizure during sleep in an eleven years girl, characterized by a burst of high voltage rapid rhythms, four times interrupted by a flattening, and followed by anterior slow waves. The EMG, recorded in the left deltoid (E.K.G. E.M.G.), shows a sudden increase in the muscular tone of the same duration as the EEG discharge.

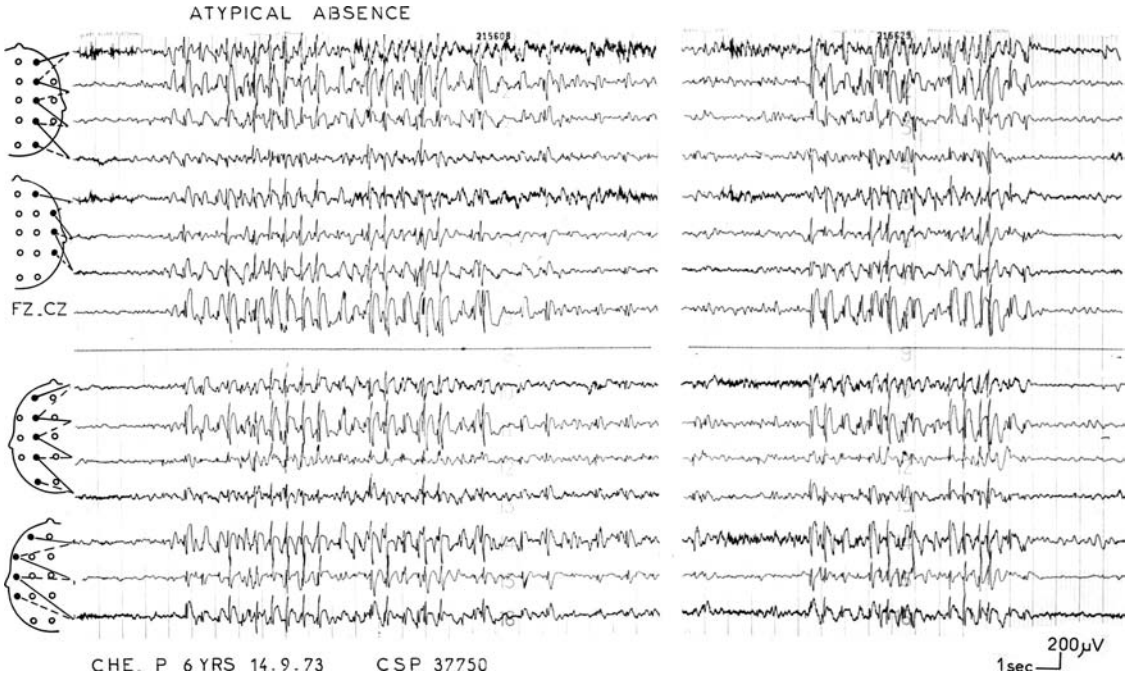

Figure 44.2 Atypical absence recorded in a 6-year-old boy, with diffuse SW of irregular frequency. There is no difference with the interictal discharge on the right of the figure.

which results in aggressiveness and a tendency to isolation. Personality disorders are nearly always present and, sometimes, evolve to a psychotic organization.

Electroencephalography

In awake patients, the EEG is abnormal in most cases, even in the early stages of the disease. Background activity is often slow and poorly structured with regards to the patient age. Interictal discharges of diffuse slow SWs, at 2–2.5 Hz, widespread over the two hemispheres, are recorded, isolated or grouped in bursts of variable duration, facilitated by hyperpnea (Figure 44.2). They can be associated to focal or multifocal slow waves, spikes and SWs, predominating in the fronto-temporal areas. Intermittent photic stimulation usually has no effect.

During sleep, cyclic organization remains normal or shows a decrease in the REM phases. Diffuse slow spike-waves become more and more repeated and their morphology changes, giving an aspect of poly-SW (Figure 44.4). Then they start with brief bursts of rapid rhythms, at 10 Hz, of high amplitude. There is no striking difference between these subclinical discharges and those accompanied by

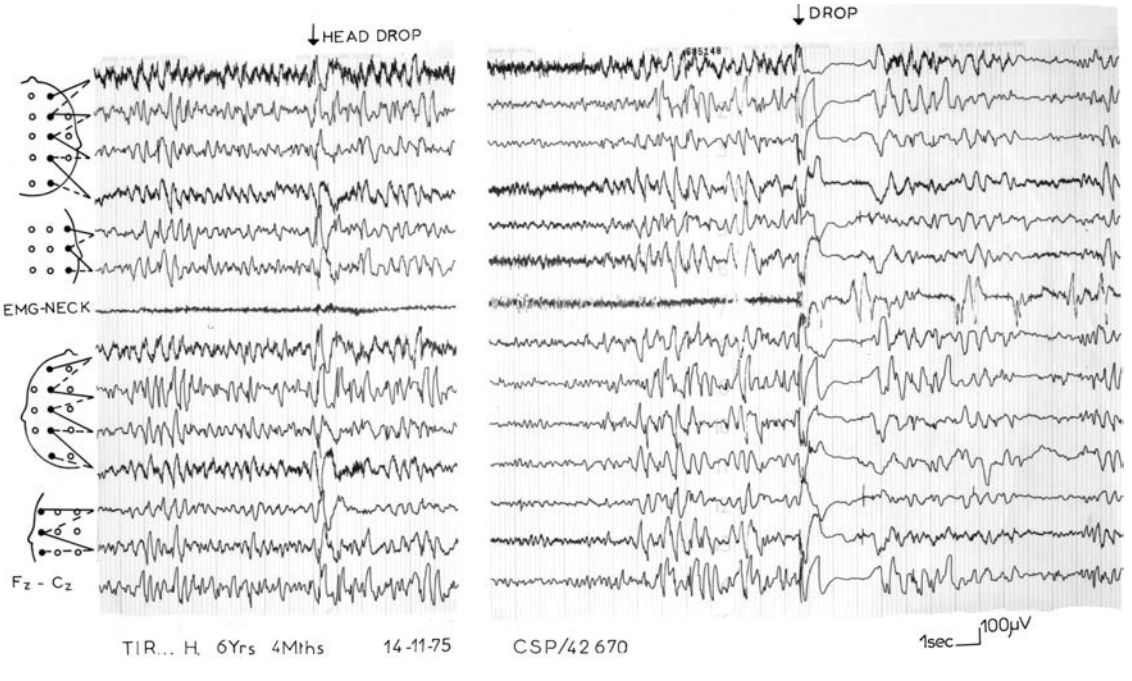

Figure 44.3 Drop attack in a 6-year-old boy. On the left, one head drop corresponding to a high voltage diffuse SW, without clear change in the EMG of the neck. On the right, fall onto the ground. The SW is followed by a flattening. The EMG seems to show a loss of tone but it is not valid because of artifacts.

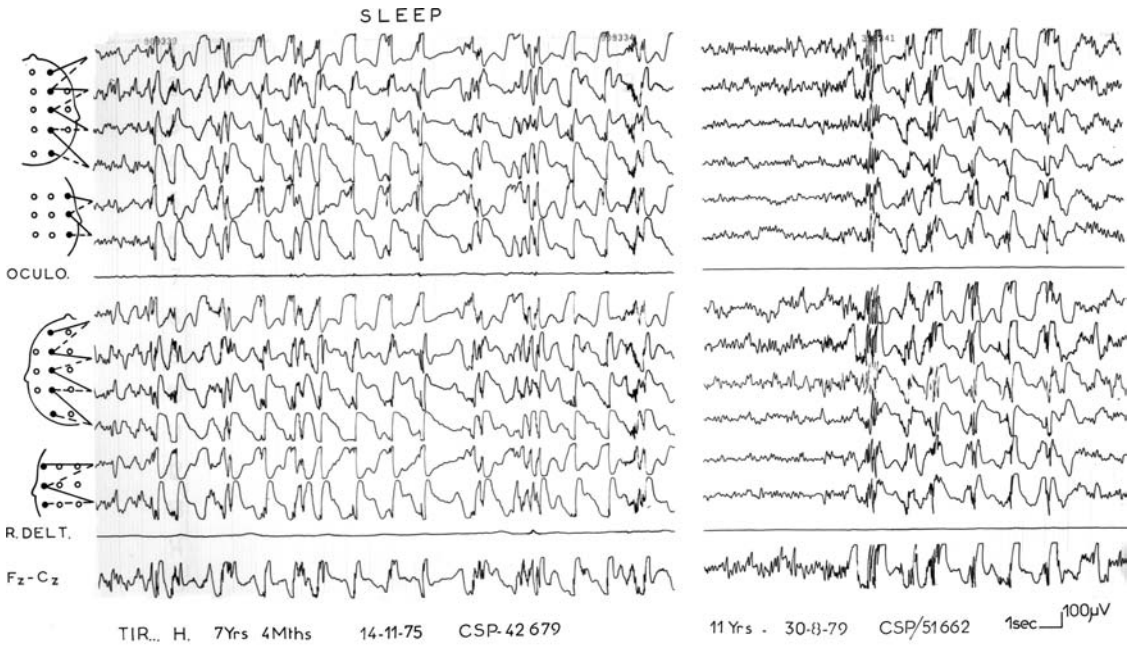

Figure 44.4 Sleep recording in a 7-years-4-month-old boy. On the left, very slow diffuse SW with brief flattenings. On the right, bursts of typical rhythms at 10 Hz.

clinical manifestations. It is important to emphasize that these discharges are the main diagnostic criterion for LGS.

Treatment

Treatment is disappointing. Seizures do not respond or respond transitorily to the antiepileptic drugs. Carbamazepine, valproate, and the benzodiazepines are useful. Results have also been obtained with some new drugs, such as vigabatrin, lamotrigine, felbamate, topiramate, and zonisamide (in Japan), but many patients are not improved by these drugs. Corticosteroids and immunotherapy can help at the onset or in worsening periods. Ketogenic diet has been used with satisfactory results in some patients.

Is LGS a surgically remediable syndrome?

According to its electroclinical characteristics LGS seems not to be considered for surgery. However, seizures are usually extremely pharmacoresistant, EEGs show numerous discharges and cognitive functioning gradually declines. Thus, it is legitimate to search for a surgical approach. Two situations in which LGS may be surgically remediable may be considered.

Surgically removable lesions

In the first situation, the patient presents with a known etiology consisting of a localized and well circumscribed lesion. In that case the removal of this lesion is able to make seizures disappear, EEG improves and behavior also. There are few examples of this type in the literature.

Angelini *et al.*[13] reported one patient who started at 4 years with atypical absences, followed six months later by tonic seizures. The EEGs showed long discharges of diffuse slow SWs without asymmetry, without focal predominance. No sleep recording was available. The CT scan was normal. Nocturnal tonic seizures increased in spite of various treatments and her behavior became abnormal. One year after the onset she presented with slight neurological impairments in the right side and EEG abnormalities clearly predominant from the left parietal region. One isotope brain scan and one left carotid angiography displayed the presence of a tumor in the parieto-temporal region, which was surgically removed. It was a type II astrocytoma. The child had no further seizures and SW disappeared in the EEGs. Two years later she was still seizure free.

More recently, Quarato *et al.*[14] published the case of one patient with an atypical, LGS suffering from atonic and tonic seizures, who was seizure free one year after the removal of a left parietal dysembryoplastic neuroepithelial tumour. In that case, EEG and clinical signs pointed to left hemisphere origin of the seizures.

We also have the case of S.G., who did not have family antecedent or a personal pathological history. At 10 years, he had a generalized tonic-clonic seizure, followed by atypical absences and tonic seizures. Sometimes his tonic seizures were preceded by a conscious onset with head and eye deviation to the right. He continued to go to school but he has increasingly poor results. At 16 years 6 months, despite antiepileptic drugs, seizures increased, becoming diurnal and nocturnal. He was referred to our center at this time. Clinical examination was normal in this right-handed boy, but his verbal expression and his ideation were slow. EEGs showed diffuse slow SWs, in bursts facilitated by hyperpnea (Figure 44.5), and numerous discharges of diffuse subclinical rapid rhythms predominant in the anterior areas (Figure 44.6). The CT scan displayed a left frontal tumor, which was surgically removed without complication and seizures disappeared. The boy's IQ was 94, with a slight

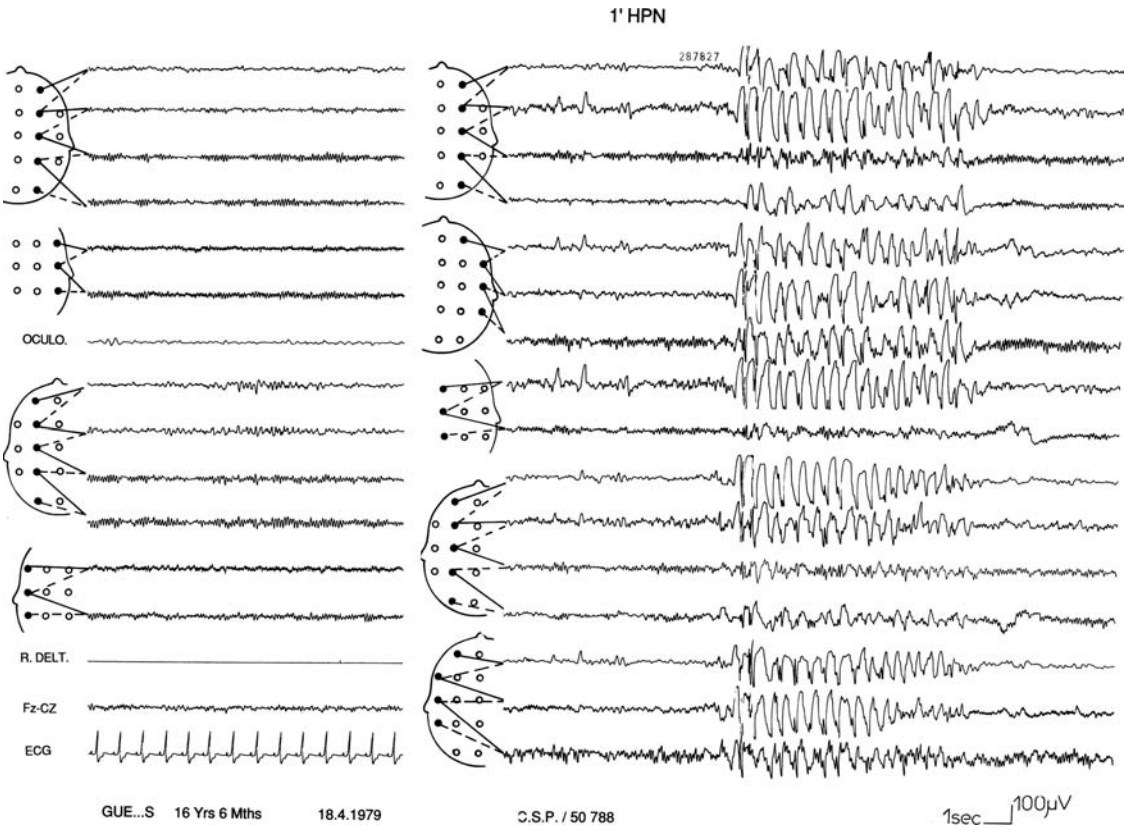

Figure 44.5 Awake EEG in a 16-year-old boy with a brain tumor. On the left, slight asymmetry with theta waves in the left anterior region. On the right, hyperpnea provokes a burst of diffuse slow SW, without clinical manifestation, preceded by sharp waves in the right fronto-central region and the vertex.

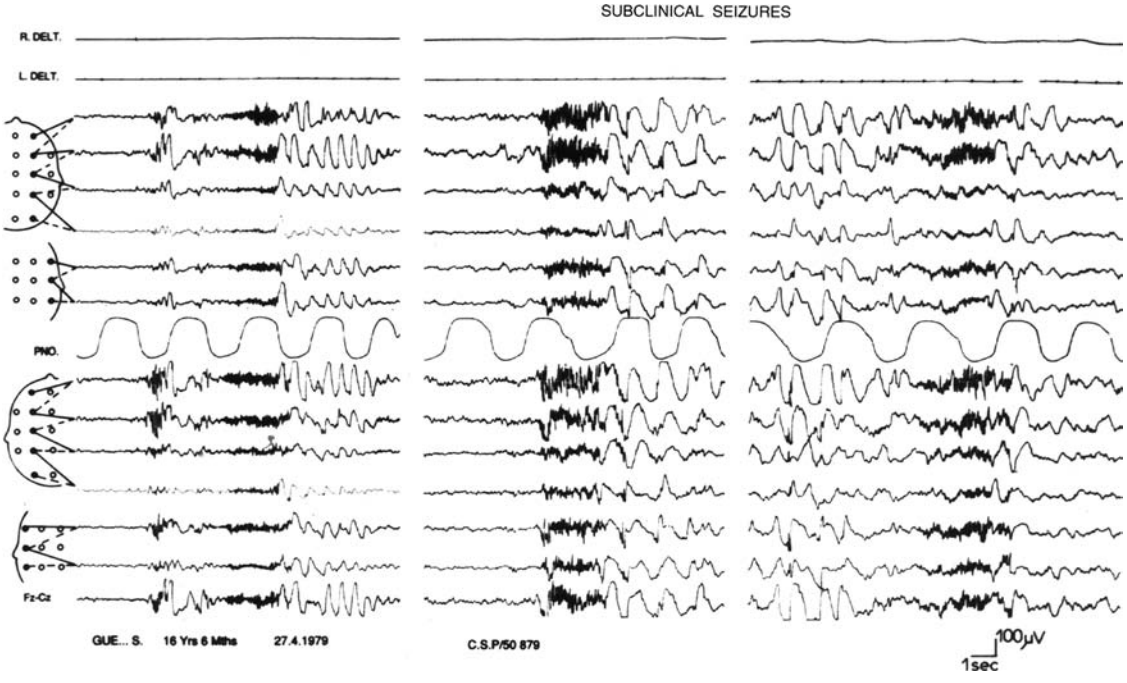

Figure 44.6 In the same boy, subclinical discharges of rapid rhythms, of variable voltage, followed by slow-waves.

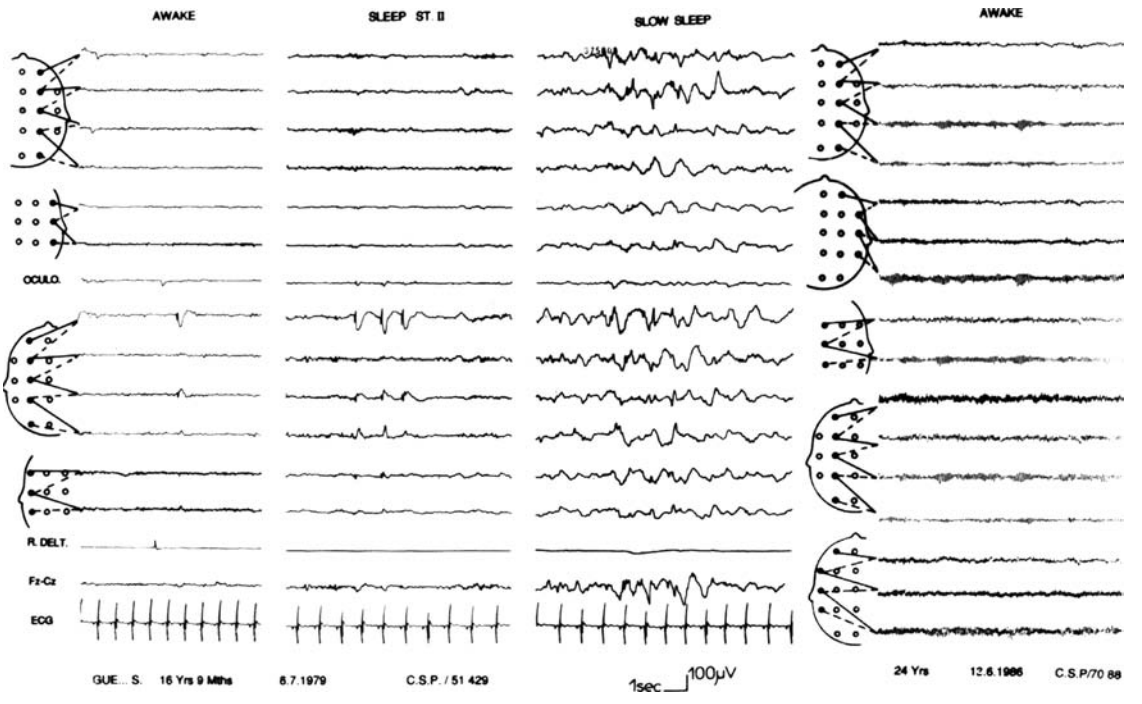

Figure 44.7 In the same boy, after the removal of the tumor. From left to right: fragment 1, rare small spikes in the left fronto-central area; fragments 2 and 3, the same spikes increased by sleep; fragment 4, normal EEG at 24 years.

frontal deficit. EEGs showed spikes localized in the left frontal region, without diffuse discharges, while awake and during sleep (Figure 44.7). Treatment was progressively reduced and stopped at 25 years. He now has a normal professional career. In this patient the LGS was related to a benign frontal tumor (low grade astrocytoma) and was cured by the lesionectomy, but this situation remains exceptional.

Other authors reported on patients with symptomatic LGS due to perinatal anoxo-ischemia resulting in porencephalic cyst who were successfully treated by surgery. However these patients were not separated from those with West syndrome and the diagnostic criteria for LGS were not well defined.[15,16] One paper by Ishikawa *et al.*[17] also reported one patient remarkably improved by this treatment.

Cryptogenic cases: lesions not surgically removable

In the second situation, by far the most usual, there is no lesion to be easily removed. Either one faces a cryptogenic case or lesions are extensive, diffuse, bilateral or not well defined: atrophy, ventricular dilation, cortical dysplasias, and other malformations. In these patients it is possible to discuss the indication of a palliative surgery, such as corpus callosotomy (CC) and vagus nerve stimulation (VNS).

Corpus callosotomy (CC)

First proposed by Luessenhop,[18] this procedure has the objective of preventing the interhemispheric propagation of the discharges presumably responsible for the falls and the generalized tonic-clonic seizures. Preoperative evaluation is of great importance to delineate the shape and integrity of the corpus callosum and to decide what will be the extent of the section.[19] In order to maintain sufficient connections for a good coordination of cognitive functions a certain amount of callosal fibers must be preserved. After several years' experience it has been determined that the anterior two-thirds callosotomy is the best procedure because the conservation of the splenium avoids the disconnection syndrome; subsequent completion of the section remains an option in patients who fail to obtain an adequate response.[20] However, recently Maehara and Shimizu[21,22] advocated for an initial complete callosotomy, arguing that in young children it gives the best results for seizure frequency as well as for psychomotor development. CC has been applied to children and adults presenting with different types of severe, pharmacoresistant, epilepsies, without possibility of resective surgery. They were focal or generalized epilepsies, with multiple seizure types, mainly drop attacks, and epileptic status, often associated with a mental deficit.

Rougier *et al.*[23,24] reviewed the literature in 1997. CC is principally effective in seizure types characterized by drop attacks, due either to a tonic axial phenomenon, or to an abrupt loss of tone. Sometimes they are completely suppressed. More often (70–80% of cases) their frequency is dramatically reduced, between 60 and 100%. Drop attacks are observed in different varieties of syndromes and are usually associated with other seizure types which are less susceptible to be improved by the operation. The best results are obtained when drop attacks are caused by a unilateral brain lesion, or when they are part of a bilateral frontal lobe epilepsy. A good result is observed in 65–75% of those patients. The results are comparable in adults and in children and the functional tolerance is higher in children, who are the best candidates.

It seems that this surgical procedure could be improved by using the gamma knife as reported by Pendl *et al.* in 1999,[25] who applied this technique to three patients, two of which with a LGS.

Results of CC for the Lennox–Gastaut syndrome

In the large body of literature concerning CC in intractable epilepsies the seizure types are usually described but the cases

of LGS are not always identified. For example, Maehara and Shimizu [21] have studied 52 patients who underwent CC for 'intractable generalized seizures' mainly represented by drop attacks, but we do not know the number of patients suffering from LGS and those from other epilepsy types. This study reported not only the seizure outcome, which was particularly good for drop attacks (80.8% seizure-free patients), but also the change in the daily life of the patients and the degree of satisfaction of their parents which was also high (57%) for the children's parents but not for the adults' parents (12%). In the series from Montreal [26] there were 73 cases of CC performed for a variety of cerebral seizures and clinical entities between 1981 and 1986. Fifty-six patients suffered from a secondary generalized epilepsy (SGE) and 14 were classified as LGS. The results were considered satisfactory. Nevertheless there was no case with complete cessation of all the seizure types. The tonic drop attacks emerged as the major indication for this procedure: they decreased between 75 and 100% in 11/23 patients (48%), with complete disappearance in seven, whereas generalized tonic-clonic seizures decreased >75% in 6/19 patients (31%) with complete disappearance in one. The authors assumed they had, at times, spectacular results in the cryptogenic LGS, with no clinical or EEG evidence of focalization, which contrasts with the results obtained by other authors. They also mentioned improvement in awareness and alertness, not attributable to changes in antiepileptic medication. In one patient, a new seizure type occurred after surgery, consisting of nocturnal focal adversive and clonic seizures. These data are consistent with the data reported by Spencer *et al.*[27,28] on the occurrence of more intense focal seizures after callosal section. In the same way Spencer *et al.*[29] have analyzed the EEG ictal patterns before and after CC, showing that the bilateral synchronous pattern was replaced by a unilateral or a focal onset, and that seizures newly localized to a lobe could occur, mainly in the frontal, sometimes in the parieto-occipital lobe. Quattrini *et al.*[30] observed the same changes in the postoperative ictal discharges. They also observed that after certain time, generally some months, lateralized discharges tend to generalize again, confirming that CC is replaced in discharge diffusion by other structures (brainstem, diencephalon).

Ritter *et al.*[31] reported 27 patients with LGS who underwent CC (19 complete, eight partial anterior). The selection criterion was the presence of drop attacks or frequent secondary generalized tonic-clonic seizures. Duration of follow up was 2–18 months (median 6 months). Overall, 70% of the patients had marked improvement in seizure control: tonic seizures decreased in frequency >80% in 14 of 23 patients (60%); GTC in nine of 15 (60%); atonic in seven of eight (87%), and seizures associated with dropping in 13 of 21 (61%). Repeated episodes of status epilepticus ceased in three of four patients.

Provinciali *et al.*[32] reported on the neuropsychological changes after partial CC in 15 patients with SGE, of which five were LGS. They tested memory, attention, visuo-motor ability, posture, motor dexterity, language, praxis and gnosis, as well as social behavior, one month before surgery, then 15–20 and 90–100 days postoperatively, without modifying the medical treatment. The short-term neuropsychological cost of this procedure appears to be low and seems to depend mostly on surgical parameters and brain conditions before the operation.

Nakatani *et al.*[33] and Sakaki *et al.*[34] reported respectively four and two patients operated upon in Japan with a satisfactory result with respect to the seizures for all, in spite of a disconnection syndrome in three patients, transient in one and lasting in two.

Gates [35] reviewed three series of CC, including 17, one and five patients with LGS in the respective series. Among them 15 achieved a satisfactory outcome. Gates reported that the presence of bilateral independent foci with capacity for secondary generalization was an indicator of good outcome.

Pinard *et al.*[36] had operated on 34 patients with more than three seizures a day, among whom eight patients were diagnosed as having LGS. Patients were followed prospectively for at least 2 years after anterior CC (19 patients) and for 1 year after complete CC (15 patients). The eight patients with cryptogenic LGS improved after anterior CC.

Septien *et al.*[37] emphasized the good results obtained in children with psychiatric problems. They had performed partial anterior CC in two children with LGS and major psychiatric troubles: frontal syndrome with hyperkinesia, distractibility, aggressiveness, alexithymia, loss of planning abilities. They observed a progressive improvement of this frontal syndrome during the 2 postoperative months, with the possibility of learning new skills, without a change in IQ. Associative functions depending on the posterior third of the corpus callosum were preserved. They thought this improvement was related to the reduction of seizures.

Claverie and Rougier[38] studied the outcome in terms of quality of life in 20 patients submitted to CC for intractable epilepsy, including three cases of LGS. In two of these three they observed a substantial change; they became capable of independent living, and one attended a specialized school. In the whole series it appeared that the psychosocial benefits obtained in 40% of the patients were linked not only to the seizure reduction but also to the precocity of the intervention.

Matsuzaka *et al.*[39] studied 22 consecutive patients who underwent an anterior CC for intractable epilepsy. Seventeen of these patients had SGE, of whom eight had LGS. A cross-correlation analysis and measurements of amplitude differences were performed between bilateral homologous regions pre-and postoperatively. The surgical outcome was excellent in 14 (63.6%), including a complete elimination of seizures in four; good in three (13.6%); and poor in five (22.7%) patients. After surgery, interictal generalized synchronous SW bursts in the SGE patients were disrupted and changed to unilateral SWs in 11 patients and to bilaterally independent SWs in six. The unilateral group had better surgical outcome than the bilateral independent group. Preoperatively the first group had significantly lower interhemispheric synchrony and fewer regional changes in the side leading in time and the side dominant for amplitude, suggesting unilaterally predominant epileptogenesis that triggered the secondary bilateral synchrony. These findings lead to the hypothesis that a considerable range of variation exists in the underlying condition of epileptogenesis in each hemisphere, even in SGE, affecting the postoperative EEG changes and surgical outcome. Preoperative quantitative EEG analyses enabled the authors to predict the underlying conditions of epileptogenesis and the surgical outcome. Unfortunately the authors were not precise in indicating to which group the patients with LGS belonged.

Kwan *et al.*[40] analyzed findings and acute changes in electrocorticograms (EcoG) obtained during CC, in order to identify any relationships with the postoperative outcome of seizure activity, in 48 patients with LGS, all followed postoperatively for more than 4 years. Of these patients, 31 (64.6%) had significant improvement in seizure control. EcoG displayed bisynchronous discharges in 79.2% of the 48 patients, and they were blocked during CC in 69.7%, who achieved the best postoperative outcomes. But the difference did not reach statistical significance. Therefore, the changes in preoperative EcoG are not predictive.

The largest series was reported by Cukiert *et al.*[41] who performed one-stage callosal section, leaving only the splenium intact, in 76 patients with Lennox–Gastaut ($n=28$) and Lennox-like ($n=48$) syndromes. However, the latter is not defined by the authors. All patients were severely mentally impaired. Mean follow-up time was 4.7 years. Worthwhile improvement (>50%) was noted in 69 patients, with 90% or more seizure reduction in 52, 100% in seven. As in other series, the drop attacks were the most responsive seizure type (92%), followed by atypical absences (82%), tonic-clonic (57%), and tonic (51%) seizures. Postoperative EEGs were obtained in 56 patients. In 42 they showed complete disruption of secondary bilateral synchrony, in six only partial disruption, in eight no change. But a postoperative acute callosal disconnection syndrome appears in 72 patients (apathy, urinary incontinence, right hemineglect, low verbal input, one mutism) which lasted for 8–50 days. After this period, the attention abilities were substantially improved.

Interestingly, in two patients who had LGS with reflex seizures these seizures were reduced by 60% in one (startle epilepsy) and disappeared in the second (tap epilepsy), unfortunately with a relapse after one year in the latter.[42]

In all series, postoperative complications and side-effects were rare. When it appears, the disconnection syndrome is transient. All the authors underline that in children CC is usually followed by an evident improvement in psychomotor development and behavior, though it is not measurable by usual assessment methods.[35,37,38]

At the end of this brief and incomplete survey, it appears that a number of patients with LGS can really improve with a partial anterior CC. In any case it is not a curative but a palliative treatment which can control the most ominous seizures represented by the drop attacks, mainly tonic in nature in this syndrome. Few papers give data on long-term results (more than 5 years' follow-up) but it is never mentioned that good results were transitory. Spencer *et al.*[26] followed patients postoperatively from 2–7 years. They indicate that 'the stability of generalized seizure control after CC continues over many years of follow up'. The problem is not knowing the factors which could allow predicting the result of this intervention. Most authors reported better outcome in patients with a lateralized lesion or lateralized EEG anomalies, but in one series[43] some cryptogenic LGS without asymmetry have been improved. Nevertheless, it is important to conduct a good preoperative EEG analysis in order to detect the type of electrogenesis in each hemisphere. The presence of a mental deficit is not a contraindication. Neuropsychological consequences are usually rare after partial section. It is recommended to perform surgery before the age of 10, in order to preserve a good intellectual outcome and to restore a good quality of life.

Vagus nerve stimulation

In the numerous publications studying the effects of VNS on epilepsy, the patients with LGS were often included in series of patients with 'refractory' or 'intractable' seizures, or with a low IQ. Few details were provided by the authors. The effect of VNS was evaluated at different times after surgery and was variable, from 50% and more seizure reduction in few patients[44,45] up to more than 90% seizure reduction.[46,47] Most of the authors also indicate some degree of improvement in behavior, such as alertness and social communication. The side-effects were never disabling, consisting of change in the voice, hoarseness, sometimes coughing, at the time of the stimulation, and usually persisted only for some weeks.

From the year 2000, LGS patients have been reported as a group and the conclusions are also variable. Moreover, the criteria for diagnosing LGS often lack and these groups include also cases designated as Lennox-like syndromes.

The best study of VNS in patients with LGS was published by Majoie *et al.*,[48] who gave the results of this procedure in 16 patients, aged from 7–18 years, accurately analyzed in terms of seizure and epilepsy type, frequency of the different seizure types, cognitive functions, quality of life and cost-effectiveness. This prospective, longitudinal cohort study included 16 'Lennox-like' patients, among whom 12 with LGS, three with myoclonic astatic epilepsy, and one with myoclonic absences, followed from 6–12 months. The overall results showed that 25% of the patients had a reduction of seizures of 50% or more, with a mean for the individual patient of approximately 20–30%. No patient was completely seizure free. There were no significant differences between the various seizure types and for patients with drop attacks ($n = 10$) only one was seizure free and one had more than 50% reduction. The effects were moderate on neuropsychological functioning, a slight improvement appearing in the group with the highest mental age and not correlated with the seizure frequency reduction. The effects on EEG were not studied, but the best results were obtained in the patients with the best EEG background activity. The side-effects were low and transitory. The cost-effectiveness analysis showed a decrease of 2876.06 € in the postoperative period of 6 months (1 € was approximately equivalent to 1 $). The same authors reported the results after a 2-year follow-up,[49] which were substantially the same with persistence of the seizure reduction rate at the same level and no more improvement in the neuropsychological functioning.

Frost *et al.*[50] reported a multicentric retrospective study of 50 LGS patients, aged from 5 to 27 years (median = 13 years), 42% younger than 12. Data were gathered at 1, 3, and 6 months after implantation. They had multiple seizure types, 66% presenting with drop attacks. At 3 months, data were available for 43 patients. Seizures had decreased by >75% in 15 (35%), and by =50% in 24 (56%), and they have increased by >50% in 3. After 6 months, data were available for 24 patients (due to the data collection cutoff point). Seizures had decreased by >75% in 9 (38%) and by =50% in 14 (58%), and no increase was reported. No patient was seizure free. According to the authors, drop attacks and atypical absences seemed to equally respond, but it was difficult to affirm that, since there was no prolonged video recording. They also mentioned an improvement in quality of life, which requires further studies because the scales they applied were very simple. The side-effects were similar to those in previous studies, but

hypersalivation and worsened behavior and hyperactivity were also noted in respectively 4 and 3 patients.

Buoni *et al* [51] reported a series of 13 patients, 7 with LGS of whom 6 with atonic seizures. Three had a 50% or more seizure frequency reduction, mainly for atonic seizures, which the authors considered one good responsive seizure type, in contrast with the results by Majoie *et al.*[48] However, their sample is small and atonic seizures are not always responsible for falls (drop attacks).

Data about the effectiveness of VNS in LGS as regards other epilepsy types are unclear. Some authors [46] found a high rate of seizure reduction (from more than 50% up to more than 90%) and others seem to indicate that it is equivalent[48] or lower. Labar, [52] in a survey of 269 patients with 1-year follow-up, concluded that VNS responsiveness was associated with older age, longer duration epilepsy and syndromes other than LGS.

As for CC, up to now there are no outcome predictive factors allowing the selection of patients with a good chance of improvment by VNS. Janszky *et al.*[53] conducted a study in 47 patients, with long-term ictal and interictal EEG recordings, with a 1-year follow-up. Only four patients had a symptomatic generalized epilepsy. They concluded that only two factors were predictive for a complete control of the seizures, the presence of a cortical dysplasia and the absence of bilateral interictal epileptiform discharges, the latter independently. These preliminary results would be rather discouraging for LGS patients.

Another group[54] also attempted to find prognostic electroclinical features and studied seizure patterns in 17 patients, mainly with focal epilepsies (16 with falls) and including four LGS patients. Only four patients had a significant seizure reduction, a better outcome occurring in those seizures with a temporal lobe onset, and the poorest outcome occurring in frontal and fronto-central seizures. In the LGS patients there were no significant improvement, except a diminution of retropulsive falls.

Conclusion

In conclusion, one must underline that none of the published patients treated by VNS for a LGS has been completely seizure free, even if one seizure type could have disappeared in few of them (atonic seizures).[51] For this reason, the choice between the two types of palliative surgery, CC and VNS, should be discussed case by case. It is known that a real improvement in quality of life is obtained only in patients who become seizure free and not in patients with a seizure frequency reduction <90%. That was demonstrated for temporal lobe epilepsy surgery[55] and for pharmacological treatment.[56] However, patients suffering from LGS are extremely handicapped and diminution of drop attacks from several per day to several per month should represent a real change in daily life and the mood of the patient and his family and caregivers. Thus, after failure of several antiepileptic drugs, if the patient is not eligible for a resective surgery, the two options should be discussed. One recent study[57] has compared the response to CC and VNS in a series of 77 patients, only 13 presenting with a LGS, for a follow-up duration of 9 months. Their results for the whole group showed better outcome after CC: 79% of patients had a 50% decrease in seizure frequency as compared with only 40% for those with a VNS ($p < 0.001$), and 57% of patients had a 80% decrease as compared with only 20% of those with VNS ($p = 0.007$). They do not indicate how many patients became seizure free. However, the number of complications was obviously higher in the CC (21%) than in the VNS (8%), as well as their severity. One patient died in the postoperative period.

CC is probably more likely to give a complete control of the most disabling seizures but is not lacking in serious risk, whereas the VNS gives less favorable results but is a safer procedure.

To be complete it is necessary to mention that deep brain stimulations have been tried in selected patients,[58] apparently with some positive results against atypical absences and tonic seizures [56,57] but this procedure does not appear to be actually used.

45 Medically intractable epilepsies not remediable by surgery

NK So

Introduction

The very title of this chapter raises a number of questions on definitions and conventions. First is the term *medically intractable*. This has to do not only with observations documenting that a patient has failed to respond to past or current trials of medications, but also to the implied improbability of a future response to further drug trials. This issue is explored in several chapters in Section 2*: Overview*. Second is the definition of *remediation*. Complete freedom from seizures is unarguably what is hoped for, as supported by psychosocial and quality of life studies which showed that improvements in employment and self-reported quality of life is correlated with a seizure-free status. However, would a 90% reduction in seizures not sometimes be worthwhile, converting a patient with 10 seizures a month to one with one seizure a month? There is indeed data to show that patients with less than 12 seizures a year report better quality of life as compared to those with more seizures. But what about a 50% reduction in seizures? While this is considered far from ideal after resection surgery, a 50% reduction in seizure frequency is the realistic expectation with vagus nerve stimulation. These questions on outcome are explored in Section 17*: Surgical Outcome.* Third is the surgery itself. There are resection procedures, large and small; disconnection procedures; the technique of multiple sub-pial resection; and vagus nerve and brain stimulation. If we include all the above techniques, and we accept that a 50% seizure reduction rate is an acceptable threshold of remediation, then in fact there is no medically intractable epilepsy that is not a candidate for surgical treatment, save for those with terminal or degenerative disorders who are considered to have too short a life expectancy.

We will briefly discuss the generalized epilepsies but this is not the place to repeat a textbook account of these seizures and syndromes. The rest of the chapter surveys those partial epilepsies that have demonstrated sub-optimal outcomes after resection surgery for which caution and extra deliberation may be advised, and those patients with partial epilepsies who were not offered epilepsy surgery. Reports of negative outcomes in the literature are subject to publication bias, so when reports are available we need to give them perhaps even greater attention.

Generalized epilepsies

The idiopathic generalized epilepsies of childhood and adolescence (and sometimes adulthood) are usually responsive to medications and fully controlled in 80%–90%, provided that medications have been judiciously selected. Pseudo-intractability arises when treatment relies on drugs that do not cover the spectrum of generalized seizures, or drugs that can aggravate generalized seizures[1] (most commonly carbamazepine and gabapentin), or because of treatment non-compliance. A small minority remains with persistent seizures despite the best treatment and compliance. It seems that those epilepsies emerging later such as *juvenile absence epilepsy* and *juvenile myoclonic epilepsy* may be more likely to face some difficulties in obtaining complete seizure control as compared with those that present earlier. There are sometimes features suggesting an overlap with symptomatic generalized epilepsy in some of these patients with difficult to control epilepsy, such as a history of some prior neurological event, or of borderline intellectual function. When pharmacological treatment has failed, such patients may be candidates for vagus nerve stimulator implantation,[2] although its use is still *off-label*.

The secondary (symptomatic or cryptogenic) generalized epilepsies represent the opposite spectrum from idiopathic generalized epilepsy. Some also call these encephalopathic generalized epilepsies. Seizures often persist throughout life and many patients have significant mental impairment and other handicaps. These patients can constitute a sizeable proportion of the patients with medically intractable epilepsy at an epilepsy center. One prototypical example is Lennox-Gastaut syndrome which starts in childhood, manifests severe epilepsy with multiple seizure types, and has associated mental retardation. The most typical seizure types are tonic, atonic (drop attacks), and atypical absence seizures, although myoclonic, generalized tonic-clonic and partial seizures also occur. The EEG shows runs of 2–3 Hz (slow) generalized spike wave complexes, bursts of generalized paroxysmal fast (10 Hz) activity, and multifocal sharp waves.[3] Other patients in the category of secondary generalized epilepsy have other combinations of multiple seizure types and multifocal sharp waves. While cases can be attributed to a specific etiology such as perinatal hypoxic-ischemic encephalopathy, malformations of cortical development, or neurocutaneous syndrome, some remain of unclear etiology. Yet others have transitional or other assorted features, making it difficult to be more specific in delineating a disease or syndrome.

Of note in a book on epilepsy surgery, some patients with secondary generalized epilepsy can superficially look as though they may have partial seizures. Simple and complex

partial seizures can indeed occur but are rarely the predominant seizure types in contrast to the different generalized seizures, and can be interpreted to be a manifestation of the multifocal nature of the disease. In ictal recordings this would be confirmed by a localizable ictal onset that is in logical agreement with the clinical signs. However, in other cases, what looks like a complex partial seizure with psychomotor automatisms on the ictal EEG first shows a generalized ictal onset pattern followed by a delayed localization of a rhythm over the temporal regions. So these may not be partial seizures in the proper sense, but a delayed recruitment of the temporal limbic system.

First corpus callosotomy [4,5,6] and later vagus nerve stimulation[7] had been used to treat patients with secondary generalized epilepsy, most commonly with the Lennox-Gastaut syndrome. Tonic, atonic, and generalized tonic-clonic seizures seem to improve most after either of the procedures. There is less consensus to the degree to which myoclonic, atypical absence, or partial seizures improve after callosotomy. Both drop attacks and atypical absence seizures were reported to improve after vagus nerve stimulation.[7]

Partial epilepsies with reduced outcomes after resection

For the sake of this discussion, we will adopt a definition of a reduced or sub-optimal seizure outcome when there is a less than 50% chance of becoming seizure free or obtaining a substantial reduction in seizures after a cerebral resection procedure. The seizure-free group corresponds to Engel Class I, while substantial reduction would correspond to Class II, and also Class III if an earlier UCLA criterion of >90% reduction in seizures is used.[8] Difficulties arise when a Class III 'worthwhile' outcome is not specified either in number of seizures or percentage reduction from baseline. The substantial reduction group would also include the Duke 'Significantly Improved' outcome of <10 seizures a year,[9] and the category of <4 seizures per year in the 1993 proposed scoring system.[10]

Identification of the conditions that lead to a less than 50% chance of seizure-free or substantial seizure reduction outcome is not presented here as an exclusion for (resection) surgery. The final decision for or against surgery will rest on a full discussion of the patient's goals, expectations for success, and tolerance of adverse outcomes. Nevertheless it brings a perspective, and helps to separate the settings for success from those less likely, which can be useful when counseling patients considering surgery. This is admittedly a higher bar than that set for vagus nerve stimulation or drug trials, where a 40% to 50% chance of a 50% or greater reduction in seizure frequency is the expected measure of success and with only a few patients becoming seizure free. But as with many human decisions, we adjust the bar set for a goal based on its associated risks. Craniotomy and excision of brain tissue inherently carry more risks. The 50% seizure-free or significant reduction cut-off is probably also less meaningful when dealing with the sometimes 'catastrophic' or 'malignant' partial epilepsies seen in infancy or childhood, where daily seizures lead to developmental standstill, making palliation without complete control a desirable objective.

Bitemporal epilepsy

Repeated studies from some of the earliest on the surgery of temporal lobe epilepsy noted a reduced outcome for seizure control in patients with bitemporal spikes.[9,11] Bitemporal interictal spikes are only one of several and a non-specific measure of bitemporal disease. Bitemporal epilepsy is now rightly defined by independent seizures recorded from each temporal lobe.[12]

Bitemporal epilepsy does not by itself stand out as a distinct syndrome. Most importantly, one should separate bitemporal epilepsy with bilateral temporal lobe disease from falsely localizing interictal and ictal EEG findings in patients with extatemporal lesions. Patients with bitemporal epilepsy do show some differences from unilateral mesial temporal lobe epilepsy. First a history of febrile seizures is less than that in patients with unilateral temporal epilepsy,[13] while a history of encephalitis and other diffuse cerebral insults is increased. Nearly all will have bilateral independent EEG spikes with or without slow waves over the temporal regions if recorded for long enough. Extracranial EEG ictal recordings are more likely to show not only independent seizure onsets, but also bitemporal non-localizable onsets, asynchronous ictal rhythms of different frequency and morphology over the temporal lobes proceeding simultaneously, and ictal patterns that switch in amplitude predominance from one temporal region to the other.[14] They are more likely to show bilateral dysfunction in a range of measures: whether MRI, MRS, memory testing. As a group, their cognitive and memory scores are more impaired than for patients with unilateral disease, and may exhibit more personality problems.

The issue to be discussed here is not that patients with demonstrated bitemporal seizures are not surgical candidates. In a review of several published series, 54% obtained a good outcome (Engel Class I and II), somewhat less than that for patients with unilateral disease.[12] What is interesting here is to look at the reasons for a bad result. The rate of seizure control is much less in series which offered most patients with bitemporal epilepsy surgery,[15–17] as compared to those that exercised additional selection.[18,19] Additional selection had been based on independent measures of mesial temporal disease: MRI findings of hippocampal atrophy and sclerosis, PET hypometabolism, and lateralized neuropsychological dysfunction that included the findings of the intracarotid amobarbital test. When there is some degree of concordance between seizure predominance as recorded by intracranial EEG and these independent tests, seizure outcome is improved. When there is no clear predominance of seizures from one side, the absence of congruent lateralization or the presence of discordant lateralization from independent tests, herald a poor outcome. It is this latter group who should be counseled on the low yield of surgery.

Multifocal epilepsy

Epilepsy with multifocal seizure onsets from non-contiguous areas, whether from the same hemisphere, or from both hemispheres is generally held to be not treatable by resection surgery. However, as we shall see later, there may be exceptions. Originally, this prohibition against operation on more than one area was probably influenced by the disastrous outcome to memory functions after bilateral surgical removal of the

temporal lobes, leading to a permanent amnesic syndrome.[20] Undoubtedly, the same prohibition applies to bilateral removal of the frontal lobes.

The causes of multifocal epilepsy are sometimes evident and visible, a consequence of a multifocal disease such as encephalitis or tuberous sclerosis. At other times the potential for multifocal epileptogenicity is understood even though not necessarily anticipated, such as when MRI imaging shows only one area of cerebral malformation, or a single scar from head injury, but investigations reveal multifocal seizure onsets. Yet other cases remain difficult to understand.

The term 'multilobar' resection was used by Rasmussen,[2] but he included in this category the failure of piecemeal resections to improve seizures in Rasmussen's encephalitis, and some cases of infantile hemiplegia with widespread epileptiform abnormalities throughout the hemisphere. The same would apply to surgery for hemimegalencephaly. These are all widespread or progressive disease states. We know that epilepsy surgery can be successful in these conditions, but calls for a more radical removal or disconnection of the diseased hemisphere. Rasmussen also presented the results of 'frontal plus' surgery at Montreal Neurological Institute.[22] This very brief report did not detail the diseases or pathologies treated. What is notable is that of 63 patients who had removals from the frontal lobe and adjacent central or temporal regions, only 10% became seizure free and another 24% had 'marked reduction' of seizures. Then there were 13 patients who had reoperations on both the frontal and temporal lobes after a failed first operation. None of these patients became seizure free.[23]

The results from Montreal contrast with results collected at the 2nd Palm Desert Conference in 1992. Between 1986 and 1990, 166 multilobar resections were performed worldwide, and 89% were seizure free or had worthwhile (>90%) seizure reduction.[24] The pathological conditions treated by multilobar resections are not known. More intriguing is a recent report of the success of staged multifocal resections in children with tuberous sclerosis.[25] It raises the question that the success or failure of multifocal resections need to be re-evaluated based on the underlying disease process. In patients with non-progressive multifocal epileptogenic lesions, surgery may work provided it does not violate patient safety and lead to unacceptable deficits.

Dual pathology

Dual pathology refers the presence of hippocampal sclerosis with another identifiable lesion in temporal or extratemporal locations. It may be considered another facet of multifocal epilepsy. Dual pathology so defined is found in about 15% of patients with partial epilepsy.[26,27] It seems more common in congenital disorders or when there is a history of an early insult. The pathological entities most commonly found associated with hippocampal sclerosis include: malformations of cortical development, porencephalic cysts, and atrophic gliotic lesions from old infarcts or contusions. Less common associations are indolent tumors and vascular malformations.

Several studies reported on the surgical outcomes in patients with dual pathologies. The numbers of patients were by the nature of this condition small. Where only one of either the lesion or the mesial temporal structures was removed surgically, the chance of a seizure-free outcome was reduced to 10%–17%, although some had significant improvement.[28–30] While there was a paucity of studies to no studies proving independent ictal onsets from the separate pathologies, this had been implicit in the observations. Selected patients who failed first surgery, became seizure free when a second surgery was performed to remove the remaining pathology. This suggests that when there is dual pathology, the surgical strategy should plan for removal of both pathological substrates, although the surgical steps can be staged.

Partial epilepsies with normal MRI findings

Seizure outcomes after surgery are generally reduced in patients with temporal and extratemporal epilepsies and normal MRI.[31,32,33,34] Several studies showed that additional preoperative non-invasive findings are extremely important to help predict a good or a poor outcome. The presence of localized interictal discharges on scalp EEG, and localized hypometabolism by PET were statistically significant predictors, while ictal scalp EEG afforded a trend but was not statistically significant in patients with neocortical epilepsy and normal MRI imaging.[35] The presence of generalized interictal discharges in scalp was a bad omen in frontal lobe epilepsy, even if there were MRI abnormalities, as only one of ten (10%) patients became seizure free.[36] In MRI negative temporal lobe epilepsy, the presence of bilateral independent or multifocal interictal discharges in scalp EEG also predicted bad outcome, with only four of 14 (29%) seizure free.[32] There is additive value to the number of concordant non-invasive tests in prediction of outcome: when two or more tests are concordant, outcome is significantly better with 60% becoming seizure free. This contrasts with a 30% seizure-free rate in patients without any localizing findings on non-invasive testing.[35]

Thus patients with neocortical epilepsy and normal imaging should be counseled on the reduced likelihood of a good surgical outcome if there are no localizing findings on non-invasive testing by scalp EEG and FDG-PET scan.

Certain malformations of cortical development

In contrast to relatively the good outcomes after resection of focal cortical dysplasia, some other developmental pathologies have not responded well to surgical treatment, whether by localized resection or by multiple subpial resection, despite intracranial EEG investigations. Of eight women with subcortical band heterotopia (double cortex syndrome) who underwent surgery, only one had significant improvement.[37] Periventricular heterotopias also did not demonstrate a good surgical outcome particularly if there is bilateral disease. In a series of ten patients operated at Montreal (seven bilateral disease), only one had a significant reduction in seizures at long-term follow-up.[38] This patient had unilateral heterotopia, and most of the abnormality was included in the temporal resection. Admittedly the resections were corticectomies that often did not include the heterotopic tissue, now known to be intrinsically epileptogenic, and part of the ictal epileptogenic zone together with overlying cortex. In a more recent surgical series in which resection targeted both the heterotopic nodules and associated cortex, excellent results were obtained in patients

with unilateral heterotopias, but not in those with bilateral heterotopia.[39]

Other subtle indices of malformation in cortical development may also be important in surgical outcomes. In a study using segmentation analysis of gray and white matter volume distributions,[40] even a subtle abnormality outside of the temporal lobe is correlated with a reduced outcome after temporal lobectomy, with only four of 14 patients (28%) becoming seizure free, as against 11 of 13 patients (85%) without such extratemporal abnormalities.

Reasons patients are not selected for surgery

Inability to localize the epileptogenic zone

A proportion of patients are rejected from surgery in any surgical series after extensive investigations, either because the epileptogenic zone could not be localized, or because testing showed multifocal abnormalities. Non-localized, non-invasive testing is typically followed by intracranial EEG investigation in patients with suspected partial epilepsy, thus the published results of intracranial EEG investigations can give us some idea of how often patients are rejected from surgery for these reasons. Non-localizing intracranial EEG studies could be a result of inability to record seizures, mistaken investigation of generalized epilepsy, failure to target the epileptogenic zone from an incorrect hypothesis of its location, inadequate electrode coverage, true multifocal epileptogenicity, and perhaps abnormal networks that cause such rapid and widespread synchronization that confident interpretation of the site of seizure onset is not possible based on current understanding and technology.

In a review by Spencer in 1981, she found that 18% of patients investigated by depth electrodes were excluded from surgery.[41] The rates were even higher in two European centers with a notable history of depth electroencephalography in that era, 23% in Milan, and 35% in Paris. For subdural EEG recordings, rather similar results were found. In a series of 50 patients from Oregon, 12 (24%) were excluded from surgery because of multifocal onset, inability to determine an onset, or bitemporal independent seizures.[42] It can be argued that the rates for unsuccessful intracranial EEG would be expected to be higher in those earlier series that did not have the advantage of MRI and other imaging techniques now in use. A more recent report on the cumulative experience of 217 patients at Montreal Neurological Institute investigated by depth electrodes found that 37 (16.5%) were excluded from surgery afterwards, and that a further nine patients (4%) had technically unsatisfactory recordings.[43] The proportion of patients with a localized epileptogenic zone falls when the preoperative MRI is negative. Only 58% of a series of 43 MRI negative patients proceeded to resection surgery after intracranial EEG investigation between 1992 and 1999, using combinations of subdural and depth electrodes.[44] Thus 15%–40% of patients with complex findings that did not permit localization of the epileptogenic zone by non-invasive data and who underwent intracranial EEG investigation failed to obtain sufficient localization to recommend surgery, with the higher number when the MRI was normal.

Epileptogenic zone located in eloquent cortex

The number of patients who are not candidates for resective surgery because of this reason is probably smaller. There are several qualifiers that make the location of the epileptogenic zone in eloquent cortex more a relative contraindication than an absolute contraindication in many cases. *First* there is the risk benefit analysis undertaken by the patient and healthcare team as to whether the potential benefit of surgery outweighs the likely postoperative deficits. This is a highly individual decision. It seems there is some degree of rank ordering with some deficits considered more acceptable than others. Thus the deficits that follow resection of the primary sensory area in the postcentral gyrus, and of the visual areas in the occipital cortex are presumably acceptable to many as a trade-off for seizure control, if only because there are surgical series of such treatments. Experience also indicates that resection of the primary motor area of the face can be tolerated with only relatively minor problems.[45] This leaves resection of primary motor areas of the arm and leg, and the language areas, as the least acceptable. To that is added permanent anterograde memory loss that can result from resection of the mesial temporal structures on one side if the other side is also diseased. This has fortunately become very uncommon with present presurgical protocols to evaluate both the structure and the function of the temporal lobes. Indeed there is now more controversy on the validity of memory assessments by the different test methods, particularly the intracarotid amobarbital (Wada) test. What is acceptable or not can be modified by a *second* consideration, namely the permanence versus the potential of recovery of the neurological deficit. When a deficit is transient, it is not at all a contraindication. Thus resection of the supplementary motor area can lead to an akinetic mute state with contralateral hemiplegia that can last several weeks before recovery.[46,47] Although some minor deficits can persist, patients appropriately counseled and prepared for this possible outcome seemed to have come out at the other end with minimal discouragement. Reversibility is influenced by a *third* factor, namely the timing of the surgical procedure in the neurodevelopmental course of the individual. The earlier the resection, the greater the chance that even essential functions can be re-established. To illustrate, all three considerations are important when evaluating a patient for hemispherectomy or one of its 'disconnection' variants. Because the epileptic conditions (e.g., hemimegalencephaly, Rasmussen's encephalitis, Sturge-Weber syndrome) that call for hemispherectomy are usually progressive or cause a 'catastrophic' decline in function, the first consideration of benefit versus risk is usually in favor of surgery. The second consideration of functional recovery is supported by empiric experience that children can regain locomotor use of the hemiplegic side, and maintain language functions. The third consideration on the timing of surgery is also important in that there is some consensus that the chances for speech development after resection of the dominant hemisphere is more likely to be assured if operation is carried out by the sixth year of age, and less likely if carried out after the age of ten. It should be emphasized that the course of speech recovery after left dominant hemispherectomy can take 6 to 12 months or more.[48]

Adults with epileptogenic zones in eloquent areas not deemed candidates for resective can nevertheless be considered for other surgical procedures. The technique of multiple

sub-pial transaction was developed for this very reason (see Chapter 126). New neurological deficits can still take place, reported in 22% by one meta-analysis.[49] Vagus nerve stimulation can be considered for palliation. There are ongoing investigational protocols for brain stimulation, either targeting subcortical structures with a view towards interruption of seizure networks, or direct brain stimulation of the epileptogenic zone by implanted intracranial electrodes, delivering an 'abortive' electrical stimulus to terminate the seizure discharge. Abortive direct brain stimulation takes advantage of advances in microelectronics and computer systems to make a responsive 'closed-loop' system that detects a seizure discharge and delivers the therapeutic output.

No resection because of other surgical risks

Resective surgery may not be offered for other surgical risks. It could be because the patient has too many other serious medical or psychiatric comorbidities that would jeopardize surgical or social recovery. But more often it is because the location of a large lesion that not only impinges on eloquent cortical areas, but also on subcortical motor tracts or major blood vessels, renders its complete removal prohibitive in terms of risk of a major neurological deficit in an otherwise intact individual.

Summary

The decision for epilepsy surgery should always be a personal one informed by discussions between the patient and her doctors. Ultimately what constitutes a desirable result with regards to seizure control, and what constitute acceptable and unacceptable risks, have to be decided by the patient. There are however instances when the epileptic condition is *inoperable*, either because the risk of a major complication is considered too great, or because the seizure focus cannot be localized. Then there are situations in which a patient may not get operated on because the chance of a successful outcome is reduced below the expected threshold. It is of course the hope of all that further technological advances and scientific understanding will improve our ability to offer surgery to those who can benefit, increase the postoperative outcome, and at the same time identify others who may be best served by non-surgical therapies.

46 Special characteristics of surgically remediable epilepsies in infants

A Gupta

Introduction

The selection of infants with surgically remediable epilepsy poses unique challenges due to several age related special characteristics.[1,2] The special characteristics span clinical presentation, seizure semiology, difficulties in examination, maturational aspects to the interpretation of scalp-EEG findings, anatomical and functional neuroimaging findings, pathological substrates, and decision making for goals, timing and type of surgery. Involvement of parents and guardians, and their level of understanding and informed consent for surgery add another dimension to the challenges. As in adults, the ultimate goal for surgical strategy in children is the identification of a focal, resectable epileptogenic zone. Surgical experience and postsurgical seizure outcome data in infants and young children from several centers around the world show encouraging seizure outcomes with low morbidity and mortality, and consensus is building on early evaluation for surgical management.[2–7] In this chapter, we focus our discussion on these special age-related differences that are important to recognize in the management of children who are likely to benefit from the surgical treatment of epilepsy. Table 46.1 compares common findings during diagnostic evaluation of pediatric and adult patients for epilepsy surgery.

Presurgical investigations in infants and young children

The presurgical investigations that are obligatory in all pediatric patients include a history and physical examination, long-term video-EEG monitoring, neuropsychological testing, and a high-resolution brain MRI (magnetic resonance imaging). Functional neuroimaging like brain FDG-PET (^{18}fluro-deoxy-glucose positron emission tomography) is often helpful as an adjunct tool, especially in patients with subtle or doubtful brain MRI findings. Other investigations such as ictal SPECT (single photon emission computerized tomography), MEG (magnetoencephalography), fMRI (functional MRI) and invasive intracranial monitoring remain challenging in this population, but may be considered in selected infants and young children. Dilated eye examination by an expert ophthalmologist, and other organ system investigations (for example, in infants with tuberous sclerosis) in consultation with other specialists such as geneticist and neurometabolic experts should be considered in appropriate circumstances prior to surgery.

Special characteristics in clinical presentation in infants

Surgically remediable epilepsy in infants often presents as catastrophic epilepsy with associated developmental regression or arrest. Medical treatment options are usually exhausted within few weeks to months of seizure onset due to rapid trials in the face of daily intractable seizures. History usually offers important clues to the etiology of epilepsy. Age of seizure onset, the course of neurological symptoms, presence of symptoms indicative of multiple organ system involvement, family history, and history of premature birth, hypoxic event, significant head trauma or central nervous system infection may offer clues to possible etiology, type of central nervous system pathology, and a possibility of bilateral or global injury. The presence of neurocutaneous markers, congenital anomalies involving multiple organ systems, stigmata of metabolic diseases, micro- or macrocephaly, and abnormal neurological findings may suggest a specific genetic diagnosis or a particular group of conditions.

Neurological examination is often challenging to elicit neurological deficits in this population. Neurological examination is helpful in presurgical evaluation if it shows unilateral hemispheric dysfunction with decreased use of one arm or side (hemiparesis), or gaze preference (homonymous hemianopsia). Recognition of subtle neurological abnormalities in infants requires experience and close observation during various activities. Mild hemiparesis may only present as early hand preference, reduced spontaneous movements of one side, poor grasp and dexterity of one hand, or unilateral small size of the limbs in early onset and long standing hemiparesis.[8,9] Subtle differences in the tone and deep tendon reflexes may also be difficult to confirm. This may be due to immaturity of the central motor systems and corticospinal tracts.

Special characteristics in evaluation of seizure semiology on video EEG

There are several differences between the semiology of partial seizures in children compared with adults. Seizure characteristics suggesting partial onset, such as specific auras in adult

Table 46.1 Comparison of common findings during diagnostic evaluation of pediatric and adult patients for epilepsy surgery. (modified from ref # 2)

Characterstic findings	Infants/young children	Adult patients
History, seizure semiology and exam		
Specific auras	Rare (unable to communicate)	Common
Seizure semiology	Stereotypic (like 'epileptic spasms' or 'bland stare')	May indicate symptomatogenic zone
Clincal seizure onset, ictal exam, postseizure recall	Unable or difficult to confirm	Easier
Ictal lateralizing features	Uncommon or unreliable	Common and reliable
Neurlogical deficit on exam	Difficult to elicit (mild hemparesis, visual fields)	Easy to elicit
Neuropsychology testing for surgical risk	Less objective (due to age, severe cognitive and behavior difficulties)	Helpful in pointing specific deficits
Scalp-EEG patterns		
Confounding factor of developmental EEG evolution	Present	Absent
Stereotypic and nonlocalizing interictal and ictal patterns	Common (hyperrhythmia, generalized or synchronous discharges)	Absent
Imaging and pathological substrates		
Confounding factor of developmental brain MRI changes	Present	Absent
Ictal SPECT	Difficult (brief frequent seizures, clusters, difficult ictal onset)	Easier
Common location and extent of lesions	Extratemporal large lesions	Temporal, smaller lesions
Common etiologies	Congenital (cortical dysplasia, malformation, tumor, perinatal stroke)	Hippocampal sclerosis, focal cortical dysplasia
Surgical considerations		
Morbidity and mortality	Higher (due to age, weight, larger resections, coexisting disablities)	Lower
Timing and best techniques for surgery	More controversial and require planning and experience	Less controversial
Invasive mapping (intracranial grids or depth electrodes)	Not practical in most infants and young children	Possible
Intraoperative neurophysiologic techniques	Limited utility, more challenging in infants	Very useful
Goals of surgery/successful seizure control	Cognitive improvement, schooling, behavior, productive adult life	Job, driving, independence

patients, are unidentifiable in infants.[10] Clinical seizure onset may be difficult to pinpoint with accuracy, especially in developmentally delayed and hypotonic infants, and this may create a challenge during scalp Video EEG and ictal SPECT.[11,12] Assessment of the ictal level of consciousness in infants is fraught with problems, and automatisms, when infrequently present, tend to be simple, bland, and predominantly oral. Furthermore, distinguishing oral automatisms from normal background behavioral activity in infants can be difficult.[13,14] Clearly identifiable and reproducible characteristics of localized seizure onset, such as clonic jerking or tonic/dystonic posturing of one extremity or one side, is rare in infants.[15] Partial seizures arising from temporal or temporo-parieto-occipital regions usually manifest with a decrease or arrest in behavioral motor activity, bland stare, with indeterminate level of consciousness and minimal or no automatisms. Partial seizures arising from frontal or fronto-parietal regions tend to present with symmetric or asymmetric bilateral tonic stiffening, sometimes preceded by or associated with bilateral eyelid blinking.[14,16] It is generally recognized that the classification of partial epileptic seizures of the International League Against Epilepsy [17] reflect experience in adult patients, and therefore, may not be as useful in children below the age of 3 years.

Special characteristics and maturational aspects of scalp EEG patterns

It is now well known that seizures in focal cortical lesions in infants may have no clinical or EEG findings to suggest partial epilepsy. Seizures are usually stereotypic infantile spasms, and scalp-EEG shows interictal hypsarrhythmia, diffuse electrodecrement during infantile spasms, and absence of focal EEG seizure patterns.[18–21] Yet, many studies have shown cessation or significant improvement in seizures after the resection of the focal cortical lesion seen on the brain MRI and PET.[4,7,19,22] Overall 65% of affected infants are free of seizures after surgery,[21] and infantile spasms with hypsarrhythmia are not predictive of poor surgical outcome. However, careful review of scalp-EEG in infantile spasms is still helpful as it may offer clues to a localized pathology by predominance of interictal sharp-waves over one region, localized slowing or decreased background activity, or absent sleep spindles over the affected region or hemisphere. Sometimes careful history and review of earlier video-EEG evaluations may show intermixing of infantile spasms with partial seizures (EEG and clinical) during early infancy eventually to be replaced or overwhelmed by infantile spasms. Ictal scalp-EEG in infants may offer clues to focal pathology by unilateral electro-decremental events, generalized but asymmetric electroencephalographic EEG patterns, or occurrence of partial EEG seizure patterns before, during, or after a cluster of infantile spasms.[2,23]

Generalized scalp-EEG patterns in the presence of focal lesion may not be limited to infants. More recently it has been recognized that scalp-EEG may show generalized and bilaterally multiregional interictal and ictal findings even in older children with an MRI lesion, and seizure freedom is possible after surgery[47]. Further, generalized discharges/slow spike and wave resolve postoperatively in such patients, and are likely to be a secondary phenomenon. Authors reported 10 children (age 3–16 years) with generalized and bilateral multiregional interictal and ictal EEG (without any solitary or predominant focal EEG) and a brain MRI lesion who were surgically treated. All had catastrophic epilepsy resistant to all possible medical treatment. Surgery was offered as a last resort after critical evaluation, parental consent and bioethics approval. MRI showed encephalomalacia in four, malformations in three, and remote stroke in three patients. On postoperative follow-up (mean 26 months), eight were seizure free, and two had rare seizures. All had remarkable improvement in quality of life. Postoperative EEG at 6 months showed resolution of generalized discharges/slow spike and wave in all patients. The authors concluded that generalized and multiregional epileptiform scalp-EEG findings (and without any single or predominantly focal EEG) may occur in older children in the presence of a brain insult early in life, and do not preclude benefit from surgery.

It is, therefore, not uncommon to see generalized EEG patterns in pediatric patients with surgically remediable epilepsy. This recognition is important, and every effort should be made to look for subtle clues to focal pathology in the EEG, and previous EEGs should be reviewed whenever available.

Special characteristics in anatomic and functional neuroimaging in infants

Brain MRI is a key investigation in planning surgical strategy at all ages, but in infants it assumes even a higher level of importance due to common occurrence of generalized or nonlocalized EEG patterns as discussed in the previous section. With the availability of high-resolution brain MRI and three-dimensional volume acquisition sequences, the brain MRI can demonstrate the presence of subtle cortical dysplasias, developmental tumors like dysembryoplastic neuroepithelial tumors, and other malformations of cortical development which are the most common pathological substrates in infants with surgically remediable epilepsy. The presence of subtle cortical dysplasia may only be evident as loss of gray-white matter junction, loss of normal white matter arborization, localized thickening of cortical ribbon, or abnormal morphology of gyri and sulci.[24]

Infants present a unique challenge in interpretation of brain MRI abnormalities that may be subtle or focal, like focal cortical dysplasias. This is due to immaturity of myelination and normal lack of gray-white matter distinction during the first year of life. The brain MRI during infancy shows a maturational dependent change in the signal intensity on T1- and T2-weighted images as the brain matures from caudal to cephalad and from dorsal to ventral surface.[25,26] The importance of finding a lesion on brain MRI can be demonstrated by several studies that showed that the complete resection of the brain MRI lesion resulted in the seizure-free outcome in a significantly higher percentage of patients when compared to those with only partial resection of the lesion or resection in the absence of a MRI lesion.[5]

Brain FDG-PET was shown to be an especially useful tool in identifying infants for epilepsy surgery, as it may show a region of abnormality that may be obscured on brain MRI due to its subtle nature and immaturity of the myelination process.[4,27,28] However, this is seldom the case these days due to improvement in MRI technology and increased expertise in detecting subtle cortical abnormalities. Other confounding factors that must be considered while interpreting brain PET in infants and young children with frequent seizures include the difficulty in accomplishing a true interictal study due to occurrence of clinical or EEG seizures just before or during the PET scan, dynamic nature of brain maturational process, and evolution of certain pathological substrates of seizures over time as in tuberous sclerosis, Struge-Weber syndrome or Rasmussen's encephalitis. Nonetheless, brain PET remains a valuable noninvasive supplementary tool in localization of the epileptogenic zone.

Ictal SPECT is increasingly being used as a diagnostic procedure for localizing epileptic seizure focus, especially in patients with extratemporal epilepsy and a normal brain MRI.[11] It has proven useful in some pediatric patients where the most common location of epileptogenic lesions is extratemporal. However, some special challenges exist in obtaining and interpreting the ictal SPECT studies in infants and young children with frequent seizures. These include difficulty in accomplishing a true interictal SPECT due to multiple daily seizures, difficulty in promptly recognizing the clinical onset of ictal behavioral changes due to age and coexistent mental retardation often resulting in a late injection, brief duration and rapid spread of spasms and other seizures of extratemporal origin, and two-time sedation that may be required for interictal and ictal study. The advent of techniques such as subtraction SPECT with co-registration on magnetic resonance imaging (SISCOM) and computer image-guided surgery has enhanced the clinical electrophysiologic evaluation of SPECT detected abnormalities in epilepsy. Recent studies have suggested that the probability of seizure-free outcome is significantly higher in patients with nonlesional extratemporal epilepsy when surgery involved the SISCOM focus than when it did not.[29–31]

The role of other neuroimaging modalities like magnetic resonance spectroscopy (MRS) and functional MRI (fMRI) in young children with catastrophic epilepsy has not been systematically studied.

Special characteristics of pathological substrates in pediatric patients

Pathological substrates of epilepsy are different in infants when compared with older children and adults. Hippocampal sclerosis, the most common etiologic factor in adult candidates for epilepsy surgery, is uncommon in infants. In pediatric epilepsy surgery series from the Cleveland Clinic Foundation,[7] hippocampal sclerosis was the cause in only 12% of 62 children (age 3 months to 12 years) and 15% of 74 adolescents (age 13 to 20 years). Whenever hippocampal sclerosis was found as the etiology of epilepsy, Pediatric patients appeared to have an especially high incidence of dual pathology with cortical dysplasia.[32]

In infants and young children, the predominant etiologies that lead to epilepsy are focal or multilobar malformation of cortical development (cortical dysplasia), and low-grade tumor. These were the cause of the epilepsy in 57% of adolescents, 70% of children, 90% of infants younger than 3 years in the Cleveland Clinic series,[7] and 90% of infants treated surgically in the series of Duchowny and colleagues.[5] Congenital hemispheric malformations of brain development such as hemimegalencephaly or extensive hemispheric malformations are also important etiologies in infants undergoing epilepsy surgery in the form of hemispherectomy.[9] Perinatal unilateral cerebral ischemic (vascular) insults, Sturge-Weber syndrome, and Rasmussen's chronic focal encephalitis are other etiologies where hemispherectomy may be indicated.[6,9] Less common indications for epilepsy surgery are etiologies like encephalomalacia related to remote trauma or infection.

The age-related differences in etiology result in an age-related spectrum of surgical procedures. Anteromesial temporal resections predominate in adults[33] but not in children. In pediatric series, extratemporal or multilobar resections or hemispherectomies composed 44% of the surgeries in adolescents, 50% in children, and 90% in infants.[5]

Special surgical characteristics in pediatric patients

Timing of epilepsy surgery

Recent pediatric series justify early epilepsy surgery in infants with catastrophic epilepsy, regardless of age.[6] Improvement in surgical techniques, anesthesia, and pediatric intensive care during peri- and post-operative periods significantly reduced the mortality and frequency of complications. The risk of proceeding with surgery must be weighed against the risk of continuing with uncontrolled seizures treated medically. If careful analysis yields a favorable risk/benefit ratio for surgery, then surgery should be considered. The usual delay from onset of seizure intractability to surgery is still in the range of 12–15 years at most centers, reflecting a reluctance to consider surgery during childhood. Complicated infants in need of epilepsy surgery should be considered for referral to specialized centers with extensive pediatric experience.[6]

Goals of epilepsy surgery

The goals of epilepsy surgery may vary according to age. In adolescents and adults, the main goals are usually related to driving, independence, and employment, and their achievement requires complete postoperative freedom from seizures.[34] For infants and children, the goals often center on relief of catastrophic epilepsy, resumption of developmental progression, and improvement in affect and behavior. For infants and young children with catastrophic epilepsy and daily seizures, even a postoperative outcome with rare or infrequent seizures may be gratifying with improvement in developmental progression. Seizures that begin in the first few years of life, regardless of etiology, constitute a risk factor for mental retardation.[8,35–37] Early surgical intervention may reduce this risk by allowing resumption of developmental progression during critical stages of brain maturation, but quantitative and prospectively collected data are scant.[5,6]

Postoperative new deficits and plasticity
